More recently, a particular type of parametric linkage known as homozygosity mapping has been undertaken in Old Order Amish families displaying a syndrome of intractable epilepsy, MR, and autism. This approach relies on intermarried families to increase the statistical power available to identify rare recessive mutations. In this case, the analysis led to the discovery of a truncating mutation in the transcript *CNTNAP2* (Strauss et al., 2006). As mentioned above, a role for this gene in idiopathic autism and language development was subsequently identified by four independent groups of investigators (Alarcon et al., 2008; Arking et al., 2008; Bakkaloglu et al., 2007; Vernes et al., 2008).

Finally, a recent intensive search for rare recessive mutations based on homozygosity mapping was reported by Morrow and colleagues (2008; *see also* Chapter 44). The authors recruited and carefully phenotyped 88 consanguineous families. They identified multiple, mostly nonoverlapping regions of homozygosity (i.e., regions of the genome in which, as a result of the fact that parents share a common ancestor, a single identical chromosomal segment is inherited from both mother and father). Although the resulting statistical scores did not quite achieve genome-wide significance, several rare, large (18 kbp to >880 kbp), inherited homozygous deletions were found disrupting either the coding or potential regulatory regions of brain-expressed transcripts, including *deleted in autism-1* (*DIA1*) (*c3orf58*), *sodium/proton exhanger 9* (*NHE9*), *protocadherin 10* (*PCDH10*), and *contactin 3* (*CNTN3*). The authors then found additional strong evidence supporting a role for the gene *NHE9*, the (Na⁺, K⁺)/H⁺ exchanger, in ASDs through the identification of a rare nonsense mutation in two male siblings with autism, one of whom had epilepsy and the other with probable seizures, in a non-consanguineous family. Overall, they identified rare amino acid changes in *NHE9* in almost 6% of patients with both autism and epilepsy versus only 0.63% of controls. Interestingly, based on an independent series of studies reported in the same publication, three of the genes located within or closest to the two largest deletions (*DIA1*, *NHE9*, *PCDH10*) were found to either be regulated by

neural activity and/or were the targets of activity-induced transcription factors, suggesting that activity-regulated gene expression during early brain development may be a common mechanism contributing to ASDs.

Rare-Variants: Common-Disease?

Copy Number Variants

Copy number variants refer to variations in chromosome structure that generally fall below the resolution of the light microscope. This type of cytogenetic variability was identified as a potential cause of developmental disorders in the mid-1990s (Folstein, 1996; Lipska & Weinberger, 1995), but it was not until 2004 that several groups (Lucito et al., 2003; Sebat et al., 2004; Iafrate et al., 2004) first identified CNVs as being widespread in apparently unaffected individuals. These discoveries both marked the development of technology that could identify previously cryptic rare chromosomal rearrangements as the cause of disease, but also suggested that assumptions regarding the biological requirement for an "intact" genome for normal development would need to be re-evaluated.

In the wake of these influential papers, the technology to detect CNVs with increasing resolution quickly followed. Moreover, given the longstanding appreciation of the potential role of gross chromosomal abnormalities to ASDs, there seemed to be a real possibility that this increasing resolution would dramatically expand the understanding of the genetic underpinnings of autism.

In 2007, Both the Autism Genome Project (AGP; as discussed previously) (Szatmari & Consortium, 2007) and Sebat et al. (2007) reported the first genome-wide detection of CNVs in patients with autism (Sebat et al., 2007). Findings from both papers were notable: first, as suggested above, several of the single observations reported in these papers have turned out to map to genomic intervals that have later been found to harbor recurrent rare abnormalities showing evidence for association with disease (Eichler & Zimmerman, 2008; Kumar et al., 2008; Miller et al., 2009; Morrow et al., 2008; Rujescu et al., 2009; Weiss et al., 2008; Glessner et al., 2009; Bucan et al., 2009; Pinto et al., 2010); second, the Sebat paper highlighted a distinction between so-called "simplex families" (those with only a single affected child), in which approximately 11% were found to carry large de novo CNVs, versus "multiplex families" (with more than one affected child), in which only 2% were found to carry similar events and controls, which had a rate of 1%. Subsequent studies have consistently replicated this finding and placed this burden in simplex families at between 3.4 and 11 percent (Itsara et al., 2010; Marshall et al., 2008; Pinto et al., 2010).

Notably, the precise results of different CNV studies may be difficult to compare. The number of CNVs identified in any investigation will depend in part on the number and

distribution of probes on the array, which contribute to the resolution of the detection platform, on whether the authors rely on predictions versus confirmations using a "gold standard" method, and on the manner in which authors categorize CNVs (e.g., studies may use different methods for defining "rare," "large," or even "de novo" CNVs). Any or all of these variables may lead to somewhat different results from groups studying identical samples.

The contribution of recurrent rare CNVs as risk factors for autism were further highlighted in reports by Marshall et al. (2008); Kumar et al. (2008) and Weiss and colleagues (2008). in which these groups nearly simultaneously identified deletions and/or duplications in the region 16p11.2 in families with autism.These and subsequent findings underscored the contribution of this region to disease and, at the same time, highlighted the issue of complex inheritance in ASDs, even in the context of searching for rare variation. As expected, many of the CNVs that were transmitted showed incomplete penetrance, which is a well-accepted phenomenon even for monogenetic traits. However, in addition, neither the de novo mutations nor the inherited duplications initially identified were found consistently in all affected members of a individual nuclear families (Bucan et al., 2009). For a rare Mendelian trait, this observation would be taken as evidence against a causal relationship for the variant. However, in complex disorders, the finding is consistent with the hypothesis that multiple risk alleles are present within these families.

A final note with regard to this very interesting region of the genome: a subsequent large-scale study of CNVs in autism (Glessner et al., 2009) did not replicate the 16p11.2 most likely due to a comparatively high rate of CNVs in this region among their control groups. The result highlights several potentially important methodological issues, including the inherent difficulties in assessing the precise frequencies of CNV from multiple array platforms using predictions alone; the impact of false-negative prediction rates; and the possible confound of population stratification (cryptic differences in the ethnic make-up of cases and controls leading to varying allele frequencies). Of note, very recent data from a large simplex autism cohort, which controlled for these confounds, strongly replicate the association of both duplications and deletions at 16p11.2 for autism spectrum disorders.

CNV analyses are currently the most practical high-resolution approach to identifying rare variation across the genome and, consequently, are both the most practical approach to testing the rare-variant: common-disease hypothesis as well as to generating leads for outlier studies. Several large scale studies have identified a variety of interesting candidate genes and molecular pathways of interest. For example, Glessner et al. (2009) reported a whole-genome CNV study of 859 ASD cases and 1409 healthy children of European ancestry and a replication sample consisting of 1336 ASD cases and 1110 controls from the AGRE sample, which consisted largely of multiplex families. They reported positive associations in previously identified candidate genes, including *NRXN1* and *CNTN4*, as well as several new putative susceptibility genes encoding neuronal

cell-adhesion molecules, including *neuroglin 1* (*NLGN1*) *and astrotactin 2* (*ASTN2).* These genes harbored recurrent CNVs that were not observed in controls. Other recurrent CNVs were found within or nearby genes involved in the ubiquitin pathway, including *UBE3A, PARK2, RFWD2,* and *FBXO40* that also were not observed in controls.

The authors noted the biological plausibility of involvement of this latter pathway in ASDs and other developmental neurogenetic disorders based on several lines of evidence including that known mutations in *ubiquitin protein ligase 3A* (*UBE3A*) are seen in 5% to 10% of Angelman Syndrome cases, *astrotactin 2* (*ASTN2*) deletions have recently been associated with schizophrenia (Vrijenhoek et al., 2008; Kahler et al., 2008), and *PARK2* (Mefford et al., 2008) mutations lead to autosomal recessive juvenile Parkinson's disease. Ring finger and W repeat domain 2 (*RFWD2*) and F box protein 40 (*FBXO40*) have not previously associated with disease-causing mutations.

Similarly, Bucan et al. (2009) performed CNV analyses using arrays with approximately 550,000 probes in 912 multiplex families from the AGRE collection and 1488 healthy controls. They identified hundreds of loci harboring rare deletions and/or duplications in unrelated probands that were not seen in the unaffected group. Moreover, they tested their findings in an additional independent cohort of 859 cases and 1051 controls. This rigorous two-step study identified previously implicated loci including the genes *NRXN1* and *UBE3A*, and pathway analysis provided further support for the involvement of neuronal adhesion molecules in ASDs. In addition, the study identified evidence for the involvement of several interesting novel transcripts, including the *benzodiazapine receptor (peripheral) associated protein 1* (*BZRAP1*) and *MAM domain-containing glycosylphosphatidylinositol anchor 2M* (*MDGA2*), which, as the authors note, shows a strikingly high similarity to *Contactin 4*.

More recently, Pinto et al. (2010) reported on a sample of 996 ASD individuals of European ancestry to 1,287 matched controls and found evidence for the involvement of *SYNGAP1, DLGAP2, SHANK2,* and the X-linked *DDX53-PTCHD1* locus. The findings with regard to SHANK2 emerged nearly simultaneously with a description of rare de novo mutations in this gene among individuals with ASD (Berkel et al., 2010) and a second subsequent report identified multiple rare protein altering sequence variants in *PTCHD1* that were transmitted from mothers to affected sons and were not found in controls (Noor et al., 2010).

Cause and Effect: Association Strategies and Rare Variants

The extremely interesting data emerging from both resequencing and CNV studies have also underscored important challenges in confirming cause-and-effect relationships between rare variants and developmental syndromes. These issues are likely to become even more pressing in the next epoch of rare

variant analyses, which will undoubtedly include a comprehensive assessment of rare variation through the simultaneous sequencing of all, or a large portion, of the human genome.

As many of the aforementioned studies have demonstrated both rare structural and sequence variation is plentiful in unaffected as well as affected individuals. This observation reinforces a point made at the outset: although highly deleterious variations are likely to be rare, rare variations are not necessarily deleterious. Clearly, in the early stages of gene discovery in Mendelian disorders, a tendency to assign pathogenecity to rare deleterious variation in a single or small number of cases was well-justified. However, as gene discovery efforts involving rare variation have been applied to complex common disorders, this conventional wisdom is being supplanted by the recognition that no class of variation is uniformly disease-related and that rare variation may contribute to ASDs in a non-Mendelian fashion.

Indeed, to date, the vast majority of findings with regard to rare recurrent CNVs and autism have been based on population association, an approach that is suited to characterizing complex patterns of inheritance. As noted above, even with regard to chromosome 16p11.2 CNVs, which are presently among the most replicated finding in this area, these variations do not exhibit the type of one-to-one relationship with affected status within pedigrees that is expected for single-gene disorders.

Given the longstanding tendency to equate rare mutation with Mendelian inheritance and common variation with complex inheritance, it is worthwhile to reflect on the increasing likelihood that rare and very rare alleles for ASDs will be found carrying risks exceeding those of common variants but falling short of those previously attributed to simple genetic diseases. To the extent that this is the case, it will be essential for researchers to confirm association of rare variation by contending with the same types of issues now recognized as critical for successful studies of common variants. These include acknowledging the superiority of genome-wide compared to candidate gene studies for initial efforts at gene discovery; establishing appropriate statistical thresholds for these types of investigations; avoiding a deluge of underpowered analyses resulting from overestimation of effect sizes; controlling for the confound of occult ethnic stratification; and ensuring that the technical quality and consistency of CNV typing, as nonrandom technical errors have clearly been a significant issue in common variant studies.

Some of these issues will be easier to address than others. For example, in some cases very large samples sizes, similar to those currently estimated to be required for common variant studies will be sufficient to ensure adequate power for CNV analyses, particularly for those recurrent CNVs that fall close to the threshold of 5% minor allele frequency. However, for some extremely rare variants, it simply may not be practical to ascertain a sample size that is sufficiently large to support allelic association analyses, unless one is focussed on recurrent de novo events.

Moreover, it is important to recall that for very rare sequence variants, once a single observation is made either in a case or control, the allele is not be likely to ever be seen again in samples of the size typically employed in such studies. Therefore, the identification of individually very rare mutations in a case group followed by the search for those same variants in a control group does not provide strong evidence for association. Instead, studies focusing on variants with allele frequencies far below 5% will likely need to be pursued by investigating the totality of rare functional sequence variants in cases versus controls, examining each group in an identical fashion—an approach commonly referred to as a mutation burden study.

The foregoing arguments point to the high value of identifying recurrent risk alleles in the 1%- to 5%-frequency range: they are of sufficiently low frequency to suggest that they may carry large effects, but they are also sufficiently common that standard allelic association strategies may be employed in attainable sample sizes. When mutation burden approaches are employed, a central challenge is presented by the sheer volume of normal rare variation throughout the genome, which may then obscure true associations. As noted above, recent studies have underscored the limitations of current bioinformatics approaches to determining the consequences of amino acid substitutions and have highlighted the value, in these analyses, of being able to truly distinguish between those rare alleles that alter protein function and those that do not (Ji et al., 2008).

The issue of statistical thresholds is also an important one for rare variant studies that has not yet been resolved. For GWAS common variant studies, it has been possible over time to arrive at commonly accepted levels for genome-wide significance. This has played an important part in transforming allelic association from a strikingly unreliable approach to one that is now leading to highly reproducible findings across all fields in medicine. With regard to rare variants, a similar consensus has not been reached. Not surprisingly, some early studies relied on nominal p-values. However, as the number of published studies grows, the resolution of array platforms increases and the numbers of CNVs found in individuals proliferate, it is increasingly important to address the issue to avoid a flood of nonverifiable findings of the type that plagued early efforts at candidate gene single nucleotide polymorphism association. Given the focus on rare and very rare variation and the expected small number of observations likely at any given locus, it may turn out be quite challenging for any study (even those with very large samples) to correct for the total number of genome-wide comparisons and still reach statistical significance. A combination of statistical analyses of the likelihood of recurrence of *de novo* events, simulation studies, and two-stage designs are likely play a role in addressing this issue.

Finally, whether one is studying rare or very rare variants, it is clear that one must consider the issue of ethnic mismatch or population stratification. There is ample evidence that recurrent CNVs show differences in frequency based on the ethnic composition of the population under study in a manner similar to that seen for common variants (Redon et al., 2006). The early history of common variant analysis was plagued by case–control mismatch leading to false-positive results.

There is every reason to expect that CNV studies involving transmitted recurrent variants are liable to the same difficulties. Fortunately, the tools are now available to derive genomic profiles of ethnic origin that can be used to match individuals and minimize the liability for this confound. This will likely be recognized in the future as an essential component of methodologically sound studies of rare sequence and structural variation, as it is now for common variant studies.

Copy Number Variants: Rethinking Genotype/Phenotype Relationships

One of the most interesting results of investigations of CNVs has been the degree to which recent findings have challenged the traditional diagnostic boundaries in psychiatry. For example, as noted, 16p11.2 CNVs have been associated with autism but have also been observed in individuals with schizophrenia, mental retardation, and seizure disorder (Marshall et al., 2008). Recent studies have found CNVs at 1q21.1, 15q11.2, and 15q13.3 that are strongly associated with schizophrenia, and these too have been encountered in individuals with autism and mental retardation (Burbach & van der Zwaag, 2009; Mefford et al., 2008). In addition, both the region 22q11.2 and 16p11.2 have been associated with both psychosis and ASDs (Weiss et al., 2008; McCarthy et al., 2009).

The chromosome 1q21.1 region has been associated with a particularly wide range of phenotypic manifestations. An initial study by the International Schizophrenia Consortium reported deletions in this region among 0.26% of patients with schizophrenia versus 0.002% in controls. Subsequent studies have identified both deletions and duplication in this region in a range of phenotypes including congenital heart defects (Christiansen et al., 2004), developmental delay (Shaffer, 2006), mild-to-moderate mental retardation, learning difficulties, and ASDs. For example, Brunetti-Pierri et al. (2008) performed array based comparative genomic hybridization on 16,577 patients with mental retardation, autism, and congenital anomalies. They identified 27 subjects with 1q21.1 deletions (0.16%) and 17 with duplications (0.1%). The deletions were compared to the rate observed in the aforementioned International Schizophrenia Consortium Study and were found to be increased. It is important to note, however, that CNV detection platforms differed between the two studies, and there was no control for population stratification.

However, a second study of this region by Mefford et al. (2008) came to similar conclusions: their sample consisted of 5218 patients referred for genetic testing, predominantly for evaluation of mental retardation (95%). Both de novo and inherited deletions and duplications were identified at similar rates to those described above. Moreover, deletions were not present among 4737 controls ($p = 1.1$ x 10^{-7})**.** The reciprocal duplication was found among nine children with mental retardation or an ASD, which again was noted to be higher than the rate observed in unaffected individuals ($p = 0.02$).

Chromosome 15q11-13 duplications of the maternal chromosome are the most common microscopic abnormalities reported among individuals with ASDs. Recently, Stefansson et al. (2008) showed statistical evidence for 15q11.2 and 15q13.3 deletions associated with schizophrenia in their large sample of 1433 schizophrenia patients and 33,250 controls.

The chromosome 22q11.2 region is the best-known region for CNVs that predispose to psychosis. Deletions in this region show variable phenotypes, including velo-cardiofacial syndrome and DiGeorge syndrome, and there are hundreds of reports documenting new findings from polymicrogyria to juvenile rheumatoid arthritis related to variations in this region. The list of associated findings has grown to more than 180 (Robin & Shprintzen, 2005). Individuals with chromosome 22q11.2 deletion syndrome have consistently been noted to be at elevated risk to develop psychiatric difficulties, especially psychosis (Murphy, Jones, & Owen, 1999). In the study by Stefansson et al., 22q11.2 deletions were present in 8 of 3838 cases of schizophrenia, but absent in 39,299 controls ($p = 4.2$ x 10^{-5}). Similarly, a number of case series have pointed to elevated rates of ASD among individuals carrying the 22q11 deletion (Fine et al., 2005; Vorstman et al., 2006).

Finally, a recent large-scale study of the 16p11.2 region demonstrated an association of duplications but not deletions in the region with schizophrenia (McCarthy et al., 2009), whereas a meta-analysis of several recently published studies, reported in the same manuscript, continued to support an association between both duplications and deletions in this interval and ASDs. As noted, the frequency of both duplications and deletions in controls has varied in recent investigations. However, as additional large-scale studies confirm these results, it will have a significant impact on our conceptualization of the current diagnostic nosology.

Although these studies are not an exhaustive listing of findings in which mutations in a region or gene has led to widely varying neuropsychiatric and developmental disorders, they clearly point to the possibility that a single genetic variation may result in multiple development outcomes. This, of course, has been observed for decades with regard to the overlap of mental retardation and autism. However, the range of phenotypic variability suggested in the current literature is far more extensive, including diagnostic categories, such as schizophrenia, that were previously thought to be entirely distinct from developmental delay. These findings may be accounted for by a variety of factors, ranging from epigenetic or environmental mechanisms, to ascertainment bias, to pleiotropic effects of CNVs. Collectively, these recent findings underscore the limitations in our understanding of the link between biology and diagnostic nosology and suggest that our notions of "clear" categorical boundaries will continue to be challenged. In addition to raising very interesting questions regarding the possible convergence of biological mechanisms involved in multiple disorders, these overlaps begin to raise important practical questions regarding how one assigns affected (or unaffected status) to individuals in genetic studies.

Summary and Conclusions

Overall, it is evident that findings from rare variant studies have played a leading role in elaborating the genetics of ASDs. From the early observations of increased rates of chromosomal abnormalities in children with these disorders to the identification of CNVs and the application of deep sequencing approaches, the study of outliers has provided the first extremely important and illuminating insights into the biology of these complex devastating syndromes.

Although the elegant and paradigm-challenging studies of rare genetic *syndromes* are discussed in other chapters, it is nonetheless interesting to note that "nonsyndromic" rare variant findings have begun to converge in some senses. As previously noted, early data suggests that some ASDs are likely the result of synaptic pathology (Zoghbi, 2003) and/or the consequence of variations in neuronal adhesion molecules including Cadherins, Contactins, Neuroligins, and Neurexins. However, it is also a near certainty that these findings are just the tip of iceberg, and a variety of processes important for establishing the basic architecture and maintaining the function of the human CNS will also be implicated in the etiology of ASDs (Page et al., 2009).

It is not at all surprising that the first biological insights into ASDs have emerged from studies of Mendelian syndromes. Given the relatively early discovery of genes underlying syndromes that overlap with ASDs, these have provided the best opportunity so far to move from gene identification to an understanding of protein function, to establishing protein–protein interactions and their roles in brain development and function, to the identification of novel therapeutic targets. Clearly, the current challenge for the field, which is already being undertaken in earnest, is to move this process of translational neuroscience from Mendelian syndromes showing features of ASDs squarely into the realm of the complex common and heterogeneous set of syndromes collectively referred to as ideopathic ASDs.

So far, the early evidence suggests that this will require a re-orientation, moving away from conceiving of rare mutations as synonymous with "Mendelian" inheritance and expecting unequivocal one-to-one relationships to embracing the notion of probabilitistic outcomes, multiple rare variant "hits" in a single individual or family and gene environment interactions—phenomena that are already well-accepted with regard to common variants.

Challenges and Future Directions

On an optimistic note, despite the methodological challenges that arise with regard to studying rare variants in complex disorders, all roads appear to lead in the same direction. The practical implications of the foregoing discussion are clear:

- Rare variant gene discovery will require large sample sizes, rigorous statistical threshold, the elaboration of appropriate genome-wide analytic methodologies, an appreciation of the central importance of ethnicity in genomic variation, and a continuing and realistic appraisal of effect sizes. Fortunately, all or nearly all of these issues have been solved with regard to genome-wide common variant studies, boding well for the future of investigations aimed at clarifying and elaborating the contribution of rare variants to autism and related conditions.
- The rapid pace of technological development in genomics provides a glimpse of where the field is headed in the future. Next-generation sequencing has already made practical the interrogation of a large percentage of the coding regions of the genome in groups of individuals.
- Sequencing of complete genomes applied to large samples of cases, family members, and controls is clearly just over the horizon. This transition will not only fuel gene discovery in ASDs but will undoubtedly presage a far better understanding of the formerly "dark," noncoding regions of the genome.
- It is likely that there will be substantial contribution of rare variation to ASDs via its influence on gene regulation and expression, topics that have so far been difficult to broach using previous generation technologies.
- The convergence of large patient collections, the increasing ability to detect rare variation both in the form of CNVs and at single base resolution, and the concomitant advances in the study of developmental neurobiology described elsewhere in this text suggest that the next few years will be a remarkable era of discovery.

Known and Possible Roles of Epigenetics in Autism

Points of Interest

- Research into the role of epigenetics in the etiology of autism has been neglected compared to the extensive genetic studies.
- For the most part, neither *de novo* mutations nor epigenetic abnormalities are detectable by linkage and association studies.
- Epigenetic mechanisms could contribute modestly to any missing causality or missing heritability of autism.
- Epigenetic analysis using chromatin-immunoprecipitation (ChIP) and analysis of DNA methylation can be used to assess the importance of epigenetics in the etiology of forms of autism that remain idiopathic—especially in milder forms of autism.
- Analysis of postmortem brain may be required to detect some epigenetic abnormalities, whereas others may be detectable in leukocytes.

The objective of this chapter is to review the known and hypothetical roles of epigenetics in the etiology of autism. Epigenetics in this medical context is commonly defined as the regulatory changes in gene function that are stable and heritable (or potentially heritable as in terminally differentiated neurons) and do not entail a change in DNA sequence. Bird (2007) provides an up-to-date discussion of how the term *epigenetics* has been used very differently within biology, and he proposes what he believes "could be a unifying definition of epigenetic events: the structural adaptation of chromosomal regions so as to register, signal or perpetuate altered activity states." This definition is intended to apply whether the effect is of long or short duration and whether inherited or not. The first definition emphasizes stability and heritability, and the heritability might be either somatic or germ-line. Although epigenetics usually involves transcriptional regulation, the first definition would include protein-based heritability

(Feinberg, 2007; Wickner et al., 2008), RNA-mediated inheritance (Rassoulzadegan et al., 2006), and stochastic, potentially heritable effects on gene expression. Stochastic contributions to etiology refers to the role of noise, or variation, in the process of gene expression in contributing to phenotypic variability, with transcriptional infidelity being one source of such noise (Raser & O'Shea, 2005; Gordon et al., 2009). The second definition is narrower in terms of mechanism but more open regarding the possibility of epigenetic changes occurring in nondividing, long-lived cells such as neurons. Both definitions involve a stable change in gene expression in the absence of a change in nucleotide sequence.

> **Epigenetic change:** alterations in chromosome structure that cause a stable change in gene expression in the absence of a change in nucleotide sequence.

> **Epimutation**: a stable change in the epigenotype or in gene expression that does not involve a change in DNA sequence.

As an example of epigenetic changes of short duration, the role of epigenetics in regulation across the various stages of the cell cycle has been reviewed (Probst, Dunleavy, & Almouzni, 2009). The terms *epigenotype* and *epigenome* are now often used to describe the epigenetic state (chromatin in all its complexities) of part or all of the genome. Although each of us has essentially one genome identical in all of our cells apart from somatic mutations, there are hundreds of eipgenomes/epigenotypes in the various cell types in our tissues (Fig. 42-1A). Numerous reviews regarding epigenetics generally (Jaenisch & Bird, 2003; Bird, 2007; Suzuki & Bird, 2008) and as it relates to disease states are available (Jiang, Bressler, & Beaudet, 2004; Jirtle & Skinner, 2007; Kaminsky, Wang, & Petronis, 2006; van, Oates, & Whitelaw, 2007; Feinberg, 2007; Hatchwell & Greally, 2007). An excellent book entitled *Epigenetics* (Allis, Jenuwein, & Reinberg, 2007)—authored by experts in the field—is available, with many chapters on different aspects of
Figure 42–1. (A) (left). DNA versus Chromatin. The genome: Invariant DNA sequence (double helix) of an individual. The epigenome: The overall chromatin composition, which indexes the entire genome in any given cell. It varies according to cell type, and response to internal and external signals it receives. (Lower panel) Epigenome diversification occurs during development in multicellular organisms as differentiation proceeds from a single stem cell (the fertilized embryo) to more committed cells. Reversal of differentiation or transdifferentiation (bottom lines) requires the reprogramming of the cell's epigenome. Modified with permission from Chapter 3 in Allis, C. D., Jenuwein, T., & Reinberg, D. (2007). *Epigenetics.* Cold Spring Harbor, NY: Cold Spring Harbor Laboratory Press. (B) (Right). DNA methylation. The maintenance methylase system preserves methylation status of CpG dinucleotides through mitosis. The parental strand of DNA is in black with the daughter strand highlighted in gray. Epigenetics and Human Disease. *Annual Review of Genomics and Human Genetics, 5,* 479–510.

epigenetics, including a thorough review of the biochemistry and molecular biology of epigenetics (Chapter 3) and a discussion of the role of epigenetics in human disease (Chapter 23).

> **Genomic imprinting:** a form of epigenetic regulation by which the activity of a gene is reversibly modified, depending on the sex of the parent that transmits it.

Genomic imprinting leads to unequal expression from the maternal and paternal alleles for a diploid locus. Genomic imprinting is well-described in plants and mammals, but it appears to be less frequent, if not absent, in egg-laying vertebrates. Perhaps the most striking evidence for a role of epigenetics in autism involves genomic imprinting as described below for interstitial duplications of chromosome 15q11-q13. In its simplest form, genomic imprinting involves one parental allele with high gene expression, whereas the other parental allele has low or absent expression. Imprinted genes typically occur in clusters with oppositely imprinted genes within the imprinted domain. Imprinted domains characteristically include an imprinting center with differential DNA methylation and differential histone modifications; regulation of imprinting usually spreads over hundreds of kilobases (kb) from the imprinting center. The terminology stating that a gene is maternally imprinted or paternally imprinted is sometimes used to imply maternal or paternal repression, respectively, but it seems preferable to refer to a gene as imprinted with maternal repression or paternal repression for greater

clarity. Thus, one would state that a gene is imprinted with maternal repression rather than that a gene is maternally imprinted. Numerous reviews of genomic imprinting in its role in human disease are available (Reik & Walter, 2001; Morgan et al., 2005; Hore, Rapkins, & Graves, 2007; Ubeda & Wilkins, 2008; Bartolomei, 2009; Butler, 2009).

Biochemistry and Molecular Biology of Epigenetic Regulation

The best characterized and most straightforward aspect of molecular epigenetics is the role of DNA methylation. DNA methylation is often associated with transcriptional silencing as on the inactive X chromosome and in regions of repetitive sequence. DNA within CpG islands located at promoters of genes is typically unmethylated whether or not the gene is expressed in a given cell type. Increasing attention is being given to differential DNA methylation within and near genes but outside of CpG islands (Meissner et al., 2008; De et al., 2009). There is also a suggestion that differential DNA methylation at "shores" of CpG islands may be important (Doi et al., 2009). A novel conversion of 5-methylcytosine to 5-hydroxymethylcytosine was described recently (Tahiliani et al., 2009), but its biological significance is unknown at present.

Box 42–1

The great majority of DNA methylation in mammalian genomes involves methylation of cytosine residues in CpG dinucleotides, although there is some methylation of non-CpG sequences, especially in embryonic stem (ES) cells (Lister, et al., 2009). A large proportion of CpG dinucleotides occur in repetitive DNA sequences where they are usually methylated, and the regions are transcriptionally silent. Another substantial proportion of CpGs occur in so-called "CpG islands," which are DNA segments with increased CpG sequence content. The CpG islands are often associated with promoters of genes and are usually in the unmethylated state, although exceptions occur as seen below for regions of genomic imprinting. A clear mechanism is available to preserve the methylated or unmethylated status of a CpG dinucleotide across DNA replication and mitosis (Fig. 42-1B). DNA replication leads to the production of two, hemi-methylated copies of the daughter DNA strands, and there exists a maintenance methylation mechanism, which will methylate the diagonally opposite C in a hemi-methylated substrate. Thus a methylated CpG can give rise to two methylated daughter strands of DNA. When an unmethylated CpG dinucleotide is replicated, the two daughter strands are both unmethylated and not recognized by the maintenance methylase system, thus leading to two daughter strands both unmethylated.

A second well-defined aspect of epigenetic biochemistry involves the covalent modification of histone proteins. The DNA is, to a large extent, wrapped around nucleosomes comprised of a histone core (Fig. 42-2A). Various histones—particularly H3 and H4—are subject to many such covalent modifications, including lysine acetylation, lysine methylation, arginine methylation, and serine phosphorylation (Figure 42-2B), which are collectively referred to as the *histone code* (Jenuwein & Allis, 2001).

> **Histone code**: covalent modifications of histones, including acetylation, methylation or phosphorylation that modify histone binding to DNA and alter chromatin structure and function.

Covalent modification of lysine is particularly complex with mono-methyl, di-methyl, and tri-methyl forms. This complex modification of lysine-4 in histone H3 is often denoted as H3K4me1, H3K4me2, H3K4me3. These histone modifications, also referred to as histone marks, are typically associated with chromatin regions having a particular function. For example, H3K4me3 and lysine acetylation are commonly associated with active promoters, whereas H3K9me3 and H3K27me3 are commonly associated with repressed promoters. Histone modifications are particularly relevant to studies of disease, because techniques are available to interrogate histone marks across the entire genome to compare disease samples to normal controls. This typically depends on the availability of antibodies that uniquely recognize a particular chromatin mark, such as H3K4me3. The histones are very tightly associated with DNA in the form of nucleosomes, and it is feasible to carry out ChIP and analyze the DNA that is precipitated by the antibody. The relationships between histone marks and chromatin functionality are quite complex and are reviewed in Chapter 10 of *Epigenetics* (Allis et al., 2007) and elsewhere (Ruthenburg et al., 2007).
Figure 42–2. A (left). Nucleosome structure. A schematic representation of histone organization within the octamer core around which the DNA (black line) is wrapped. Nucleosome formation occurs first through the deposition of an H3/H4 tetramer on the DNA, followed by two sets of H2A/H2B dimers. Unstructured animo-terminal histone tails extrude from the DNA-nucleosome core, and the core consists of structured globular domains of the eight histone proteins. Modified with permission from Chapter 3 in Allis, C. D., Jenuwein, T., & Reinberg, D. (2007). *Epigenetics*. Cold Spring Harbor, NY: Cold Spring Harbor Laboratory Press. B (Right). Sites of Histone Tail Modifications. The amino-terminal tails of histones host the vast majority of known covalent modification sites as illustrated. Modifications do occur in the globular domain (boxed), some of which are indicated. In general, active marks include acetylation (turquoise Ac flag), arginine methylation (yellow Me flag), and some lysine methylation such as H3K4 and H3K36 (green Me flag). H3K79 in globular domain has anti-silencing function. Repressive marks include H3K9, H3K27, and H4K20 (red Me flags). Green = active mark, red = repressive mark. Reproduced with permission from Chapter 3 in Allis, C. D., Jenuwein, T., & Reinberg, D. (2007). *Epigenetics*. Cold Spring Harbor, NY: Cold Spring Harbor Laboratory Press. (See Color Plate Section for a color version of this figure.)

There are also many non-histone proteins that become stably or transiently associated with chromatin. These include various transcription factors, repressors, and large complexes of proteins that mediate replication and transcription. There are also large complexes of proteins referred to as histone remodeling complexes that play a major role in placing and removing various histone marks, as discussed in Chapters 11 and 12 of *Epigenetics* (Allis et al., 2007) (Fig. 42-3). As an example, these include various histone methylases, histone demethylases, and histone deacetylases (HDACs) (Aalfs & Kingston, 2000). The biochemistry of these histone remodeling complexes is the subject of rapidly progressing research.

Biology and Heritability of Epigenetics

The heterogeneity of the epigenotype in different cell types within a single individual is enormous compared to the lack of heterogeneity of the genomic sequence in a single individual. Except for somatic mutation, every cell in the body has the same genomic sequence. In contrast, the epigenotypes of cells across tissues and across development differ dramatically. There is evidence that the epigenotype changes with age (Gravina & Vijg, 2009). Indeed, it is the epigenetic information that causes a hepatocyte to be stably different than a neuron. Reviews of the role of epigenetics in development are available (Reik, 2007). Epigenetic errors in brain development could theoretically contribute to the etiology of autism. Given the tens of millions of sites for potential differences in DNA methylation and histone modification and the diploid nature of the genome, one could reasonably argue that no two cells in the body have precisely the same detailed epigenotype at any given moment in time, although functionally equivalent genotypes are probably relatively common within a single cell type. There certainly are millions of epigenetic differences between a hepatocyte and a neuron. Although the term *epigenome* has been used loosely to describe epigenetic variation, it seems likely that there are as many functional epigenotypes or epigenomes as there are cell types in the body.

The heritability of genetic and epigenetic information also differs dramatically. The vast majority of mutations are
Figure 42–3. Coordinated Modification of Chromatin. The transition of a naive chromatin template to active euchromatin (left) or the establishment of repressive heterochromatin (right), involving a series of coordinated chromatin modifications. In the case of transcriptional activation, this is accompanied by the action of nucleosome remodeling complexes and the replacement of core histones with histone variants (yellow—namely, H3.3). Reproduced with permission from Chapter 3 in Allis, C. D., Jenuwein, T., & Reinberg, D. (2007). *Epigenetics*. Cold Spring Harbor, NY: Cold Spring Harbor Laboratory Press. (See Color Plate Section for a color version of this figure.)

inherited, but germline de novo point mutations have been appreciated for decades, although de novo copy number variations (CNVs) have only been appreciated more recently. Despite these de novo germline mutations, the genomic sequence is highly heritable in transmission from parent to offspring. In contrast, epigenetic information has the potential to be entirely heritable or entirely nonheritable. There is compelling evidence that certain epigenetic marks can be transmitted from a parent to offspring both in plants (Chandler & Stam, 2004) and in mammals (Morgan et al., 1999; Rassoulzadegan et al., 2006). In contrast, other epigenetic marks can be completely erased and reset in the course of transmission from parent to offspring, as occurs at every generation for sites of genomic imprinting. In fact, within genomic imprinting, both extremes are simultaneously present. In the mother, the state of all maternally derived alleles will be entirely heritable and all paternally derived alleles will be erased and reset. The reciprocal is true for paternal inheritance. Thus, one might say that epigenetic information or the epigenotype is semi-heritable or variably heritable. Although genomic imprinting displays the ability for the epigenotype at a locus to be relatively completely heritable on one parental allele while at the same time being nonheritable on the other allele, presumably intermediate states of heritability can occur as well, such as partial erasure and resetting of the epigenotype in the course of germline transmission. This relatively unpredictable behavior of the epigenotype as regards heritability creates significant challenges for the interpretation of complex data from human control and disease populations.

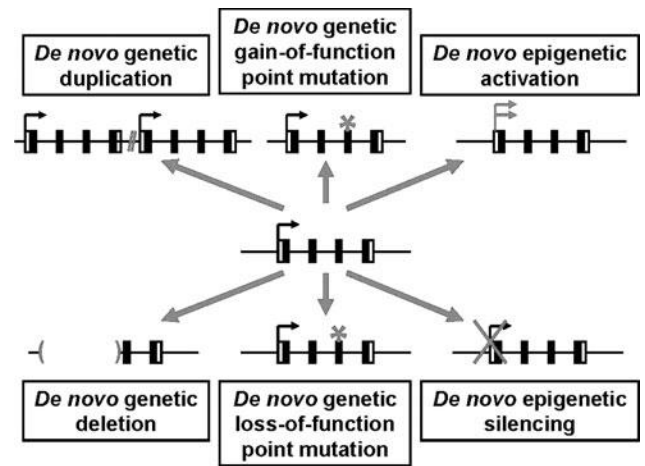
Does epigenetics contribute to any missing heritability in autism? The puzzle of missing heritability (McCarthy & Hirschhorn, 2008; Maher, 2008; Manolio et al., 2009) is exemplified by the evidence that the heritability of height is very high, yet the putative loci identified by genome-wide association studies (GWAS) account for only a tiny fraction of this heritability. In the case of autism, one puzzle is that concordance is very high in monozygous twins (MZ) but low in dizygous (DZ) twins. This seeming contradiction is likely explained primarily by the role of de novo mutations, which will cause concordance in MZ but not DZ twins, although de novo epimutations could contribute as well. Recent mutations occurring in the last few generations in a family with reduced penetrance can also contribute to heritability in siblings that will not be detected efficiently by GWAS (Shinawi et al., 2009). There are multiple possible sources for "missing heritability" (Maher, 2008), but epigenetics is certainly among them. Purely epigenetic effects will generally not be detected by GWAS, although they might be detected if they were heritable over many generations, but this is unlikely given the semi-heritable nature of epigenotypes. Epigenetic contributions might be abrupt and precise, as in a de novo epimutation that silences a single gene. Alternatively, they might be incremental and affect the genome more broadly if, for example, cumulative nutritional changes over decades and centuries altered DNA or histone methylation.


Figure 42–4. Large mutations, small mutations, and epimutations. Large mutations (copy number variants; CNVs) typically delete or duplicate a complete copy of a gene resulting in under- or overexpression, although position effects on regulatory elements can have unpredictable outcomes. Point mutations can inactivate a gene (nonsense or frameshift), increase or decrease or otherwise alter (e.g., dominant negative) the function of a transcribed RNA or the resulting protein. Epimutations can up- or down-regulate expression, most often at a transcriptional level.

Epimutations and Transgenerational Inheritance

Any known genetic mutation has the potential to provide a precedent for a similarly acting epimutation (Fig. 42-4). We know large deletions and duplications can cause decreases or increases, respectively, in the abundance of a protein, and we know of point mutations that can cause loss of function or gain of function. Analogous epimutations are possible. Figure 42-4 depicts a circumstance for dominant mutations and epimutations. One can imagine recessive epimutations analogous to recessive mutations and perhaps speculatively even an individual with a recessive mutation on one chromosome and a recessive epimutation on the other chromosome. This might be considered as a compound heterozygous mixed genetic and epigenetic genotype/epigenotype.

The potential for inheritance of epigenetic states has been referred to as *transgenerational inheritance* (Pembrey, 1996). Sex-specific, male-line transgenerational effects in humans and transgenerational effects related to nutrition, early life circumstances, and longevity have been discussed (Pembrey et al., 2006; Kaati et al., 2007). Nadeau (2009) has reviewed how "many studies showed that a remarkable variety of factors including environmental agents, parental behaviors, maternal physiology, xenobiotics, nutritional supplements and others lead to epigenetic changes that can be transmitted to subsequent generations without continued exposure." A proposed distinction between heritable germ-line epimutation and transgenerational epigenetic inheritance has

been suggested (Chong, Youngson, & Whitelaw, 2007), whereby the first is envisioned as an "atypical" (perhaps disease-causing) epigenetic state and the second represents more of a continuum of common epigenetic states.

The Barker hypothesis focuses on how the *in utero* environment—specifically reduced fetal growth—is associated with a number of chronic conditions later in life. The Barker hypothesis does not necessarily invoke transgenerational heritability of epigenetic effects, but it is commonly believed to imply an epigenetic mechanism (Waterland & Michels, 2007). Numerous reports have emphasized the potential for harmful, epigenetically mediated effects such as adverse environmental effects (Franklin & Mansuy, 2009), a metabolic ghetto effect (Wells, 2009), and the potential epigenetic impact of abuse and neglect (Neigh, Gillespie, & Nemeroff, 2009). Meaney and colleagues have published multiple studies suggesting that maternal licking behaviors in rats alters hippocampal glucocorticoid receptor gene expression in the pups by altering the acetylation of H3K9 and the DNA methylation at the promoter (Fish et al., 2004). These data argue that maternal postnatal behavior can alter the epigenotype of offspring. More recently, these investigators have presented data suggesting epigenetic differences in postmortem brain from suicide victims with a history of childhood abuse compared to brain from either suicide victims with no childhood abuse or controls (McGowan et al., 2009).

Methods for Epigenetic Analysis

One approach to the study of epigenetic differences in disease compared to control tissues is to analyze gene expression at the transcript or protein level, which reflects the combined genetic and epigenetic effects, and then try to deduce whether any differences are of genetic or epigenetic origin. Alternatively, one can attempt to study the epigenotype directly. The methods for analysis of covalent histone modifications are well-developed and quite satisfactory, although they are by no means mature (*see* Box 42-2).

The methodology for genome-wide analysis of DNA methylation is much more problematic than that for analysis of histone modifications. There are numerous restriction enzymes that will digest DNA differentially depending on its state of methylation. Many procedures have been developed using these methylation-dependent restriction enzymes to deduce the DNA methylation status at specific CpG dinucleotides. A variety of methods utilize these restriction enzymes to enrich for methylated or unmethylated DNA, and these selected DNAs are then quantified often using array technology. Methods based on the use of restriction enzymes detect polymorphisms in recognition sites, which may appear as false-positive evidence of methylation differences. Another powerful technique is the use of bisulfite sequencing to distinguish methyl C residues from C residues in DNA. Although the molecular details are relatively complex as explained

Box 42–2

Here, chromatin is isolated from cells or tissue usually with formaldehyde cross-linking and is fragmented to yield material with a DNA length of 150–500 bp; ~150 bp of DNA wraps around one nucleosome. ChIP can be performed with formaldehyde cross-linking (X-ChIP) or without cross-linking (native ChIP, N-ChIP) for tightly associated proteins such as histones. For more loosely associated non-histone chromatin proteins, X-ChIP is ordinarily required. An antibody is used to precipitate the chromatin fragments with a particular epitope. Initially, ChIP was performed using PCR amplification of target regions to identify DNA segments which were immunoprecipitated by a particular antibody. Subsequently, analysis of precipitates was performed on microarrays for quantification of large numbers of sites in the genome (ChIP-chip). More recently, DNA precipitates are commonly analyzed by high throughput parallel DNA sequencing (ChIP-seq). In 2008, the U.S. National Institutes of Health funded a series of Reference Epigenome Mapping Centers; *see* NIH Roadmap for Medical Research, Roadmap Initiatives, Epigenomics (http://nihroadmap.nih.gov/epigenomics/). The pros and cons of the Roadmap initiative are debated (Madhani et al., 2008; Henikoff, Strahl, & Warburton, 2008).The mapping centers have all adopted ChIP-seq as the standard methodology for analysis of histone modifications. Although new covalent modifications are still being defined, and better antibodies are sorely needed, it can be anticipated that ChIP-seq will be applied widely in the studies of control compared to disease samples. In September 2009, the NIH Roadmap Initiative funded as series of grants focused on the epigenomics of human health and disease.

elsewhere (Xi & Li, 2009), this method uses a chemical modification of DNA such that in subsequent sequencing methyl-C will be retained as C and unmethylated-C residues will be converted to T in the sequence. One foreseeable optimal bisulfite strategy will be to perform genome-wide bisulfite shotgun sequencing (BS-seq) (Lister et al., 2009), but this is currently cost-prohibitive for large-scale, high-throughput studies. Meanwhile, alternative strategies, such as reduced representation BS-seq (RRBS) (Smith et al., 2009), comprehensive high-throughput arrays for relative methylation (Irizarry et al., 2008), and other restriction enzymes methodologies are being used to compare control and disease samples. The methodology to be employed to analyze DNA methylation in disease research projects is likely to continue to evolve rapidly. If the cost of genome-wide BS-Seq were to drop by two orders of magnitude, as some experts predict, it might become feasible to use this strategy for disease studies. Another very useful method is array-based analysis of the percent methylation at individual CpG positions (Bibikova et al., 2006), and a recent improvement with the ability to analyze 450,000 CpG sites in a single array analysis (HumanMethylation450 DNA Analysis BeadChip; Illumina Inc. San Diego, CA) makes this a very attractive option for disease projects at present.

The computational methods necessary for genome-wide epigenetic analysis are extremely challenging and in a relatively early stage of development. The ability to compare the genome-wide epigenotype between cell types and between individuals is being refined. In addition, various analyses of DNA methylation and ChIP are being performed on mixed cell populations, such as mixed leukocytes isolated from blood or mixtures of neuronal and non-neuronal cells in brain tissue, and there is no method, at present, to assign the data to individual cell types within the populations other than prior fractionation of cell populations.

Although ChIP for the analysis of histone modifications is widely performed, ChIP analysis for proteins more loosely associated with chromatin is less well-standardized, but there are numerous demonstrations of the feasibility for such analysis—for example, using antibodies to methyl-CpG binding proteins. ChIP can be used to distinguish transcription initiation from transcription elongation using antibodies against RNA polymerase II (Gilchrist, Fargo, & Adelman, 2009). ChIP-seq using antibodies against CCCTC-binding factor has been used to characterize chromatin barriers and their tissue specificity (Cuddapah et al., 2009). ChIP-seq using an antibody against enhancer-associated protein p300 is useful in localizing enhancers and defining their tissue specificity (Visel et al., 2009; Heintzman et al., 2009). This analysis has the potential to discover both genetic and epigenetic abnormalities affecting enhancers. ChIP was used to study the polycomb group (PcG) and trithorax group (trxG) proteins in Drosophila (Schuettengruber et al., 2009), and similar studies will be important in mice and humans.

Difficulties Encountered in Epigenetic Studies of Human Disease

The major obstacle in epigenetic studies of human disease lies in the fact that all cell types can differ from each other and that only a limited number of cell types are easily accessible from living patients and controls. In the context of autism, one could hypothesize that there might be epigenetic changes in specific neural cell types, such as Purkinje cells, various classes of hippocampal neurons, and so forth. The epigenetic differences of disease importance may be present in all cells of the body or they may be unique to individual cell types. Examples of epigenetic differences detectable in all cell types and epigenetic differences restricted to selected populations are both available from disorders of genomic imprinting, such as Prader-Willi syndrome (PWS), Angelman syndrome, Beckwith-Wiedemann syndrome (BWS), and others. For example, the differential DNA methylation at the imprinting center for the PWS/Angelman syndrome domain is detectable in all cell types that have been studied, and it is stable in cultured cells. In contrast, the imprinted expression of the Angelman syndrome gene (*UBE3A*) is prominent in many neurons, but expression is not imprinted or at least not as dramatically differential in glia and somatic cell types (Yamasaki et al., 2003). In genetic studies, one can safely assume that the genomic sequence is similar in leukocytes to that in other parts of the body, and even DNA from cultured lymphoblasts is quite useful for large studies because of the unlimited amounts of DNA available, although cell culture artifacts—particularly involving aneuploidy—are found in lymphoblast cultures (Redon et al., 2006). Thus, utilization of blood leukocytes, cultured skin fibroblasts, and cultured lymphoblasts all have a very substantial risk that epigenetic abnormalities present in brain may not be reflected in these cell types.

One additional option has emerged with the emphasis on stem cell research. It is now possible to develop induced pluripotent stem cells (iPSCs) from cultured skin fibroblasts (Byrne, Nguyen, & Reijo Pera, 2009), and this offers the possibility that such cells can be induced to differentiate toward a neural pathway. These differentiated iPSCs might provide an opportunity to study neural-specific properties of cells from living patients. For example, there is a report of attempts to model the pathogenesis and treatment of familial dysautonomia using patient-specific iPSCs (Lee et al., 2009). This strategy has some potential to greatly facilitate studies of epigenetics in autism.

If one resorts to epigenetic analysis of postmortem brain tissue, there are still numerous obstacles, including the limited number of samples available and the potential for agonal and postmortem artifacts. Although disease-specific brain banks exist, there are important limitations and cautions in their utilization particularly as regards heterogeneous preservation of specific RNAs and proteins (Ferrer et al., 2008). Agonal effects on gene expression profiles occur (Tomita et al., 2004), although the levels of miRNAs may be less susceptible to artifact (Zhang et al., 2008). The pH of the postmortem tissue is a helpful index of agonal effects (Vawter et al., 2006). Studies of histone modifications using ChIP (Huang et al., 2006) and studies of DNA methylation (Ernst et al., 2008; Byun et al., 2009) in postmortem tissues are believed to be relatively resistant to artifact. Premortem effects of medications, diet, age, smoking, and other factors, such as epilepsy, also could lead to secondary changes not related to the causative factors for autism. In the case of point mutations and CNVs causing autism, it is feasible to collect blood samples from hundreds and even thousands of affected patients for comparison to appropriate controls. This is important because of the presence of extreme heterogeneity in autism such that mutations in any one locus will likely account for less than 1% of all cases. In comparison, brain tissue is available for perhaps a few hundred cases or less, and the ability to obtain strong statistical evidence that a particular epigenetic abnormality found in brain is associated with autism will be extremely difficult. In addition, it usually is not feasible to study the heritability of any brain-specific epimutations. If one finds an epigenetic abnormality in neurons from postmortem brain in a case of autism, then there is usually no ability to obtain similar data from living or deceased parents. The presence of cellular heterogeneity within most

brain regions provides another important challenge. For example, epigenetic abnormalities restricted to Purkinje cells and not affecting cells in the granular or molecular layer cells are likely to be difficult to detect in a fragment of cerebellum containing all cell types.

Epigenetics and Disease States

Epigenetic abnormalities may occur through a variety of mechanisms that include both primary and secondary effects, as enumerated in Table 42-1. There are many examples of primary genetic mutations causing secondary epigenetic abnormalities associated with intellectual disability and/or autism. Most of these involve trans-acting effects on all the chromosomes in the genome as is the case for Rett syndrome and other disorders as listed in Table 42-1 (*see* reviews for disease-specific information; Ausio et al., 2003; Bickmore &

Table 42–1.
Secondary and primary epigenetic abnormalities associated with human disease

A. Primary Genetic with Secondary Trans-Acting Epigenetic Effects

> 1. Rett syndrome, MECP2 duplication, immunodeficiency–centromeric instability–facial anomalies (ICF) syndrome, alpha-thalassemia/intellectual disability syndrome X-linked (ATRX), Rubinstein–Taybi syndrome, Coffin–Lowry syndrome, and mutations in *JARID1C, EHMT1, NRLP2, NRLP7, ZFP57*

B. Primary Genetic with Cis-Acting Secondary Genetic Effects

> 1. Fragile X syndrome, deletions of imprinting centers, PWS, Angelman Syndrome

C. Combined Co-Primary Genetic and Epigenetic Interaction

> 1. Parent-of-origin dependent PWS or Angelman Syndrome for the same deletion 15q11-q13
>
> 2. Parent-of-origin-dependent autism with duplication of chromosome 15q11-q13
>
> 3. Uniparental disomy where genetic trisomy or monosomy is rescued to result in UPD.

D. Pure Epigenetic Mechanism Spontaneous or Environment-Induced

> 1. Imprinting defect causing PWS, Angelman Syndrome, or BWS with no imprinting center deletion or mutation with or without assisted reproductive technology.
>
> 2. Epimutation of HNPCC
>
> 3. Possible epimutation of UBE3A, hypothetical epimutation silencing of known autism genes such as *NRXN1, SHANK3, NLGN4X/Y*
>
> 4. Hypothetical similar to licking behavior induced epigenetic changes in rat
>
> 5. Hypothetical similar to folic acid effects on Agouti locus in mouse and *SYBL1* in human

van der Maarel, 2003; Urdinguio, Sanchez-Mut, & Esteller, 2009). Another example that could provide a precedent for autism is a report of homozygous mutation in *NLRP2* in a mother resulting in multiple offspring with BWS (Meyer et al., 2009). Given the numerous genes involved in chromatin modification, many more such disorders will certainly be described.

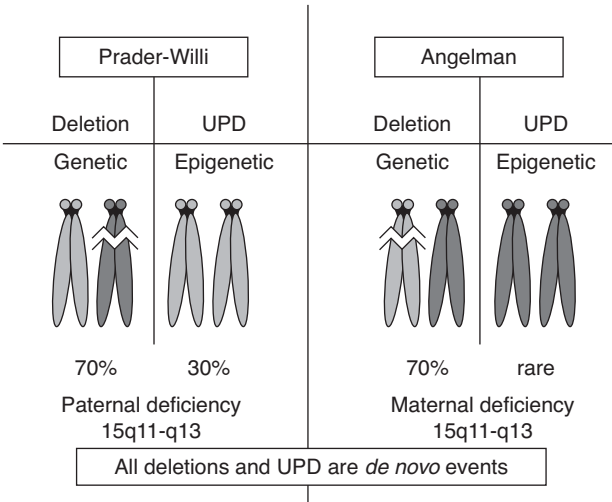
In contrast to genome-wide effects, primary genetic mutations may be cis-acting—that is, they may have secondary epigenetic effects only on the chromosome on which the abnormality occurs, as is the case for Fragile X syndrome and deletions of imprinting centers. There are also numerous examples of combined co-primary genetic and epigenetic effects giving rise to phenotypes. This is particularly well-demonstrated by disorders involving genomic imprinting. Deletions of the paternal copy of chromosome 15q11-q13 cause PWS, whereas the same deletion on the maternal chromosome causes Angelman syndrome (Fig. 42-5). The available data regarding PWS and Angelman syndrome are particularly instructive regarding the potential for epigenetic abnormalities causing human disease, because duplication of this same region is one of the more common genetic/epigenetic abnormalities causing autism. The data from PWS and Angelman syndrome provide numerous lessons. The most common cause of these disorders is a 5- to 6-Mb deletion whose phenotype depends on the chromosomal parent of origin. Thus, the primary abnormality is entirely genetic, although the expression of the phenotype entirely depends on the epigenetic state of the chromosome. In contrast, the PWS can be caused by maternal uniparental disomy (UPD), and Angelman syndrome can be caused by paternal UPD. In these cases, there is usually an initial genetic abnormality, such as


Figure 42–5. Genetic deletion or epigenetic uniparental disomy (UPD) give rise to indistinguishable phenotypes. UPD = uniparental disomy. Modified with permission from Jiang, Y., Bressler, J., & Beaudet, A. L. (2004). Epigenetics and Human Disease. *Annual Review of Genomics and Human Genetics, 5,* 479–510.

monosomy or trisomy conception, followed by genetic rescue to disomy status but with both chromosomes coming from a single parent. In this case, the genetic abnormalities result in a final product that is entirely epigenetic in that there is no abnormality of nucleotide sequence. Another important lesson is that both of these forms of genetic and epigenetic PWS/Angelman syndrome are of de novo origin. For the most part, neither genetic nor epigenetic de novo events will be detected by linkage or association studies, unless the genotyping detects the mutation itself, as can occur when arrays used to analyze single nucleotide polymorphisms (SNPs) detect large deletions or duplications. There are also two forms of imprinting defects causing PWS and Angelman syndrome. There are genetic forms involving small deletions of the imprinting center with secondary epigenetic effects. There are also imprinting defects with no evidence of any genetic mutation, and these are believed to be strictly epigenetic imprinting defects. There is some evidence that assisted reproductive technologies may increase the risk of epigenetic imprinting defects, causing Angelman syndrome and BWS (Owen & Segars, Jr., 2009). Thus, the experience from PWS and Angelman syndrome demonstrates that there can be extremely complex mixtures of genetic and epigenetic abnormalities causing a single phenotype and that many of the events may be of de novo, rather than inherited, origin. We have suggested that this fits a mixed epigenetic and genetic and mixed de novo and inherited (MEGDI) model for the etiology of a phenotype, and we have suggested that de novo and epigenetic abnormalities might explain the relative lack of success in using linkage and association studies to identify autism genes (Jiang et al., 2004).

Finally, there is the possibility of a pure epigenetic abnormality, such as the silencing of a single gene. Figure 42-4 depicts the potential for de novo point mutations to cause loss-of-function or gain-of-function for a gene. Similarly, a CNV may delete or duplicate a gene with corresponding reduced or increased expression, respectively. Finally, a strictly epigenetic abnormality might cause silencing of a gene, which ordinarily should be active, or activation of expression of a gene, which ordinarily should be silenced. All of these mechanisms can lead to increased or decreased function for a particular gene product. It now appears relatively clear that a very large fraction of autism associated with intellectual disability and dysmorphic features is caused by recent or de novo CNVs or point mutations (Jacquemont et al., 2006; Sebat et al., 2007; Marshall et al., 2008). These mutations are typically deleterious in terms of reproductive fitness, and the mutations ordinarily persist for only one or a few generations in the family. If a genotype is incompatible with reproduction, all cases will be of de novo origin (e.g., *SHANK3* deletion). If a mutation is highly penetrant but compatible with reproduction, one may see a parent-to-child transmission of a phenotype such as intellectual disability and/or autism affecting both parent and child. This is common for deletion of chromosome 15q13.3 (Shinawi et al., 2009). If a mutation is incompletely penetrant, then one may see a parent with the mutation and a normal phenotype, whereas the child has the mutation with an autism phenotype. For those genes where a loss-of-function mutation with the resulting haploinsufficiency causes an autism phenotype, it is always theoretically possible that an epimutation silencing one allele of the gene would also cause autism. There is one report of what may be an epimutation causing autism involving methylation of the CpG island at the promoter for *UBE3A* (Jiang et al., 2004), but no similar cases have been found. There is evidence of epimutations causing mismatch repair defects, leading to hereditary nonpolyposis colon cancer (*see* below). For the severe portion of the autism spectrum associated with intellectual disability and dysmorphic features, it now seems that de novo and recent deleterious mutations account for the majority of cases. Presumably, many loss-of-function point mutations will be discovered in similar patients without CNV mutations. It is possible that a smaller fraction of cases could be caused by epigenetic abnormalities of individual genes, but this has yet to be clearly documented.

For the milder end of the autism spectrum, typically associated with more normal cognitive function and absence of dysmorphic features, the etiology remains much less clear. For this population, the dividing line between affected versus unaffected status is more difficult to define. To the extent that genetic abnormalities are involved, we might speculate that these abnormalities could be more subtle, involving lesser degrees of dysregulation; if a single mutation or epimutation confers a major risk, then this may be associated with relatively low penetrance and variable expression. Factors with low penetrance may be difficult to detect in linkage and association studies. The large body of data from studies of linkage and association suggests that no one individual gene with highly penetrant mutations has a particularly large role in this population. One widely tested hypothesis to explain this milder portion of the autism spectrum is a multilocus epistatic model (Bonora et al., 2006). In this model, multiple loci would contribute to the autism risk in a single individual. This hypothesis generally would assume that the genotypes involved are ancient and might be detected by linkage disequilibrium, as in genome-wide association studies. The multilocus epistatic model remains a viable possibility for the milder portion of the autism spectrum, but many other etiological mechanisms also are possible. One can hypothesize that epigenetic abnormalities might be important, and these might be heritable, partially heritable, or not at all heritable. One can hypothesize environmental effects, and it is attractive to consider the possibility of environmental effects being mediated through epigenetic mechanisms.

Epimutations That Cause Disease

Errors in erasing and resetting the genomic imprint during gameteogenesis could cause epimutations.

Gametogenesis: process by which diploid precursor cells undergo cell division and differentiation to form mature haploid gametes (egg and sperm).

Maternal mutations in *NLRP7* that cause recurrent biparental complete hydatidiform molar pregnancies (Murdoch et al., 2006) and maternal mutations in *NLRP2* that cause recurrent BWS (Meyer et al., 2009) represent genetic mutations that cause secondary epimutations. Imprinting defects associated with BWS can be either germline or de novo, and UPD is often mosaic (Riccio et al., 2009; Weksberg, Shuman, & Beckwith, 2010) Epimutations of chromosome 11p15 that affect the *H19* and/or *IGF2* genes are the most common cause of Silver-Russell syndrome (Bartholdi et al., 2009). Mutations in *ZFP57* are associated with transient neonatal diabetes and a global imprinting disorder compatible with life (Mackay et al., 2008).

Primary epimutations with no apparent genetic precursor that affect the mismatch repair genes *MLH1* or *MSH2*, resulting in hereditary nonpolyposis colon cancer and other cancers (Suter, Martin, & Ward, 2004; Chan et al., 2006), represent convincing and compelling examples of how epimutations could theoretically be occurring in autism. Initial and subsequent reports (Cropley, Martin, & Suter, 2008) demonstrate how these epimutations may be inherited or de novo and affect a single locus. De novo epimutations may be mosaic or may be present in all cells tested, with the latter implying a germline origin. One can easily hypothesize that epimutations silencing genes such as *NRXN1, NLGN4X/Y, SHANK3, CNTNAP2*, or others (Sutcliffe, 2008) could cause autism and that these epimutations might be brain- or neuron-specific and quite difficult to detect.

Epigenetics and Autism, Schizophrenia, and Related Phenotypes

The etiology of autism and schizophrenia are increasingly viewed as intertwined. Deletions of single regions can cause a wide spectrum of phenotypic abnormalities, as exemplified by the ability of deletions of 15q13.3 and *CHRNA7* to cause intellectual disability, autism, schizophrenia, epilepsy, and bipolar disorder with incomplete penetrance (Shinawi et al., 2009). Data of this type has led to the suggestion that schizophrenia, and by inference autism, might be described as: "one disorder, multiple mutations; one mutation, multiple disorders" (Sebat, Levy, & McCarthy, 2009). For other CNVs involving chromosome 16p11.2, there is the suggestion that deletions cause autism and intellectual disability (Weiss et al., 2008), whereas duplications cause schizophrenia (McCarthy et al., 2009b).

Crespi and colleagues have suggested that imprinted genes may play an important role in both autism and schizophrenia (Crespi, 2008; Badcock & Crespi, 2008). The possibility that schizophrenia and autism might have some diametrically opposite and/or overlapping biochemical or physiological components to their etiology has been discussed (Crespi, Stead, & Elliot, 2009), and these could involve a complex mixture of genetic and epigenetic mechanisms.

It has been suggested that epigenetic abnormalities may be important in the etiology of schizophrenia (Oh & Petronis, 2008). This might be compatible with suggestions that epigenetic mechanisms may play a role in memory formation and that DNA methylation and histone acetylation may work in concert to regulate memory formation and synaptic plasticity (Levenson & Sweatt, 2005; Miller, Campbell, & Sweatt, 2008).

There are some intriguing data suggesting that *in utero* exposure to famine during the Dutch Hunger Winter at the end of World War II increased the risk of schizophrenia and schizophrenia spectrum personality disorders (Hoek, Brown, & Susser, 1998). Similar data from a Chinese famine support the notion that *in utero* exposure to famine increases the risk of schizophrenia (St. Clair et al., 2005). Epigenetic studies of the Dutch cohort performed six decades after the famine found less DNA methylation of the imprinted *IGF2* gene compared with their unexposed, same-sex siblings (Heijmans et al., 2008) and found that the differences depended on the sex of the exposed individual and the gestational timing of the exposure (Tobi et al., 2009). Given the increasing examples where the same CNV is associated with both autism and schizophrenia (Sebat et al., 2009), and the sex ratio in autism relative to the differential effect of famine dependent on fetal sex, the possibility of a link between *in utero* nutrition and autism is intriguing.

The famine connection is easily linked to the possible role of folic acid deficiency, because the famine increased the risk of neural tube defects as well as schizophrenia (Hoek et al., 1998). It is known that folic acid and intake of related metabolites can influence one-carbon metabolism and DNA methylation in vivo. Methylation of DNA and methylation of histones both play important roles in epigenetic regulation. There is evidence that folic acid and metabolite intake can influence gene expression in mice and humans. In mice, the widely cited example of the effect of diet on expression of the agouti viable yellow allele has been studied extensively (Wolff et al., 1998; Waterland & Jirtle, 2003). There is limited analogous evidence in humans that folic acid and metabolite intake can affect gene expression (Ingrosso et al., 2003). From the possibility of opposite biochemical mechanisms for autism and schizophrenia, one can speculate that folate deficiency might increase the risk of schizophrenia and that folate excess might increase the risk of autism. The apparent increase in the diagnosis of autism has occurred over an interval when folic acid intake in many countries started increasing in the mid-1970s and increased progressively to include fortification in the late 1990s. This has led to discussion of the relevance of folic acid intake to autism (Jiang, Bressler, & Beaudet, 2004) and to speculation that increased folic acid intake may increase the risk of autism (Leeming & Lucock, 2009). In contrast, data from Schmidt et al. (Abstract 2009 IMFAR Meeting http://imfar.confex.com/imfar/2009/webprogram/Paper4182.html) suggest the increased

folic acid intake may reduce the risk of autism. There is some evidence that autism is associated with impaired methylation capacity and increased oxidative stress (James et al., 2004) and that treatment with methylcobalamin and folic acid might improve glutathione redox status (James et al., 2009).

Examples of Studies of PostMortem Brain in Autism

The LaSalle laboratory has published numerous studies of autism brain including evidence that MeCP2 expression is reduced in autism brain in association with aberrant *MECP2* promoter methylation (Nagarajan et al., 2008; Hogart et al., 2009). There is a report that reduced expression of the oxytocin receptor is associated with significant increases in the DNA methylation in the peripheral blood cells and temporal cortex in autism (Gregory et al., 2009). Detailed genome-wide analyses of the epigenotype in postmortem brain are just beginning to appear. In a first-of-its-kind study, DNA methylation changes were described in the frontal cortex and in the germline associated with schizophrenia and bipolar disorder (Mill et al., 2008). The results suggested that systemic epigenetic dysfunction may be associated with major psychosis. The authors also found that DNA methylation of the *BDNF* gene in frontal cortex was correlated with genotype at a nearby nonsynonymous SNP previously associated with major psychosis. Two earlier reports of gene-specific analyses found increased methylation of the reelin promoter in schizophrenia brain (Abdolmaleky et al., 2005) and decreased methylation of the *COMT* promoter in schizophrenia and bipolar disorder brain (Abdolmaleky et al., 2006).

We have performed genome-wide analyses of postmortem brains from PWS, Angelman syndrome, and controls to demonstrate the feasibility of detecting known epigenetic abnormalities using genome-wide methods. Using methylated DNA immunoprecipitation, we found the expected absence of methylated DNA at the PWS imprinting center (PWS-IC) in Angelman syndrome brains, but PWS brains were not detectably different from controls (Fig. 42-6). Using restriction enzyme methods that detect enrichment of unmethylated DNA, we found the expected absence of the unmethylated DNA at the PWS-IC in PWS brains, but Angelman syndrome brains appeared normal (unpublished and not shown). These results demonstrate that two methods—one each to detect methylated and unmethylated DNA—may be required to detect all abnormalities. Bisulfite sequencing has the potential to quantify methylated and unmethylated sites in a single analysis.

We have performed similar studies using ChIP-chip and ChIP-seq to compare PWS and Angelman syndrome brains to controls. ChIP analysis using an antibody to H3K4me3 detects the difference in the active promoter for *SNRPN*, which is present in controls but absent in PWS brains (Fig. 42-7), but Angelman syndrome brains are not distinguished from controls. ChIP-chip using an antibody to H3K9me3 detects the absence of this mark in Angelman syndrome brains compared to controls but does not detect any difference between PWS brains and controls (unpublished and not shown). Thus, ChIP must use multiple antibodies to different histone marks to detect all abnormalities.
Figure 42–6. Analysis of DNA methylation using methylated DNA immunoprecipitation (MeDIP). Genomic DNA from control, PWS deletion, and Angelman deletion were first digested with *Mse*I restriction enzyme and then immunoprecipitated using an antibody against 5-methyl-cytosine (Weber et al., 2005). Precipitated DNA was co-hybridized with its respective input on the Nimblegen CpG island arrays. At the PWS-IC on chromosome 15, a peak of methylated DNA on the maternal chromosome is detected in control and PWS DNA but not Angelman DNA. Right panel is an expanded view of the region with the red arrows. X. Z., unpublished. (See Color Plate Section for a color version of this figure.)
Figure 42–7. Native chromatin immunoprecipitation with microarray analysis (N-ChIP-chip). N-ChIP-chip was performed using an antibody against H3K4me3, in both a PWS-UPD and control cerebellum samples. H3K4me3, a mark indicative of transcription, is known to be absent at the SNRPN-DMR in PWS deletion and UPD samples. Immunoprecipitates were individually hybridized to an Agilent whole genome promoter array and plots of enrichment for two chromosomes superimposed (top two panels, green = control and pink = PWS). The largest difference of H3K4me3 enrichment genome-wide was detected at the *SNRPN* promoter evident by the presence of a single green peak on chromosome 15 (red arrow in middle panel). This finding was additionally confirmed by individually hybridizing samples to custom Agilent tiling arrays of 15q11-q13 (bottom panel). R.P., unpublished. (See Color Plate Section for a color version of this figure.)

Epimutations: Genetic, Epigenetic, Environment, and Stochastic Interactions

The epigenotype is intrinsically more variable and more plastic compared to the sequence of the genome (Fig. 42-8A). The epigenotype can dramatically alter gene expression. Thus there is abundant potential for the genotype, the environment, and stochastic factors to alter the epigenotype. There must be a specific epigenotype for the egg and the sperm at the moment of fertilization, but there is evidence that the epigenotype is changing even in the fertilized oocyte (Reik, 2007), and epimutations could occur prior to and immediately after fertilization. Errors in erasing and resetting the genomic imprint during gameteogenesis could cause epimutations as discussed above.

Potential for Epigenetic Therapy

The fact that the epigenotype is potentially alterable during life opens the possibility at least for epigenetic pharmacotherapy (Szyf, 2009). There are numerous histone deacetylase inhibitors, and there are animal studies exploring effects on gene expression in brain. The most widely studied HDAC inhibitors are trichostatin A and suberoylanilide hydroxamic acid (Fig. 42-8B). Data are also available for histone methyltransferase inhibitors and DNA demethylating agents such as 5-aza-cytidine and zebularine. There is a report of long-term oral administration of zebularine to mice with minimal side effects and prevention of intestinal tumors (Yoo et al., 2008).

Changing Incidence?

There has been extensive debate as to whether the incidence of autism has increased over the last 20 years as is discussed in other chapters in this book. Although there is definitely an increase in the diagnosis of autism, the apparent increase may be partially or completely explained by diagnostic substitution, diagnosis of milder phenotypes, and/or increased awareness (King & Bearman, 2009; Fombonne, 2009). If there is a true increase, this is of enormous importance, as this would suggest that some change in the environment is affecting the incidence of autism and that reversal of this environmental effect should lower the incidence of autism. Understanding
Figure 42–8. A (Upper panel). Interaction between genetics, epigenetics, and environment to give rise to phenotype. B (Lower panel) Potential for pharmacologic modification of the epigenome. Exposure to Dnmt inhibitors such as 5-aza-cytidine (5-aza) or zebularine can result in a loss of DNA methylation, and exposure to HDAC inhibitors such as suberoylanilide hydroxamic acid (SAHA) can result in the acquisition of histone acetyl marks and subsequent downstream modifications, including active histone methyl marks and the incorporation of histone variants. The cumulative chromatin changes can lead to gene expression. Modified with permission from Chapter 3 in Allis, C. D., Jenuwein, T., & Reinberg, D. (2007). *Epigenetics.* Cold Spring Harbor, NY: Cold Spring Harbor Laboratory Press. (See Color Plate Section for a color version of this figure.)

the basis for a true increase in incidence, if it exists, would also likely have benefits in terms of both treatment and prevention of autism generally. The possibility of a true increase in incidence is interesting from a general perspective, as some environmental effect would be implied, and environmental factors such as maternal diet at the time of pregnancy, prenatal ultrasound, prenatal or postnatal exposure to chemical toxins, and many other factors changing over the decades can be hypothesized to affect the risk of autism. Vaccines and mercury exposure have been widely debated (Baker, 2008) and like most other environmental factors can be hypothesized to act through epigenetic mechanisms. From an epigenetic perspective, the fact that folic acid intake increased substantially in many countries from the late 1970s through the 1990s is interesting, because it can affect DNA methylation and gene expression as discussed above.

An Overall Synthesis

In 2004, we proposed a mixed epigenetic and genetic and MEGDI model (Fig. 42-9) that might apply to autism (Jiang et al., 2004). In this context, de novo includes mutations or epimutations arising in the affected individual or in the

preceding few generations but excludes ancient mutations. This model is in sharp contrast to a multilocus epistatic model in which the causative factors are hypothesized to be ancient mutations that would be discoverable through linkage and association studies including GWAS. The MEGDI model would predict that GWAS would not, for the most part, detect de novo or epigenetic abnormalities, although some might be detected if the mutation or epimutation were inherited for a few generations. The MEGDI model was proposed at a time when chromosome abnormalities were known to cause a small fraction of cases of autism (Vorstman et al., 2006), but the role of CNVs was yet to be recognized (Sebat et al., 2007). Deletions with modest reductions in fitness may yield virtually any ratio of de novo to inherited cases among probands. Numerous reciprocal duplications of well-known deletion syndromes are commonly associated with autism with reduced penetrance (e.g., duplications of the regions deleted in DiGeorge, Willams, and Smith-Magenis syndromes). The recognition of the role of CNVs in the etiology of autism and the implications for point mutations in genes within the CNVs is the most dramatic advance in understanding the cause of autism over the last few years, and the data fit well within the MEGDI model but not with the multilocus epistatic model. For severe autism phenotypes associated with intellectual disability, birth defects, and dysmorphic features, CNVs may be found in as much as a

Figure 42–9. A *m*ixed *e*pigenetic and *g*enetic and mixed *d*e novo and *inherited* (MEGDI) plus environment model for autism. *SHANK3* and *MECP2* refer to mutations in these genes and *UBE3A* refers to possible epimutation. I-dup 15q11-q13 is interstitial duplications which cause autism when maternal but usually not when paternal.

one-fourth of patients (Jacquemont et al., 2006). The general experience in diagnostic laboratories is that disease-causing CNVs are found in very few higher functioning, nondysmorphic patients or in those diagnosed with Asperger's syndrome.

Do the studies of the role of CNVs in severe autism leave any role for epigenetics in this population? Presumably, epimutations will not account for a large fraction of cases in this cohort of patients, although a few may yet be discovered, and a significant contribution is still possible. The CNVs and small mutations in the causative genes therein are generally expected to account for the majority of cases of severe autism, and whole-genome or whole-exome sequencing is widely expected to identify many additional mutations in this population. The association of advanced paternal age with autism (Reichenberg et al., 2006) could be compatible with a role of de novo point mutations, although the effects are small, and maternal age may be important as well (Durkin et al., 2008; King et al., 2009), perhaps through nondisjunction contributing to confined placental mosaicism (Leschot et al., 1996) or uniparental disomy. There are no data regarding the possibility of a parental age effect on the risk of epimutations.

How might the MEGDI model fit for the etiology of the higher functioning, nondysmorphic autism population? This population has a much higher male:female ratio compared to the lower functioning dysmorphic population. Certainly mutations contributing to this group are likely to be less penetrant and be associated with significant reproductive fitness, although such mutations need not be ancient. In general, the etiology of high-functioning autism is much less understood,

with ancient mutations, recent mutations, epimutations, and environmental factors all remaining very feasible. The sex ratio could be explained by changes in genes mapping to the X or Y chromosome (sex-linked effects) or to sex-limited effects on autosomal genes. Sex-limited effects are mediated by the genes that directly cause sex determination, primarily *SRY* that cause maleness in humans. For severe autism, mutations in X-linked genes may be sufficient to explain the modest increase in male:female ratio. A good example of a sex-limited effect is provided by mutations in *BRCA1* and *BRCA2* that cause breast cancer with a much higher penetrance in females than in males. A proposal for a unified genetic theory for sporadic and inherited autism (Zhao et al., 2007) is equivalent to a sex-limited effect on autosomal genes. A recent review of sex-limited gene expression (Williams & Carroll, 2009) is thought-provoking regarding the sex bias in milder forms of autism. The authors concluded, "A common theme emerging from these studies is that the integration of sex determination and other transcriptional inputs by cis-regulatory elements is central to the development and evolution of sexually dimorphic traits." This is consistent with the precedent for a sex-dependent mutation in an enhancer associated with Hirschsprung disease (Emison et al., 2005) and is of interest regarding the sex bias in mild autism. The epigenetics of sex differences in the brain was reviewed recently (McCarthy et al., 2009a). There is no obvious basis to hypothesize that the prominent sex effect in mild autism is primarily genetic or epigenetic or primarily of de novo or inherited origin. A moderately or highly penetrant inherited genetic effect involving a single X-linked, Y-linked,

or autosomal locus in a large fraction of cases is essentially ruled out by the failure to detect such an effect using linkage and association studies. A multilocus epistatic hypothesis remains very viable and would likely involve primarily autosomal genes. An epigenetic hypothesis involving sex-linked or sex-limited effects also remains very viable. Epimutations might be inherited in some cases or entirely erased and corrected with germline transmission. The full role of epigenetics in the etiology of autism remains to be delineated.

Conclusions

There are many disorders that cause autism in which primary genetic abnormalities are associated with secondary epigenetic abnormalities in trans affecting the entire genome (e.g., *MECP2* mutations) or in cis on the mutated chromosome (e.g., Fragile X syndrome). There is at least one case where genetic and epigenetic factors work in concert such that maternal interstitial duplication of chromosome 15q11-q13 cause autism but paternal duplications are usually benign. Although single-gene epimutations have been described for a few genes, no examples of single-gene epimutations have been described convincingly to date. Because the etiology of severe autism with intellectual disability and dysmorphic features is increasingly documented to be caused by recent and de novo mutations, there is the potential for some analogous epimutations in some of these patients. The etiology of mild autism and Asperger's syndrome is much less clear, and epigenetic and other mechanisms all deserve further study.

Challenges and Future Directions

- Either global or single-gene epigenetic abnormalities could contribute to the etiology of autism as primary, secondary, or modifier factors.
- Environmental effects including nutritional factors could play a role in the etiology of autism mediated by epigenetic mechanisms.
- Epigenetic analysis is challenging because key abnormalities may be brain-specific or even cell-specific, as would be the case if epigenetic changes were limited to hippocampal or Purkinje neurons.
- Epigenetic analysis of DNA methylation and chromatin structure in postmortem autism compared to control brain is now feasible and should be carried out for both mild autism and severe autism.

Isolated Populations and Common Variants

Points of Interest

- Isolated populations are characterized by a decrease in genetic heterogeneity, and this has been successfully used to identify genes underlying Mendelian disorders.
- The genetic risk for common disorders is conferred by a multitude of variants of which each only increases the risk of the disease marginally. These genetic variants are often common in the population and can be detected using genome-wide association studies (GWAS).
- Genome-wide association analyses have shown that for some complex disorders and traits, the genetic risk factors are more uniform in population isolates compared to outbred populations, thereby increasing the statistical power to detect them.
- Many of the genetic susceptibility factors identified in isolated populations have also been shown to confer risk in outbred populations, suggesting that the genetic risk factors for at least some phenotypes are similar in isolates and other populations.

Isolated Populations

Isolated populations are defined as populations originating from a small number of founders, experiencing only limited immigration, and where expansion has primarily taken place through population growth. The lack of immigration often results from either geographical or cultural isolation. These populations are also sometimes termed *founder populations*. The value of isolated populations in the identification of genes for Mendelian disorders can be considered to be undisputed, as numerous Mendelian genes have been identified in these special populations (*see also* Chapters 44 and 41, this volume).

Examples include identification mutations in the connexin 26 gene in nonsyndromic deafness in the Bedouin population and genes for 35 Mendelian disorders in the Finns (Guilford et al., 1994; Carrasquillo et al., 1997; Norio, 2003a; Norio, 2003c). However, the possible advantage of using isolated populations in identification of genetic risk factors for complex traits has been highly debated, and only recent successes have validated the place of isolated populations in complex trait-mapping approaches.

Genetic Characteristics of Isolated Populations

The identifying characteristic of isolated populations is the reduced genetic diversity, which can be observed using uniparentally inherited mitochondrial DNA and Y chromosomal genetic markers, as well as autosomal data. The decrease of genetic diversity, which can still be observed in isolates today, is a direct consequence of the genetic bottleneck caused by the limited number of founders. Many population isolates have undergone multiple bottlenecks caused by famines, war, or internal migrations subsequent to founding. Recent, rapid population growth is a prerequisite for the population to be useful for genetic mapping, as an adequate number of affected individuals are available for genetic mapping of disorders or traits that have a low frequency in the population. The same demographic phenomena that give rise to decreased genetic diversity also result in extended linkage disequilibrium (LD) and increased homozygosity. The drastic reduction in population size in the form of one or several genetic bottlenecks during the population history has resulted in changes in the allele frequencies caused by genetic drift. In addition to differences in allele frequencies, the bottlenecks together with random drift have, in some populations, resulted in a distinctive pattern of disorders (Morton et al., 2003; Norio, 2003a; Charrow, 2004).

Linkage disequilibrium (LD) is the non-random association of alleles at two or more loci. Linkage disequilibrium can be observed as pairwise correlation between the allele frequencies of genetic markers.

Genetic bottleneck is an event in which the population size is drastically reduced. A type of genetic bottleneck termed a *founder effect* is an event in which a new population is established by a small random sample of the original population.

Genetic drift is the random change in relative frequency of alleles. Genetic drift is especially emphasized in small populations, where it can lead to drastic changes in allele frequency or even to fixation or total elimination of alleles.

Environmental Factors

In addition to genetic homogeneity, environmental and cultural factors often are also less heterogeneous in isolates compared to large, admixed populations. Factors such as shared language and religion increase social cohesion, which, in addition to a common education system, health care, and similar diet, minimizes the environmental heterogeneity. In many isolated populations, lifestyle choices can be affected by cultural customs or restrictions, which can in some cases be used beneficially in genetic mapping. In a study of genetic risk factors for asthma in the Hutterite population, the fact that smoking is prohibited and very rare reduced the variability in this environmental risk factor for the phenotype of interest (Ober et al., 2008). In many isolated populations, population registries or church parish records are available for genealogical studies, and allow construction of extended pedigrees with multiple affected individuals and identification of common founders for distantly related individuals.

Finland as an Example of the Archetypal Isolate

Finland is an example of a typical founder population that has undergone many of the population history events typical for isolates. The population history of Finns is well-known and corresponds well with the genetic substructure observed today (Sajantila et al., 1996; Kittles et al., 1999; Jakkula et al., 2008). The population was originally founded by a small number of individuals and has undergone multiple consecutive bottlenecks, resulting in reduction of genetic diversity. For thousands of years, only the coastal regions of the country were inhabited, settled originally thousands of years ago by two small settling groups with European and eastern Uralic origin. An internal migration, which took place only 500 to 600 years ago, resulted in the inhabitation of the sparsely populated eastern and northern regions of the country termed the *late settlement region* (Peltonen et al., 1999; Norio, 2003b). The youngest subisolates in northeastern Finland were first inhabited 300 to 400 years ago by a few dozen families and have remained almost entirely isolated until World War II. The Finnish

population experienced a famine that, together with subsequent epidemics, killed approximately one-third of the 400,000 strong population in 1696 through 1698. After this, population growth has been rapid, starting from 250,000 in the late seventeenth century to the present population of more than 5 million. Population growth has occurred in relative isolation without major immigration because of the remote location of Finland, as well as cultural reasons resulting from the Finnish language, a part of the Uralic language family, which is not spoken elsewhere in Europe, with the exception of Hungary and Estonia (Varilo et al., 2000; Varilo et al., 2003). As groups inhabiting the late settlement region have been small, and new settlements were geographically isolated, the internal migration has formed classical bottleneck effects, which together with isolation have resulted in significant population structure observed today (Jakkula et al., 2008).

The unique population history of Finland has led to enrichment of certain alleles and extinction of others by genetic drift. This has resulted in a unique pattern of disorders, consisting of 36 Mendelian, mostly recessive disorders that are overrepresented compared to any other population. These disorders are often referred to as the Finnish disease heritage. The genes for all but one of these disorders have been identified, and for most disorders one major mutation accounting for all—or a significant subset of—cases have been identified. Further, some Mendelian disorders common in European populations, such as phenylketonuria and cystic fibrosis, are absent from Finland (Norio, 2003a). The publicly available health-care system provides equal health care across the country and detailed, standardized medical records for careful delineation of the phenotype of interest. The training in medical schools across the country is highly uniform, resulting in highly standardized diagnostic criteria in all hospitals across the country. Population registries cover several centuries and make it possible to trace genealogical connections across dozens of generations as well as information about geographical origins of the genetic variants.

Complex Disorders

Complex, or common, disorders are caused by multiple genetic risk factors, of which each only increases risk marginally, but a large number of genetic susceptibility variants together with environmental risk factors result in the disorder. The first steps in the elucidation of the genetic mechanisms responsible for complex disorders were taken when the Human Genome Project deciphered the sequence of the human genome (Lander et al., 2001; Venter et al., 2001). Following the completion of the human sequence, another colossal project, the International HapMap project, aimed to characterize the variation in the human genome in European, African, and Asian populations (The International HapMap Consortium, 2005; Frazer et al., 2007). As a result of these efforts, millions of variants in the human genome, termed

single nucleotide polymorphisms (SNPs), have been identified. The HapMap project mainly aimed to characterize SNPs that are commonly observed in populations, but genome-wide sequencing efforts feasible today have drastically increased the rate at SNP detection and also have enabled the identification of SNPs that are rare in the population or even private to single individuals (Levy et al., 2007; Wang et al., 2008; Wheeler et al., 2008).

Single nucleotide polymorphism (SNP) is a form of DNA sequence variation where two nucleotides differing between individuals in a population occur at the same position in the genome.

The International HapMap project is a large collaborative project aiming to identify and characterize genetic similarities and differences in human beings (www.hapmap.org). In the first stage, four populations (a population with Northern European descent, a Japanese population, a Chinese population, and the African Yoruba population) were included, but in subsequent stages, several populations have been added to the project.

The term common SNP refers to a SNP with a high minor allele frequency (>5%) in the population, whereas SNPs with a low (<1%) minor allele frequency are termed *rare*. Current genetic mapping methods enable identification of rare variants with a high impact on the phenotype of interest, as well as SNPs with a small impact on the phenotype if they are common enough in the population. A multitude of rare SNPs probably also confer small effects on susceptibility to disorders, but statistical power of current methods does not allow for identification of this type of variation.

Genetic Architecture of Complex Disorders

Primarily, two opposing but complementary hypotheses exist concerning the genetic model of complex disorders (Reich & Lander, 2001; Bodmer & Bonilla, 2008). The role of rare variants in common disorders proposes that the disorders are caused by a small number of variants, each with a large effect on the phenotype with a low frequency (<1%) in the population (*see* Chapter 41, this volume). Rare variants are often population-specific, as founder effects have established different rare variants in each population. Approaches to identify rare variants include linkage analysis and resequencing of interesting candidate genes in large families with multiple affected individuals and possibly other distinct clinical features such as early age of onset. A review of 61 rare variants identified in complex disorders has shown that rare variants are associated with odds ratios ranging from 1.1 to more than 5, with the percentage of variants increasing toward the high end of the odds ratio spectrum, and the mean odds ratio is 3.74 (Bodmer & Bonilla, 2008).

Odds ratio is a measure of effect size. In genetic studies, the odds ratio often refers to the odds of having a disorder for an individual carrying a specific genetic variant relative to individuals not carrying the genetic variant.

The common variant hypothesis proposes that common disorders are caused by the interaction of numerous small effect variants, which are all common in the population. The assumption that common variants comprise risk factors for common disorders has been termed the *common disease-common variant hypothesis* (Lander, 1996; Chakravarti, 1999). The smaller the effect size of the SNP, the larger the study set needed to obtain statistically significant results. Of 217 common variants affecting complex phenotypes summarized by Bodmer and Bonilla (2008), most odds ratios are smaller than 2, and the mean odds ratio is 1.36.

Usually the genetic architecture for complex disorders displays components of both rare and common risk variants (*see also* Chapter 38, this volume). Here, isolates can offer a significant advantage as pedigrees with multiple affected individuals can be ascertained, suggesting inheritance closer to a monogenic model, with rare high-impact variants, implicating candidate genes that can subsequently be tested in the general population. This approach was used to identify genes underlying familial combined hyperlipidemia, a disorder where multiple types of dyslipidemia co-occur and result in significant risk of premature coronary heart disease. Initially, linkage to 1q21 through q23 was identified in Finnish families with familial combined hyperlipidemia (Pajukanta et al., 1998). Finmapping using SNPs in three genes in the linked region identified *USF1* as the susceptibility gene for familial combined hyperlipidemia (Pajukanta et al., 2004). Subsequently, variants in *USF1* have been shown to confer susceptibility for common disorders such as coronary heart disease and metabolic phenotypes in both Finns and other populations (Komulainen et al., 2006; Holzapfel et al., 2008; Kristiansson et al., 2008; Meex et al., 2008).

Dyslipidemia is an abnormal level of lipids in the blood.

Genome-Wide Association Studies

During the last few years, the combination of novel, high-throughput genotyping methods and careful characterization of the variation in the genome have made it possible to conduct hypothesis-free GWAS in large populations to identify genetic determinants for common disorders, as proposed by Risch and Merikangas (1996) more than a decade ago in a seminal paper. The results obtained from the HapMap project in the form of catalogs of frequencies of variants in the genome and their pairwise correlation (LD) have been imperative for the progress of this gene-mapping method. By screening a sufficiently large number of SNPs (usually hundreds of thousands or millions), the common variants in the whole genome can be tagged by these SNPs through LD. SNPs where allele frequencies show statistically significant deviations between cases and controls indicate genes or chromosomal regions affecting the trait of interest. This is referred to as a GWAS, and it enables identification of genetic risk factors for disorders and traits without *a priori* hypothesis of the genes or biological processes involved in the phenotype. Although the early GWAS did not always produce reproducible results, when sample sizes were increased to provide adequate power to detect the common, low-impact

variants, replicated genetic risk factors were identified for a multitude of phenotypes, and meta-analysis of existing data sets provided further novel susceptibility variants (Wellcome Trust Case Control Consortium (WTCCC), 2007; Cooper et al., 2008; Zeggini et al., 2008; Aulchenko et al., 2009).

Successes in Identification of Common Variants in Isolated Populations

Before GWAS became standard practice, the biggest advantage conferred by isolated populations was envisaged to be the increased LD, as a smaller number of markers would be needed to tag the entire genome (Shifman & Darvasi, 2001; Service et al., 2006). However, today this gain is mostly theoretical, as genotyping is performed using predesigned SNP sets, which have been chosen to tag the majority of allelic variation in the genomes of outbred European populations. It is therefore not surprising that tagSNPs chosen using the HapMap European population perform well in several isolates (Service et al., 2007). However, it has been suggested that the tagging power of these SNPs, even for rare haplotypes, is better in isolated populations because of the excess of information provided by the off-the-shelf genotyping chips in populations with high LD.

The more significant value of isolated populations in genetic mapping of complex disorders is the reduced genetic variability, which has resulted in enrichment of a subset of susceptibility alleles in the population compared to outbred populations. As isolates have undergone bottlenecks during the population history, the susceptibility variants often reside on a more homogenous haplotypic background compared to mixed populations (Figure 43-1). The enrichment of certain susceptibility variants will require fewer individuals to find theses shared genetic factors. In the following, as well as in Table 43-1, a few examples illustrating the power of isolated populations in complex gene identification are presented.

> *Haplotype* is the combination of alleles at multiple loci, which are transmitted together on the same chromosome.

One of the success-stories of common variant mapping in isolates have been provided by data from the Icelandic company deCODE genetics. The combination of extensive genotype and phenotype data from a significant proportion of the inhabitants of the entire country with extensive genealogical records has led to the identification of numerous susceptibility variants for complex disorders and traits. Iceland was populated approximately 1000 years ago, and the genetic roots of the current population can be traced back to Scandinavia and the British Isles, resulting in admixture at the time of founding (Helgason et al., 2001). The population has undergone several bottlenecks caused by diseases and famine and has grown rapidly in the last 100 years to the present size of 320,000. Data from studies of mitochondrial DNA suggests that the population has undergone considerable and rapid genetic

drift, resulting in decrease of genetic diversity characteristic of isolated populations (Helgason et al., 2003, 2009). Genome-wide linkage analysis and GWAS have identified common genetic risk variants for multiple phenotypes, including atrial fibrillation and ischemic stroke (Gudbjartsson et al., 2007; Gretarsdottir et al., 2008), bone mineral density and fractures (Styrkarsdottir et al., 2008, 2009), essential tremor (Stefansson et al., 2009), glaucoma (Thorleifsson et al., 2007), multiple types of cancer (Gudmundsson et al., 2007a, 2007b; Stacey et al., 2007; Goldstein et al., 2008; Gudmundsson et al., 2008; Stacey et al., 2008; Rafnar et al., 2009), pigmentation (Sulem et al., 2008), myocardial infarction and aneurysms (Helgadottir et al., 2007, 2008), and type 2 diabetes (Grant et al., 2006). In these studies, the genomic control method was used to control for population structure and relatedness (Helgason et al., 2005). In some studies, previously identified linkage peaks in the same population were used to prioritize regions for follow-up in cases where no genome-wide significant results were identified in the primary stage of the GWAS.

In a study utilizing the combined power of linkage and association, individuals from the Croatian island of Vis were
Figure 43–1. The genetic risk factors for complex traits are heterogenous in outbred populations (top). When an isolate is founded, the population goes through a genetic bottleneck, and a random selection of the original genetic risk factors are present in the new subpopulation. If the founder population is small, then random effects caused by genetic drift are accentuated. Some of the original genetic risk factors are eliminated and others are significantly enriched compared to the founder population. (See Color Plate Section for a color version of this figure.)

Table 43–1.
Examples of isolates used in genome-wide linkage or association studies of complex phenotypes

Population	Age	Phenotypes	References
Amish	250	Bipolar disorder, blood pressure, type 2 diabetes	Ginns et al., 1996; Hsueh et al., 2000; Rampersaud et al., 2007; McArdle et al., 2008
Antioquia (Colombia), Central Valley of Costa Rica	300–400	Bipolar disorder	Herzberg et al., 2006; Jasinska et al., 2009
Ashkenazi	2000	Breast cancer	Gold et al., 2008
Azores (Portugal)	650	Schizophrenia	Sklar et al., 2004
Finland	300–2000	Schizophrenia, multiple sclerosis, familial combined hyperlipidemia, asthma, fasting glucose levels, height	Hovatta et al., 1999; Laitinen et al., 2004; Pajukanta et al., 2004; Chen et al., 2008; Sanna et al., 2008; Kallio et al., 2009
French Canadians	300–400	Coronary heart disease, Crohn's disease	Raelson, et al., 2007; Engert et al., 2008
Hutterites	100	Asthma	Ober et al., 1998; Ober et al., 2008
Iceland	1000	Bone mineral density, breast cancer, myocardial infarction, exfoliation glaucoma, height, prostate cancer, type 2 diabetes	Gudmundsson et al., 2007; Helgadottir et al., 2007; Steinthorsdottir et al., 2007; Thorleifsson et al., 2007; Gudbjartsson et al., 2008; Stacey et al., 2008; Styrkarsdottir et al., 2008
Northern Sweden	350	Familial prostate cancer, affective disorders	Berthon et al., 1998; Venken et al., 2005
Pima Indians	>10,000	Diabetes, BMI, early onset type 2 diabetes	Hanson et al., 1998; Hanson et al., 2007
Sardinia	3000	Asthma, height, obesity, fasting gluciose levels	Balaci et al., 2007; Scuteri et al., 2007; Chen et al., 2008; Sanna et al., 2008
The Netherlands, subisolate	<400	Parkinsons	Bertoli-Avella et al., 2006
Vis (Croatia)	>1000	Systolic blood pressure, serum urate concentration, serum creatinine, anthropometric traits	Vitart et al., 2009; Barbali et al., 2009; Polašek et al., 2009

used to identify genetic variants affecting systolic and diastolic blood pressure, as this isolated population had a high prevalence of hypertension (Kolcic et al., 2006). Vis is a remote island in the Adriatic Sea off the coast of Croatia, which has experienced several bottlenecks during its history. In this study, first a genome-wide QTL analysis for systolic blood pressure was performed, and then SNPs were tested for association in the linkage peaks in the Vis population. The 15 most significant SNPs were further tested for association in the British 1958 Birth Cohort, and association was replicated for two SNPs. The SNP showing most significant association to systolic blood pressure, located close to potassium voltage gate channel gene (*KCNB1*), showed a much bigger effect size in the Vis data than in the British 1958 Birth Cohort (Barbalic et al., 2009).

The identification of genetic risk factors for complex disorders in isolated populations has raised the question of the validity of these risk variants in outbred populations. GWAS have shown that many of the genetic susceptibility factors identified in GWASs conducted in isolated populations can be replicated in outbred populations. The North American Hutterite population was founded by only 62 individuals, and current individuals can be linked to these founders through multiple lines of descent in a 13-generation pedigree. This population has remained genetically isolated

through cultural isolation from the rest of the North American population. The communal lifestyle of the Hutterites ensures a highly similar environment, decreasing the variance in any environmental risk factors. A GWAS was performed in 753 Hutterites to identify genetic factors affecting the serum level of chitinase-like protein (YKL-40), which is linked with asthma. The most significantly associated SNP was found in the promoter of the *CHI3L1* gene encoding the YKL-40 protein. This SNP was subsequently shown to be associated with asthma, bronchial hyperresponsiveness, and measures of pulmonary function in very small data sets consisting of 63 to 121 individuals from the Hutterite population. Further, the same SNP was found to be associated with asthma in two bigger data sets from populations of European descent (Ober et al., 2008).

Similar results, suggesting that genetic risk factors identified in isolates can be extended to other populations, were obtained in a GWAS for lipid levels comprising close to 5000 individuals from the late-settlement region of Finland. Several of the identified risk loci had been reported previously in other populations. In addition, six novel loci were identified. Larger data sets will be needed to determine whether these variants represent isolate specific risk variants or if they can be replicated in larger data sets (Sabatti et al., 2009).

Careful characterization of the population structure is imperative for the most efficient study design for GWAS. The available genetic data, combined with careful genealogical data, have shown distinct substructure in isolates such as Finns and Icelanders (Helgason et al., 2005; Jakkula et al., 2008). In Finland, the aggregation of grandparents of individuals affected with rare Mendelian disorders is well-documented, but some subisolates also have shown higher frequencies of complex disorders (Hovatta et al., 1997; Sumelahti et al., 2001). With proper selection of cases and controls, this approach has proved successful in mapping genetic risk factors for complex disorders. The prevalence of multiple sclerosis (MS) is twice as high in an internal subisolate of Finland compared to the rest of the country (Sumelahti et al., 2001). Using available genealogical data and carefully matched controls originating from the same, geographically limited region, two risk genes were identified using only 68 individuals connected to two large pedigrees having common ancestors 14 to 16 generations ago. The first risk haplotype, located under a previously identified linkage peak at chromosome 5p, identified complement component 7 (C7) as a genetic risk factor for MS. The haplotype association was replicated in an independent sample from the same Finnish subisolate, and the risk haplotype correlates with increased expression of C7. A trend toward association was also observed in other European populations, suggesting that the risk variant has been enriched in the internal isolate but conferring susceptibility to MS in other populations as well (Kallio et al., 2009). Subsequently, the same Finnish subisolate was used to identify a SNP in signal transducer and activator of transcription 3 (*STAT3*) gene conferring susceptibility to MS. This finding was replicated in several data sets, including MS cases both from Finland and other populations (Jakkula et al., 2009). In these studies, the careful selection of geographically matched cases and controls was imperative for the identification of the risk loci, as preliminary analysis using less strictly matched controls did not result in findings that could be replicated in other data sets.

The successes of these studies are all based on careful study design utilizing the enrichment of certain susceptibility alleles that have been originally carried to the isolates by random founder effect and enriched by genetic drift. The power of combining linkage with association, in the form of extended haplotypes or IBD sharing, has enabled identification of risk variants in relatively small sample sizes. Although many of the identified risk variants have also been identified to confer susceptibility in outbred populations, the enrichment of the risk allele in the isolates enabled their identification using relatively small sample sizes.

Challenges in Genetic Mapping in Isolates

Although isolated populations provide excellent opportunities for identification of genetic risk factors for genetic disorders, there are some drawbacks that need to be considered in the study design stage. As isolated populations are usually smaller than outbred populations, it should be established that a large enough cohort of affected individuals can be ascertained from the population, considering the frequency of the trait of interest and the size of the population. One of the drawbacks often encountered when the initial region of interest has been identified is the LD structure. Although extended LD can be helpful in initial localization of the risk loci, it can make it harder to identify causative variants within the block of strong LD. Therefore, it might be beneficial to include a more admixed population in the fine mapping stage of the study where LD blocks are shorter. Replication of initial findings can prove to be challenging, especially if the isolate is small and the disorder is rare, as all available samples have already been used in the initial mapping effort. It should also be noted that replication will not be observed using highly strict criteria for statistical significance if the risk variant is significantly enriched in the isolate, and only confers a small risk in the replication population. However, even if the effect of the variant is limited to the isolate, characterization of these risk variants can prove to be beneficial in other populations, as it could help understanding of the underlying biology of the trait.

The assumption that high-impact variants are enriched in founder populations is not always true. A recent study of genetic risk factors with metabolic phenotypes in the Kosrae population revealed a similar spectrum of genetic risk variants compared to other, more outbred, populations. The Kosrae, a native population of the Federated States of Micronesia, display both decreased genetic diversity and extended LD resulting from founder effects and multiple bottlenecks (Bonnen et al., 2006). In common with many other populations worldwide, the prevalence of obesity and metabolic disorders is increasing in this population (Shmulewitz et al., 2001). An effort was initiated to identify genes for these disorders in the Kosrae hypothesizing that founder effects, bottlenecks, and genetic drift have concentrated a small number of high-impact genetic risk variants in this population. In the study, simulation studies showed that the study design provided ample power to identify common alleles explaining 5% or more of the variation in the phenotype. However, no common genetic risk factors for metabolic traits were identified in this population. The results suggest that even in a highly inbred population such as the Kosrae, for many quantiative phenotypes, common alleles only have a modest effect and no enriched risk variants exist (Lowe et al., 2009).

Conclusions

Isolated populations have been used successfully in genetic mapping of Mendelian disorders because of the reduced genetic heterogeneity. Emerging results from GWAS suggest that for some phenotypes, isolated populations also offer advantages in mapping of common genetic risk factors. As each isolate is uniquely different because of different demographic histories, careful characterization of the population

substructure is crucial for optimal study design. Encouragingly, several studies have shown that the genetic risk factors originally identified in the isolates were replicated in outbred populations, validating the role of isolated populations as a useful tool in genetic mapping studies.

Challenges and Future Directions

- It is already clear from the GWAS performed to date that the genetic architecture for complex traits ranges from being controlled by highly penetrant rare variants to common, low-risk variants. The characterization of the genetic architecture of specific traits and disorders is incomplete, and future studies will show if it will differ between populations.
- Although many studies have shown that genetic risk factors for complex disorders identified in isolates can be generalized to more outbred populations, the role of isolate specific risk variants remains poorly understood. It will also be challenging to replicate isolate-specific findings, as sample sizes are usually limited.
- The characterization of genetic risk factors for complex disorders using GWAS is only the first step of understanding the role these variants play in the etiology of the disease. The next step will be to pinpoint the actual causative variants and to functionally characterize their role in the biological processes involved in the phenotype of interest. Whether isolated populations can aid in this step as well (e.g., as a result of the homogenous environmental factors) remains to be discovered.

Isolate Populations and Rare Variation in Autism Spectrum Disorders

Points of Interest

- Autism is highly heterogeneous at the genetic level.
- Forward genetics offers important opportunity for progress as it relates to the neurobiology of the condition.
- Rare variation may play an important role, and loci of major effect have been previously reported.
- Recessive mutations may play an important role by analogy to intellectual disability, and pedigrees with recent shared ancestry offer increased power for mapping such loci.
- Loci discovered by these approaches may be generalizable to populations without recent shared ancestry.
- Studies in isolate populations and of rare variation offer an important approach to gene discovery, which is complementary to other ongoing efforts to studies of common variation.

Autism is one of the most severe neuropsychiatric conditions emerging in childhood. Autistic symptoms include complex behavioral and cognitive deficits that appear prior to age 3 years (American Psychiatric Association and American Psychiatric Association Task Force on DSM-IV, 2000). These symptoms include abnormal communication and social interaction, rigid and repetitive stereotyped behaviors, and atypical information processing. There are core deficits in social reciprocity—that is, expressing emotions and understanding the emotions of others known as "theory of mind" (Baron-Cohen et al., 1985). Children with autism have uneven cognitive profiles, with strengths in some areas—that is, "splinter domains"—yet general weaknesses in executive function and seeing the big picture known as "central coherence" (Happe & Frith, 2006). Approximately 50% of autistic individuals have some degree of intellectual disability (ID, formerly mental retardation) (Fombonne, 1999), and approximately 25% have epilepsy (Danielsson et al., 2005); therefore autism, ID, and epilepsy are likely to share some biological links with autism. Intellectual disability ranks first among all chronic conditions causing disability in the United States (U.S. National Center for Health Statistics, 1996). Autistic disorder is one of several neurodevelopmental conditions categorized in the DSM-IV as the pervasive developmental disorders (PDDs), which also include Asperger's Syndrome, Rett's Syndrome, Childhood Disintegrative Disorder, and PDD-not otherwise specified (PDD-NOS) (American Psychiatric Association and American Psychiatric Association Task Force on DSM-IV, 2000). The prevalence of autism is high and at least four times more common in boys than girls. Prevalence estimates vary across studies but are approximately 1:300–800 for autistic disorder and 1:200 for all PDD, which appears to be a 10-fold increase in the last 10 to 20 years (Fombonne, 1999; Fombonne, 2003). Some degree of this increase is likely attributable to increased awareness and broadening the diagnostic spectrum; however, the prevalence is high and may be increasing. As most autistic individuals require lifelong assistance, the financial costs to society are very high, whereas the emotional costs to family members cannot even be estimated (Ganz, 2007).

The Options for Diagnosis and Treatment of Autism are Limited

Currently, there are a small number of genetic tests (i.e., array comparative genomic hybridization [aCGH], or Fragile X Syndrome) and metabolic tests that may provide a biological diagnosis (Martin & Ledbetter, 2007; Beaudet & Belmont, 2008). Otherwise, diagnosis is limited to neuropsychological assessments alone. Treatments for autism are similarly limited. Behavioral and educational training has partial efficacy in a subset of children, particularly when started early. Indeed, this has led to the proposal of using "developmental medicines" in a time-restricted fashion to augment response to

behavior treatments during development, as is being pursued for Fragile X (Dolen & Bear, 2005). However, psychopharmacological studies thus far have been largely limited to antipsychotics (mostly risperidone) and antidepressants for behavior symptoms. Indeed, children with PDD have been traditionally excluded from pharmacotherapeutic trials. Overall, advances in diagnostic subtyping and a deeper, translational understanding of pathophysiology is an important foundation for future treatment trials (Geschwind, 2009).

Autism is Highly Genetic and "Forward Genetics" Offers Opportunity for Progress

Our understanding of the neurobiology of autism is rudimentary (Abrahams & Geschwind, 2008). Perhaps the most established fact is that autism is highly genetic. Autistic disorder is the most strongly genetically influenced, childhood neuropsychiatric disorder (Bailey et al., 1995). There is a 60% to 90% concordance rate of autism in monozygotic twins as opposed to a 0% to 10% rate in dizygotic twins. Autism has an approximately 45-fold higher recurrence risk in families versus the general population. Given this fact, "forward genetics" (taking whole-genome approaches with patients and families, and moving from the phenotype to identifying specific genes and mutations) is an extremely important approach for discovering the core patholobiology of autism.

The disease causing mutations in *Presinilin* and *APP* were found in a relatively rare early-onset form of Alzheimer's disease in large, highly informative pedigrees (Tanzi et al., 1996; Tanzi & Bertram, 2005). As with the forward genetics approach of Alzheimer's disease, this approach has been taken with autism with some success (explained below for the *Neuroligin* gene), yet the opportunities from this approach have not been systematically exhausted for autism. The subject of this chapter is to outline the hypotheses central to the forward genetic approaches of isolate populations and rare variants. This chapter will outline these hypotheses and provide a rationale for this approach—particularly from the point of view of populations with recent shared ancestry that may be enriched for autosomal recessive loci. Finally, this chapter will outline some of the early data in this area of autism spectrum disorder (ASD) genetics.

The central hypotheses of the rare variant and isolate population approach in ASDs are outlined below. To stress, we contend that this approach to mutation discovery in autism represents an important complementary approach. Given the complex and heterogeneous genetic architecture of ASDs, this approach, together with a variety of additional approaches (including rare and common copy number studies as well as rare and common sequence association studies) are required to develop a full understanding of the genetic underpinning of this profound and complex condition (Geschwind, 2008; Walsh et al., 2008).

The central hypotheses of the rare variant and isolate population approach in ASDs as discussed in this chapter are outlined below:

1. ASDs are genetically heterogeneous.
2. A subset of ASDs worldwide will result from individually rare, highly penetrant loci.
3. As a syndrome of neurodevelopmental conditions, ASD genetics will be informed by two other syndromes of neurodevelopment—namely, intellectual disability (ID) and epilepsy.
4. As ASDs (at least for lower-functioning autism) appear to decrease reproductive fitness, a subset of loci are likely to be de novo and/or recessive (X-linked or autosomal recessive).
5. Autosomal recessive loci underlying autism susceptibility will be enriched in populations with recent shared ancestry.
6. Although genome-wide association studies are undoubtably important, linkage studies may remain as an important complementary approach, particularly in special founder populations.
7. Pedigrees with rare, highly penetrant loci may involve syndromic forms of autism that may involve ID or epilepsy.
8. Pedigrees from isolate populations or with syndromic forms of autism may be highly informative to other forms of ASDs with more complex genetic architecture.

Autism Spectrum Disorders Display Genetic Heterogeneity With Some Cases Caused by Loci of Major Effect

We hypothesize that at least for lower-functioning autism, a subset of the genetic architecture may resemble that for ID. Intellectual disability naturally is caused by a large number of chromosomal anomalies, submicroscopic copy number variants (CNVs), and a large number of Mendelian forms—particularly de novo, X-linked, and autosomal recessive (Figure 44-1) (Stromme, 2000). To date, 90 of the 818 (11%) annotated genes on the X chromosome have been found to harbor mutations in X-linked recessive ID, some of which have autistic symptoms (Gecz et al., 2009). Based on these findings, one may hypothesize that autosomal recessive causes of ID and autism will also be common, particularly in pedigrees with recent shared ancestry; however, systematic searches for autosomal recessive genes are in the very early stages.

The genetic architecture of autism is highly heterogeneous. Up to 3% of cases of autism are caused by microscopically detectable chromosomal anomalies. Chromosomal anomalies are common in autism, of major effect, and found throughout the genome (Abrahams & Geschwind, 2008). Some of the chromosomal regions, such as chromosome 7 and 15q11-13, have shown overlap with loci from linkage and association studies.
Figure 44–1. Causes of severe intellectual disability. The genetic architecture for ID may be helpful in conceptualizing at least a subset of autism. For ID, only 27% of cases cannot be accounted for by a discrete cause. 22% of diagnoses can be traced to a chromosomal disorder, and 21% of diagnoses are the result of a genetic syndrome. Other causes of intellectual disability include developmental brain abnormalities, metabolic/neurodegenerative disorders, congenital infections, and peri- and postnatal causes. Data from Stromme P and Hayberg G. (2000) Aetiology in severe and mild mental retardation: A population based study of Norwegian children. *Developmental Medicine and Child Neurology 42*, 76–86. (See Color Plate Section for a color version of this figure.)

Other regions include 2q37, 5p15, 11q25, 16q22.3, 17p11.2, 18q21.1, 18q23, 22q11.2, 22q13.3, and Xp22.2-22.3. One prominent example of genomic rearrangements in autism is the inverted duplication of proximal chromosome 15q11-13 (Cook et al., 1997). Given the frequency of chromosomal anomalies, novel high-resolution methodologies for analyzing genomic copy number variants (duplications/insertions and deletions), such as array CGH (aCGH) or high-density SNP chips, are currently being employed to study autism. Indeed, estimates of up to 10% of autism may be explainable by known genetic causes, including chromosomal anomalies, submicroscopic copy number variants or known genetic syndromes with autistic symptoms—that is, "syndromic autism," such as Fragile X syndrome (Martin & Ledbetter, 2007). Notably, a significant fraction of children who present with ASDs without clear syndromic features of Fragile X (in some studies up to 2%, although it is likely lower in the majority of clinics) will test positive for Fragile X syndrome (Reddy, 2005). In addition, a small number of Mendelian forms of autism, mostly X-linked, have been identified, such as mutations in the *Neuroligin* genes (Jamain et al., 2003; Laumonnier et al., 2004).

Many genetic syndromes are associated with ASDs, including Fragile X Syndrome, Tuberous Sclerosis, Angelman Syndrome, Rett Syndrome, Timothy's Syndrome, Joubert Syndrome, or MR syndromes resulting from mutations in *HoxA1* or *ARX* (Muhle et al., 2004; Moss & Howlin, 2009). All of these conditions are caused by loci of major effect, are generally X-linked and frequently de novo, or are autosomal recessive. These conditions may give clues as to the biological etiology of autistic symptoms. Fragile X syndrome is particularly significant. Approximately 2% of boys with idiopathic autism (i.e., without any syndromic features of Fragile X Syndrome) test positive for mutations at the Fragile X locus (Reddy, 2005), and the condition may be particularly frequent in populations with ASD

(Brown et al., 1986); therefore, this genetic test already serves as a tool for diagnostic subtyping in autism.

Finally, there are a large number of cases of ASD wherein CNVs (most prominently de novo CNVs) represent highly penetrant susceptibility loci (Cook & Scherer, 2008). Finally, the remaining majority of autism is idiopathic. The majority of idiopathic autism is likely polygenic—that is, caused by the combination of multiple genes of small effect—or even epigenetic. A core debate in autism genetics is whether autism is caused by the complex interaction of common disadvantageous alleles, or rare, highly penetrant deleterious lesions. Given heterogeneity, these models likely co-exist and thereby may be complementary, and studies to explore each mechanism (rare families with highly penetrant lesions as well as association studies) must be undertaken. However, for at least a subset of ASDs (including both syndromic and lower-functioning ASDs) a large number of individually rare, highly penetrant loci may be implicated with a genetic architecture that resembles intellectual disability (Figure 44-2). Indeed, several of these known loci may be shared or found in a range of conditions, including ID and ASDs but also others such as epilepsy (15q13 CNVs [Helbig et al., 2009; Miller et al., 2009]) and schizophrenia (multiple CNVs, with the longest standing example including 22q11 deletions [2008]).

Figure 44-3 demonstrates our hypotheses for the genetic architecture of ASDs, whereby at least a subset of the lower-functioning cohort has a genetic architecture resembling that of ID, and the remainder—particularly that of the higher functioning cohort—may have more complex genetic architecture. To stress, this is only a model at this stage, and the presentation

Summary: ASD molecular genetics
Figure 44–2. A subset of ASD has genetic architecture composed of diverse, individually-rare loci. The causes underlying ASDs are largely unknown: up to 87.4% of cases cannot be traced to a distinct genetic mechanism. Of the remaining 12.6% of cases, 5% may be attributed to de novo copy number variants (CNVs), and 2% may be attributed to silencing of the *FMR1* gene (associated with Fragile X mental retardation). The remaining cases suggest that aberrations in genes associated with Rett's Syndrome, tuberous sclerosis, and various synaptic proteins may contribute to the etiology of ASDs. Data from Abrahams, BD and Geschwind, DH. (2008) Advances in Autism Genetics: On the threshold of a new neurobiology. *Nature Reviews Genetics, 9*, 341–355. (See Color Plate Section for a color version of this figure.)

Hypothesis

- Syndromic autism
- Individually rare, monogenic or oligogenic
- Highly penetrant loci

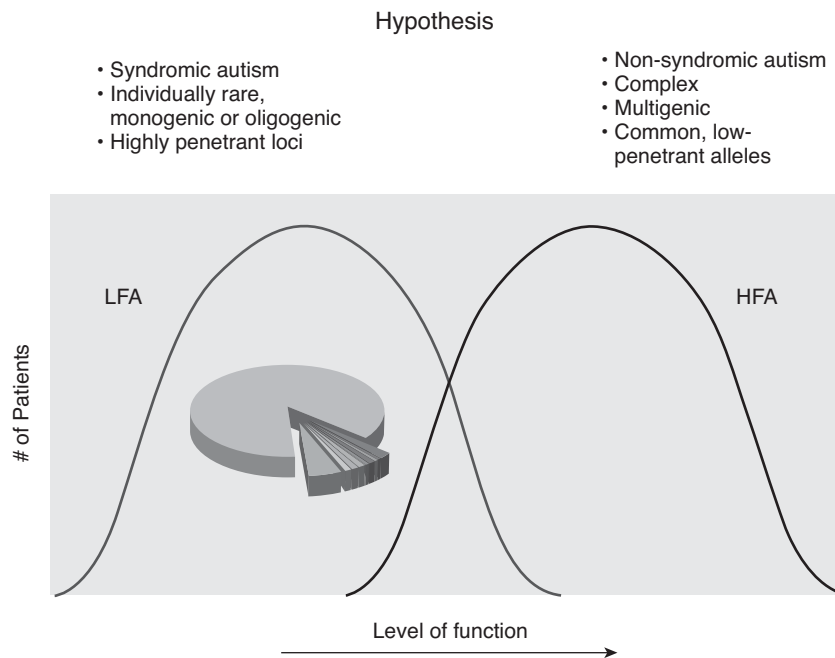
- Non-syndromic autism
- Complex
- Multigenic
- Common, low-penetrant alleles


Figure 44–3. Hypothesis of the genetic architecture of ASD. ASDs may be conceptualized in a bimodal nature within the diagnosed population, with two populations of patients diagnosed: one at the low-functioning level (low-functioning autism [LFA]), which might have a genetic architecture similar to ID, and one at the high-functioning level (high-functioning autism [HFA]), which might have more complex genetic architecture. Naturally this is a straw-man hypothesis but this underlying conceptualization may have use in bringing together different schools of thought in the ASD genetics field. (See Color Plate Section for a color version of this figure.)

of the ASD population as falling into two dichotomous groups is likely an oversimplification. Further, although the examples of common variants in ASDs that have been substantiated or replicated with whole-genome significance or through meta-analysis are few, there are a few examples of even higher-functioning autism being caused by rare, highly penetrant loci such as NLGN3 and NLGN4 mutations, although these examples are exceedingly rare (Jamain et al., 2003).

Genes and Loci Implicated by Linkage

Relatively few genes have been definitively identified for idiopathic, nonsyndromic autism. Indeed, for the majority of situations wherein loci have been found in ASDs, similar mutations have also been found in ID. Carefully designed genome-wide linkage screens in autistic disorder have identified heterogeneous linkage peaks, on 1q21-22, 2q21-33, 3q25-27, 7q11-12, 7q31-36, 13q14.1-14.2, 15q11-13, 16p13, 17q21, and others. Candidate genes have also been tested by association, however because of heterogeneity and limited power of available samples, examples of strong associations are few (Campbell et al., 2006; Alarcon et al., 2008; Arking et al., 2008). Among the most convincing evidence implicating a gene in autism has been obtained from single pedigrees— namely, the recent studies implicating *Neuroligin3* and *Neuroligin4* in ASDs (Jamain et al., 2003; Laumonnier et al., 2004). Laumonnier et al. (2004) described an extended French pedigree segregating three distinct phenotypes: autism

alone, MR alone, or autism with MR. This example of *NLGN* mutations in autism represents another example of a locus of major effect in autistic symptomology, although the occurance of these mutations are exceedingly rare.

Recent Shared Ancestry Facilitates Mapping Autosomal Recessive Conditions

Although many studies have assumed a modified form of dominant inheritance, some segregation analyses of autism suggest that affected individuals represent about 0.16 to 0.2 of all offspring, more suggestive of recessively inherited loci (Ritvo et al., 1985); however, existing evidence does not allow a clear choice. Recessive inheritance characterizes vast numbers of metabolic, developmental, and degenerative diseases of the nervous system, many of which can cause autistic symptoms. If we accept the likelihood that autosomal recessive genes cause some ASDs, then conducting homozygosity mapping offers a powerful, systematic way for finding such loci by enrolling families with consanguinity. Populations in which there is a high prevalence of recent shared ancestry within pedigrees (such as the Middle Eastern Arabic countries, Turkey, and Pakistan) have a different spectrum of genetic disease from populations where recent shared ancestry is less common (2006; Teebi & El-Shanti, 2006). In Saudi Arabia, Jordan, and many other Gulf countries, 40% to 60% of

marriages involve first cousins (Teebi & Farag, 1997). Populations with a high degree of recent shared ancestry show rates of congenital neurological disease that are two- to three-fold higher than Western populations, and this increased incidence has been attributed repeatedly to the action of recessive genes (Teebi & Farag, 1997) (Figure 44-4). There is also a reduced rate of de novo chromosomal causes of disease in these populations (Teebi & Farag, 1997; Hoodfar & Teebi, 1996). Parents with recent shared ancestry (independent of socioeconomic factors)—for example, cousins may also be a risk factor for disorders of cognitive development (Morton, 1978). Recent shared ancestry also facilitates gene mapping by allowing homozygosity mapping (Lander & Botstein, 1987; Kruglyak et al., 1995). Homozygosity mapping offers increased power from individual pedigrees as well as diminishing the problems imposed by locus heterogeneity and variable expressivity. With increased power per pedigree, there is a reduced need to pool across pedigrees and, potentially, across heterogeneous conditions. In addition, some countries wherein recent shared ancestry is prevalent in pedigrees also have very high fertility rates, with large families (on average ≥6 children per mother) also simplifying genetic linkage analysis and allowing gene mapping to be often accomplished using just one or two extended families.

The power of consanguineous pedigrees for mapping recessive genes is illustrated (Figure 44-5A) by showing the maximal theoretical LOD score for genetic linkage in a pedigree with unrelated parents (left), first-cousin parents (middle), and second-cousin parents (right). The LOD score triples when we go from unrelated to first-cousin parents and increases further when parents are more distantly related. This effect reflects the fact that the consanguinity includes more individuals from the pedigree in the linkage calculation (Lander & Botstein, 1987; Kruglyak et al., 1995). Also shown in Figure 44-5B are two pedigrees with equal power (i.e., number of of meioses) for mapping autosomal recessive traits. The one at the left represents a pedigree in which parents are second cousins. Such pedigrees may be common in referral clinics in regions of the world where pedigrees with recent shared ancestry may be more common; however, the pedigree on the right, which has equal power, is fairly uncommon worldwide. In addition to the factors listed above, some countries with recent shared ancestry—particularly Saudi Arabia—tend to have a remarkably tribal structure. The majority of the 16 million ethnic Saudi people belong to 8 major tribes (consisting of up to 1 million people each) and 12 smaller tribes, with high tendencies to marry within tribes (Teebi & Farag, 1997). Each tribe tends to have its own founder mutations resulting from the fact that each tribe derives initially from founder populations equivalent to just a few tents of people. Even where definable shared ancestry is absent, the likelihood of homozygosity for founder mutations is high. These patterns make mapping of recessive autism loci feasible, whereas the possibility of founder mutations makes fine mapping and gene identification a realistic possibility. As described with the example of the Amish described below, studying founder populations in genetics is not new, and many of the features of the populations described above for those with recent shared ancestry are true to a degree for other populations around the world that have also been studied by geneticists, such as the Ashkenazi Jewish population, the French Canadian population, the Icelandic population, or the Old Order Amish population.
Figure 44–4. Consanguinity increases rate of recessive disorders. Causes of medical referrals between offspring with parental consanguinity versus offspring without. Autosomal recessive conditions are more than twice as common among offspring with parental consanguinity (1st cousin), than among those without (unrelated) (33.3% versus 12.4%), while chromosomal abnormalities are more than twice as common among offspring of unrelated unions in comparison with those of 1st cousin unions (15.7% versus 6.7%). Data from Hoodfar, E. and A. S. Teebi (1996). Genetic referrals of Middle Eastern origin in a western city: inbreeding and disease profile. *Journal of Medical Genetics,* **33**(3), 212–215. (See Color Plate Section for a color version of this figure.)
Figure 44–5. Consanguineous pedigrees have increased power for mapping autosomal recessive loci. A. Simulated LOD scores from families with two affected offspring segregating a recessive trait when the parents are unrelated (left), first cousins (center), or second cousins (right). B. Model pedigrees each with equal power for mapping autosomal recessive loci. The consanguineous pedigree as drawn is common in regions of the world wherein consanguinity is common. The pedigree without parental consanguinity is exceedingly challenging to find anywhere in the world. **C.** Pedigrees with ASD with parental consanguinity from the Homozygosity Mapping Collaborative for Autism. In many cases, not all unaffected siblings have been included in the pedigree.

Lessons From Autosomal Recessive Loci for Brain Malformations Such as Joubert Syndrome

One hypothesis outlined above for the approach taken in rare isolate populations (hypothesis 7 above) is that genes and loci found in pedigrees from isolate populations may be relevant to non-syndromic autism or "complex" autism. Indeed this hypothesis has been tested, and a recent report has confirmed that a common haplotype of *AHI1* (a gene mutated in some forms of Joubert syndrome as discovered by homozygosity mapping) in populations without recent shared ancestry appears to be associated with ASDs (Alvarez Retuerto et al., 2008). This same haplotype had been previously implicated in schizophrenia. Overall, these data suggest that *AHI1* may have rare highly penetrant mutations in Joubert syndrome (which is associated with autistic symptoms) and common variation in the same gene may be associated with neuropsychiatric disorders with cognitive and developmental components such as ASD and/or schizophrenia. This is early evidence to

support the hypothesis (#7) that loci from rare syndromic forms of autism may yield important clues in non-syndromic or "complex" autism.

Lessons From a Rare Autosomal Recessive Mutation in the Old Order Amish in Focal Epilepsy

Given recent shared ancestry in the U.S. Older Amish population, there are several examples of autosomal recessive conditions that have been reported in this population and an important example of a mutation in a cohort with focal epilepsy, relative macrocephaly, and focal dysplasia was reported (Strauss et al., 2006). Affected individuals in the pedigree were also identified to have a high rate of PDD-NOS. Using homozygosity mapping, Strauss et al. identified a homozygous mutation in the contactin-associated protein-like 2 (CASPR2), which is encoded by CNTNAP2.

Based in part of the identification of a translocation that disrupted this gene, and also on the PDD symptoms in the

Amish epilepsy pedigree, CNTNAP2 became the subject of intense study through gene resequencing and gene association studies (Alarcon et al., 2008; Arking et al., 2008; Bakkaloglu et al., 2008). Again, these findings provide support for the notion that syndromic forms of autism may provide critical clues for loci in non-syndromic ASDs.

Lessons From Genetic Studies of Non-Syndromic MR in Populations With Recent Shared Ancestry

To date, although homozygosity mapping has been very successful for rare neuromedical conditions with distinctive brain malformations and other syndromic features (Barkovich et al., 2005), genes have also been identified for non-syndromic MR (NSMR) using homozygosity mapping (Basel-Vanagaite et al., 2007). Also, promising loci for other non-syndromic neurologic conditions, such as deafness (Tariq et al., 2006), or complex neurologic traits, such as stuttering, are under active study (Riaz et al., 2005). For NSMR, Basel et al. (2006) successfully identified mutations in CC2D1A in autosomal recessive NSMR by homozygosity mapping (Basel-Vanagaite et al., 2006). Some cases of autism are highly related to NSMR (Laumonnier et al., 2004), and thereby the successful use of

homozygosity mapping for NSMR is strong preliminary support for its application to familial ASDs.

A Systematic Search for Autosomal Recessive Loci in Populations with Recent Shared Ancestry: The Homozygosity Mapping Collaborative for Autism

Given the hypotheses, rationale, and data described above, in 2005, a systematic approach for studying autosomal recessive loci in populations with recent shared ancestry was started through international collaboration. Clinician research collaborators in several centers began to enroll pedigrees with children affected by autism and with recent shared ancestry. These efforts are ongoing and the initial studies have been published by Morrow et al. (2008). Figure 44-6 demonstrates the locations of the most active centers of the collaboration.

The study plan for the HMCA is described in Figure 44-7. Pedigrees were enrolled through clinician collaborators and examples are shown in Figure 44-5C. To establish thorough research diagnoses, international participating clinicians received training in accepted autism research scales. When research scales were not available in the language of their country, these clinicians enrolled patients and family members

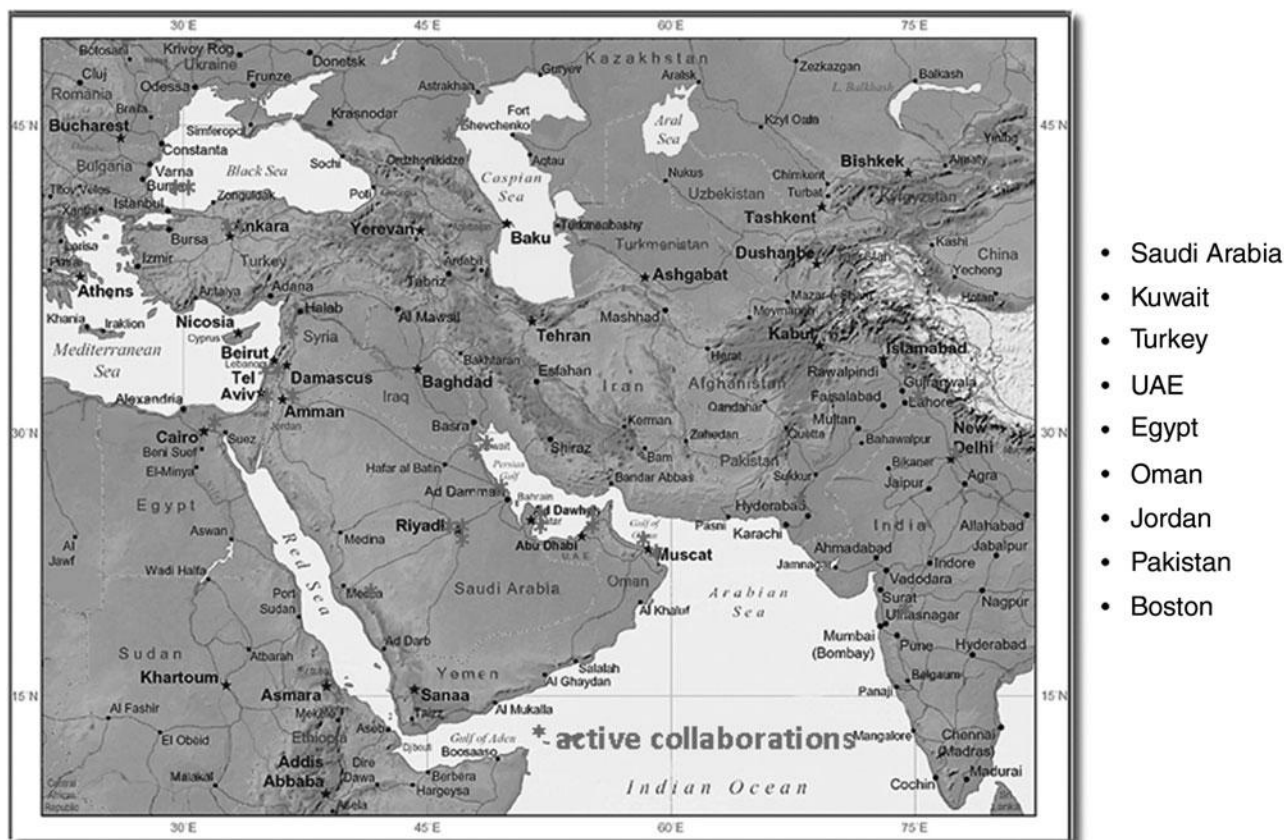
- Saudi Arabia
- Kuwait
- Turkey
- UAE
- Egypt
- Oman
- Jordan
- Pakistan
- Boston


Figure 44–6. Homozygosity Mapping Collaborative for Autism (HMCA). The approach of the HMCA involves collaborators from around the world with a focus in the Middle East. Asterisks indicate locations of active collaborations. In these countries, traditions of marriage between cousins increase the prevalence of recessive disorders, which can be traced using homozygosity mapping. (See Color Plate Section for a color version of this figure.)
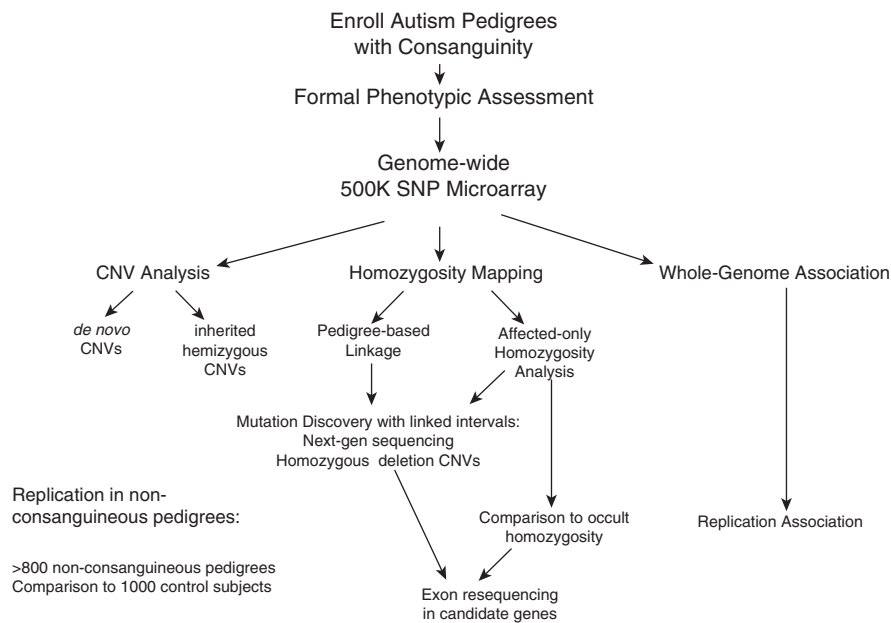

Figure 44–7. HMCA Study Plan. The approach taken by the Homozygosity Mapping Collaborative for Autism (HMCA) involves enrollment of subjects from consanguineous families affected by autism, phenotypic assessment, and genome-wide SNP micro-array analysis.

based on DSM-IV-TR diagnoses that were informed by these clinicians' experiences with validated research scales. Additional direct assessments of patients were conducted by clinical members of the Boston team, which included a multidisciplinary group, such as developmental psychologists, pediatric neurologists, a clinical geneticist, and a neuropsychiatrist. Reliability between clinician assessments was high; a description of clinical assessment is available.

An increased role for inherited factors in autism with shared ancestry was suggested by a low rate of de novo CNVs (Morrow et al., 2008). Additionally, in the multiplex families (which provided support for linkage through homozygosity mapping), implicated loci were heterogeneous, with each pedigree providing support for distinct loci. This latter data-point again underscores the heterogeneity of the condition even in this special founder population. Notably, several loci were mapped that contained large, inherited homozygous deletions that are likely mutations. The largest deletions implicated genes, including *PCDH10* (protocadherin 10); *DIA1* (deleted in autism1, or c3orf58), and *NHE9*. A subset of genes—particularly *NHE9* (Na$^+$/H$^+$ exchanger 9)—was studied in pedigrees without recent shared ancestry through resequencing, and additional potential mutations in patients with unrelated parents were found. Interestingly, the proportion of patients with *NHE9* gene alterations that were likely deleterious was only slightly higher in autistic children than in normals overall but was significantly higher in patients with autism and comorbid epilepsy. The initial patient in the pedigree with recent shared ancestry also had autism with epilepsy. This finding, as for AHI1 and CNTNAP2, provided further support that loci implicated in special populations may be generalized, albeit in this case an intermediate phenotype of

autism (autism with epilepsy). As shown in Figure 44-7, in addition to homozygosity studies, these samples were included in the recent whole-genome association study and linkage studies. This collaborative, which is ongoing, is now also involved in a major deep resequencing study utilizing next-generation sequencing methods. Overall, the initial results of the HMCA have provided important clues and insights. Nonetheless, it is evident that the genetic dissection of ASDs, even in these special founder populations, is only at the beginning stages, and there is a great deal more work to be done. In particular, larger epidemiologic sampling of these special populations combined with novel, more high-throughput methods will capitalize further on this approach, which stands in complement to other ongoing, critical efforts in ASD genetics.

Conclusion

In conclusion, "forward" genetics efforts in ASDs offer a critical opportunity to tackle this profound and costly problem. Given the heterogeneity of ASD genetics, it is without a doubt that multiple concurrent approaches to dissecting the genetic susceptibility of the condition is necessary. Examination of isolate populations and rare variants is one such complementary and important approach. Stemming from the notion that rare, highly penetrant genetic factors may explain a subset of the genetic architecture, this approach draws heavily from the field of ID and epilepsy genetics, syndromic forms of autism, and rare pedigrees. It is based on the following hypotheses: *(1)* ASD is genetically heterogeneous; *(2)* a subset of

ASDs worldwide will be caused by individually rare, highly penetrant loci; *(3)* As a syndrome of neurodevelopmental conditions, ASD genetics will be informed by two other syndromes of neurodevelopment—namely, ID and epilepsy; *(4)* as ASD (at least for lower-functioning autism) appears to decrease reproductive fitness, a subset of loci are likely to be de novo and/or recessive (X-linked or autosomal recessive); *(5)* autosomal recessive loci underlying autism susceptibility will be enriched in populations with recent shared ancestry; *(6)* although genome-wide association studies are undoubtedly important, linkage studies may remain as an important complementary approach, particularly in special founder populations; *(7)* pedigrees with rare, highly penetrant loci may involve syndromic forms of autism that may involve ID or epilepsy; and *(8)* pedigrees from isolate populations or with syndromic forms of autism may be highly informative to other forms of ASDs with more complex genetic architecture. Although this endeavor for ASDs is in the very early stages, and there is much work ahead, there are some initial clues and loci that are being followed up extensively, as the field moves forward with expanded study-sized and novel genomic methods.

Challenges and Future Directions

- Large epidemiologic studies of autism in special populations with recent shared ancestry.
- High-throughput sequencing of linkage peaks and genome-wide in samples with recent shared ancestry to characterize full extent of recessive genetic changes, which may be associated with disease.
- Large-scale sequencing of candidate targets emerging from above studies in populations without recent shared ancestry to test possibility of general significance of loci to non-founder populations.

Rett Syndrome and *MECP2*-Related Disorders

▦

Points of Interest

- RTT is a clinical diagnosis that predicts genetic alterations, but a fraction of individuals do not have any identified genetic alterations.
- Mutations in *MECP2* are found in the majority of people with typical RTT. Some defined atypical variant forms of RTT have mutations in other loci (e.g., *CDKL5, FOXG1*).
- Mutations in *MECP2* have been identified in neurodevelopmental disorders that do not have the distinctive clinical features of RTT.
- Both loss of MeCP2 function and increasing the amount of MeCP2 protein leads to neurodevelopmental disorders in people as well as distinct phenotypic abnormalities in mice. Thus, the precise level of MeCP2 with a cell is critical for the normal functioning of the nervous system.
- Because the spectrum of phenotypic and neuroanatomic abnormalities that occur as a result of alterations in MeCP2 protein level display similarities to a number of neurodevelopmental disorders, understanding these *MECP2*-related disorders and the functional changes that occur at a molecular and cellular level will likely provide insight into a number of neurodevelopmental disorders such as autism.

In the 1960s, Andreas Rett, an Austrian pediatrician, noticed two markedly impaired girls in his waiting room with similar relentless hand-wringing. He recognized that these girls also shared a number of additional clinical features. By reviewing his charts, he identified a cohort of girls with this unique condition, which he reported in a German language journal (Rett, 1966). The condition was not routinely recognized until 1983, when Bengt Hagberg and colleagues published a series of 35 similar cases (B. Hagberg et al., 1983) in English and gave it the eponym by which it is commonly referred, Rett Syndrome (RTT; OMIM 312750). Since that time, not only have a large

number of additional cases been identified, but mutations in *Methyl-CpG-binding protein 2* (*MECP2*) have been determined to cause RTT (Amir et al., 1999). Although this is a relatively rare condition, affecting 1.09 per 10,000 females by age 12 years (Laurvick et al., 2006), broad interest in this disorder exists because clinical features found in RTT are also seen in a number of other neurodevelopmental disorders, as well as adult neurological and psychiatric conditions. Additionally, the spectrum of clinical disorders caused by either decreasing or increasing MeCP2 function (*MECP2*-related disorders) has grown to include autism, Angelman Syndrome-like features, intellectual disability in boys with associated neuropsychiatric features, and neuropsychiatric features such as anxiety and depression in women. The fact that alterations in MeCP2 function can cause such a wide range of clinical features with similarities to many other neurological and psychiatric disorders both in children and adults argues for a common pathogenic mechanism. This chapter provides a brief outline of the clinical features of typical RTT and describes the genetic locus mutated in the majority of typical RTT. The clinical aspects and genetics of atypical forms of RTT and other *MECP2*-related disorders are presented, followed by an introduction to the molecular function of MeCP2 and animal models of RTT and *MECP2*-related disorders.

▦

Typical Rett Syndrome

Diagnosis of Rett Syndrome

Typical, or classic, RTT is a clinical diagnosis based on the presence of clinical features that meet defined consensus criteria (Table 45-1) (Neul et al., 2010). The diagnosis of typical RTT requires a period of regression, specifically of hand and spoken language skills, the development of gait abnormalities (or the failure to walk), and the onset of characteristic hand stereotypies. In a previous consensus criteria published in

2002 (B. Hagberg, Hanefeld, Percy, & Skjeldal et al., 2002), acquired microcephaly was a necessary criteria, however it has been recognized that a significant fraction of people with RTT do not have acquired microcephaly, therefore this requirement has been removed in the recent criteria. However, because it is a clinical feature that can alert a clinician to the potential diagnosis and it is a distinctive feature in the disorder, acquired microcephaly is included as a preamble to the criteria as a feature that should raise suspicion for the diagnosis. In addition to the above listed required features, the diagnosis of typical RTT also requires grossly normal development in the first six months of life and the exclusion of any other possible known causes of neurological dysfunction.

It has long been recognized that some individuals present with many of the features of RTT but do not exhibit all the necessary criteria for the diagnosis of typical RTT. Consequently, a separate set of criteria, derived from the criteria for typical RTT, were devised for these "atypical" cases (Table 45-1). (Neul et al., 2010). Such persons may have a more severe presentation than typical RTT, with no period of normal development (known as the congenital variant), or may have a greater degree of preserved function (known as the preserved speech variant [PSV]). As these atypical variants demonstrate important features concerning both the clinical and genetic heterogeneity found in RTT, the specific clinical and genetic features will be discussed at length later.

Despite the fact that the majority of cases of typical RTT have mutations in *MECP2* (discussed below), RTT remains a clinical diagnosis. This may strike some as anachronistic. If most cases of RTT have mutations in a *MECP2*, why not define the disease by the presence of a mutation in *MECP2*? There are two important reasons that a *MECP2* mutation does not equal the clinical condition and vice versa. First, although the majority of individuals with typical RTT have a *MECP2* mutation, at least 5% do not, despite clearly having the clinical condition (Neul et al., 2008). Therefore, having a *MECP2* mutation is not *necessary* for the clinical diagnosis. In fact, some people with features of RTT have mutations in other genetic loci (discussed later). Second, *MECP2* mutations can also be found in people who do not manifest the clinical features of RTT. Therefore, mutations in this locus are not *sufficient* to make the diagnosis. Throughout the course of this chapter, the clinical and genetic knowledge to demonstrate this argument will be presented. In light of the importance of both the clinical condition and the details of the genetic alterations, when characterizing individuals, it is worthwhile to state *both* the clinical condition and the genetic mutations—for example, typical RTT with a disease-causing mutation in *MECP2*, atypical RTT with a disease-causing mutation in *CDKL5*, and so forth.

Clinical Features of Rett Syndrome

Early Development

RTT is a neurodevelopmental disorder that primarily affects girls, causing intellectual disability, loss of purposeful hand

Table 45–1.

Consensus criteria for diagnosis of RTT

RTT Diagnostic Criteria
Consider diagnosis when postnatal deceleration of head growth observed.

Required for Typical or Classic RTT
1. A period of regression followed by recovery or stabilization
2. All main criteria and all exclusion criteria
3. Supportive criteria are not required, although often present in typical RTT

Required for Atypical or Variant RTT
1. A period of regression followed by recovery or stabilization
2. 2 out of the 4 main criteria
3. 5 out of 11 supportive criteria

Main Criteria
1. Partial or complete loss of acquired purposeful hand skills
2. Partial or complete loss of acquired spoken language
3. Gait abnormalities: Impaired (dyspraxic) or absence of ability
4. Stereotypic hand movements such as hand wringing/squeezing, clapping/tapping, mouthing and washing/rubbing automatisms

Exclusion Criteria for Typical RTT
1. Brain injury secondary to trauma (peri- or postnatally), neurometabolic disease, or severe infection that causes neurological problems
2. Grossly abnormal psychomotor development in first 6 months of life

Supportive Criteria for Atypical RTT
1. Breathing disturbances when awake
2. Bruxism when awake
3. Impaired sleep pattern
4. Abnormal muscle tone
5. Peripheral vasomotor disturbances
6. Scoliosis/kyphosis
7. Growth retardation
8. Small cold hands and feet
9. Inappropriate laughing/screaming spells
10. Diminished response to pain
11. Intense eye communication - "eye pointing"

Adapted with permission from Neul et al., 2010.

use and spoken language, stereotypic hand movements, and a particular gait abnormality. The clinical course follows a specific disease progression. Individuals with RTT initially undergo apparently normal development after a normal pregnancy and delivery (B. Hagberg et al., 1983) with normal height, weight, and head size. In retrospect, they are considered "good" babies, typically relatively placid (A. M. Kerr, Montague, & Stephenson, 1987; Leonard & Bower, 1998; Naidu, 1997; Nomura & Segawa, 1990b; Witt-Engerstrom, 1987). Individuals who ultimately develop RTT reach typical

developmental screening milestones appropriately, and no concerns with development at this time are noted (A. M. Kerr & Stephenson, 1985; Witt-Engerstrom & Gillberg, 1987), although retrospective review of early family videos revealed subtle movement abnormalities (Einspieler, Kerr, & Prechtl, 2005a, 2005b; A. M. Kerr et al., 1987; Witt-Engerstrom, 1987). Development begins to stagnate between 6 to 18 months without clear developmental regression.

Regression

After this period of developmental stagnation, dramatic and relatively rapid regression prominently affecting hand and spoken language skills occurs between approximately 1 to 4 years of life over a variable interval of several days to a year. The loss of skills is relative to the degree that specific skills had previously been acquired. For example, a child who previously had at best achieved nuanced babbling may become essentially mute, whereas a child who had distinct spoken words may revert to babbling. Social interaction and communication become impaired with the development of autistic features such as a dislike for being held, avoidance of eye contact, or unresponsiveness to human contact. Some children display screaming episodes in which they appear to be in pain, sometimes raising concern for an infectious encephalitic process. Before the onset of additional typical clinical features of the disorder, individuals may be diagnosed with an autistic spectrum disorder or a neurodegenerative condition. Some of the distinctive clinical features, such as hand stereotypies, may manifest at this stage, but they often are not apparent until regression has ended. A history of regression is considered to be an essential criteria for the diagnosis of classic, or typical, RTT (B. Hagberg, 2002).

Stabilization

After the period of distinct regression of developmental skills, a period of relative stability ensues. Notably, the children show improvement in mood, eye contact, and general sociability in affected individuals, which clearly distinguishes RTT from other relentless neurodegenerative conditions or typical autism. Communication using intense eye gaze and eye pointing begins, which is a very prominent and distinctive feature of RTT (B. Hagberg, 2002) and distinguishes this condition from classic autism. Hand stereotypies and other characteristic features of the disorder become prominent and clearly mark affected individuals as having the specific disorder. In the era before the discovery of the genetic basis of RTT, the diagnosis of RTT was rarely made until this stage.

Distinct Clinical Features

Hand Stereotypies

Probably the most readily recognized feature of RTT is the repetitive hand-wringing, washing-like motion, or hand-clapping behavior. These movements are typically midline but may also be lateral, on the head, or behind the back (Temudo et al., 2007). They occur only during wakefulness and vary in frequency both between and within individuals, often worsened with anxiety or stress. These stereotypies appear to inhibit volitional hand use, as mild improvement in volitional hand use occurs after splinting of the arms at the elbows (Aron, 1990; Bumin et al., 2002; Kubas, 1992; Sharpe, 1992; Sharpe & Ottenbacher, 1990). With age, the movements become slower and simpler in concert with increased rigidity (FitzGerald et al., 1990; Nomura & Segawa, 1990a; Temudo et al., 2007). Notably, although hand-washing stereotypies are often considered to be pathognomonic of RTT, recent work has indicated that such behaviors may not be specific to RTT (Temudo et al., 2007).

Gait and Movement Abnormalities

Although some individuals never learn to walk or completely lose the ability during regression, many are able to walk. However, all have some degree of gait abnormality with a characteristic dyspraxic, wandering quality. Elements of ataxia are also present and the stance is typically wide-based. Affected individuals also have a variety of movement abnormalities including dystonia, tremor, myoclonus, and bruxism. Muscle tone is initially hypotonic with the development of increased limb tone and rigidity as the child ages.

Growth Failure

Although birth head size, weight, and height are typically normal, individuals with RTT suffer from pervasive growth failure. The rate of head growth declines as early as 2 months and may result in frank acquired microcephaly (G. Hagberg, Stenbom, & Engerstrom, 2001). Most individuals with RTT are markedly underweight and short, despite apparently normal appetite, although a subset have increased body mass indices (Renieri et al., 2008). Hand and foot growth are also impaired. Although objectively their hands are small, they often appear long and slender because of decreased muscle mass of the intrinsic muscles of the hands and fingers, likely secondary to decreased volitional hand use (personal observation). Additionally, bone mineral density is low (Budden & Gunness, 2003; Motil et al., 2008), and some individuals have increased bone fractures (Motil et al., 2008), which may be identified on routine X-ray without any clear proximate cause.

Seizures and Nonepileptic Spells

All affected individuals have abnormal electroencephalograms (EEGs) after age 2 years with slowing of background activity, spike, and slow spike and wave activity (Glaze, 2002). Seizures are present in some individuals, but the reported prevalence of seizures varies widely, from 30% to 80% (Glaze et al., 1987; Glaze, Schultz, & Frost, 1998; Hagne, Witt-Engerstrom, & Hagberg, 1989; Steffenburg, Hagberg, & Hagberg, 2001). The source of this variation is likely the spectrum of nonepileptic

events that can be confused with true epileptic seizures. These nonepileptic events can manifest as vacant spells associated with breath-holding (Cooper, Kerr, & Amos, 1998), dystonic posturing, or paroxysmal dyskinesias (personal observation). Video EEG recordings during these spells show no electrographic seizure activity (Cooper et al., 1998). It has been proposed that these nonepileptic events may result from brain stem dysfunction. In general, typical anti-seizure medications do not show significant efficacy toward these nonepileptic spells; however, use of topirimate reduced breathing irregularity in individuals being treated for epilepsy (Goyal, O'Riordan, & Wiznitzer, 2004). The frequency of these nonepileptic spells, the potential for confusion with cortical seizures, and the inherent increased risk of seizures in this population demonstrate the importance of careful evaluation with video EEG monitoring to determine the exact nature of such spells.

Autonomic Dysfunction

A serious clinical issue in RTT is the high incidence of sudden unexpected death, which accounts for up to 25% of the deaths of affected individuals (A. M. Kerr et al., 1997). Although the exact nature of such deaths is unknown, the variety of autonomic abnormalities found in girls and women with RTT suggests that this autonomic dysfunction may be a factor (Guideri et al., 1999; Julu et al., 1997; Sekul et al., 1994). Evidence of cardiac rhythm abnormalities exist including decreased beat-to-beat variability of their heart rate (Guideri et al., 1999; Julu et al., 2001), tachycardia (Rohdin et al., 2007; Weese-Mayer et al., 2006), and bradycardia (Madan et al., 2004; Rohdin et al., 2007). Furthermore, the electrocardiograms of a significant fraction of affected individuals have a prolonged corrected QT interval (Ellaway et al., 1999; Sekul et al., 1994).

Respiration is altered in the majority of girls and women with RTT, and many have markedly irregular breathing with periods of hyperventilation and/or apnea (Julu et al., 2001; Rohdin et al., 2007; Weese-Mayer et al., 2006). The breathing irregularities are exaggerated in novel, stress-inducing environments. Detailed analysis of respiratory patterns during wakefulness (Weese-Mayer et al., 2006) has revealed that breathing in RTT is more irregular, faster, and deeper than in control individuals even in "normal" non-apneic periods. In contrast to previous reports of complete normalization of respiration during sleep, prolonged in-home studies have shown both an equal number of apneas during daytime and nighttime (Rohdin et al., 2007) and faster, more irregular breathing during nighttime (Weese-Mayer et al., 2008). Although these studies lack coincident EEG measurements to unequivocally determine the sleep–wake state, the overall findings suggest some degree of breathing dysfunction during sleep and wakefulness.

Analysis of the relationship between breathing and heart rate has revealed a lack of coordination between the two, suggesting alteration in the medullary network that controls and integrates these systems (Julu et al., 2001; Rohdin et al., 2007; Weese-Mayer et al., 2008). This notion is supported by evidence from mouse models and human pathological studies of alterations in both the serotoninergic and noradrenergic systems within the medulla, both critical in the modulation of cardiorespiratory rhythms (Paterson et al., 2005; Viemari et al., 2005).

Nearly all affected individuals have cool extremities—especially their feet, which at times can be cold and mottled (A. M. Kerr & Julu, 1999). Interestingly, an anecdotal report indicates that the cool extremities likely have a sympathetic nervous system origin. An accidental unilateral sympathectomy was performed in an affected individual undergoing spinal fusion for scoliosis,. After recovery, the foot on the sympathectomy side was warmer, despite the opposite foot remaining as cool as presurgically (Naidu et al., 1987).

The gastrointestinal system shows significant alterations. Most girls and women with RTT have disrupted oromotor function and difficulty swallowing, with frequent choking and gagging on food (Motil et al., 1999). Furthermore, many are afflicted with severe gastroesophageal reflux and constipation (B. Hagberg et al., 1983), two issues that cause significant morbidity in affected individuals. Additionally, the motility of the esophagus, stomach, and duodenum is uncoordinated (Motil et al., 1999).

Late Motor Decline

As they enter their teens and twenties, many affected individuals show a protracted decline in motor skills and develop a hypoactive pattern of behavior ("couch potatoes"). Parkinsonian features such as rigidity, hypomimia, and retropulsion also become more prominent (FitzGerald, Jankovic, Glaze et al., 1990; FitzGerald, Jankovic, & Percy, 1990; B. Hagberg, 2005). Associated musculoskeletal alterations such as scoliosis and contractures can become serious enough to warrant surgical intervention (Smeets, Schrander-Stumpel, & Curfs, 2008). Although this motor decline sometimes impairs independent ambulation, a number of affected individuals continue to walk throughout their lives (Smeets et al., 2008). Although previously considered to be fatal by the teenage years, survival into at least middle age is typical and should be anticipated (Kirby et al., 2009). This improvement in survival likely reflects the greater attention currently paid to monitoring nutritional status and providing additional nutritional support when needed (Motil et al., 2009).

Neuropathology

The brains of individuals with RTT are small, as expected from the small head size, but neuropathology has revealed no gross abnormalities, gliosis, or migrational defects (D. D. Armstrong, 2005b). However, there is decreased synaptic density (Belichenko et al., 1994), decreased dendritic arborization (D. Armstrong et al., 1995), and increased neuronal cell packing in the hippocampus (Kaufmann & Moser, 2000). Importantly, no signs of cell loss or neurodegeneration have been observed (Jellinger et al., 1988), indicating that RTT is not a neurodegenerative process.

Genetics of Rett Syndrome

Because RTT typically manifests in females, the hypothesis arose that it was the result of an X-linked dominant genetic alteration with male lethality (B. Hagberg et al., 1983). The majority of cases are sporadic; however, rare familial cases have allowed exclusion mapping of the X-chromosome and localization to Xq27-qter. Analyzing candidate transcripts within the region has revealed mutations in *MECP2*, located at Xq28, in both familial as well as sporadic cases (Amir et al., 1999). The vast majority (95%) of people with typical RTT have mutations in *MECP2* (Neul et al., 2008). Most of the mutations found in sporadic cases arise from the parental germline (Trappe et al., 2001) and often occur at CpG mutational hotspots by deamination of methylated cytosines, which creates a C-T transition.

The coding sequence of *MECP2* spans four exons that encode two splice isoforms of the protein that differ in their amino-terminus (Kriaucionis & Bird, 2004; Mnatzakanian et al., 2004). Additional mRNA species complexity exists because *MECP2* has a large 3′untranslated region (3′UTR) that contains multiple polyadenylation sites. Alternative use of these polyadenylation sites generates four 3′UTR isoforms, with the longest transcript being the dominant species in the brain (Coy et al., 1999). There are highly conserved sequence regions within the 3′UTR (B. Kerr et al., 2008), suggesting a role in regulation of MeCP2 expression, and recently a microRNA (miR132) was found to bind to the 3′UTR and regulate MeCP2 translation (Klein et al., 2007).

An interesting genetic feature of the rare familial cases of RTT is the presence of the pathogenic mutation in *MECP2* in asymptomatic carrier mothers and other female relatives. Because *MECP2* resides on the X-chromosome, one source of this variation in expressivity is the pattern of X-chromosome inactivation (XCI). In females, only one X-chromosome is active in any cell whereas the other is inactivated. The process of inactivation occurs during development and usually results in a random pattern, with half the cells in her body expressing the maternal X-chromosome and half expressing the paternal X-chromosome. In most girls with typical RTT, the XCI pattern is random, with half of the cells expressing a wild-type copy of *MECP2* and half expressing the mutated version. However, the asymptomatic carriers have markedly skewed XCI, with most of the cells in their body expressing the wild-type copy of *MECP2* (Wan et al., 1999). It should be noted that there are rare boys who have the clinical features of RTT. The majority of these have mutations in *MECP2* and additional genetic abnormalities such as X-chromosomal aneupleudy or somatic mosaicism, which allows mosaic expression of wild-type and mutant alleles of *MECP2* similar to that which results in girls with RTT secondary to XCI. Although these cases are presented in the section titled "*MECP2*-related disorders," it should be noted that they do have typical RTT, despite being boys.

X Chromosome Inactivation (XCI): In females, only one X-chromosome is active in any cell, whereas the other is inactivated. The process of inactivation occurs during development and usually results in a random pattern, with half the cells of the body expressing the maternal X-chromosome and half expressing the paternal X-chromosome.

Skewed XCI: In most girls and women, XCI is a random process that results in roughly the same percentage of cells expressing genes from the maternal chromosome as from the paternal chromosome. However, in some people, non-random skewing of XCI is observed with a larger fraction of cells expressing genes from one of the parental chromosomes than the other. This may be the result of selective pressure during development favoring cells expressing one parental X-chromosome over the other. In people with mutations in *MECP2*, all informative examples of skewed XCI have been shown to favor the "good" X-chromosome containing the non-mutated copy of *MECP2*. This suggests that cells that express a mutated version of MeCP2 may be at a developmental disadvantage compared with cells expressing a normal version of MeCP2.

Phenotypic Variation in Rett Syndrome

Although RTT is defined by a distinct set of clinical features, clinical severity varies considerably among individuals. One explanation for the difference in expressivity of the atypical cases, as well as variation in typical cases, is variation in the degree of XCI skewing. As mentioned above, this is most apparent in the extreme case of an asymptomatic mother with complete XCI skewing. In the same way, incomplete XCI skewing can explain some of the variation seen in individuals with RTT (Amir et al., 2000); however, it accounts for only 20% of the clinical variability seen in typical RTT (Archer, Evans, Leonard et al., 2006).

Another possible source of variation is the molecular nature of the specific mutation in *MECP2*. Hundreds of pathogenic mutations in *MECP2* have been associated with RTT (Christodoulou et al., 2003), including missense, nonsense, frameshift, and large DNA rearrangements that typically remove large regions of the coding sequence (Archer, Whatley et al., 2006; Pan et al., 2006; Ravn et al., 2005). The fact that large DNA rearrangements that completely disrupt gene expression and point mutations result in the same clinical condition implies that these point mutations are loss-of-function mutations. Despite the large number of pathogenic mutations, eight common missense and nonsense mutations (Figure 45-1)—all the result of C-T transitions—account for approximately 70% of all typical RTT cases (Bebbington et al., 2008; Neul et al., 2008). Additionally, a number of small insertions and deletions in the carboxy-terminal domain (CTD) result in frameshift mutations that lead to similar truncations late in the protein. As a group, these CTD truncations account for approximately 7% to 12% of all typical RTT cases (Bebbington et al., 2008; Neul et al., 2008). Finally, large DNA rearrangements account for approximately 7% of typical RTT cases (Neul et al., 2008). Thus, in total, more than 80% of individuals with typical RTT have 1 of these 10 mutations.

This fact has allowed genotype/phenotype correlation studies to be performed. In general, mutations that truncate the protein before the nuclear localization sequence (NLS) are more severe than missense mutations or truncations after the NLS (Huppke et al., 2002; Smeets et al., 2005). Recent studies have had the power to detect phenotypic differences between the common mutations and have found that p.Arg168X, p.Arg255X, p.Arg270X, and large rearrangements are more severely affected, whereas p.Arg133Cys, p.Arg294X, p.Arg306Cys, and CTD truncations are milder (Bebbington et al., 2008; Neul et al., 2008).

Atypical Forms of Rett Syndrome

Individuals who have regression and cardinal features of RTT but do not meet the consensus criteria for the disorder are termed *atypical variants*. These variants may have clinical features more severe than typical RTT, present with milder manifestations, or have features not commonly associated with typical RTT (B. A. Hagberg & Skjeldal, 1994). Although the majority of individuals with typical RTT have mutations in *MECP2* (Neul et al., 2008), only 58% of atypical cases have
Figure 45–1. *MECP2* genetic locus, common mutations, and proposed function of MeCP2 protein (A) *MECP2* coding sequence spans four exons and encodes a protein that contains at least three molecular domains, the Methyl-Binding Domain (MBD), the Transcriptional Repression Domain (TRD), and the Carboxy-Terminal Domain (CTD). The gene also contains a large 3′ untranslated region (3′UTR, not drawn to scale), which has highly conserved areas that likely represent a major region of regulation of gene transcription and translation. Several hundred disease-causing mutations have been identified in *MECP2* but there are hot-spots for mutations. The eight most common point mutations and the frequency these mutations are present in typical RTT (Neul et al., 2008) are shown above the gene illustration. In addition to the common point mutations, a number of small insertions and deletions are found that cause frame-shift mutations and thus truncations in the CTD. As a group, these Carboxy-Terminal Truncations are found in approximately 7% of typical RTT cases. Not shown are large DNA deletions that disrupt most or all of the coding sequence of *MECP2* and account for an additional 7% of typical RTT cases. The protein product of this locus, MeCP2, is believed to function primarily as a regulator of gene transcription. The MBD binds methylated cytosines incorporated in DNA (B). The Transcriptional Repression Domain (TRD) interacts and recruits histone deacetylase complexes (B) containing Sin3A and Histone Deacetylase 1 and 2 (HDAC1,2). These HDAC complexes remove acetyl groups (small balls) from histones (large ovals) which causes the chromatin to adopt a tight closed structure that represses local gene transcription (B). Recent work has found that MeCP2 also forms a complex with the transcriptional activator CREB (Chahrour et al., 2008). This interaction is believed to increase local gene expression (C). An additional role (not shown) for MeCP2 as a regulator of RNA splicing has been proposed (Young et al., 2005), possibly by interactions between the CTD and splicing factors (Buschdorf & Stratling, 2004).

mutations in *MECP2* (A. K. Percy et al., 2007). Recent genetic studies have demonstrated that certain atypical forms are commonly associated with *MECP2* mutations, whereas mutations in other loci are associated with other distinct clinical forms of RTT (Table 45-2).

Forme Fruste Variant

Clinical Features and Genetics of Forme Fruste Variant of Rett Syndrome

One bridge between the typical RTT presentation and asymptomatic female carriers is the "forme fruste" variant (B. Hagberg & Rasmussen, 1986; B. A. Hagberg & Skjeldal, 1994). In this variant, the presence of a clear history of regression of hand skills and language is present, but the regression may occur later or be milder than that typically seen in RTT. Furthermore, the degree of retained or regained skills may be increased compared with typical RTT, and the distinct hand stereotypies found in typical RTT may be absent or less severe. In the evaluation of 12 forme fruste individuals, 9 were identified with mutations in *MECP2* (Huppke et al., 2003; Huppke et al., 2006; Smeets et al., 2003). Eight of these are pathogenic mutations commonly associated with typical RTT (p.Arg133Cys, p.Thr158Met, p.Pro225Arg, p.Arg306Cys, c.1164del44). One had a missense mutation of uncertain significance (p.Glu10Gln) not found in typical RTT. Skewing was observed in 5 of these 9 cases.

Preserved Speech Variant

Clinical Features of Preserved Speech Variant

One of the most interesting and possibly the most common variant of RTT is the PSV, also known as the Zapella variant. These individuals experience a post-regression restoration of some spoken language. This variant has been reported in more than 90 cases (Fukuda et al., 2005; Huppke et al., 2000; A. M. Kerr et al., 2006; Nielsen, Ravn, & Schwartz, 2001; Oexle et al., 2005; Renieri et al., 2008; Yamashita et al., 2001; Zappella,

Gillberg, & Ehlers, 1998; Zappella et al., 2003; Zappella et al., 2001). Affected individuals develop hand stereotypies and undergo the typical progression of the disease; however, regression may be very gradual such that it is only noticed in retrospect (Zappella et al., 1998). The amount of spoken language regained varies from multiple single words to multiple word sentences. The speech pattern is abnormal with pronoun reversal (using third person), echolalia, and perseverative repetition of particular phrases.

In contrast to typical RTT, a large percentage of people with PSV have no evidence of head growth deceleration (Renieri et al., 2008), and, in fact, a subset have macrocephaly (Oexle et al., 2005; Renieri et al., 2008). Further, many people with PSV do not show growth failure—rather, some PSV individuals are overweight and a fraction are obese (Renieri et al., 2008). Although uncommon in typical RTT, some individuals with PSV show increased aggression both toward themselves and others.

Many PSV individuals will show autistic traits and some will fulfill criteria for autism (Zappella et al., 2003). In contrast to typical RTT in which these autistic features are mostly restricted to the regression period, some PSV individuals may continue to show some autistic features after the regression. The autistic features that have been noted are decreased facial expression, poor reciprocal interaction, decreased ability to share emotions, absence of symbolic or imaginative play, and repetitive, echolalic speech. Without attention to the history of regression and the recognition of hand stereotypies (which may have disappeared later in life), the diagnosis of a variant of RTT may be overlooked.

Genetics of Preserved Speech Variant

PSV is allelic with typical RTT, with the majority of the reported cases having mutations in *MECP2*. Many of the specific mutations identified in PSV are also found in typical RTT, although there is a bias toward particular mutations in PSV. In the 64 reported cases of PSV with MECP2 mutations (Fukuda et al., 2005; Huppke et al., 2000; A. M. Kerr et al., 2006; Nielsen, Henriksen et al., 2001; Petel-Galil et al., 2006; Renieri et al.,

Table 45–2.
Atypical forms of RTT

Variant Name	Clinical Features	Genetic Associations	
		MECP2 Mutations	Other Loci
Forme Fruste	Delayed regression, retained skills	9 of 12 cases (75%)*	None identified
Preserved Speech	Post-regression restoration of some language	64 of 92 cases (~70%)**	None identified
Early Seizure	Seizures within the first six months, or seizures before regression	Very Rare (<0.1%)#	CDKL5 NTNG1
Congenital	No period of normal development. Hypotonia and delayed from birth	Very Rare (only 4 reported cases)##	FOXG1

*(Huppke et al., 2003; Huppke et al., 2006; Smeets et al., 2003).
**(Renieri et al., 2008).
#(Archer, Evans, Edwards et al., 2006).
##(Huppke et al., 2000; Monros et al., 2001; Smeets et al., 2003).

2008; Scala et al., 2007; Smeets et al., 2003; Yamashita et al., 2001; Zappella et al., 2001), 25 have p.Arg133Cys (39%) and 21 have CTD truncations (33%). In comparison, although these two mutation groups are commonly found in typical RTT, they only represent 5% and 7%, respectively (Neul et al., 2008). It is useful to note that in typical RTT, these mutations display the least severe clinical symptoms. This supports the notion that the PSV is on the mild end of a phenotypic continuum with typical RTT. However, a small number of cases with PSV have p.Arg168X, which results in more severe cases of typical RTT (Neul et al., 2008). Thus, the specific *MECP2* mutation cannot entirely account for the presentation of the mild PSV condition. Although XCI skewing is one possible mechanism by which the phenotypic manifestations of a specific mutation could be altered, the majority (22 of 26) of the reported cases of PSV for which XCI has been analyzed and informative show random XCI (<80% skewing). Therefore, other mechanisms such as genetic modifiers need to be considered to explain the mild PSV phenotype in the face of random XCI.

Early Seizure Variant

Clinical Features of Early Seizure Variant

Although a number of individuals with typical RTT have seizures during their lifetime, it is uncommon to have seizures during the first 6 months of life (Steffenburg et al., 2001). However, a subset of individuals who have features of RTT and are plagued by early onset of severe seizures (Goutieres & Aicardi, 1986; Hanefeld, 1985). These cases have been described as an early seizure variant, also known as the Hanefeld variant. Some of these individuals have myoclonic spasms that appear similar to infantile spasms, although not necessarily with the characteristic hypsarrythmic pattern on EEG (Goutieres & Aicardi, 1987). A major issue in terms of the classification of these individuals with a variant form of RTT is regression. Many people with this early seizure variant do have a period of regression; however, this is often in the midst of severe, intractable epilepsy. Because loss of previously acquired skills can be seen in other conditions with severe intractable epilepsy, it is not clear if the regression found in these individuals shares the same etiology as that seen in typical RTT (Goutieres & Aicardi, 1987).

Genetics of Early Seizure Variant

CDKL5

Few early seizure variant cases have been associated with mutations in *MECP2*—less than 1 out of 345 in a large British cohort (Archer, Evans, Edwards et al., 2006). Recently, mutations in a different X-linked locus, *CDKL5*, have been associated with some of these cases (Bahi-Buisson et al., 2008; Evans et al., 2005; Mari et al., 2005; Nectoux et al., 2006; Rosas-Vargas et al., 2008; Scala et al., 2005; Tao et al., 2004; Weaving et al., 2004). From these reported cases, a general clinical pattern is emerging. These individuals do not have a period of

normal cognitive development, and all have seizures in the first 3 months of life. Many have some of the features found in RTT, such as acquired deceleration of head growth, impaired hand skills, impaired language, and some form of hand stereotypies. However, most of these cases lack some of the most critical features of RTT: a clear history of regression and the typical disease progression. Furthermore, autistic features are present in 85% with reduced social interaction and poor eye fixation (Bahi-Buisson et al., 2008). This is in contrast to the intense eye gaze found in girls with typical RTT. As the number of individuals identified with CDKL5 mutations grows, it is becoming clear that the clinical features found in these individuals are distinct from those people with typical RTT, and the ongoing diagnosis of these individuals with RTT is questionable. As in typical RTT with *MECP2* mutations, the majority of reported individuals are girls, with the few reported boys with *CDKL5* mutations showing a much more severe clinical course with Lennox-Gastaut type epilepsy, spastic quadriplegia, cortical blindness, and profound intellectual disability (Weaving et al., 2004).

An initial report suggested that CDKL5 protein directly interacts with and phosphorylates MeCP2 (Mari et al., 2005). Because MeCP2 is phosphorylated in an activity-dependent fashion (W. G. Chen et al., 2003; Martinowich et al., 2003), this was proposed to be the molecular link that explained the phenotypic similarities of individuals with mutations in *MECP2* and those with mutations in *CDKL5*. However, a subsequent study failed to show the physical association or the phosporylation of MeCP2 by CDKL5 (Lin, Franco, & Rosner, 2005), and in fact recent work indicates that CDKL5 protein is localized to the cytoplasm and interacts with a Rho GTPase signalling pathway to modulate neuronal morphogenesis (Chen et al., 2010).

Congenital Variant

Clinical Features of the Congenital Variant

A subset of individuals with features of RTT has been identified, with evidence of developmental delay and hypotonia from birth (Goutieres & Aicardi, 1987; Rolando, 1985); this subset has been classified as a congenital variant of RTT. The reported cases have hand stereotypies, hyperventilation, gait abnormalities, hand dysfunction, and autistic features. A major challenge in individuals with such a presentation is determining whether they have evidence of regression, a cardinal feature of RTT (Goutieres & Aicardi, 1987). Dr. Hagberg described congenital RTT as "very rare and should be regarded with skeptism" (B. Hagberg, 2002) because of the difficulty in determining whether there is a true developmental regression in these individuals.

Genetics of the Congenital Variant

Similarly to the early seizure variant, most cases with the congenital variant have no mutations in *MECP2* or in *CDKL5*

(Erlandson et al., 2003; Scala et al., 2007). In total, *MECP2* mutations have only been identified in four individuals with the congenital variant of RTT (Huppke et al., 2000; Monros et al., 2001; Smeets et al., 2003). However, recent reports have identified mutations in another locus, *FOXG1*, in people with the congenital variant (Ariani et al., 2008; Papa et al., 2008; Jacob et al., 2009; Mencarelli et al., 2010). These cases are marked by severe early psychomotor delay, microcephaly by 3 months, stereotypic hand movements, no acquisition of spoken language, and corpus callosum hypoplasia (Ariani et al., 2008).

MECP2-Related Disorders

The recognition that mutations in *MECP2* cause RTT led to the discovery of *MECP2* sequence changes in a variety of neurodevelopmental conditions in both females and males. These individuals clearly do not have clinical features of RTT, so it would be inappropriate describe them as "Rett Syndrome." Rather they represent the broad group of *MECP2*-related disorders. The clinical features as well as the molecular details of these various disorders vary and will be presented in detail.

Girls With *MECP2* Mutations and Non-Rett Syndrome Clinical Features

Three non-RTT clinical presentations have been observed in girls and women with mutations in *MECP2*: girls with Angelman Syndrome-like features, girls with autism, and individual cases of girls with other neurological or psychiatric features (Table 45-3).

Girls With Angelman-Like Features

Similarities between Angelman Syndrome and RTT were recognized before the identification of the specific genetic cause of RTT (Scheffer et al., 1990); however, a major distinguishing feature is the absence in Angelman Syndrome of a period of normal development followed by developmental regression (Jedele, 2007). The similarity between these two neurodevelopmental conditions led to the molecular investigation of

MECP2 in individuals with clinical features of Angelman Syndrome but no molecular changes at 15q11-13 (Hitchins et al., 2004; Milani et al., 2005; Turner et al., 2003; Watson et al., 2001). Mutations in *MECP2* were identified in a fraction of these individuals; however, careful review of clinical history after the discovery of *MECP2* mutations revealed that these people had clinical features more consistent with a diagnosis of RTT. However, four cases with RTT disease-causing mutations in *MECP2* did not have evidence of regression and were felt to meet the criteria for Angelman Syndrome (Milani et al., 2005; Turner et al., 2003; Watson et al., 2001). In total, *MECP2* mutations are not a common cause of Angelman Syndrome (Hitchins et al., 2004; Milani et al., 2005; Turner et al., 2003; Watson et al., 2001), but some individuals with *MECP2* mutations can present with features more compatible with a diagnosis of Angelman Syndrome than RTT.

Autism in Girls With Mutations in *MECP2*

From early on, it has been recognized that there are features (such as apparently normal development followed by loss of skills, decreased eye contact and avoidance of social contact) present during regression in RTT that are similar to those observed in idiopathic autism. In the 1980s, Gillberg and colleagues noted that a large percentage (80%) of people ultimately diagnosed with RTT were initially characterized as having autism (Gillberg, 1987, 1989; Witt-Engerstrom & Gillberg, 1987), leading to the prediction that a common neurobiological substrate exists for the two disorders (Gillberg, 1989). A recent report found a smaller but significant percentage (17.6%) of individuals with RTT receiving an initial diagnosis of autism (D. J. Young et al., 2008). This overlap in clinical features led investigators to look for mutations in *MECP2* in cases with autism and no clear features of RTT. Screening a cohort of 69 girls with autism identified two individuals with mutations in *MECP2* (Carney et al., 2003). Both alterations are changes previously found in girls with typical RTT (c.1157del41 and p.Arg294X) and are clearly pathogenic. In contrast, a number of studies have attempted to identify pathogenic sequence changes within the coding sequence for *MECP2* in individuals with autism without success (Beyer et al., 2002; Coutinho et al., 2007; Harvey et al., 2007; Li et al., 2005;

Table 45–3.
MECP2 **mutations in girls with other neurodevelopmental disorders**

Clinical Presentation	*MECP2* Mutations	Frequency of *MECP2* Mutations
Angelman Syndrome-like	Loss of function mutations seen in RTT	Isolated cases
Autism	Loss of function mutations seen in RTT	Rare (0.5%)
Various clinical features		
Electrical Status Epilepticus of Sleep	c.880del8	Isolated case
Learning disability	c.1164del44	Isolated case
Learning disability, obese, aggressive	p.P152A[#]	Isolated case

[#]Mutation shared with father.

Lobo-Menendez et al., 2003; Shibayama et al., 2004; Vourc'h et al., 2001; Xi et al., 2007). In total, 1119 individuals (378 females, 741 males) were screened, and only three potential mutations in *MECP2* coding sequence or introns were identified—all within girls. Only two are clearly pathogenic, giving a frequency of 2 of 378 (0.5%) in girls and 0 of 741 in boys.

Recently, analysis of the UTRs of *MECP2*—specifically the large, well-conserved 3′UTR—identified sequence changes within the 3′UTR of *MECP2* in boys and girls with autism (Coutinho et al., 2007; Shibayama et al., 2004) and a boy with attention deficit and hyperactivity disorder (Shibayama et al., 2004). These sequence changes were not found in normal controls (Coutinho et al., 2007; Shibayama et al., 2004), and *MECP2* mRNA expression was reduced in peripheral monocytes from four individuals with these 3′UTR sequence changes (Coutinho et al., 2007). Interestingly, these 3′UTR sequence changes are in concert with recent experiments (described below) in a mouse model (Samaco et al., 2008) and in cell culture (Klein et al., 2007) that demonstrate that the 3′UTR is critical for controlling MeCP2 levels and that subtle changes in MeCP2 level may result in neurodevelopmental disorders. The 3′UTR alterations observed in autism (Coutinho et al., 2007; Shibayama et al., 2004) may disrupt these critical regions. A detailed dissection of the critical regions within the 3′UTR is needed to conclusively determine this hypothesis. With such knowledge, methods for systematic screening of human cases of neurodevelopmental problems could be undertaken.

Other Clinical Conditions in Girls Associated With MECP2 Mutations

The recognition that pathogenic mutations in *MECP* can present asymptomatically in familial cases as a result of dramatically skewing of the XCI to favor the chromosome of the wild-type allele led to the notion that variation in XCI skewing could alter the clinical presentation of individuals with pathogenic mutations. These individuals might show cognitive and/or neurological impairments but lack distinctive features of RTT. A number of individuals with various neurological features and sequence changes have been identified, and they can be clustered into two groups—those with clearly pathogenic mutations in *MECP2* and those with sequence changes in *MECP2* of uncertain significance.

A subset of individuals with sequence changes in *MECP2* and intellectual disability (ID) but lacking a clear history of regression have been identified. In two cases, clearly pathogenic mutations in *MECP2* were identified (Huppke et al., 2003; Huppke et al., 2006). In the first, a frameshift mutation (c.880del8) was found in a girl with electrical status epilepticus of sleep who previously had no history of regression, slow development of single spoken words, microcephaly, stereotyped hand movements, but normal gait and good hand function (Huppke et al., 2003). A later frameshift mutation (c.1164del44) was found in an older child with learning disabilities and episodes of uncontrolled aggression, the ability to

read, write, and perform simple mathematics (Huppke et al., 2006). She was able to ride a bike and inline skate. She did have bouts of hand stereotypies and hyperventilation when in stressful situations but not otherwise and had no history of regression. She had evidence of skewing of her XCI (84:16). Three other cases have been presented that have mutations in *MECP2* in affected girls with no history of regression; however, they were between ages 2 and 4 years at evaluation, and it is possible that they had not yet undergone regression (Kammoun et al., 2004), which can occur as late as age 6 years (Huppke et al., 2006). A report identified a sequence change in *MECP2* (p.Pro152Ala) in an obese girl with a learning disability, normal hand use, aggressive outbursts, and a diagnosis of PDD-NOS (Adegbola et al., 2008); however, the pathogenic nature of this mutation was unclear because although it alters in vitro biochemical features of MECP2, it was also present in the girl's father who had a milder clinical condition.

Finally, although most familial cases have been reported to have "asymptomatic" female carriers, no systematic formal evaluation has ever been undertaken. In one of the families used to identify the genetic cause of RTT, the mother of an affected individual was found to have motor-coordination issues, mild learning disability, and skewed XCI (Wan et al., 1999). One mother who shared a large deletion of the *MECP2* locus with her daughter with RTT and a son with congenital encephalopathy was reported to have a history of attention problems at school, longstanding severe depression and anxiety, and infrequent hand tremors (Hardwick et al., 2007). Although these could have been present as coincident conditions, the recent finding of consistent neuropsychiatric features in the female carriers of a duplication of *MECP2* (Ramocki et al., 2009) raises the issue that similar subtle changes may exist within the "asymptomatic" female carriers of loss-of-function mutations in *MECP2*. Detailed neuropsychiatric evaluations of these individuals are needed to identify such psychiatric features.

Boys With *MECP2* Mutations

Because RTT was originally recognized only in girls, a genetic explanation was proposed that RTT was the result of an X-linked dominant mutation that resulted in male lethality. An alternative hypothesis is that the sporadic nature of RTT could be explained by a mechanism in which mutations occur on an X-linked gene during spermatogenesis. The identification of mutations in MECP2 has demonstrated that this hypothesis is partially correct, with the majority of MECP2 mutations occurring spontaneously during spermatogenesis (Girard et al., 2001; Trappe et al., 2001). However, a number of boys with mutations in *MECP2* have been identified. They fall into three general categories: boys with clinical features of RTT, boys with congenital encephalopathy, and boys with other neurodevelopmental features (Table 45-4). These three classes of clinical features in boys are the result of specific genetic abnormalities in *MECP2*.

Table 45–4.
MECP2 mutations in boys

Clinical Category	_MECP2_ Mutation Type	Frequency	Unique Aspects
Typical or atypical RTT	Loss-of-function mutations seen in RTT	14 cases reported[*]	Mosaicism of X-chromosome due to X-chromosomal aneuploidy or somatic mosaicism (similar to females), rare cases without mosaicism
Congenital Encephalopathy	Loss-of-function mutations seen in RTT	17 cases reported[**]	Severe, death resulting from cardiorespiratory failure
ID with neurological features	Mutations not found in typical RTT	4 of 1559 from population screening[***] 20 cases with p.Ala140Val[#]	XLMR families, psychotic features, spasticity, tremor
ID with recurrent infections	Duplications of _MECP2_	1%–2% males with XLMR or severe encephapathy[##]	Female carriers display subtle neuropsychiatric features

Boys With Rett Syndrome

A handful of cases have been reported of boys who meet the clinical criteria for typical or variant RTT. In many of these cases, mutations in _MECP2_ that are associated with typical RTT in girls have been identified. The majority of the boys with typical RTT and mutations in _MECP2_ have either complete X-chromosome aneuploidy (Kleinfelter Syndrome 47, XXY) (Hoffbuhr et al., 2001; Schwartzman et al., 2001), mosaic X-chromosome aneuploidy (47XXY/46XY) (Leonard et al., 2001; Vorsanova et al., 2001), or somatic mosaicism for the _MECP2_ mutation (J. Armstrong et al., 2001; Clayton-Smith et al., 2000; Topcu et al., 2002). In all of these cases, the presence of these unusual genetic features allows for mosaic expression of the mutant _MECP2_ allele in these boys, similar to the mosaicism that is found as a result of normal XCI in girls with typical RTT.

Interesting reports exist involving boys who appeared to have normal chromosomes (46 XY), no evidence of somatic mutation, and features of RTT (Budden, Dorsey, & Steiner, 2005; Dayer et al., 2007; Masuyama et al., 2005). These three cases share clinical features. The _MECP2_ mutation found in the boys were all inherited from their mothers. In two of the cases (Budden et al., 2005; Dayer et al., 2007), the mothers were completely asymptomatic and had skewed XCI. In the third case (Masuyama et al., 2005), the mother had mild MR and microcephaly. The causative _MECP2_ mutation was also found in affected sisters with RTT in two of the families (Budden et al., 2005; Masuyama et al., 2005). An interesting similarity in these cases is the presence of mutations of _MECP2_ (p.Arg133Cys, p. Ser134Cys, and c.1158del44) that confer a milder phenotype in typical RTT girls (Neul et al., 2008) and are common in PSV (_see_ above). This suggests that _MECP2_ mutations that confer a milder phenotype in girls can, when present in boys, create a phenotype that is very similar to typical RTT in girls. In contrast, boys who have _MECP2_ mutations that confer increased clinical severity in typical RTT girls (i.e., p.R168X) display severe infantile encephalopathy (described below). One exception to this general trend has been reported: a boy who meets the criteria for typical RTT, has a normal male karyotype with no evidence of mosaicism, and has a c.816dup7 mutation in _MECP2_ (Ravn et al., 2003). Such unusual cases could provide material for future studies to identify genetic modifiers.

Boys With Congenital Encephalopathy

Boys with _MECP2_ mutations and a distinct clinical picture of congenital encephalopathy have been found in families with a sister who has typical RTT (Geerdink et al., 2002; Hardwick et al., 2007; Milunsky et al., 2001; Venancio et al., 2007; Villard et al., 2000; Wan et al., 2001; Zeev et al., 2002), families with multiple affected boys (Hoffbuhr et al., 2001; Lundvall, Samuelsson, & Kyllerman, 2006), and sporadically (Kankirawatana et al., 2006; Leuzzi et al., 2004; Lundvall et al., 2006; Lynch et al., 2003; Schule et al., 2008). In total, 17 cases of male congenital encephalopathy have been identified with _MECP2_ mutations, and a clinical and molecular picture of this disorder is evolving.

First, the type of _MECP2_ mutations associated in nearly all the cases of male congenital encephalopathy are either found in girls with typical RTT or are predicted to disrupt the protein in a manner similar to those mutations found in typical RTT. Second, the clinical features and course is consistent among these affected individuals and is distinct from the clinical features found in RTT. In general, affected individuals present with evidence of severe neonatal hypotonia and poor feeding. Many show respiratory abnormalities shortly after birth that continue throughout life, manifesting as periodic breathing, central hypoventilation, apnea, and respiratory

insufficiency. Most affected individuals die within the first 3 years of life, often because of respiratory arrest, although the oldest reported case was alive and ventilatory-dependent at 6 years of life (Milunsky et al., 2001). Interestingly, in one case it was noted that at the end of life, the affected individual had marked bradycardia (Schule et al., 2008). Acquired deceleration of head growth is common, with many affected individuals ultimately developing microcephaly. Cognitive development is severely impaired, with most gaining few skills. Affected individuals have severe axial hypotonia with limb rigidity. Additionally, many affected individuals are reported to show various movement abnormalities such as myoclonus, tremor, chorea, and dyskinesias.

Although only a relatively small number of cases of boys with congenital encephalopathy and *MECP2* mutations have been identified, consideration for *MECP2* testing should be made when presented with a boy with neonatal or early encephalopathy, respiratory abnormalities, hypotonia with developing limb rigidity, and abnormal movements. An estimation of the de novo maternal mutation frequency in *MECP2* suggests that the incidence of boys with these mutations should be approximately 1:50,000 to 1:100,000, indicating that this may be an under-recognized condition.

Intellectual Disability in Boys With Additional Neurological Features

Mutations in *MECP2* have been discovered in families that display an X-linked mental retardation (XLMR) pattern with multiple affected boys (Couvert et al., 2001; Klauck et al., 2002; Meloni et al., 2000; Orrico et al., 2000; Winnepenninckx et al., 2002; Yntema, Oudakker et al., 2002) and in boys with ID without a clear family pattern (Bourdon et al., 2003; Campos et al., 2008; Couvert et al., 2001; Kleefstra et al., 2002; Laccone et al., 2002; Moog et al., 2003; Moog et al., 2006; Xi et al., 2007). The clinical features present in these individuals are variable, with cognitive skills ranging from moderate to severe ID. Additional features include obesity, tremor, spasticity, and neuropsychiatric problems, including mood instability, psychosis, and mania.

A pattern emerged that the sequence alterations observed in these boys were never seen in girls with typical RTT. Although some of the sequence alterations result in clear changes to the coding sequence of *MECP2,* such as nonsense mutations (p.Gln406X), frameshift mutations (c.1411del2), or large in-frame deletions (c.1161del240), a number caused missense mutations of uncertain significance are also found (Bourdon et al., 2003; Campos et al., 2008; Couvert et al., 2001; Klauck et al., 2002; Laccone et al., 2002; Moog et al., 2003; Moog et al., 2006; Orrico et al., 2000; Winnepenninckx et al., 2002), many of which appear to be benign polymorphisms (Laccone et al., 2002; Yntema, Kleefstra et al., 2002). Multiple population studies have been conducted in boys with ID assessing for pathogenic alterations in *MECP2* with little success (Bourdon et al., 2003; Donzel-Javouhey et al., 2006; Lesca et al., 2007; Ylisaukko-Oja et al., 2005; Yntema, Kleefstra

et al., 2002). In total, of the 1559 individuals tested in these studies, four sequence changes have been identified, with only one clearly altering the coding sequence (c.1161del240 [Yntema, Oudakker et al., 2002]), one missense mutation that has been recurrently identified in boys with ID (p.Ala140Val, *see* below), and two mutations of uncertain significance (p.Arg435Gln and p.Lys284Glu). These findings indicate that care must be taken to determine the functional significance of sequence alterations in *MECP2* associated with intellectual disability in boys, preferably by pedigree analysis to determine that the change is only found in affected individuals.

Although not necessarily definitive genetic proof of causality, *de novo* sequence changes suggest a higher likelihood of pathogenesis. Three *de novo* mutations in *MECP2* have been found in boys with ID: p.Pro225Leu, p.ProP405Leu, and c.1141del2 (Campos et al., 2008; Kleefstra et al., 2002). Both the p.Pro225Leu and the p.Pro405Leu alterations are found in severely affected boys, and p.Pro405Leu has also been identified in a boy who inherited it from his mother who has borderline IQ (Moog et al., 2006), which supports the notion that this is a pathogenic change. The frameshift mutation (c.1141del2) causes a late truncation (p.379fs) similar to the frameshift mutations found in girls with typical RTT, which is consistent with the notion that late truncating mutations represent a hypomorphic allele with the production of a partially functional protein (Neul et al., 2008).

Besides p.Pro405Leu, the only other recurrent *MECP2* mutation identified in boys with ID is p.Ala140Val, identified in a total of 17 affected individuals from three families (Klauck et al., 2002; Orrico et al., 2000; Winnepenninckx et al., 2002) and three sporadic cases (Cohen et al., 2002; Couvert et al., 2001). Aside from ID, many of these individuals also have tremor, spasticity, and neuropychiatric features such as hypomania or frank psychosis (Cohen et al., 2002). In all cases identified to date, the mutation was maternally inherited; however, the clinical phenotype of the carrier females is variable, with reports of mild ID (Orrico et al., 2000), below average intelligence (Klauck et al., 2002), or normal intelligence (Couvert et al., 2001; Winnepenninckx et al., 2002) despite random XCI in all informative cases. This variability has led some to question the pathogenic nature of this mutation (Laccone et al., 2002). In vitro analysis of molecular function indicates that this molecular change alters the ability of the protein to repress transcription, allowing promiscuous transcriptional repression from nonmethylated promoter sequences (Kudo et al., 2002; Kudo et al., 2003). Mice expressing this p.Ala140Val mutation have neuronal abnormalities such as increased cell-packing and decreased dentric branching, supporting the notion that this is a pathogenic change to *MECP2* (Jentarra et al., 2010)

Duplications of *MECP2*

The identification of behavioral and epileptic phenotypes in mice that overexpress MeCP2 (Collins et al., 2004) led to the prediction that genomic duplications of *MECP2* would

result in neurodevelopmental abnormalities in humans. Subsequently, duplication of *MECP2* was identified in a boy with ID and features of RTT, including hand stereotypies and loss of hand skills (Meins et al., 2005). This led to the identification of a duplication in a large XLMR family in which all affected boys had progressive spasticity in addition to ID (Van Esch et al., 2005). The prominent XLMR and spasticity led to the identification of a number of additional XLMR families (Clayton-Smith et al., 2008; Friez et al., 2006; Lugtenberg et al., 2009), which when combined suggested that *MECP2* duplications may have accounted for 1% of XLMR cases (Lugtenberg et al., 2009). Additional cases of boys with *MECP2* duplications were identified through chromosomal micro-array analysis of individuals with ID (del Gaudio et al., 2006; Smyk et al., 2008) or by screening boys with a history of encephalopathy (Lugtenberg et al., 2009). The size of the duplicated region varies and contains a number of coding regions; however, in aggregate, the critical region can be refined to a region containing *MECP2* and the closely linked gene *interleukin receptor-associated kinase I* (*IRAK1*) (Van Esch et al., 2005).

Aside from the common feature of ID, generally in the moderate-to-severe range, other consistent clinical features have emerged. Individuals present with distinct infantile hypotonia, and then many develop progressive spasticity (Lugtenberg et al., 2009). Acquisition of the ability to walk is delayed and most have markedly impaired speech.

One of the most striking features of people with duplications is the history of recurrent infections, primarily respiratory (del Gaudio et al., 2006; Friez et al., 2006; Van Esch et al., 2005; Lugtenberg et al., 2009; Smyk et al., 2008; Ramocki et al., 2009). A significant percentage of affected individuals (40%) die before 25 years of life (Lugtenberg et al., 2009). In one study, four of five individuals who survived more than 15 years required tracheostomies secondary to recurrent pneumonias. Although swallowing problems might contribute to the recurrent respiratory infections, evidence exists for specific immunological deficits that might contribute to the propensity toward recurrent infections. Although detailed analysis of the immune system in many cases has not been performed, low serum IgA levels were detected in 4 of 10 cases evaluated in one study (Friez et al., 2006). Additional research is needed to determine whether low serum IgA is a consistent finding with duplications of this region and whether it is the result of duplication of *MECP2* or duplication of a linked locus.

Autistic Features in MECP2 Duplications

Autistic features were noted in a fraction of the individuals reported in one study (del Gaudio et al., 2006), but formal clinical evaluation for autism was not performed in that or previous studies. When eight boys with genomic duplications containing *MECP2* were formally evaluated using the Autism Diagnostic Observational Schedule, seven met or exceeded the criteria for autism and the remaining individual met the criteria for autistic spectrum disorder (ASD) and all

exceeded the cutoff criteria for autism using the Autism Diagnostic Inventory (Ramocki et al., 2009). With consistent clinical characterization, it is likely that autism or autistic features will be present in the majority of boys with genomic duplications including *MECP2*, but currently no studies have been performed to determine the percentage of individuals with ASD who have increased copy number variations of *MECP2*.

All carrier females of duplications including *MECP2* whose XCI status was evaluated displayed markedly skewed XCI, with many showing complete (100%) skewing. Most of these individuals have been characterized as "asymptomatic" or "normal"; however, limited or no clinical evaluation was presented on these individuals. When formal neuropsychological analysis was performed on a cohort of female carriers, an interesting constellation of neuropsychiatric features emerged (Ramocki et al., 2009). There was variation in the IQ, as assessed using the Wechsler Abbreviated Scale of Intelligence with two women in the low average range, two women in the average range, one woman with high average intelligence, and two women with superior range intelligence. On the other hand, all of the women reported symptoms consistent with anxiety, compulsive behaviors, and inflexible personality when assessed with the Symptom Checklist-90-R. Notably, many had been diagnosed with anxiety and depressive symptoms before the birth of the affected son. None of the carrier mothers had autism, but four of seven evaluated with the Broad Autism Phenotype Questionnaire (BAPQ) exceeded the cutoff for the broad autism phenotype. These results suggest that an extra copy of *MECP2* in females may cause various psychiatric features including features identified using the BAPQ. Although this finding was identified in families with more severely affected boys, it is possible that *de novo* duplications in this genomic region might be present in females with sporadic presentation of anxiety, depression, or features identified by the BAPQ. This finding warrants further investigation to determine whether duplications or other alterations in *MECP2* expression or function contribute to these clinical features.

Biological Insights from Basic Studies of Rett Syndrome and *MECP2*-Related Disorders

Molecular Function of MECP2

MeCP2 belongs to the methyl-CpG-binding domain family of proteins (Hendrich & Bird, 1998). These proteins have a conserved methyl-CpG-binding domain (Figure 45-1) that binds methylated CpG dinucleotides (Lewis et al., 1992; Nan, Meehan, & Bird, 1993). In addition, MeCP2 contains two other molecular domains: a transcriptional repression domain (Nan, Campoy, & Bird, 1997), which recruits corepressors such as histone deacetylases (Jones et al., 1998; Nan, Cross, & Bird, 1998), and a carboxy-terminal domain (Chandler et al.,

1999), which may interact with splicing factors (Buschdorf & Stratling, 2004) to regulate RNA splicing (J. I. Young et al., 2005).

Because MeCP2 binds methylated CpG dinucleotides and can recruit corepressors, the function has been considered to be a repressor of gene transcription (Figure 45-1). However, recent experiments have indicated that MeCP2 can also act as a transcriptional activator (Chahrour et al., 2008; Yasui et al., 2007) and is associated with a well-known transcriptional activator, CREB1. Within the hypothalamus, MeCP2 activates a number of neuropeptides such as *Corticotropin-releasing hormone* and *oxytocin* (Chahrour et al., 2008). Given the role of various neuropeptides in the regulation of stress responses and social behavior (Meyer-Lindenberg, 2008; Winslow, 2005; Winslow & Insel, 2002), the alteration in expression of these molecules may help explain particular phenotypes as well as offer possible therapeutic targets.

An interesting target of MECP2, *brain-derived neurotrophic factor* (*Bdnf*), was identified using a candidate gene approach (W. G. Chen et al., 2003; Martinowich et al., 2003), which indicated that *Bdnf* expression was repressed by MECP2. However, in vivo analysis revealed the BDNF protein levels are decreased in animals lacking Mecp2 (Chahrour et al., 2008; Chang et al., 2006; Wang et al., 2006) and increased in an animal model that overexpressed MeCP2 (Chahrour et al., 2008). Chang and colleagues demonstrated that increasing *Bdnf* expression in *Mecp2^{null/Y}* partially rescued the phenotype (Chang et al., 2006). Thus, modulation of *Bdnf* activity may be a useful therapeutic modality in the treatment of RTT.

> **Transcriptional regulator**: Gene expression (transcription) is controlled by a variety of protein and non-protein factors and mechanisms. Factors that increase gene expression are called transcriptional activators and those that decrease gene expression are transcriptional repressors. Evidence exists that MeCP2 functions as a regulator of gene transcription, both as an activator by recruiting repressors and as an activator by recruiting activators.

Animal Models of MeCP2 Dysfunction

Mouse Models of Rett Syndrome

Mouse models of RTT have been generated that reproduce features of the human disorder (R. Z. Chen et al., 2001; Guy et al., 2001; Lawson-Yuen et al., 2007; Pelka et al., 2006; M. Shahbazian et al., 2002). Male animals that lack MeCP2 develop severe neurological abnormalities and die between 8 and 12 weeks of life (R. Z. Chen et al., 2001; Guy et al., 2001; Pelka et al., 2006). Heterozygous female mice lacking one copy of *Mecp2* develop similar phenotypes as the hemizygous male mice, albeit at a much later time period and with increased variability (R. Z. Chen et al., 2001; Guy et al., 2001). This variability in phenotypic expression in heterozygous female animals likely results from nonrandom XCI in individual animals (J. I. Young & Zoghbi, 2004). There is evidence of decreased

synapse formation in neurons from animals that lack MeCP2 function (Chao, Zoghbi, & Rosenmund, 2007).

Two additional mouse models of RTT have been created with the intention of mimicking human disease-causing mutations. Recently, a mouse was generated that contains the most common human allele, p.Arg168X. This allele behaves like the null allele and the animals display very similar phenotypes, including early death (Lawson-Yuen et al., 2007). On the other hand, a mouse that expresses more of the protein, truncated at amino acid 308 (M. Shahbazian et al., 2002), shows a slower progression of phenotypes including increased anxiety, memory problems, social behavior abnormalities, and hypoactivity (McGill et al., 2006; Moretti et al., 2005; Moretti et al., 2006; M. Shahbazian et al., 2002). Strikingly, these mice develop forepaw stereotypies that appear very similar to affected girls (M. Shahbazian et al., 2002).

A conditional allele of *MECP2* was generated by placing DNA sequences (loxP) around the majority of the *Mecp2* coding sequence. When this flanked-loxP ("floxed") allele is crossed to a transgenic animal that expresses the site-specific recombinase Cre, recombination occurs between the loxP sites removing the *Mecp2* coding sequence generating a null allele of *Mecp2* (R. Z. Chen et al., 2001; Guy et al., 2001). Using this conditional knockout (CKO) strategy has revealed that animals lacking MeCP2 function in the postmitotic neurons reproduce some of the features seen in the complete null animals, such as weight abnormalities and impaired social behavior, demonstrating the critical role of MeCP2 function in postmitotic neurons (R. Z. Chen et al., 2001; Gemelli et al., 2006).

Because *Crh* is misregulated within the PVN in a mouse model of RTT (McGill et al., 2006), the role of MeCP2 within the PVN was assessed using the CKO strategy outlined above (Fyffe et al., 2008). Animals lacking MeCP2 function in the PVN, supraoptic hypothalamic nuclei, posterior hypothalamic nuclei, and the nucleus of the lateral olfactory tract of the amygdala are markedly obese because of hyperphagia and have novelty-induced aggression. Interestingly, although most people with RTT are not aggressive and are underweight, the combination of increased aggressiveness and weight is observed in a number of people with the PSV (Renieri et al., 2008).

Concentrations of spinal fluid biogenic amine metabolites are reduced in RTT, therefore Samaco and colleages (Samaco et al., 2009) selectively removed MeCP2 function from either the serotoninergic neurons or neurons expressing tyrosine hydroxylase, which produce dopamine and norepinephrine. Animals lacking MeCP2 within the serotoninergic neurons showed a reduction in serotonin and were aggressive, whereas animals lacking MeCP2 in the tyrosine hydroxylase neurons had a reduction in dopamine and norepinephrine and had movement abnormalities.

MECP2 Misexpression Mouse Models

Twofold overexpression of MeCP2 in wild-type mice resulted in a progressive neurological phenotype (Collins et al., 2004;

Luikenhuis et al., 2004). Overexpression of MeCP2 results in decreased survival, aggressiveness, motor dysfunction, and seizures (Collins et al., 2004). These results indicated that tight control of MeCP2 levels is critical within neurons and only a twofold increase in expression is detrimental. The discovery that twofold excess of *MECP2* causes a progressive neurological abnormality in mice preceded the identification of humans with a duplication of this locus, demonstrating the value of mouse models not only in the understanding of pathogenesis of human disease but also in the prediction of genetic causes of disease. Interestingly, neurons from these transgenic mice overexpressing Mecp2 seem to form excessive synapses when grown in culture, the opposite phenotype to that observed in animals lacking Mecp2 function (Chao et al., 2007).

Further reinforcing the notion that tight regulation of MeCP2 levels are critical for normal neuronal function, reduction of MeCP2 by approximately 50% of mice caused a variety of neurological phenotypes including learning problems, motor dysfunction, altered pain recognition, and breathing irregularities (B. Kerr et al., 2008; Samaco et al., 2008). The reduction in *Mecp2* mRNA expression in these mice is likely secondary to genetic engineering that introduced a *neomycin* cassette into the 3′UTR of the endogenous *Mecp2* locus (Guy et al., 2001), disrupting the primary 3′UTR *Mecp2* isoform that predominates within the brain (Coy et al., 1999; B. Kerr et al., 2008). Within the region disrupted in the binding site for miR132, a microRNA has been shown to repress *Mecp2* translation (Klein et al., 2007). Although this is the opposite of what was observed when this region was disrupted, it emphasizes the importance of the 3′UTR in the regulation of MeCP2 levels. Just as the phenotypes observed from overexpression of MeCP2 in mice predicted a human disorder, it is likely that a human neurodevelopmental disorder will result from reduction of MeCP2 levels by half, similarly to that observed in mice. Suggestively, Coutinho and colleagues identified sequence changes in the 3′UTR of *MECP2* from people with autism and found decreased expression of *MECP2* mRNA in leukocytes from some of those samples (Coutinho et al., 2007).

Genetic Rescue in Animal Models

The fact that gross brain formation is normal in RTT and there is no evidence of neurodegeneration led to the hypothesis that restoring MeCP2 function after the development of disease would ameliorate symptoms. The possibility of disease reversal would be extremely important in the treatment of this disorder. Two research endeavors have demonstrated that in mouse models, postnatal restoration of MeCP2 function partially or completely rescues the disease process (Giacometti et al., 2007; Guy et al., 2007). Strikingly, restoring MeCP2 function, even after clear onset of disease phenotypes, is sufficient to reverse the disease process (Guy et al., 2007). Although these experiments do not provide a direct method of therapy for humans with RTT, they do provide hope that reversibility in this disorder is possible.

Cellular Requirement for MeCP2 Function

MeCP2 protein is highly expressed in the brain, specifically in neurons. In fact, previous work has suggested that it is only expressed within neurons and not expressed in glial (Shahbazian et al., 2002), which has led to the hypothesis that the primary function of MeCP2 resides within neurons. This hypothesis is supported by experiments showing that removing *Mecp2* from postmitotic neurons in mice reproduces neuronal phenotypes, albeit later in life and to a lesser degree (R. Z. Chen et al., 2001). Furthermore, inducing expression of *Mecp2* in postmitotic neurons in mice that otherwise lack *Mecp2* partially rescues the phenotype present in these animals (Luikenhuis et al., 2004). In fact, there is no survival difference when *Mecp2* expression is restored in both neurons and glia compared with expression in neurons alone (Giacometti et al., 2007). However, recent work has shown that MeCP2 has important function in astrocytes as well as neurons and that MeCP2 may have a cell nonautonomous role in these non-neuronal cells. *Mecp2* expression is observed within glial lineages at a much lower level than in neurons (Ballas et al., 2009; Maezawa et al., 2009). Astrocytes that lack MeCP2 grow more slowly in vitro, express higher levels of *Bdnf*, and do not support the growth of wild-type neurons in vitro as well as wild-type astrocytes (Maezawa et al., 2009). Surprisingly, in vitro growth of wild-type neurons in conditioned media from astrocytes lacking MeCP2 is inhibited; similarly, neurons lacking MeCP2 appear to have improved growth and development when grown in conditioned media from wild-type astrocytes (Ballas et al., 2009). Thus, these results indicate that MeCP2 may have an important function within astrocytes as well as in neurons. Further work will be required to determine the in vivo significance of these results and to determine the relative contribution of these two lineages in the nervous system.

Treatment

No cure for RTT or *MECP2*-related disorders exist and treatment is directed toward symptomatic amelioration using a combination of pharmacotherapy, nutritional supplementation, physical and speech therapy, and surgical intervention. Successful interventions include anti-epileptic drugs or vagal nerve stimulator (Wilfong & Schultz, 2006) for seizures and aggressive nutritional support for growth failure (Motil et al., 2009). Future symptom-directed therapies are targeting breathing dysfunction (Roux et al., 2007), anxiety, and dystonias.

Genetic and molecular knowledge are allowing the conceptual development of therapies targeted to specific molecular defects identified in these disorders. For example, determination of altered BDNF protein levels has led to interest in chemical compounds that can increase the level of BDNF, which in animal models can improve respiration (Ogier et al., 2007). Recent work has suggested that treatment with a tripeptide from insulin-like growth factor 1 can improve
Figure 45–2. Clinical, cellular, and molecular abnormalities caused by changes in MeCP2 activity. Along the top of the figure is a representation of increasing MeCP2 activity ranging from no activity (None) on the left of the figure, through "Normal" activity in the middle of the figure, to "Excess" activity (putatively, although it is possible that increasing the amount of MeCP2 protein might generate new functional activity not typically seen by MeCP2 or even interfere with normal MeCP2 function) on the right side. Below are the clinical features that are found in both girls and boys. In girls, decreased or loss of MeCP2 activity leads to Rett Syndrome (RTT). Some people with milder loss of function mutations or other factors such as skewing of XCI display milder clinical features such as autism and intellectual disability (ID). On the other side of the activity gradient are women with duplication of the *MECP2* locus, putatively leading to excessive MeCP2 activity. These individuals are mothers of boys with similar duplications. On careful neuropsychological testing, these carrier mothers show evidence of depression, anxiety, and meet criteria for the Broad Autism Phenotype. Alterations in MeCP2 activity also cause a variety of clinical features in boys ranging from severe early encephalopathy with decreased MeCP2 function to autistic features, recurrent infections, and ID in boys with an excess of MeCP2 activity due to a duplication in the *MECP2* locus. Below the clinical phenotypes is a cartoon representation of neurons showing the alterations in the dendritic arbors that occur as a result of changes in MeCP2 activity. The drawings below are diagrams showing the changes in synaptic density (represented by dots) along dendrites within the small dotted boxes on the neuron drawing. Decreased MeCP2 activity leads to decreased dendritic arborization, decreased synaptic density, and decreased expression of activity dependent genes such as *Bdnf*. On the other extreme, overexpression of MeCP2 leads to increased *Bdnf* expression and increased synaptic density, and likely will lead to increased dendritic arborization, although this has not yet been characterized. The neuron arborization drawings for decreased and normal MeCP2 activity were modeled after (Schule et al., 2008) and the drawings illustrating the increased synaptic density were modeled after (Chao et al., 2007).

lifespan in male null animals (Tropea et al., 2009). As additional molecular changes are identified, further preclinical and possibly clinical trials will be developed.

Recently, clinical trials on two genetic disorders, cystic fibrosis (CF) and Duchenne Muscular Dystrophy (DMD), have started using a novel chemical compound, PTC124, that allows "read-through" of premature stop codons resulting from point mutations (Welch et al., 2007). Preclinical trials on animal models of both DMD and CF demonstrated efficacy in improving function (Du et al., 2008; Welch et al., 2007). Because a significant percentage of individuals with RTT have mutations that cause such premature stop codons, many families and clinicians have become interested in the prospect of using this or a related compound in RTT. Given the additional complication of crossing the blood–brain barrier and the

importance of tight regulation of MeCP2 protein levels within neurons, detailed preclinical testing on animal models will be needed prior to any clinical study.

Conclusion

Despite the identification of the genetic cause of RTT, the diagnosis of RTT remains a clinical diagnosis because a mutation in *MECP2* is neither necessary nor sufficient to make the diagnosis. Although loss-of-function mutations in *MECP2* can cause the well-defined clinical condition RTT, growing evidence exists that a wide spectrum of clinical disorders can occur in both boys and girls from a loss or decrease of MeCP2

function as well as a putative increase of MeCP2 function as a result of duplication of *MECP2* locus (Figure 45-2). As a group, these *MECP2*-related disorders may be a common cause of neurodevelopmental, neurological, and psychiatric disorders; furthermore, *MECP2* may be involved in common molecular systems disrupted by a variety of neurodevelopmental disorders.

One possible explanation for the manifestation of various neurodevelopmental problems as a result of alterations in MeCP2 function may be the fact that these alterations appear to affect synaptic development. Decreased MeCP2 activity leads to decreased dendritic arborization (Figure 45-2) in girls with RTT (D. D. Armstrong, 2005a) and boys with congenital encephalopathy (Schule et al., 2008) and decreased synapse formation in neurons from mice lacking *Mecp2* grown in culture (Chao et al., 2007). In a complementary fashion, increasing *Mecp2* dosage in transgenic mice leads to increased synapse formation when neurons are grown in culture (Chao et al., 2007). Although detailed neuropathological studies have not yet been done in people with duplication of *MECP2* or in transgenic animals that overexpress MeCP2, it is likely that an increase in dendritic arborization will be present in these situations.

Gene expression changes that result from alterations in MeCP2 function also show a monotonic relationship to such alterations, with decreased MeCP2 activity leading to decreased expression of genes such as *Bdnf* and *Crh* and increased MeCP2 activity leading to increased expression of the same genes. Similarly, a different set of genes show increased expression when MeCP2 function is lost and decreased expression when MeCP2 protein levels are increased (not shown). Although not all gene expression changes identified are in genes that show distinct activity dependent expression, the identification of such gene expression changes leads to the hypothesis that MeCP2 function may be critical for the interpretation and integration of stimuli that causes activity-dependent gene expression. The generation of an appropriate immediate and long-term response may be one of the key roles of MeCP2, and when this system is altered either by decreased or increased function, aberrant adaptation may occur. In the nervous system, aberrant adaptation is potentially manifested by alterations in synaptic and dendritic formation. Because one of the common pathological features identified in many neurodevelopmental disorders is alterations in dendritic arborization and synapse formation (Belichenko et al., 1994; Huttenlocher, 1974, 1991, 2000; Irwin, Galvez, & Greenough, 2000; Jay et al., 1991; Raymond, Bauman, & Kemper, 1996), understanding these *MECP2*-related disorders may provide insight into many disorders of cognition and neuronal function.

Challenges and Future Directions

- What are the additional factors that modify the clinical features resulting from *MECP2* mutations other than mutation type and XCI?

- What is the incidence of *MECP2* mutations in non-RTT neurodevelopmental disorders?
- What methods can be used or developed to test the functional consequence of sequence changes in *MECP2* of uncertain significance?
- What is the common underlying relationship between RTT and other neurodevelopmental disorders?
- How can biological knowledge of MeCP2 function and animal models be used to design and test treatments for RTT and other *MECP2*-related disorders?
- What is the relative contribution to the disease phenotype from MeCP2 dysfunction within specific cells (neurons versus glia) and within different regions of the nervous system?

Fragile X: A Molecular and Treatment Model for Autism Spectrum Disorders

Points of Interest

- FMRP is a regulator of translation for many messages important for synaptic plasticity, including the messages of genes implicated in autism.
- Lack of FMRP in individuals with FXS is associated with enhanced downstream activity of the metabotropic glutamate receptor 5 (mGluR5) system, which causes enhanced long-term depression (LTD) and weak synaptic connections.
- Use of mGluR5 antagonists rescues the synaptic deficits, the behavior problems, and the cognitive deficits of the fragile X knock-out mouse.
- Preliminary studies in humans suggest that an mGluR5 antagonist, fenobam, is helpful for behavior and prepulse inhibition with no significant side effects.
- Minocycline lowers the elevated MMP9 levels in the fragile X mouse, rescues synaptic abnormalities, and improves behavior and cognition with 1 month of treatment after birth. Studies of minocycline treatment have begun in children with FXS.

Overview

Both the premutation (55-200 CGG repeats) and the full mutation (>200 repeats) of the fragile X (*fragile X mental retardation 1*; *FMR1*) gene are associated with autism or autism spectrum disorders (ASDs), although these associations occur through different molecular mechanisms (Farzin et al., 2006; R. J. Hagerman, 2006; Hatton et al., 2006; Kaufmann et al., 2004; Rogers, Wehner, & Hagerman, 2001). The full mutation typically causes methylation of the promoter region of the *FMR1* gene, disrupting transcription, translation, and *FMR1* protein (FMRP) production. It is the

lack or deficiency of FMRP that leads to fragile X syndrome (FXS). The premutation causes an elevation of the *FMR1* mRNA, leading to a gain-of-function effect and toxicity to the cells and causing both neurodevelopmental and neurodegenerative effects (Figure 46-1).

Full-mutation females and males with mosaicism (either CGG-size mosaicism or methylation mosaicism) produce a varied range of FMRP levels (Tassone et al., 1999). The range of overall intellectual abilities correlates with FMRP levels (Loesch, Huggins, & Hagerman, 2004). Individuals with a mild FMRP deficiency present with a normal or borderline IQ and also experience learning disabilities, social deficits, and emotional problems, such as anxiety; this latter group represents about 15% of males and 70% of females with FXS (de Vries et al., 1996; R. J. Hagerman, 1992). Those individuals who produce little or no FMRP fall on the other end of the FXS spectrum and experience moderate-to-severe intellectual disability. Those patients with FXS and a lower IQ are more likely to have autism (Bailey et al., 2001; Kaufmann et al., 2004; Rogers et al., 2001). A new FMRP ELISA measure has been developed that quantitates the level of FMRP and demonstrates significant variability, even in the normal populations (Iwahashi et al., 2009). The FMRP ELISA will be studied in normals, in those with autism without the *FMR1* mutation, and in those with *FMR1* mutations to see if levels correlate with social deficits.

Approximately 30% of those with FXS have autism, and another 20% to 30% have pervasive developmental disorder-not otherwise specified (PDD-NOS; Harris et al., 2008); the remaining individuals do not meet criteria for ASDs but exhibit autistic-like features, including hand-flapping, hand-biting, and poor eye contact (Hatton et al., 2006; Kaufmann et al., 2004; Rogers et al., 2001). Although the level of FMRP may initially correlate with the presence of autism (Hatton et al., 2006), this relationship disappears when controlled for IQ (Loesch et al., 2007).

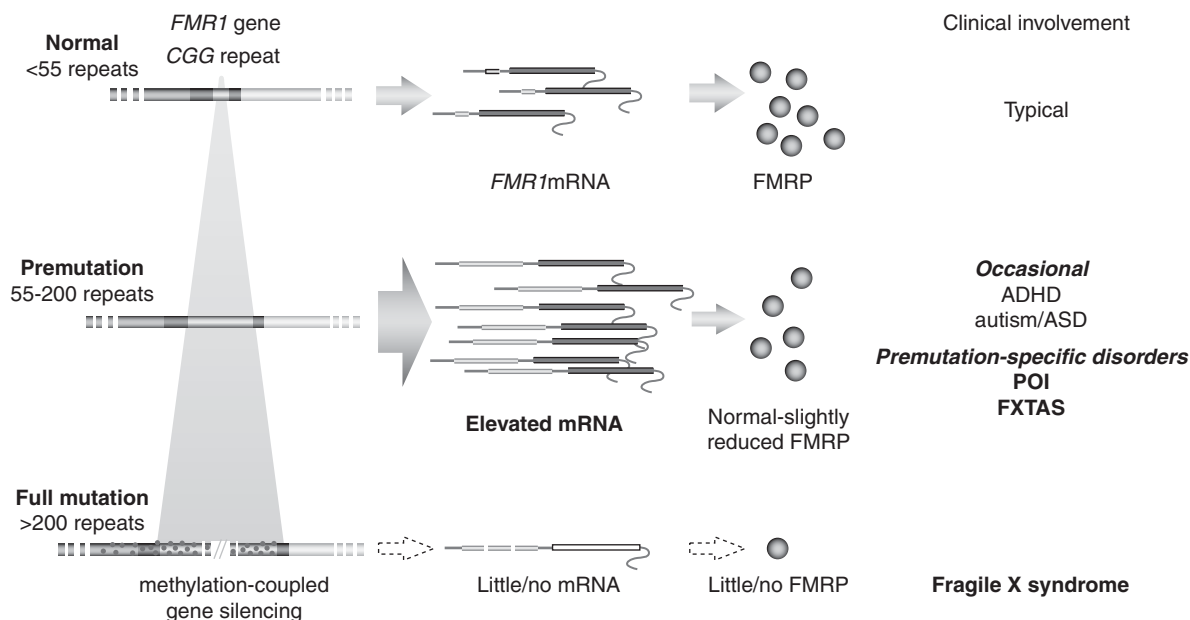
Although the level of FMRP is usually normal among individuals with the premutation (also called "carriers"


Figure 46–1. Dependence of *FMR1* expression on the length of the CGG repeat. Premutation alleles result in elevated mRNA levels (increased RNA synthesis); the increased CGG repeat in the mRNA partially blocks translation, resulting in slightly lowered protein levels in the premutation range. Full-mutation alleles are generally hypermethylated and silenced, thus producing little or no mRNA or protein. Elevated mRNA is now believed to give rise to the premutation-specific disorders, FXTAS and POI, and may also occasionally contribute to children with developmental delays, ADHD, or autism. Fragile X Syndrome is caused by the absence of the protein FMRP. (See Color Plate Section for a color version of this figure.)

because these individuals were once thought to be clinically unaffected), the level of *FMR1* mRNA is elevated from two to eight times normal levels (Tassone et al., 2000). The elevated, expanded-CGG-repeat mRNA leads to a "toxic" gain of function that results in neuronal and astrocytic dysfunction, leading in turn to early cell death and dysregulation of specific proteins (P. J. Hagerman & Hagerman, 2004b). Clinical involvement in carriers can take several forms, which are all distinct from FXS. In approximately 40% of older male carriers and 8% of older female carriers, ascertained through known fragile X families, a neurodegenerative disorder known as fragile X-associated tremor/ataxia syndrome (FXTAS) develops (Coffey et al., 2008; Jacquemont et al., 2004). FXTAS is characterized by tremor, ataxia, cognitive decline, autonomic dysfunction, neuropathy, brain atrophy, and white matter disease (Berry-Kravis et al., 2007; Leehey et al., 2007; Sullivan et al., 2005). Also, in 20% of adult females with the premutation, primary ovarian insufficiency (POI) develops.

In some children with the premutation, developmental problems occur, including autism or ASDs, and attention deficit hyperactivity disorder (ADHD; Aziz et al., 2003; Clifford et al., 2007; Farzin et al., 2006; S. W. Harris et al., 2005). These neurodevelopmental problems also appear to be related to RNA toxicity during early development, although there may be additional contributing factors of environmental and genetic origin. Nevertheless, these problems are common in carriers who present clinically; they are, however, less common in those with the premutation who are identified by cascade testing in a family tree (Farzin et al., 2006).

For those with FXS, recent advances in understanding the neurobiology of the disorder have led to the development of new targeted treatments. These treatments can reverse the brain abnormalities in the animal models of FXS, leading to rescue of the dendritic spine defects, behavioral problems, and cognitive deficits (Dolen & Bear, 2008; Nakamoto et al., 2007).

The key to understanding the relationship between FXS and autism is the fact that FMRP is an RNA transport protein that also regulates the translation of many mRNAs. Most of the proteins that FMRP regulates are involved with synaptic plasticity. FMRP normally inhibits the translation of these proteins until a glutamate signal is received at the postsynaptic terminus, resulting in stimulation of metabotropic glutamate receptors. FMRP is then briefly dephosphorylated (several minutes)—releasing the translational inhibition—followed by subsequent rephosphorylation of FMRP and reinhibition of protein synthesis (Antion et al., 2008; Narayanan et al., 2007). In the absence of FMRP, there is significant dysregulation of a number of pathways that have been associated with autism, including upregulation of the mGluR5 pathway (Bear et al., 2004; Huber et al., 2002), upregulation of the mTOR pathway, downregulation of the PTEN pathway (Klann, personal communication, 2008), downregulation of the $GABA_A$ receptors (D'Hulst et al., 2006; D'Hulst et al., 2007), and downregulation of the dopamine pathway (Wang et al., 2008). The following chapter details the clinical, molecular, and treatment aspects of the association between fragile X mutations and ASDs.

Phenotypic Features of Fragile X Syndrome

FXS occurs as a result of a deficiency or absence of FMRP. In the full mutation, this occurs when the *FMR1* gene is fully methylated, inhibiting transcription of the gene. In approximately 20% of cases of the full mutation, the gene is incompletely methylated and a small percentage of cells are able to transcribe mRNA (Tassone et al., 2000). This incomplete methylation, also known as methylation mosaicism, enables individuals to typically produce greater than 10% but less than 50% of normal FMRP levels, as measured in blood (Tassone et al., 1999a).

Another molecular variation is size mosaicism, where some cells have the premutation and other cells have full-mutation alleles. In these cases, cells with the premutation will produce FMRP. The higher the percentage of premutation cells to full-mutation cells, the higher the level of FMRP produced. Therefore, individuals with size mosaicism typically have a higher IQ and fewer physical characteristics typical of FXS (Loesch et al., 2004).

Most individuals with FXS have prominent ears, a high-arched palate, a long face, hyperextensible finger joints and flat feet (R. J. Hagerman, 2002b), but typically the physical appearance is normal (*see* Figure 46-2). These features relate to a connective tissue problem in FXS that is most obvious in young children. Although the lack of FMRP appears to disrupt the elastin fibers of connective tissue (R. J. Hagerman, 2002a), most individuals do not look dysmorphic. Other common physical features include soft, velvet-like skin and a long face, which is common in adulthood. Greater than 90% of adult males with FXS also present with macroorchidism (large

testicles). In early puberty, testicle size increases dramatically. By age 15 years, testicular volume stabilizes at two to four times normal size (Butler et al., 1991). There is a greater amount of connective tissue in the large testicles, but fertility is normal.

As FXS is an X-linked disorder and sperm only house the premutation and not the full mutation, daughters of men with FXS will receive only the premutation allele from their fathers. Sons of men with FXS will be unaffected because they receive the unaffected Y-chromosome. Each child of a woman with the full mutation will have a 50% chance of inheriting the full mutation because the mother has two X-chromosomes—one with the full mutation and one normal. More commonly, mothers of children with FXS have the premutation; the premutation will expand to a full mutation when passed on by the mother at a rate that depends on the size of the premutation. For example, 70 repeats will expand to a full mutation about 40% of the time, but 90 repeats or higher will almost always expand to a full mutation when this allele is passed on through a female to the next generation (Gane & Cronister, 2002; McConkie-Rosell et al., 2007).

Often children with FXS will not be diagnosed until they are 3 years or older, when delays (especially in language) are brought to medical attention and the child is referred for a developmental evaluation (Bailey, Skinner, & Sparkman, 2003). Children with FXS also have an enhanced response to sensory stimuli, as documented by electrophysiological studies (Miller et al., 1999; Roberts et al., 2001). Their sympathetic response is upregulated, leading to enhanced anxiety, and their vagal response is deficient particularly with transitions. These altered responses occur more in those with autism and FXS compared to those without autism and FXS

(a)   (b)

Figure 46–2. A girl (**a**) and a boy (**b**) with the full mutation and Fragile X Syndrome. Notice that the girl has no obvious physical features suggesting Fragile X Syndrome.

(Roberts et al., 2001; Roberts et al., 2006). Boys with FXS have been found to have an enhanced cortisol release after stress (Hessl et al., 2002), which may also be related to the enhanced sympathetic activity and anxiety. Hall et al. (2006) found that the enhanced cortisol release was correlated with increased eye aversion in FXS. However, in a more recent report, the increase in autistic behaviors in FXS was associated with lowered cortisol levels (Hall et al., 2008).

Although the majority of patients with FXS hand-flap, hand-bite, and have poor eye contact, the diagnosis of autism is not related to these behavioral features. The studies in the Kaufmann lab have eloquently demonstrated that autism in FXS is related to an impairment in complex social interactions and language deficits rather than an impairment in nonverbal behaviors (Budimirovic, 2006; Kau et al., 2004; Kaufmann et al., 2004). Social withdrawal is a key element in the development of autism in FXS, which is somewhat different from idiopathic autism that demonstrates more social aloofness and social indifference rather than social avoidance (Budimirovic, 2006). The social avoidance may be related to the sensory and autonomic issues described above, and it is (relating to social avoidance, rather than autonomic issues) typically manifested as anxiety. These features constitute an important subtype of autism related to FXS, and the anxiety features are likely to improve with targeted treatments described below. In addition to language deficits involving verbal reasoning, recognition of emotions and labeling of emotions are associated with ASDs in FXS (Budimirovic et al., 2006). Other studies have also documented language deficits in those with FXS and ASDs (Lewis et al., 2006; Philofsky et al., 2004). Overall, both IQ and adaptive behavior are lower in those with FXS and autism compared to those with FXS alone (Hatton et al., 2006; Kau et al., 2004; Kaufmann et al., 2004; Rogers et al., 2001).

It is difficult to assess autism in FXS because the phenotype may change at different times of the day or with different evaluators, even when standardized instruments are used. In our studies that utilize the ADOS-G, the ADI-R, and DSMIV-R criteria, we convene a conference of all of the evaluators/clinicians to review the data and reach consensus on the diagnosis (S. W. Harris et al., 2008). To address these problems, Roberts and colleagues (Roberts et al., 2007) developed a novel social approach scale (SAS) to measure the modulation of social interactions over time in patients with FXS. They coded aspects of social interaction, including eye contact, physical movement, and facial expressions over a few hours in two encounters. Although almost all patients with FXS had difficulty with all three aspects of social interaction initially, the individuals with autism and FXS did not become more sociable over time. They maintained a flat profile, demonstrating continued problems in all aspects of social interactions. Improved eye contact over time was the best predictor for lowered autistic behavior in FXS (Roberts et al., 2007).

The autism phenotype is heterogeneous in FXS because of a number of medical and genetic factors. The presence of additional medical problems affecting the CNS can increase the risk of autism in the FXS population. For example, seizures occur in about 12% of children with FXS without ASDs but increase to 28% in those with FXS and ASDs (Garcia-Nonell et al., 2008). Presence of a second genetic condition in addition to FXS, such as Down syndrome, also increases the likelihood of autism (Roberts, Chapman, & Warren, 2008).

The most remarkable secondary genetic condition involved in predisposing a child with FXS to autism is the Prader-Willi Phenotype (PWP) of FXS. Approximately 70% of those with the PWP of FXS have ASDs (Nowicki et al., 2007). In the PWP of FXS, individuals exhibit symptoms of hyperphagia, lack of satiation after meals, obesity, and hypogenitalia. Recently, expression levels of cytoplasmic *FMR1* interacting protein (CYFIP), coded within the 15q deletion region of the PWP, were lower in PWP of FXS compared to FXS without PWP and typically developing individuals (Nowicki et al., 2007). Because CYFIP interacts with the Rac GTPase, it has an additional impact on synaptic plasticity that may explain why lowered CYFIP expression predisposes an individual with FXS to autism. However, CYFIP expression has also been found to be upregulated in individuals with autism and the 15q11-13 duplications but not FXS (Nishimura et al., 2007). Studies exploring changes in the serotonin transporter (*5HTT*) and *BDNF* genes are also underway to assess whether other allelic changes in individuals with FXS that may increase the prevalence of autism.

There are a number of similarities between idiopathic autism and FXS. Individuals with either disorder have large heads with rapid brain growth in early childhood (Chiu et al., 2007; Courchesne, Carper, & Akshoomoff, 2003). Chiu et al. (2007) have demonstrated that the head size in those with FXS plus autism grows faster in early childhood than for those with FXS without autism. Approximately 18% of those patients with idiopathic autism and extreme macrocephaly have a *PTEN* mutation (Butler et al., 2005). The *PTEN* gene regulates cell growth, and studies are now underway to assess how the absence of FMRP may dysregulate *PTEN* activity. In FXS, there is also enhanced phosphorylation of the PTEN protein, leading to its lowered function and (possibly) the large brains in children with FXS, particularly those with autism and FXS (Chiu et al., 2007). Other systems that are dysregulated in FXS include the GABA pathway, which is downregulated, and the mTOR pathway, which is upregulated (Bassell & Warren, 2008; Zupan & Klann, personal communication 2009). The mTOR pathway is also upregulated in individuals with tuberous sclerosis, which is a frequent cause of autism. The overlap of neurobiological pathways between those individuals with FXS and those with other forms of autism is important to elucidate because targeted treatments may be helpful for more than one cause of autism, as described below.

As mentioned, a subgroup of individuals with FXS and idiopathic autism have seizures (Berry-Kravis, 2002; Musumeci et al., 1999). Seizure activity is important to identify early with an electroencephalography (EEG), because treatment with an anticonvulsant can dramatically improve a child's language and social responsiveness (R. J. Hagerman, 2002a). For many individuals, anticonvulsant treatment prevents the disruption

of connectivity caused by abnormal spike wave discharges and subsequently enables an individual to engage in their environment and avoid emerging social deficits (Garcia-Nonell et al., 2008).

Prepulse inhibition (PPI) deficits occur in individuals with FXS and in individuals with autism (Frankland et al., 2004; Hessl et al., 2008; Perry et al., 2007). PPI is a measure of frontal gating or inhibition, and it is likely related to abnormalities in the GABA and the mGluR5 systems. In both autism and FXS, there are GABA and glutamate abnormalities that are described below (El Idrissi et al., 2005; Gruss & Braun, 2004). The PPI deficit is a consistent abnormality with test–retest reliability in FXS, and it is therefore a good quantitative measure to be used in medication studies in FXS (Berry-Kravis et al., 2009).

Interesting similarities and differences have been seen in neuroimaging studies of both FXS and autism. Both disorders have a large cerebrum, and in FXS the caudate and thalamus are large, whereas the cerebellar vermis is small (Mostofsky et al., 1998; Reiss & Dant, 2003). In a direct comparison of young children with FXS and young children with idiopathic autism compared to controls, Hazlett et al. (2009) found that the amygdala was significantly larger in those with autism compared to FXS and controls, whereas the caudate was larger in those with FXS compared to autism and controls. In girls with FXS, the smaller the size of the cerebellar vermis, the more severe the autistic behaviors (Mazzocco et al., 1997). Girls with FXS also have reduced basal forebrain and hippocampal activation, which are two areas of the brain important to memory encoding and attention (Greicius et al., 2004). Hoeft et al. (2007) used tasks to test executive functioning and found that the FXS group had reduced activation in the right ventrolateral prefrontal cortex (VLPFC) compared to both autistic and typically developing individuals. They also found increased left VLPFC activation in those with FXS, suggesting possible compensation for this right fronto-striatal deficit (Hoeft et al., 2007). Dalton et al. (2008) compared face processing and gaze fixation in FXS and autism groups and found that both groups had similar deficits in gaze fixation to human faces, with decreased activation patterns in the fusiform gyrus. The FXS group, however, had greater activation than the autism and control groups in brain regions associated with fear and emotional face processing including the left hippocampus, the right insula, the left postcentral gyrus, and the left superior temporal gyrus, suggesting a divergent neural cause for face-processing deficits between FXS and idiopathic autism groups (Dalton et al., 2008).

Involvement in Premutation Carriers

Individuals with the premutation have 55 to 200 CGG repeats. Methylation does not occur in the premutation range, so FMRP levels are usually normal or close to normal. However, the higher the repeat size, the higher the level of mRNA. In individuals with more than 150 CGG repeats, the level of

FMRP can be mildly decreased, and subtle physical features of full FXS may be observed, such as prominent ears, loose connective tissue with hyperextensible finger joints, and macroorchidism (R. J. Hagerman, 2006; Tassone et al., 2000). Some behavioral features are also similar to FXS, including ADHD symptoms, poor eye contact, shyness, and social anxiety (Farzin et al., 2006).

Occasionally a patient in the premutation range will present with cognitive deficits, autism, or ASDs—characteristics more commonly found in those with a full mutation and FXS (Aziz et al., 2003; Farzin et al., 2006; Goodlin-Jones et al., 2004). Often in these cases, a significant FMRP deficit can be documented, but not always (Tassone et al., 2000). However, for the most part, premutation carriers have a normal IQ.

The most significant problem in the premutation range is the elevation of mRNA, which can lead to an RNA toxicity that does not occur in the full mutation. The excess mRNA binds to other proteins and causes dysregulation of proteins essential to normal neuronal functioning (P. J. Hagerman & Hagerman, 2004a). As premutation carriers age, inclusions form in neurons and astrocytes and are eosinophilic and intranuclear. Inclusions are a hallmark of the fragile X-associated tremor/ataxia syndrome (FXTAS) (Greco et al., 2006). As previously mentioned, this disorder occurs in approximately 40% of older adult male carriers and 8% of aging female carriers, ascertained through families with known FXS probands, and is characterized by intention tremor, gait ataxia, neuropathy, brain atrophy, and white matter disease on MRI (Coffey et al., 2008; Jacquemont et al., 2003; Jacquemont et al., 2004). The RNA toxicity also has an impact on the ovary in female carriers and approximately 16% to 20% experience POI, with menstruation ceasing before age 40 years (Sullivan et al., 2005; Wittenberger et al., 2007).

Recently, a study of 146 adult female carriers was conducted, and the cohort was divided into those with FXTAS and those without FXTAS. Approximately 50% of those with FXTAS had thyroid disease—particularly hypothyroidism—and 42% had fibromyalgia, both significantly different from age-matched controls (Coffey et al., 2008). Muscle pain was also common in those who did not have a medical diagnosis of fibromyalgia and even in those without FXTAS. Zhang et al. (2005) have reported three cases of multiple sclerosis (MS) in 106 cases of premutation females, which is a higher rate than the general population. A woman who had a severe case of MS over a 15-year period was diagnosed with the premutation 1 week before she died. At autopsy, she had the inclusions of FXTAS in addition to MS lesions with neuroinflammation (Greco et al., 2008). These studies suggest an association between the premutation and autoimmune disease that requires further investigation. This association may be related to the proteins that become dysregulated in the premutation neuron, including upregulation of the heat-shock proteins hnRNP A2, myelin basic protein, lamin A/C and alpha-B-crystallin (which may be an important antigen for MS) (Greco et al., 2008). It is also possible that the elevation of mRNA may stimulate toll receptors that may, in turn, stimulate autoimmunity (Greco et al., 2008).

The increased prevalence of autism and ASDs in boys with the premutation who present clinically (73%), compared to their premutation brothers identified through cascade testing (8%) and normal brothers without the premutation (0%), suggests that the premutation can predispose an individual to autism (Farzin et al., 2006). Emerging evidence suggests that the RNA toxicity mechanism may also affect early development. Cultures of neurons with the premutation have reductions in branching and larger synaptic size compared to normal neurons (Chen et al., 2009). This mechanism is distinct from the decreased FMRP mechanism found in FXS. Placement of the premutation in cultured neural cells alters cellular morphology, including formation of intranuclear inclusions, and leads to reduced cell viability (Arocena et al., 2005). Because neuronal death occurs more readily in FXTAS cases, neural cells are likely to be more vulnerable to environmental toxicity, which can further exacerbate cell loss. An example of this vulnerability to environmental toxins was seen in a carrier woman who developed tremor and ataxia while undergoing chemotherapy for cancer (O'Dwyer et al., 2005). This effect, however, disappeared once the patient ended her chemotherapy. Further study of environmental toxicity in the young premutation carrier may shed light on why there is such a high frequency of ASDs in male carriers.

Neurobiological Mechanism Leading to Targeted Treatments in FXS

Because FMRP inhibits the translation of many messages, the absence or deficiency of FMRP leads to a dramatic upregulation of proteins throughout the brain but especially in the hippocampus and amygdala (Qin et al., 2005). A number of these proteins have been identified, including MAP1B and PSD95, which are involved in the postsynaptic complex (R. J. Hagerman, Rivera, & Hagerman, 2008). FMRP also regulates additional proteins known to be involved with autism when their genes are mutated, such as SHANK, neuroligen 3 and 4, CYFIP, Arc, Sema3F, and neurorexins (J. C. Darnell, 2005; Darnell personal communication 2010; Nowicki et al., 2007). Therefore, the cascade of dysregulated proteins triggered by the lack of FMRP provides a molecular link between autism and FXS. The resulting changes in synaptic plasticity, glutamate, GABA and dopamine pathways represent the overlap between FXS and idiopathic autism or autism caused by other mutations (Belmonte & Bourgeron, 2006) (*see* Figure 46-3).

Autism is a behavioral diagnosis defined by DSMIV-TR and is known to be attributable to a number of different gene mutations, with possible environmental overlays to vulnerable genetic conditions. The goal of the clinician is to determine the genetic diagnosis responsible for the behavioral diagnosis in a child with autism. Although FXS is a specific genetic diagnosis, it is the most common known single gene cause of autism (Persico & Bourgeron, 2006; Reddy, 2005; Wassink, Piven, & Patil, 2001). Because of this connection, the fragile X

DNA test should be carried out in all children who are diagnosed with autism or ASDs (R. J. Hagerman et al., 2008). This testing is particularly important now that targeted treatments are becoming available to ameliorate the neurobiological abnormalities present in FXS.

The most important pathway upregulated by the absence of FMRP is the mGluR5 pathway (Huber et al., 2002). This pathway mediates the weakening of synaptic function (long-term depression; LTD) in the brain, particularly in the hippocampus. Changes affecting the mGluR5 system are considered to be the primary cause of intellectual deficiency in FXS; this relationship between FMRP, LTD, and FXS is known as the mGluR5 model of FXS (Bear, Huber, & Warren, 2004; Dolen & Bear, 2008). FMRP normally inhibits protein translation in this pathway, which controls LTD. FMRP deficits cause internalization of the AMPA receptors and has been directly demonstrated in hippocampal slices (Nakamoto et al., 2007), leading to enhanced LTD in FXS. The normalization of FMRP levels or the use of mGluR5 antagonists can reverse these changes both in vitro and in vivo (de Vrij et al., 2008; Dolen et al., 2007; Nakamoto et al., 2007). In the mouse, fly, and even zebrafish models of FXS, the use of mGluR5 antagonists or cross-breeding with an mGluR5 deficit animal can improve the behavioral and cognitive phenotype of FXS (Dolen et al., 2007; McBride et al., 2005; Nakamoto et al., 2007; Tucker, Richards, & Lardelli, 2006; Yan et al., 2005).

Initial studies of mGluR5 antagonists utilized 2-methyl-6-phenylethynyl-pyridine (MPEP) in the animal models of FXS. MPEP rescued the seizure phenotype in the fragile X knockout mouse (KO) (Yan et al., 2005), and it also normalized the mating behavior and the overall life-span of the *Drosophila* model of FXS (McBride et al., 2005). However, MPEP is genotoxic to humans so it cannot be used with individuals with FXS. Lithium has some mGluR5 antagonist effects and has also been utilized in the *Drosophila* model and in the KO mouse with effects similar to MPEP (McBride et al., 2005; Yan et al., 2005). An open trial of lithium was tried in several patients with FXS, and benefits were seen in behavior over several months. In addition, some cognitive improvements were also noted (Berry-Kravis et al., 2008). Therefore, further controlled studies should be carried out to understand if lithium benefits cognition and behavior problems, including autism in FXS. Lithium is neuroprotective in aging, so it may have beneficial effects on the neurological problems associated with aging in carriers experiencing FXTAS.

Recently, researchers (Porter et al., 2005) found that fenobam, an anti-anxiety agent that demonstrated efficacy in phase II trials in the 1980s, acts as an mGluR5 antagonist. It has therefore become a candidate for a targeted treatment for FXS. A recent study of pharmacokinetics and toxicity has been completed in 12 adults with FXS who were given a dose of 50 to 150 mg orally (Berry-Kravis et al., 2009). We found the peak blood level at 3 hours after oral dosing, and no significant side effects were seen at any dose. We also found that the deficit in PPI (a measure of frontal gating) typically seen in FXS (Frankland et al., 2004; Hessl et al., 2008) was significantly
Figure 46–3. The interactions of FMRP and other proteins in neurons. Akt – protein kinase B (PKB); CYFIP – cytoplasmic interacting *FMR1* protein; elF4E – E74-like factor 4; ERK – extracellular signal-regulated kinases, synonym for mitogen-activated protein kinase (MAPK); FMRP – fragile X mental retardation protein; Homer – scaffolding protein; MAPB1 – microtubule-associated protein 1B; MEK – mitogen-activated protein kinase (MAPK); mGluR – metabotropic glutamate receptor; Mnk – MAP kinase integrating kinase; mTOR – mammalian target of rapamycin/FK506 binding protein 12-rapamycin associated protein 1 (FRAP1); NMDA-R – ionotropic *N*-methyl-D-aspartic acid receptor; P70 S6K – p70 ribsomal S6 protein kinase; PAK3 – P21 (CDKN1A)-activated kinase 3; PDK – 3-phosphoinositide-dependent protein kinase; PI3K – class I phosphoinositide 3-kinses; PIKE – PI 3-kinase enhancer; PSD95 – postsynaptic density protein; PTEN – phosphatase and tensin homolog; Rac/Ras – small guanosine triphosphatases. Figure drawn by Dr Andrea Schneider, MIND Institute, UC Davis Medical Center.

improved on fenobam (Berry-Kravis et al., 2009). After a single dose of fenobam, many individuals, demonstrated a decrease in hyperactivity and anxiety with a calming effect that lasted about 4 hours. Additional mGluR5 antagonists are currently being developed by several pharmaceutical companies, and these, too, will be studied in patients with FXS. Recently a controlled trial has been initiated with Arbaclofen, an R isomer of Baclofen. Arbaclofen acts as a GABA agonist and has been used in patients with cerebral palsy and significant spasticity. The R isomer has significant mGluR5 antagonist effects, so it

is being studied in phase III trials in FXS at multiple centers. Anecdotal evidence has shown that Baclofen and Arbaclofen are also helpful in some patients with idiopathic autism (Berry-Kravis, 2008). Arbaclofen controlled trials are taking place in both children and adults with FXS and idiopathic autism.

The development of biomarkers distinct from the behavioral phenotype is in progress to tease out those individuals in the autism group who would benefit from mGluR5 antagonists. Patients with autism who have PPI deficits similar to those with FXS may be one possible subgroup (Hessl et al., 2008).

One promising biomarker may involve the rate of ERK phosphorylation, which is slowed in FXS. This rate has been shown to improve in the lithium open trial in FXS (Berry-Kravis et al., 2008), and it will be studied in other mGluR5 antagonist studies.

Fragile X KO mouse studies have also demonstrated abnormalities in the GABAergic pathways. Decreased expression of the GABA$_A$ receptor, particularly the delta subunit, has been noted by D'Hulst and colleagues (D'Hulst et al., 2006; D'Hulst & Kooy, 2007). Other subunits are also underexpressed in the KO mouse, including the alpha, beta, and gamma subunits (D'Hulst et al., 2006). Even in the *Drosophila* model of FXS, the GABA receptors show approximately 50% reduction (D'Hulst et al., 2006). FMRP has been shown to bind the delta subunit of the GABA receptor, so it is postulated that FMRP is responsible for its transport and localization, which would be disrupted in FXS (Miyashiro et al., 2003). Decreased GABAergic function has been shown to interfere with cholinergic function in electrophysiological studies in the KO mouse (D'Antuono, Merlo, & Avoli, 2003). Therefore, treatments that can target the GABAergic abnormalities in FXS may also be beneficial to a broader group of neurotransmitter abnormalities, including cholinergic function.

Another treatment possibility for the GABAergic abnormalities in FXS is the neurosteroid anticonvulsant ganaxolone. This medication is a modulator of the GABA$_A$ receptor and an agonist—particularly for the delta receptor. Ganaxolone is a synthetic analog of allopregnanolone; however, it does not have any active hormonal effects (Monaghan, McAuley, & Data, 1999). It is an anticonvulsant that has demonstrated efficacy in infantile spasms through phase II studies without significant side effects, with the exception of mild sedation, even in young children. A controlled trial in patients with FXS will hopefully take place in the future to assess efficacy in behavior and cognition.

Conclusion

FXS is the most common inherited cause of intellectual disability and autism known. There is an absence or deficiency of FMRP in FXS leading to the upregulation of many proteins and pathways important for other forms of autism. All children with ASDs should be tested for mutations in the *FMR1* gene and both premutations and full mutations can lead to ASDs. Presently, a variety of targeted treatments are being tested for efficacy in children and adults with FXS. It is likely that targeted treatments for FXS will lead the way for new treatments in idiopathic autism, including the use of mGluR5 antagonists.

Challenges and Future Directions

The field of targeted treatments is just beginning for many neurodevelopmental disorders, and it holds the promise of reversing both intellectual disability and autism. At this time,

fragile X is leading the way because of the advances in the neurobiology for this disorder. At the National Fragile X Foundation International Conference in 2008, Nelson reported that an mGluR5 antagonist demonstrated reversal of the brain structural abnormalities in the adult KO mouse (Nelson et al., 2008). This leads to the hope that even in adulthood, these medications will make a significant difference for patients with FXS and perhaps for those with autism and other neurodevelopmental disorders.

- To actually reverse intellectual disability and autism in those with FXS, the targeted treatments need to be coupled with learning programs that will give the appropriate stimulation to the synapse, particularly in adults.
- The use of computer programs, brain rehabilitation programs, and innovative new learning approaches are necessary, and must be utilized simultaneously with targeted treatments to reach the goal of reversing the cognitive and behavioral deficits of those with FXS both with and without autism.

Commentary

⊞ Daniel H. Geschwind

Autism Genetics and Genomics: A Brief Overview and Synthesis

Autism genetics has been one of the most exciting and dynamic fields in psychiatric genetics over the last decade. The field has moved from having virtually no significant leads about the genetic etiology of autism to knowing the molecular genetic basis of ASD in between 10 and 20% of cases (Abrahams & Geschwind, 2008; Kaymakçalan & State, Chapter 41; Lamb, Chapter 38; Morrow & Walsh, Chapter 44, this volume). Despite these advances and all of the surrounding hype and excitement, however, there are many unanswered questions and looming controversies. Therefore, it is very reasonable to take a philosophical perspective, asking circa 2010, "Where has autism genetics led us?" After all, the major reason for finding genes is to understand the biology and pathophysiology of the disorder, so as to lead to better diagnosis and treatment. For more in-depth coverage of specific topics in autism genetics, I refer the reader to the far more comprehensive chapters on whole genome linkage and association (Lamb, chapter 38), medical genetics and intellectual disability (Dykens & Lense, chapter 15; Miles, chapter 40), quantitative endophenotypes (Cantor, chapter 39), the role of rare variation (Kaymakçalan & State, chapter 41), the study of common variation in genetic isolates (Rehnström & Peltonen, chapter 43), homozygosity mapping in genetic isolates (Morrow & Walsh, chapter 44), epigenetics (Person et al., chapter 42), and the overlap of autism with model syndromes such as Fragile X and Rett syndrome (Hagerman et al., chapter 46; Neul, chapter 45).

One of the major themes of autism genetic research has been the acceleration of progress in finding genes over the last decade, and certainly the last five years, primarily due to technology. In fact, one could take the position that technological advances have had as much or more influence than careful consideration of phenotype or overriding genetic theories, and therefore technology and marketing has guided much work in autism genetics.

In the 1980s, the development and refinement of the autism diagnosis using modern tools such as the Autism Diagnostic Interview Revised (ADI-R) and the Autism Diagnostic Observation Schedule (ADOS) permitted international and cross-institutional collaborations to employ a common diagnostic rubric. This was essential for growing the samples to sizes necessary for international genetic studies. However, since that time, with a few exceptions, relatively little has been done to delineate phenotype-genotype relationships, especially when seen in the context of many of the large-scale genetic studies that have been done. This is not meant as a criticism, but an observation based on the fact that molecular technology has expanded and has done much to permit the prevalent culture of "genotyping large numbers and seeing what we find" that now predominates. In fact, in support of the "genotype first" approach, one can reasonably argue that it is cheaper to genotype now and phenotype later, after one identifies a set of contributory or causal mutations that can be used to define cases with genetically homogeneous etiologies (so-called inverse-mapping).

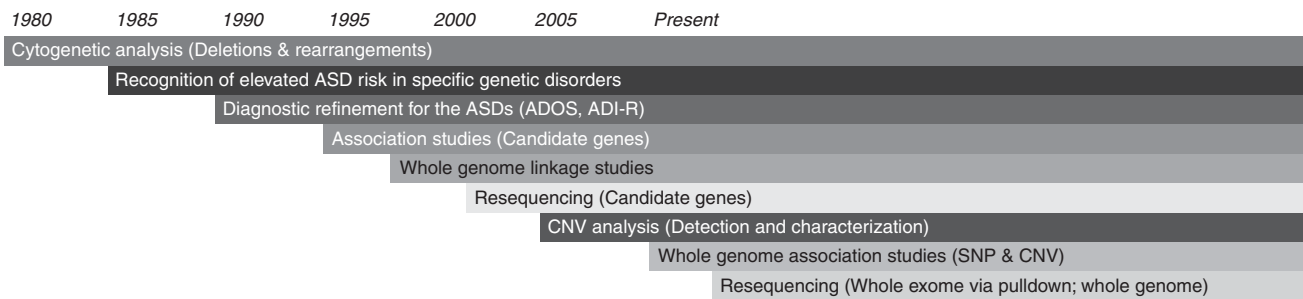
So, if we relate the major progress in autism genetics to the prevailing technologies (Figure C6-1, adapted from Abrahams & Geschwind, 2010), we can see that, early in the field, karyotyping and light-microscope resolution cytogenetic analysis predominated, identifying mostly rare cytogenetic rearrangements that were visible by eye, and an occasional molecularly defined cytogenetic lesion (Cook et al., 1997). At the same time, whole-genome linkage studies (Table C6-1; see Lamb, Chapter 38) were being developed and planned. The advent of linkage was permitted by the development of what, at the time, were relatively high-resolution linkage maps of the human genome and commercial platforms on which such markers could be typed. Subsequent to this, in the late 1990s, it became feasible to perform candidate gene association studies, testing single nucleotide polymorphisms (SNPs; Table C6-1), one gene at a time. Candidate gene studies, even those under linkage peaks, quickly fell out of favor, as it became possible to do whole-genome studies. Once dense SNP maps of the human genome were established, based on the HapMap (Table C6-1) project and microarray based assays became widely available


Figure C6–1. Methodological changes have accelerated progress in ASD genetics. Collection of large cohorts via international collaboration together with array-based technologies enabling genomewide interrogation of variation has resulted in major advances. Similar progress will come from massively parallel sequencing of partial and whole genomes. Although such experiments are soon likely to become routine, interpretation of results, particularly in the context of diverse phenotype data, will require massive computational infrastructure. Adaptation of Figure 23.4.1 from Abrahams, B. S., & Geschwind, D. H. (2010). Autism genetics. In M. Speicher, S. E. Antonarakis, and A. G. Motulsky (Eds.), *Vogel and Motulsky's human genetics* (chapter 23, pp. 699–714). Berlin, Springer, with authors' permissions.

from commercial entities, efficient whole genome association and analysis of copy number variation (CNV) became possible. Now, NextGen (Table C6-1) sequencing is becoming available in major academic centers, so that whole-exome (Table C6-1) or whole genome sequencing of individual patients and controls is being planned. All of these advances and changes in approach, although potentially related to underlying differences in hypotheses or the theoretical underpinnings of the genetics of complex traits, have nevertheless been mostly driven by widespread platform availability and hence feasibility of such genomewide studies. There is no arguing that each new method is more powerful than what has come before. But, as the field has been carried in this tide of technology, we may have failed to adequately address many critical issues of disease phenotypes and disease boundaries that now currently face us.

Prominent Genetic Models

Common Variation (Polymorphisms) Versus Rare Variation (Mutations)

Common genetic polymorphisms, are defined as those with a population frequency of at least, a relatively arbitrary threshold that depends on who is drawing the bar. Such variants are presumed to act incrementally to increase risk for disease, as they have been propagated over generations and have not been selected against by evolution (hence their relatively high population frequency). Therefore, common genetic polymorphisms are thought to be factors that act in combination with other genetic, environmental, or epigenetic influences to increase one's risk for a disease (Lamb, chapter 38; Rehnström & Peltonen, chapter 43, Cantor, chapter 39). Rare variants, or mutations, in contrast, undergo purifying selection (Table C6-1) and are typically considered causal, or having a major effect (Kaymakçalan & State, chapter 41; Lamb, chapter 38; Morrow & Walsh, chapter 44). Most whole genomewide

association approaches have relied on the concept that common variation modulates risk in common diseases such as autism (Lamb, chapter 38; Rehnström & Peltonen, chapter 43). Even in population isolates, where inbreeding could be conceived as enriching for recessive mutations (Morrow & Walsh, chapter 44), the use of northern European population isolates has been championed as an efficient way to reduce genetic heterogeneity and increase power to find common ASD-related variation (Rehnström & Peltonen, 2010). Thus, "common disease is caused by common variation" has been the prevailing model until recently.

However, over the last two years, identification of rare variants has become the new mantra in neuropsychiatric genetics (Kaymakçalan & State, chapter 41; Morrow & Walsh, chapter 44). This change is driven by several factors. These include: (1) the small effect size observed in whole genome association studies, which are only well powered to detect common variation (Lamb, chapter 38; Wang et al., 2009; Weiss et al., 2009); (2) that association signals from common variation do not appear to account for major linkage signals, or overlap with major linkage peaks (Stone et al., 2007; Strom et al., 2009; Wang et al., 2009; Weiss et al., 2009; As linkage can detect signals from both rare and common variation, the lack of association signals large enough to explain the overlying linkage peaks implies that rare variants therefore underlie linkage peaks); and (3) the emerging recognition of the role of rare, de novo, and recurrent structural chromosomal variation (Kaymakçalan & State, chapter 41; Sebat et al., 2007). Although rare single base pair mutations (Jamain et al., 2003; Laumonnier et al., 2004) and large chromosomal structural variation were identified, the latter in conjunction with intellectual disability (Jacquemont et al., 2006; Vorstman et al., 2006), the broader role of rare variants in autism was really fueled by the initial finding that de novo copy number variants (CNV) contributed up to 10% of autism cases without severe intellectual disability (Marshall et al., 2008; Sebat et al., 2007). Based on these data and modeling of family data, it was suggested that rare, Mendelian mutations with lower penetrance

Here we summarize the putative functions of some of the current ASD candidate genes. Assignment of genes to functional categories is relatively arbitrary and is just meant to emphasize the heterogeneity of molecular and biological functions implicated. It must be acknowledged that many of the genes have multiple functions and their categorization, based on current knowledge, is incomplete. Abbreviations are as follows: *AHI1* Jouberin; *ASD* autism spectrum disorder; *ASMT* acetylserotonin *O*-methyltransferase; *AVPR1A* vasopressin V1a receptor; *BZRAP1* benzodiazapine receptor (peripheral), associated protein 1; *CACNA1C* calcium channel, voltage-dependent, L type, alpha 1Csubunit; *CACNA1G* calcium channel, voltage-dependent, T type, alpha 1G subunit; *CACNA1H* calcium channel, voltage-dependent, Ttype, alpha 1H subunit; *CDH9* cadherin 9; *CDH10* cadherin 10; *CADPS2* calcium-dependent secretion activator, 2; *CNTN4* contactin4; *CNTNAP2* contactin-associated protein-like 2 precursor; *DHCR7* 7-dehydrocholesterol reductase; *DISC1* disrupted in schizophrenia1; *DOCK4* dedicator of cytokinesis 4; *EN2* homeobox protein engrailed-2; *FMR1* fragile X mental retardation 1 protein; *GABRB3*gamma aminobutyric acid receptor subunit beta-3 precursor; *GRIK2* glutamate receptor, ionotropic kainate 2 precursor; *ITGB3* integrinbeta-3 precursor; *MDGA2* MAM domain containing glycosylphosphatidylinositol anchor 2; *MECP2* methyl-CpG-binding protein 2; *MET* met proto-oncogene; *MR* mental retardation; *NLGN3* Neuroligin 3; *NLGN4X* Neuroligin-4, X-linked precursor; *NRXN1*Neurexin-1; *OXTR* oxytocin receptor, PDDs pervasive developmental disorders; *PRKCB* protein kinase C, beta, *PTEN* phosphataseand tensin homolog, *RELN* Reelin precursor, *SCN2A* sodium channel, voltage-gated, type II, alpha subunit; *SEMA5A* sema domain, seven thrombospondin repeats (type 1 and type 1-like), transmembrane domain (TM) and short cytoplasmic domain, (semaphorin) 5A; *SHANK3* SH3 and multiple ankyrin repeat domains protein 3; *SLC6A4* sodium-dependent serotonin transporter; *SLC25A12* calciumbindingmitochondrial carrier protein Aralar1; *TSC1* hamartin; *TSC2* tuberin; *UBE3A* ubiquitin-protein ligase E3A.a. Table and data adapted with permission from Abrahams, B. S., & Geschwind, D. H. (2008). Advances in autism genetics: On the threshold of a new neurobiology. *Nature Reviews. Genetics, 9,* 341–355.

in females would potentially be the cause in a majority of ASD cases (Zhao et al., 2007).

Certainly, a rare, major gene model is consistent with other developmental disorders, such as X-linked intellectual disability (ID), where rare or even private Mendelian-acting mutations in nearly 100 genes have been identified (Chiurazzi et al., 2008; Gecz et al., 2009) and there is little support for the role of common variation in this condition. One prediction from this model would be that as the resolution of CNV detection methods increases, a larger proportion of ASD would be found attributable to these specific mutations, especially in simplex autism cases. Here, the data are still being analyzed but the data so far has not shown an increase in the number of causal variants in parallel with increases in resolution. Additionally, CNV are just one form of rare mutation. Single base pair mutations, although thought to be less frequent than CNV, could formally account for the majority of ASD. Further, it is plausible that rare variants even underlie some or many of the association signals to common variants (Dickson et al., 2010). So, until whole exome resequencing is completed on a large number of cases, the Mendelian or de novo rare variant model will not be fully tested and the extent of the contribution of rare variants to ASD will remain hotly debated.

Another set of observations to be considered when weighing the relevance of Mendelian models of ASD is the presence of less severe aspects of the core features of autism observed in many families with ASD probands, the so-called broader phenotype of autism. Aspects of social cognition, developmental language impairment, and rigid personality characteristics are all observed at higher frequency in first-degree relatives of ASD probands than in the general population (Bailey et al., 1998; Bolton et al., 1994; Bolton et al., 1998; Constantino et al., 2004; Constantino & Todd, 2000; Fombonne et al., 1997; Le Couteur et al., 1996; Pickles et al., 2000; Piven & Palmer, 1999; Piven et al., 1997; Tager-Flusberg, 2004; Tager-Flusberg & Joseph, 2003). This would suggest that common alleles of smaller effects are segregating in families and modulate individual aspects of ASD observed in unaffected first-degree relatives (see discussion on endophenotypes below). Furthermore, twin studies of the core domains underlying ASD demonstrate that they are separable, distinct domains that quantitatively relate to the normal distribution of these traits in the population (Happe & Ronald, 2008; Ronald et al., 2006a). This apparent tension between de novo or major Mendelian mutation models can be simply resolved if one accepts that there are different classes of families, those in which the ASD presents in a de novo or Mendelian fashion, those predominantly segregating common variation and those with a mixture of the above, sprinkled with intermediate effect-size alleles. The existence of different classes of families is supported both by family studies (Losh et al., 2008; Virkud et al., 2009), and genetic modeling (Zhao et al., 2007), which is consistent with the growing appreciation for the extraordinary heterogeneity in ASDs' etiologies and the likely presence of a range of genetic and gene-environment models (Abrahams & Geschwind, 2010).

Are de novo or Rare Inherited CNV "Causal?": A Merging of Models

Even in our current state of relative ignorance, a potentially informative picture is emerging with regard to CNVs and their inheritance patterns. First, it must be acknowledged that many of the known causes of ASD, such as cases of rare genetic syndromes or certain forms of large recurrent CNV have variable expressivity (Table C6-1) and markedly reduced penetrance (Table C6-1) with regard to the phenotype of autism. The majority of these mutations cause a variety of syndromes, ranging from global developmental delay, syndromic epilepsy, intellectual disability, and autism to schizophrenia (Abrahams & Geschwind, 2008, 2010). The usual Mendelian model that underlies typical rare variant models must be modified to include the notion of intermediate alleles with intermediate effect sizes. So, the genetic models now have to be modified to include a wide range of risk alleles from rare mutations with large to intermediate effect sizes, as well as common variants, albeit common variants with very small effect sizes, typically under 1.3 (see Lamb, chapter, for overview). Thus, one can envision a continuous distribution of familial risk, ranging from alleles of small and intermediate effect size to major mutations.

A very salient example of data supporting this notion is the recent work by Bucan et al. (2009), who performed a genome-ewide analysis of copy number variation to identify those involving exons. The rationale behind this is that, analogous to the case for single base pair changes, CNV involving changes in protein sequence are most likely to be functional. Strong support for this contention comes from the observations that CNVs involving exons have been shown to be deleterious based on evidence of strong negative selection, which is most evident for deletions, but also holds for duplications, as both are under significantly more negative selection than intronic CNVs. Therefore, on aggregate, CNVs involving exons (eDels) are the most likely CNV to be pathogenic. Using a very stringent approach requiring any eDels to be identified in three independent cases from different families and none in more than 2500 controls, approximately a dozen new potential autism loci were identified (Bucan et al., 2009). In contrast to several earlier studies, these investigators were able to obtain statistical support for individual CNVs. Several of these, including BZRAP1, a benzodiazepine receptor associated protein, as well as MADCAM1, which shows high homology to CNTN4, are thought to regulate synaptic transmission, and were replicated in independent samples. Similarly, CNV involving UBE3A and NRXN1, both relatively established autism risk loci, were also identified.

However, even these known loci showed complex transmission patterns consistent with reduced penetrance and multifactorial inheritance. In NRXN1, for example, there was incomplete segregation with disease and a control carrier frequency of nearly 50%. This again suggests that even at these presumed major functional loci, these mutations cannot be considered causal and they are not acting in a purely Mendelian

fashion. For CNVs in NRXN1, it is not just the case of variable expressivity, but very reduced penetrance, as a significant fraction of neurotypical individuals carry the deletions. This is similar to the case of 15q13 deletions, which were originally associated with autism (Pagnamenta et al., 2009). Subsequent investigations found these CNV in unaffected subjects, as well as those with a wide range of neurodevelopmental phenotypes from epilepsy to developmental delay, ID, and autism (Ben-Shachar et al., 2009; Shinawi et al., 2009; van Bon et al., 2009).

Mendelian mutations leading to neurodevelopmental disorders that encompass autism, most of which are rare, now include over a dozen disorders (Abrahams & Geschwind, 2008). In some of these, such as Beckwith-Wiedemann syndrome or Fragile X, the percentage of children having the syndrome and autism is under 25%. In others, such as the cortical dysplasia-focal epilepsy syndrome due to recessive mutations in CNTNAP2, or 3p deletion duplications involving CNTN4, maternally inherited duplication at 15q, and 16p deletions, the proportion of children having autism may be greater than 50%. Some argue that this is no different than other known Mendelian causes of ID, or neurological disorders, such as the inherited frontotemporal dementias (FTD). In FTD, dominantly inherited mutations

in one gene lead to a very wide range of neurodegenerative diseases, including motor neuron disease and Parkinson's disease, not infrequently, within the same family (Chow et al., 1999; Rademakers et al., 2007). However, this still begs the question as to whether the large variability in phenotype, which includes being essentially unaffected with respect to autism, is modulated by stochastic factors in the environment, or modifier genes of smaller effect size (e.g., see Figure C6-2).

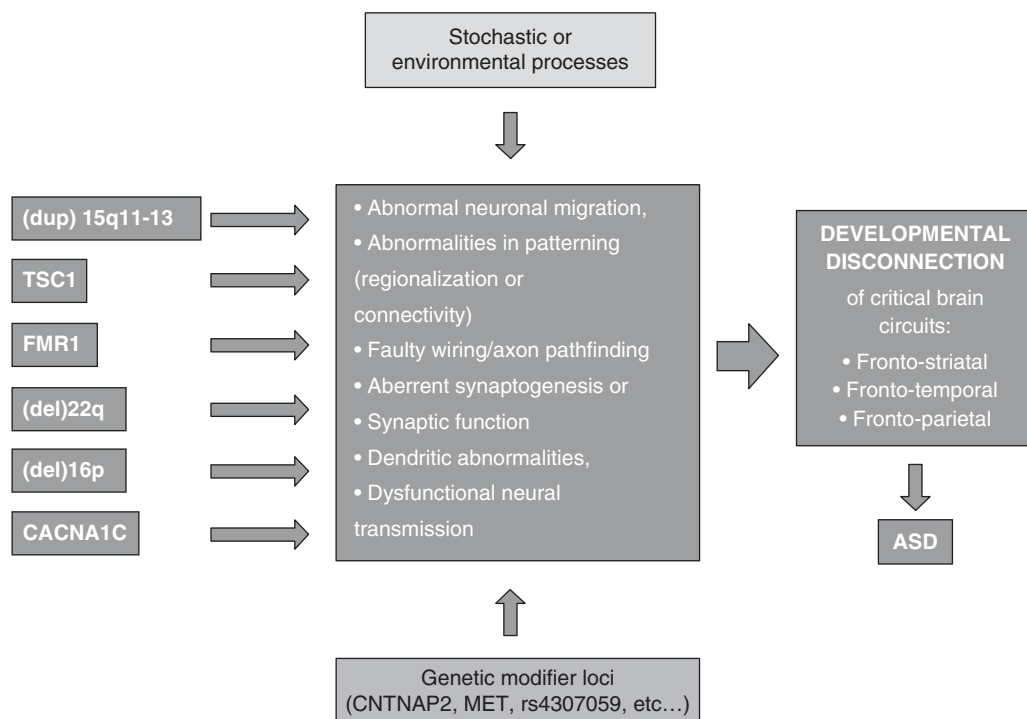
Does this complexity limit the power of studying these rare disorders to gain a foothold in understanding autism pathophysiology? On the contrary, since these rare alleles have a major effect, they provide a great opportunity for connecting genotype to phenotype. Here one has the advantage of starting with a relatively genetically homogeneous population, which opens up the possibility of performing inverse mapping—that is, rather than the usual genetics paradigm of defining a phenotype and then searching for genotype, one starts with the genotype and carefully studies the phenotype. This may be especially powerful in circumstances where a significant proportion with a given recurrent mutation do not have autism. These individuals can be used as a comparison group with those that are autistic, to identify any neurobiologically


Figure C6–2. Convergence of genes on neural systems. Here we illustrate a working model for how major affect autism risk alleles, such as those shown at the left, might act to lead to autism. Since these Mendelian conditions are not specific for ASD (perhaps with the exception of (dup)15q11-13 syndrome), and typically lead to ID, either environmental or genetic factors must modify their affects on brain development. The biological pathways through which such genes are known to act (shown in the middle box) are myriad. We hypothesize that, while certainly these or other molecular and biological pathways provide potential source of convergence, the ultimate convergence must lie in neural systems. At a neural systems level, the convergent process will likely be disconnection of the circuits outlined in the far right box, since these systems are thought to underlie the core deficits of ASD.

relevant phenotypes that distinguish those with autism from those without the diagnosis. So, studying the cognitive, neuroimaging, or gene expression profile phenotypes in rare "single gene" disorders provides one potentially powerful means for trying to understand the range of phenotypes associated with a particular mutation and how a particular genetic abnormality leads to specific nervous system dysfunction at the cell, synapse, and circuit level.

The key issue for the clinician, neurobiologist, practitioner, and therapist is, how do these rare variants contribute to phenotype? How are they modified? Is there any specificity, and do particular variants or affected pathways lead to specific forms of autism for which a specific treatment or trajectory can be predicted? This is hard work, and will require identification of variants in very large sample sizes and concerted comprehensive efforts to phenotype clinical samples. Such an effort has already begun (Christa Leese-Martin and David Ledbetter, personal communication) and will be critical in such mobilization of clinical populations, either in the United States or in countries with more centralized or public health care, as it provides an efficient means for understanding the roles of these variants in autism pathophysiology.

How Might Common Variation Influence the Development of ASDs?: The Endophenotype Model

The absence of strong association signals for common variants in studies of ASD genetics has been taken as evidence for rare, causal mutations, as discussed above. However, an alternative (and potentially complementary) model considers that the broad phenotype of autism, while highly heritable, is not itself related as strongly to specific genetic risk factors as its component cognitive or behavioral domains. Given the presence of the broader phenotype of ASD in first-degree relatives of those with an ASD, and the evidence from twins, it seems very reasonable to test whether common genetic risk factors are related to more elemental, heritable aspects of autism, such as language, social cognition, or any other relevant biomedical measurements, rather than the broad syndrome of ASD itself. Such a model considers autism as the outcome of a set of risk alleles that modulate the normal continuum of quantitative variation of cognition and behavior in humans (Cantor, chapter 39; Constantino, 2010; Happe et al., 2006; Ronald et al., 2006b). This approach attempts to increase power by focusing on more elemental, presumably less heterogeneous, quantitative phenotypes.

From this perspective, autism-related traits should be measured, and are presumed to be present even in those who are unaffected within families, but to a lesser extent. This notion is supported by numerous family studies that have observed subthreshold social and language related traits in both siblings and parents (i.e., first-degree relatives) of autistic probands as referenced above. Furthermore, the neural circuitry underlying these distinct neuropsychological domains, while sharing some common elements, are also distinct, especially at a cortical level. Since genes act during development to orchestrate the development of these brain structures and circuits, genetic variation would therefore be expected to have domain-specific effects, in addition to effects shared across domains. For example, development of specific frontal lobe structures might be under the influence of specific sets of genes, in which variation would affect the specific cognitive and behavioral domains served by the particular frontal lobe circuits. In contrast, ubiquitously expressed synaptic genes would be expected to have more widespread effects on intellectual functioning; mutations in such genes would be more likely to cause general intellectual disability (ID).

In support of this model, we found that common variation in the gene CNTNAP2, whose expression is enriched in human frontal-striatal circuits during development, was found to modulate variation in language delay in families with two or more probands with ASD (Alarcon et al., 2008). Subsequently, the same region of CNTNAP2 was related to quantitative endophenotypes, such as nonword repetition, in subjects with specific language impairment (Alarcon et al., 2008; Vernes et al., 2008; see also Cantor, Chapter 39, and Lamb, Chapter 38, this volume).

The identification of common variation that contributes to phenotypic variation across two distinct neurodevelopmental disorders involving language provides one clear example that supports the quantitative endophenotype model of ASD (Cantor, chapter 39). However, the major stumbling block in applying such a quantitative trait locus (QTL) approach is defining the appropriate intermediate traits or endophenotypes to be used in such analyses. Very few family studies have been done using modern phenotyping methods, as well as assessment of phenotypes appropriate for modern cognitive neuroscience such as neuroimaging, electrophysiology, as well as more advanced, more localizing cognitive tasks (Bilder, 2008; Bilder et al., 2009). There are many issues and challenges facing studies attempting to apply quantitative measures to identify autism risk loci, as highlighted in the chapter in this volume by Rita Cantor (Cantor, chapter 39). However, the inherent power in QTL methodology mitigates against the potential difficulties identifying and measuring relevant heritable phenotypes. For example, measures of language delay, quantitative measures of social cognition, as well as a simple composite heritable measure of nonverbal communication (NVC) derived from the ADI-R, appear promising (Cantor, chapter 39). These endophenotypes, such as NVC or ADI-measured language delay, are not the most sophisticated measures that modern cognitive neuroscience has to offer; however, they are heritable traits and clearly related to the diagnosis of ASD, and so represent a reasonable starting point for such studies. It will be critical to develop sophisticated approaches grounded in a contemporary conception of brain-behavior relationships to the identification of appropriate autism-related traits or endophenotypes and to apply these in large-scale studies. This is one of the very important frontiers in neurobehavioral genetics (Bilder, 2008; Freimer & Sabatti,

2003; Sabb et al., 2009), as it will take us closer to defining more specific neurobiological entities that underlie ASD pathophysiology.

A Synthesis/Where Are We Now?

Does the Genetics Point to Specific Molecular Pathways and What Might That Mean for Treatment?

Now that whole genome association, whole genome linkage studies, and whole genome copy number analyses have been performed in several thousand cases and controls, we can certainly say that individual common alleles clearly have small effect sizes and can not account for the linkage signals in most cases. At the same time, rare variants have been identified, but very few, if any, are entirely specific for autism, again consistent not only with heterogeneity, but with extreme complexity. These data implicate gene-gene and gene-environment interactions in molding the phenotype in most cases of autism, leading to a very complex picture, even in the individual. This means significant heterogeneity not only in the genes involved, but also in the mode of inheritance of ASD. In some individuals, a single major gene may interact with environmental or other common genetic factors, and in others, multiple common or rare genetic factors may interact, with or without environmental or epigenetic factors to cause an ASD (Geschwind, 2008).

What does this genetic heterogeneity mean for treatment? One promise of genetics is to identify potentially treatable etiologies. So, despite the heterogeneity, is there evidence for convergence on one or a group of final common molecular pathways that could be targets for therapeutic development? Here, if we begin to agglomerate the findings from multiple sources, it seems that many potential categories of molecular or biological function emerge, ranging from cell adhesion, vesicle release and neurotransmission, synaptic development and function, to RNA splicing and brain patterning (Table C6-1; see also Abrahams & Geschwind, 2008; Bill & Geschwind, 2009). Perhaps specific pharmacologic therapies could be tailored to ameliorate the problems caused by etiologically similar pathways, such as those highlighted above. Similarly, knowing this degree of etiological heterogeneity may allow one to design treatment studies that use knowledge of genetic etiology to understand how different forms of ASD respond to treatment.

Autism vs. ID: At What Level Is the Specificity of Autism Derived?

Since many of the genes now known or suspected to contribute to ASD were initially discovered as causes of intellectual disability, another obvious, but important question is raised: why do mutations that frequently cause ID also lead to a proportion with autism? Although almost half of patients with ASD have ID, the two are distinct disorders. Many patients with ASD not only have intact functions such as memory, but indeed may have superiority in certain cognitive arenas, including visuo-spatial skills. Furthermore, most patients with mild ID do not suffer from the same social disabilities as those with an ASD.

From a neurologic and a cognitive neuroscience perspective, the behavioral and cognitive specificity of the syndrome of autism must be due to the maldevelopment or injury to specific brain circuits that underlie the core cognitive and behavioral features of ASD (Figure C6-2; Abrahams & Geschwind, 2008; Geschwind & Levitt, 2007). This model predicts that the largest point of convergence in the ASDs will be on neural systems, rather than on a few specific molecular pathways or one anatomical feature, such as the synapse (Figure C6-2). These neural systems are certainly those involved in social cognition and language, which implicates areas of frontal, anterior temporal, and cingulate cortex, and their major connections in the posterior superior temporal and parietal lobes, as well as subcortical regions, such as the striatum (Abrahams et al., 2007; Geschwind & Levitt, 2007; Mundy, 2003). The developmental expression pattern of genes such as CNTNAP2 (Abrahams et al., 2007) and Met (Mukamel and Geschwind, unpublished) supports this model, but this hypothesis sorely needs to be explored in a more systematic manner. So, as more and more autism genes are identified, putting them within a rubric of both molecular pathways (e.g., Konopka et al., 2009; Vernes et al., 2008) and brain circuitry (e.g., Abrahams et al., 2007) will be critical to understand how they lead to autism and other related neurodevelopmental disabilities.

This effort to understand how genes influence brain development and function to cause ASD will require going beyond conventional pathway analysis to network biology, so as to understand the systems level organization of gene and protein networks (Geschwind & Konopka, 2009; Figure C6-3). A necessary foundation for understanding how such a complex phenotype emerges will require integrating genomewide protein and gene interaction data with temporal and spatial expression data that relates individual molecules and functional pathways to specific brain regions or circuits.

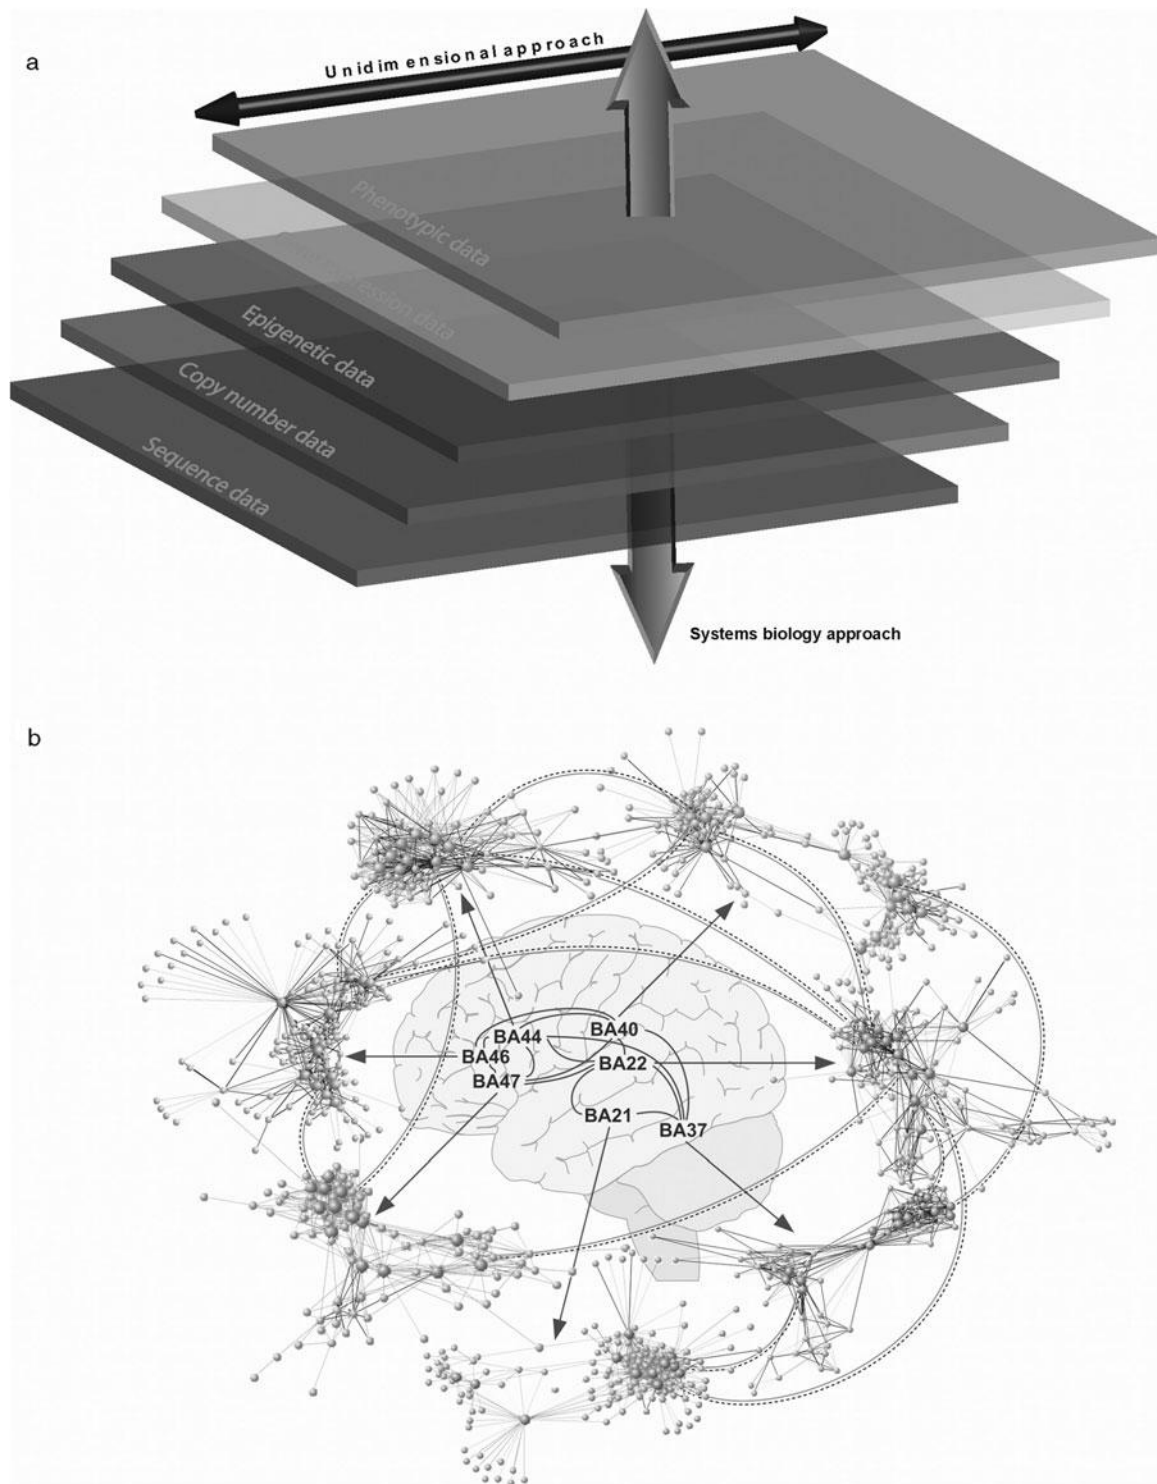
So too, is it necessary to carefully integrate animal model work, along with a consideration of evolutionary issues. A mouse brain is not merely a small human brain, and yet there is much we can learn from mouse genetics and behavior, as well as basic in vitro cell biology to inform our understanding of human brain development and autism. The optimal multi-pronged approach needs to involve genomic approaches along with high throughput assays to screen rare and common variants for functionality (Geschwind & Konopka, 2009). In turn, these data will need to be integrated within an emerging understanding of the neurobiology of human brain evolution and development, finally connecting these molecules to the development of language and social cognition, key core elements that are disrupted in autism.


Figure C6–3. A systems biology approach for integration of genetic, genomic, and phenotype data. (a) The traditional experimental approach to the complexity of neuronal systems and diseases usually encompasses one or two layers of information. Typically, efforts are directed toward genetic (sequence variants, epigenetic modifications), genomic (gene expression), or phenotypic (electrophysiological, clinical) data. The systems biology approach strives, within reason, to consider all of these aspects concurrently, via the creation of comprehensive relational databases. The identification of a higher structure in high-dimensional datasets (for example via network methods) facilitates the connection between different types of information (e.g., genetic vs. genomic data). (b) Here, we illustrate a potential systems level integration of regional brain gene expression, coupled with network-based analysis methods and imaging data, to provide insights into brain connectivity. This is a stylized imagining of combining diffusion tensor imaging data for language areas with gene expression and WGCNA analysis to uncover integration of gene coexpression across brain areas, as well as novel brain region wiring. The lines suggest information flow in both directions, and can also be extrapolated to suggest excitatory and inhibitory interconnections. The integration of network analysis, gene expression data, and imaging analysis will elucidate the relationships among key genetic drivers in distinct regions and their relationship to brain regional connectivity in normal conditions and in disease. Environmental Risk Factors in Autism: Results from Large-Scale Epidemiologic Studies

Points of Interest

- Advanced parental age is a consistent indicator of higher risk for autism, with contributions from both the mother and father. However, it should not be construed as a cause but rather a marker of biologic processes yet to be discovered.
- A few studies have observed greater risk for children of recent immigrants into developed countries from less developed ones.
- Some infections during pregnancy appear to confer increased risk, with no particular specificity to these findings, suggesting that a maternal inflammatory response rather than the microbiologic agent may influences brain development.
- Research on obstetric and perinatal factors has been sparse and has often produced mixed results, perhaps arising from weaknesses in the analytic approaches used.
- Much attention has addressed mercury, but no rigorous studies have indicated an elevated risk either from prenatal or postnatal exposures to this metal.
- Residence close to freeways near the time of delivery is associated with higher risks, suggesting a possible role for toxic chemicals in vehicle exhaust.
- Pesticide exposures during the prenatal period have been associated with increased risk for autistic behaviors, with studies identifying several different classes of compounds.
- Other exogenous factors that plausibly could increase risk include several nutrients, endocrine-disrupting chemicals, certain air pollutants, and medically related exposures, along with geneXenvironment interactions.

The multifactorial etiology of autism is now well-accepted. This concept applies both across the population and within the individual, such that multiple events or exposures contribute to surpassing the threshold beyond which the organism can simply no longer adapt. Although inherited gene profiles confer susceptibility and may, for a small percentage of cases, be sufficient by themselves to cause autism, numerous lines of evidence support a critical role for environmental factors. The lack of complete concordance in monozygotic twins (Steffenburg et al., 1989; Bailey et al., 1995), as well as variation in severity in concordant pairs, leaves little room for doubt that nongenetic exposures contribute to the neuropathology of autism. Even where chromosomal rearrangements, mutations, and copy number variants are identified, these alterations are often de novo events and hence may be attributable to upstream environmental insults. The strong link between congenital rubella and autism, with a relative risk (RR) of 100 or higher (Chess, 1977) calculated using estimates of background prevalence of 4 per 10,000 for that time period (Fombonne, 2003), provides concrete evidence that the risk for this complex neurodevelopmental disorder can be profoundly influenced by the prenatal environment, though clearly this specific factor plays little if any role in the present period.

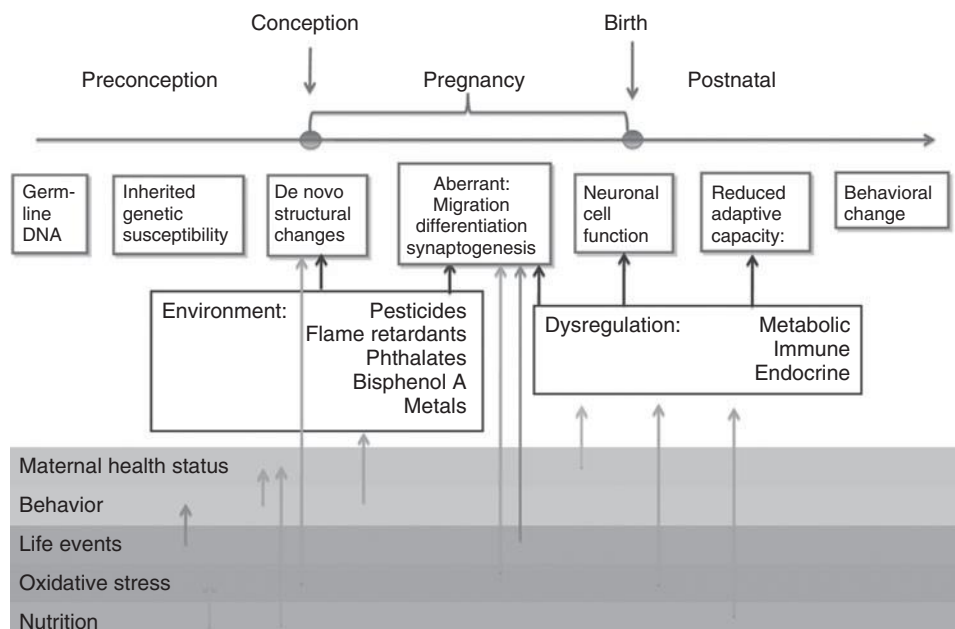
Mechanisms by which environmental insults may alter the course of CNS development, resulting in the final behaviorally defined syndrome of autism, are manifold. Figure 47-1 presents a schemata, in which the developing organism is subject to a variety of exposures over time, with susceptibility factors such as behavior, life events, nutrition, and so forth, moderating or exacerbating the effects. Exposures, whether chemical, physical, or microbiological, may act directly upon neural cells, interfering with critical processes of proliferation, migration, differentiation, synaptogenesis, programmed apoptosis, and myelination, or may affect the expression of genes that regulate such embryonic/fetal/infant processes (e.g., by interacting with the genome to alter methylation), resulting in activation or suppression of such genes. They operate during sensitive periods of gestation by disrupting endocrine systems and altering the hormonal milieu necessary for fetal brain development.


Figure 47–1. Environmental influences on development. (See Color Plate Section for a color version of this figure.)

Environmental exposures could contribute to a dysregulated immune system that interacts at the molecular level with glial cells and astrocytes, creating a neuroinflammatory condition. This list is not an exhaustive one. Moreover, none of these mechanisms need be exclusive, nor does one sensitive time period preclude another. The complexity and plasticity in brain development dictate that if multiple insults are necessary to the pathogenesis of autism, then critical events could occur before or at the time of conception, during embryogenesis, throughout gestation, at the time of parturition, and during the first year or so of life. In other words, the search for etiologic clues should not be limited to a single time window.

In comparison with the predictors of other adverse outcomes in early life such as deficits in cognitive development, perinatal mortality, or suboptimal birth characteristics (low birth weight, preterm delivery), the literature on environment and its etiologic role in autism is, on the whole, rather sparse. This chapter presents findings from large-scale epidemiologic studies that address risk and protective factors for autism. Rather than a simple summary of findings, this exposition synthesizes the literature through critical evaluation of both methods and evidence, highlighting areas in need of further investigation. Here environment is broadly defined to include exogenous factors ranging from chemicals in household products or ambient air to dietary nutrients, and from infections to injections and other medical treatments and procedures, with the exposure periods covering the periconceptional period through infancy and up until the symptoms have fully manifested. We will not concern ourselves with risk markers such as birth weight or APGAR scores. We define large-scale as a study with a minimum of 100 subjects and a minimum of 50 cases of autism.

Conducting large-scale epidemiologic studies that are entirely free of bias is virtually impossible. Nevertheless, rigorous methods applied during all three of the design, data collection, and statistical analysis phases can minimize those biases. For a summary of epidemiologic study designs and their advantages/disadvantages, see Box 47-1. A variety of textbooks can be consulted regarding data collection methodology, and similarly for statistical analysis of observational data. Ultimately, the standard by which one judges the quality of a study and hence the credibility of the findings is the degree to which the investigators have reduced the chances of confounding, selection bias, and information bias, and have conducted an analysis that is valid. In turn, validity of the statistical methods requires that they are appropriate to the design, selection process of the study participants, and data collection, and especially, to the hypothesis and aim of the investigation. A *null association*, which is the lack of a link between an exposure and an outcome, is difficult to establish and requires multiple studies (each of which is large enough and sufficiently free of bias) that together result in the weight of evidence being adequate to be deemed definitive.

Much has been written about epidemiologic study designs (Rothman, 2002; Rothman et al., 2008), but a few issues are of special concern for studies of autism: *(1)* the abundance of ecologic studies on autism, reflecting the immature state of autism epidemiology. An ecologic design and the corresponding analysis correlate rates of exposure with rates of an outcome, and are inherently the weakest approach for etiologic research (they are better suited to generating hypotheses); *(2)* the principles of control selection for etiologic epidemiology (e.g., Wacholder, McLaughlin et al., 1992; Wacholder, Silverman et al., 1992a, 1992b). The use of an

Box 47–1.

Study designs in epidemiology

Study Designs in Epidemiology	Description	Advantages	Disadvantages	Strength of Evidence
Case series	Assembly of a group of patients with similar disease or health condition profiles. Description of attributes, usually obtained cross-sectionally.	Can be conducted within a clinic, using patient population. Simple, inexpensive.	Does not provide a control group for comparison (although in some instances comparative population data may be accessible).	Very weak.
Ecologic	Division of a population, often by geographic or temporal distribution into groups. Comparison of rates of an exposure with rates of a health condition to look for correlation.	Can be conducted using pre-existing data collected for other, e.g., administrative, purposes. Inexpensive to conduct.	Lacks individual data and hence is subject to serious biases: Assumes factors not examined remain constant over time and/or across geographic regions. Control for confounders at ecologic level is usually inadequate. Ecologic fallacy can occur, whereby the subjects with exposure within a group are not those with the disease or health condition, even though exposure and disease are correlated across groups.	Weak.
Cross-sectional	Study population is selected irrespective of exposure or disease. Prevalence of exposure conditional on disease or vice versa can be calculated. Comparison of disease is made between exposed and unexposed or by level of exposure.	Data can be collected at one point or during one period of time, on both exposure and health outcome. At most, one contact with a participant is required. Individual-level data are collected on health outcomes and confounders.	Temporality of the relationship between exposure and outcome may not be discernible. Because temporality is required for causal inference, no causal inference can be made from cross-sectional studies, unless outside data on timing of exposure is available.	Moderate.
Case-control	Study population is sampled separately for cases and controls (i.e., different sampling probabilities are applied). Inclusion criteria (other than health status) must be equivalent. Associations are measured as odds ratios, representing the comparison of the odds of exposure in cases to the odds of exposure in controls. For rare health conditions, this is equivalent to the relative risk: risk of disease in the exposed vs. risk of disease in the unexposed.	Individual data are collected. Often characterized by high quality data on health outcomes. Useful for health conditions with multifactorial etiology, as many risk factors can be examined simultaneously. Similar to the cross-sectional study, data can be collected at virtually one time point or period of time, usually requiring only one contact with participant. Strengthened by collection of data on multiple potential confounding variables, especially if obtained from objective sources.	Because this is a retrospective study, obtaining high quality exposure data can be difficult. This design is subject to "reporting bias" whereby persons with a health condition may recollect their past differently than others who are not affected. Use of objective measures of exposure, such as medical records, exposure databases, or biological or environmental samples representing past exposures is recommended whenever possible.	Moderate. Can be strong if data on exposures are obtained from objective sources, or other evidence of lack of "reporting bias" can be obtained, and if outcome data are of high quality.

Box 47–1. (*Contd.*)

Study Designs in Epidemiology	Description	Advantages	Disadvantages	Strength of Evidence
Cohort	Cohort at start of the study must be free of the health condition under investigation. Cohort may be defined through a cross-sectional study (ignoring exposure distribution), or by sampling strata with and without exposure (or at different levels). Rates of incidence of the health condition are compared (using rate ratios or related derivations thereof) for those with and without exposure.	Individual data are collected. Cohort studies ensure that the exposure information is generally obtained prior to the occurrence of the outcome, permitting inference related to causality. Also, they ensure that exposure data is collected in a manner that is not influenced by the health outcome of the individual. Can be used to examine multiple health outcomes in the same study, as well as multiple exposures. Permit prospective collection of data on multiple potential confounding variables.	Depending on the length of follow-up required before sufficient numbers of cases occur, losses to follow-up can induce bias under certain conditions. Because cohort studies can assess multiple outcomes, attention to each specific outcome may be lower than in some case-control studies.	Strong. Can be moderate if quality of exposure or outcome data is weak.
Randomized clinical trial	Participants are randomly allocated to a treatment/exposure (yes/no), which is then administered, preferably in a blinded manner for the participant and the investigator. To achieve blinding, some type of placebo is necessary. Comparison of incidence of health outcome in the treated vs. placebo groups, measured by the rate ratio (or related derivation).	Provides basis for causal inference, since treatment/exposure is assigned independently of risk factors for the health outcome. If the trial is sufficiently large, random allocation can protect against major confounding.	Not an ethical design to study an exposure with potential for harm that outweighs benefits. Some participants will refuse to be in a study if they can't choose the treatment or know which group they are assigned. If treatment is complex, invasive, or causes serious side effects, compliance may be low and may give rise to confounding.	Very high, particularly if sample size is adequate to ensure that random allocation achieves even distribution of confounders across treatment groups.

inappropriate control group in a case-control study can lead to invalid results when the likelihood of an exposure in the controls differs from that of the general population that produced the cases. A single control group of children with other developmental disorders, therefore, may not be appropriate, regardless of whether the subjects are aware of their exposures. For example, pesticide exposures from proximally located agricultural fields may also be associated with other developmental deficits or conditions. Use of friend controls would similarly be inappropriate when examining any exposure that is associated with, for instance, socioeconomic status or geography because friendships tend to be formed with persons who are of similar socioeconomic level. In the extreme this would result in identical or very similar exposure distributions in controls and cases, biasing toward the null any true association with autism.

Other considerations arise during the fieldwork and analytic phases. During data collection, epidemiologists are concerned about blinding the team obtaining exposure data or conducting laboratory analyses of samples, and the degree to which recall may be influenced by an interviewer or by parents' knowledge of their child's diagnosis. Notably, biases can arise through omission and/or commission in data collection, but also in the analysis, e.g, when subjects with missing data items are excluded. Whereas the broader need for explicit conceptual models to guide analysis is recognized in many disciplines, less well-appreciated is the bias introduced by inappropriate adjustment for intermediate or marker variables. (Only under certain defined conditions will this strategy provide a valid measure of association (Petersen et al., 2006).) Understanding the conditions for generalizability is fundamental to interpreting the results and their applicability more broadly than the study source population. In assessing the adherence to sound epidemiologic principles, the abilities to transcend significance testing, to give proper relative weight to random vs. systematic error, and to distinguish the small from large biases, are paramount.

The remainder of the chapter provides a synthetic overview of the extant literature relevant to the noninherited etiologic factors in autism, highlighting promising leads that may point to causal and modifiable exposures. It is not intended, in the space available, to be comprehensive, and many relevant topics have been omitted, such as research conducted on environmental factors in relation to other neurodevelopmental impairments or psychiatric conditions. We begin with the literature on sociodemographic characteristics, focusing on how variables such as parental age, ethnicity, social class, and seasonality are a source of clues about etiology, including environmental exposures. The second section concerns medical exposures, and comprises infections and immunology, fertility treatments, obstetric factors, and vaccines. The third section in this chapter addresses traditional environmental exposures, most of which are, to some extent, involuntary: metals, pesticides, air pollutants, endocrine-disrupting chemicals, and other compounds we breathe, ingest, or absorb dermally. Finally, the limited research on lifestyle, including

smoking, alcohol, nutrients, and diet, is described, along with topics holding for future work. Throughout this chapter, the methodologic hurdles, unresolved discrepancies, and types of mechanisms implied by the results are woven into the text.

Sociodemographic Factors: Clues about Environmental Exposures

The association between sociodemographic characteristics and autism appeared early in the history of autism research, with the first descriptions of Leo Kanner (1943), who wrote that the parents of the children with autism were highly educated and very successful professionals. Since then, epidemiological studies have investigated further the associations between autism and socioeconomic status, as well as race/ethnicity, place and season of birth, parental age, and child's sex. In most of these areas, the research has produced conflicting results. Salient studies on several of these sociodemographic factors are summarized in Table 47-1.

Socioeconomic Level

The association of higher socioeconomic status (SES) with autism has been widely reported but the results are not uniform. Markers of SES included maternal education in a cohort study involving over 4,000 autism cases from California (Croen et al., 2002) and family income of a large group of cases and controls in metropolitan Atlanta (Bhasin & Schendel, 2007). Children of mothers with a postgraduate education were twice as likely to have a diagnosis of autism compared to children of mothers who did not graduate from high school, after adjustment for multiple factors, and risk rose incrementally with each increase in level of education (Croen et al., 2002). In multivariate-adjusted models for the Atlanta study, however, whenever race was significant, education was not, and the association with family income was attenuated; conversely, in models where education was significant, race was not. This co-confounding suggests the study sample had limited power to disentangle the influences of race, education, and income. Durkin and colleagues reported no association of maternal education with risk of autism after adjustment for a large number of factors (Durkin et al., 2008).

Several European studies failed to show evidence of an association with socioeconomic indicators. Fombonne and du Mazaubrun reported no difference comparing social class distribution of 134 cases in four French regions with data from the census (Fombonne & du Mazaubrun, 1992), or in a larger birth cohort study with case identification through review of medical records (Fombonne et al., 1997). In an active screening project of a birth cohort in Sweden, Gillberg et al. (1991) found no variation in rates of autism by social class, based on father's occupation. In a larger study, encompassing all births in Denmark after 1972 and diagnoses until 1999, no association was seen for either maternal education or parental wealth

Table 47–1.

Selected demographic factors and autism

Demographic Factor	Major Studies*	Design	Findings (95% Confidence Intervals)**	Strengths & Limitations: Bias, Confounding	Notes on Interpretation of Findings
Socioeconomic status	Fombonne et al. (1997)	Birth cohort, 174 cases in 1985 birth cohort, from population of 325,000.	No differences in three regions: chi-square statistics (df) were 7.3 (5), 10.9 (5), and 2.9 (4). No excess of higher SES occupations.	Occupation of the head of household was categorized based on national classification system.	Cases identified through special education records and confirmed by psychiatrist.
	Croen et al. (2002)	Birth cohort, 4,381 cases of autism from population of 3.5 million live births.	Compared with < high school education: OR = 1.4 (1.3, 1.6) for high school education OR = 1.9 (1.7, 2.1) for college education OR = 2.0 (1.7, 2.3) for postgraduate education.	SES variable was maternal education from birth certificate. Cases from California DDS*** database, derived from a passive surveillance system. Adjusted for downstream variable and multiple highly correlated variables, which may have introduced bias.	Probable underascertainment of cases among those with low education resulting from lack of active case-finding in DDS*** system. Control for birth weight, an intermediate variable, could have distorted true association in an unpredictable direction.
	Bhasin & Schendel (2007)	Case-control, 617 cases from MADDSP****, 617 population-based controls.	Median family income, (referent = middle): OR = 0.5 (0.3, 0.6) for low income, OR = 1.6 (1.2, 2.3) for high income. Maternal education (referent = 12 years) OR = 0.9 (0.6, 1.5) for <12 years, OR = 0.9 (0.6, 1.2) for 13 to 15 years, OR = 0.9 (0.6, 1.3) for 16 years, OR = 1.3 (0.8, 1.6) for 16+ years.	SES variables were: maternal education (individual-level) and family income (median in Census tract of mother's residence). Strong association with income but not education in adjusted models (but not unadjusted) may have been a result of high correlation between these variables and also with maternal age and race.	Although difficult to tease apart which SES factor is most related, SES does show a strong association with autism diagnoses, even in this population-based study that used active case finding from review of existing medical and school records.
	Durkin et al. (2008)	Birth cohort from CDC's ADDM***** network; 1,251 cases from a population of 250,000 births.	Compared with high school graduates, OR = 1.0 (0.8 or 0.9, 1.2) for each of the other levels of education.	Large multisite study with standardized criteria for case definition. SES variable = maternal education. Adjusted for numerous covariates. Adjusted for downstream (potentially intermediate) variables (gestational age and birth weight for gestational age), which may have introduced bias.	Large study with standardized case definition and active case-finding methods. Lack of association between maternal education and autism may be a result of high correlation with maternal age and adjustment for potential intermediate variables.
	Larsson et al. (2005)	Case-control, 698 cases, 17,450 controls from all births in Denmark in the year 1972.	Compared with elementary education, OR = 0.92 (0.75, 1.13) for high school or some college, OR = 0.89 (0.67, 1.19) for baccalaureate, master's or doctoral degree. Compared with highest quartile of wealth, OR = 0.83 (0.67, 1.02) for high-middle wealth, OR = 1.09 (0.85, 1.38) for low-middle wealth, OR = 1.30 (0.97, 1.75) for lowest quartile.	SES variables were parental income and maternal education. Adjusted for birth characteristics (APGAR score, birth weight for gestational age, gestational age), as well as prenatal care; these variables could have been intermediates on a causal pathway, potentially resulting in biased ORs.	Large study. Provides marginal evidence for higher risk among children of lower-income families. This and the lack of association between maternal education and autism may have stemmed from adjustment for intermediate variables and/or close association of income, education and both parental ages. Alternatively, there may be no association in a country with a high level of access for all.

	Baird et al. (2006)	Population cohort in South Thames, UK, 81 cases of autism.	Compared with children whose parents had not completed secondary education, OR = 5.0 (1.99, 12.7) for those whose parents had at least a secondary education.	Two-stage case ascertainment beginning with screening from special needs register for child health services. Study assessed proportion of identified cases that had been previously identified by locally based assessment.	Study design was able to identify significantly lower ascertainment of ASD in children born to parents of low education using records based on existing diagnoses made locally. In contrast, the complete ascertainment indicated no SES association with ASD.
Immigrant status	Lauritsen et al. (2005)	Population cohort, with 818 incident autism cases from Danish Psychiatric Central Register of population of 944,000 births.	Compared with children whose mothers were born in Denmark, OR = 1.42 (1.10, 1.83) for maternal birthplace outside Europe.	Adjusted for child's age, gender, calendar year of diagnosis, age of each parent, history of psychiatric disorders in the mother, father, or sibling, and urbanicity of residence.	Large sample size, and relatively thorough adjustment for covariates. Provides some evidence for parental place of birth effect, but some of the adjustment variables could have been downstream, potentially biasing the results.
	Hultman et al. (2002)	Case-control: 408 cases 2,040 controls, population-based in Sweden and matched on sex, year, and hospital of birth.	RR = 3.0 (1.7, 5.2) for maternal birth outside Europe or North America.	Linked Swedish national registries for births and inpatients. Adjusted for numerous confounders such as maternal age, parity, country of birth, smoking, hypertensive diseases, etc. Unclear whether results shown were also adjusted for some downstream factors such as delivery type, birth weight, and child's APGAR score.	Population-based study with comprehensive data on maternal medical conditions and labor and delivery factors. Based on inpatient records for autism spectrum disorders, and hence may include only most severe cases. Controlled for confounders; may have inappropriately adjusted for downstream variables, which could have biased the RR.
	Gillberg et al. (1991)	Population cohort of children born 1975 through 1984 in city of Goteborg or county of Bohuslan, and residing in the same locale in 1988, n = 77,000.	RRs not given, explicitly: 11.6/10,000 prevalence in Goteborg, vs. 7.2/10,000 in rural area where no immigration was said to occur.	No clear denominator data on immigration in the population. Immigrants were from a variety of regions: other Nordic countries, Central and Southern Europe, England, Asia, Africa, and South America.	Authors assert that the increase in prevalence from a previous survey was accounted for by autism diagnoses in immigrant children.
Parental age (maternal, paternal, or both)	Lauritsen et al. (2005)	Population cohort, with 818 incident autism cases from Danish Psychiatric Central Register of population of 944,000 births.	Compared with mothers 25 to 29 years of age, OR = 1.68 (1.07, 2.63) for ages <20 years, OR = 1.19 (0.96, 1.47) for ages 20 to 24, OR = 1.08 (0.89, 1.29) for ages 30 to 34, OR = 1.18 (0.92, 1.53) for ages 35 to 39, OR = 1.17 (0.90, 1.97) for ages 40+. Compared with fathers 25 to 29 years of age, OR = 0.81 (0.60, 1.09) for ages <25 years, OR = 1.08 (0.89, 1.29) for ages 30 to 34, OR = 1.35 (1.07, 1.70) for ages 35 to 39, OR = 1.61 (1.19, 2.18) for ages 40 to 44, OR = 1.21 (0.78, 1.86).	Adjusted for child's age, gender, calendar year of diagnosis, parental education, history of psychiatric disorders in the mother, father, or sibling, and urbanicity of residence.	Relatively large sample size and thorough adjustment for confounders. If ages of the two parents were highly correlated, ability to distinguish independent effects of either one would have been limited. Demonstrates increasing risk with advancing age for both mothers and fathers.

Table 47–1. (Contd.)

Demographic Factor	Major Studies*	Design	Findings (95% Confidence Intervals)**	Strengths & Limitations: Bias, Confounding	Notes on Interpretation of Findings
Parental age (con't)	Larsson et al. (2005)	Case-control, 698 cases, 17,450 controls from all births in Denmark in the year 1972.	Compared with mothers 25 to 29 years of age, OR = 1.54 (0.87, 2.74) for ages <20 years, OR = 1.03 (0.80, 1.34) for ages 20 to 24, OR = 1.18 (0.95, 1.48) for ages 30 to 34, OR = 1.07 (0.76, 1.52) for ages 35 to 39, OR = 1.55 (0.87, 2.74) for ages 40+. Compared with fathers 25 to 29 years of age, OR = 0.61 (0.42, 0.89) for ages <25, OR = 1.10 (0.88, 1.38) for ages 30 to 34, OR = 1.28 (0.96, 1.69) for ages 35 to 39, OR = 1.36 (0.96, 1.93) for ages 40+.	SES variables were parental income and maternal education. Analysis of age of each parent adjusted for age of the other. Adjusted for birth characteristics (APGAR score, birth weight for gestational age, gestational age), as well as prenatal care; these variables could have been intermediates on a causal pathway, potentially resulting in biased ORs.	Large study. Appears to suggest a U-shaped relationship of maternal age with autism risk. However, adjustment for intermediate variables or for multiple variables correlated with parental age may have constituted overadjustment, potentially leading to attenuated ORs. High correlation between the two parents' ages may have hampered ability to accurately measure independent effects.
	Reichenberg et al. (2006)	Cohort of military conscriptees, n=319,000 for paternal age analysis, n=132,000 for maternal age analysis, born over 6 consecutive years (dates not specified) in Israel.	Compared with mothers 15 to 29 years of age, OR = 0.87 (0.54, 1.41) for ages 30 to 39, OR = 2.68 (0.81, 8.96) for ages 40+. Compared with fathers 15 to 29 years of age, OR = 1.62 (0.99, 2.65) for ages 30 to 39, OR = 5.75 (2.65, 12.46) for ages 40 to 49.	Diagnoses generally made by clinical team. Analysis of age of each parent adjusted for age of the other. Maternal age available for less than half the cohort; paternal age for 84%. Adjusted for socioeconomic status, but this variable was not defined. Wide age range for the referent group. Small cell sizes for parents over age 40 years, especially mothers.	High proportion missing maternal information, which may have been related to parents' ages. Small cell sizes resulted in large random error. High correlation between the two parents' ages and the wide age range of the referent group limited ability to accurately measure independent effects. Adequacy of adjustment for SES is indeterminate.
	Croen et al. (2007)	Cohort of 133,000 births 1995 through 1999 in a northern California HMO. Autism/ASD cases diagnosed by April 2005.	Compared with mothers 25 to 29 years of age, OR = 0.62 (0.30, 1.27) for ages <20 years, OR = 0.86 (0.62, 1.18) for ages 20 to 24, OR = 1.04 (0.83, 1.31) for ages 30 to 34, OR = 1.18 (0.92, 1.53) for ages 35-39, OR = 1.27 (0.83, 1.95) for ages 40+. Compared with fathers 25 to 29 years of age, OR = 0.45 (0.15, 1.41) for ages <20, OR = 0.86 (0.57, 1.30) for ages 20 to 24, OR = 1.14 (0.89, 1.48) for ages 30 to 34, OR = 1.38 (1.04, 1.84) for ages 35 to 39, OR = 1.52 (1.10, 2.10) for ages 40+.	Diagnoses based on ICD criteria applied to medical records. Used proportional hazards model to adjust for differences in length of follow-up by date of birth. Adjustment for four socioeconomic factors (both parents' educational levels, both parents' race ethnicity), and adjustment for the other parent's age may have constituted overadjustment, given that these six variables may have had strong correlations among them. This could have biased estimates of some of these variables, including parental ages.	For ASD, results of each parent's age, modeled as a continuous variable and adjusted for the other, were similar. For autistic disorder, paternal age appeared to have a stronger effect. High quality, carefully constructed and consistent diagnostic criteria applied for ASD definition. Authors correctly refrained from adjusting for birth characteristics. The use of proportional hazards models assumes that censoring is independent of outcome, which may not be the case, given the strong temporal trend of autism in California.

Durkin et al. (2008)	Birth cohort from CDC's ADDM***** network; 1,251 cases from a population of 250,000 births.	Compared with mothers 25 to 29 years of age, OR = 0.7 (0.5, 1.0) for ages <20 years, OR = 0.9 (0.8, 1.1) for ages 20 to 24, OR = 1.1 (0.9, 1.3) for ages 30 to 34, OR = 1.3 (1.1, 1.6) for ages 35+. Compared with fathers 25 to 29 years of age, OR = 0.6 (0.4, 1.0) for ages <20, OR = 0.9 (0.7, 1.1) for ages 20 to 24, OR = 1.0 (0.9, 1.2) for ages 35 to 39, OR = 1.4 (1.1, 1.8) for ages 40+.	Large multisite study with standardized criteria for case definition. Analysis of age of each parent adjusted for age of the other and for numerous SES factors, as well as for site. Adjusted for downstream (potentially intermediate) variables (gestational age and birth weight for gestational age), which may have introduced bias.	Large study with standardized case definition and active case-finding methods lends confidence in the data quality. Some attenuation of the associations for both maternal and paternal age could have occurred because of adjustment for intermediate variables. Nevertheless, provides strong evidence that both maternal and paternal age contribute to increased risk for autism in offspring.
Shelton et al. (2010)	Population cohort of 5 million births 1990 through 1999, in California. ASD cases, n = 12,000 from statewide DDS* system.	Compared with mothers 25 to 29 years of age, OR = 0.86 (0.80, 0.92) for ages <25, OR = 1.12 (1.06, 1.19) for ages 30 to 34, OR = 1.31 (1.22, 1.41) for ages 35 to 39, OR = 1.51 (1.35, 1.70) for ages 40+. Compared with fathers 25 to 29 years of age, OR = 0.76 (0.71, 0.82) for ages <25, OR = 1.10 (1.04, 1.18) for ages 30 to 34, OR = 1.24 (1.15, 1.33) for ages 35 to 39, OR = 1.36 (1.26, 1.47) for ages 40+. However, these values were heterogeneous for fathers, depending on the mothers' age. For mothers 30+ years of age, paternal age was not a significant risk factor for ASD.	Very large cohort of 5 million births, data on covariates quite complete. DDS ascertainment is estimated to be 75 to 80% complete. Father's age missing for 9.6% of controls, 7.0% of cases.	Extremely large cohort with small percentage of missing data. Finely stratified analysis with adjustment for covariates indicated consistent increases in ASD risk as maternal age increased, regardless of paternal age. Similar analysis showed increases in ASD risk for paternal age only when mother was <30 years of age. This study was unique in assessing heterogeneity of age effects of each parent's age stratified on other parent's age.

*Major studies included those with at least 50 cases and 100 total subjects. However, no attempt was made to be comprehensive or complete.

**All findings shown in this table are multivariate adjusted associations.

***DDS = Department of Developmental Services of the State of California, an agency that coordinates services for persons with developmental disorders who have functional disabilities, but does not conduct active case finding.

****MADDSP = Metropolitan Atlanta Developmental Disabilities Surveillance Program, which conducts active case finding using school and medical records.

*****ADDM = Autism and Developmental Disabilities Monitoring Network, a CDC program that conducts active surveillance in various selected states within the United States.

(Larsson et al., 2005). Baird and colleagues, reporting results from the UK using an active case finding through screening and assessment, noted that existing local records showed a strong underascertainment of autism cases among children from parents with low education: children of parents who completed secondary education had fivefold higher odds of having a previous diagnosis of autism, among those identified from the active screening program (Baird et al., 2006).

Taken as a whole, evidence supporting an association with higher SES largely comes from the United States or from databases with passive surveillance and the resultant underascertainment. Where cases are identified through active screening, population-wide surveillance is conducted, or access to health care is universal (Denmark, France, and Sweden), socioeconomic differentials tend not to be found (Larsson et al., 2005; Fombonne et al., 1997; Gillberg et al., 1991). Associations with social class therefore may represent a greater rate of success when parents with higher education advocate for their children as compared with those having less education. Based on the evidence to date, socioeconomic differences seem unlikely to reveal clues about environmental factors in the development, as opposed to the clinical diagnosis, of autism.

Race/Ethnicity

Reported differences in prevalence by race and ethnicity have not been consistent. In California, one report found African-American children were at higher risk for autism compared with Caucasian children (Croen et al., 2002). As a high percentage of African-Americans in California reside in Los Angeles, where overall reporting of autism in the Department of Developmental Services (DDS) system is greater than elsewhere in the state, this finding may be spurious as a result of confounding by geography. In addition, Hispanic children in California were less likely than Caucasians to have an autism diagnosis, possibly due to language barriers and reluctance of families with an undocumented parent or other relative to report to centers affiliated with DDS, a state agency. In contrast, Yeargin-Allsopp et al. (2003) did not find any association between race and autism in a study from metropolitan Atlanta using all sources, with results varying by source of diagnostic information (health records, schools). In a study of Medicaid-eligible children who later were diagnosed with autistic disorder (AD), African-Americans were far less likely to receive an ASD diagnosis on their first visit (Mandell et al., 2007) and were more than 1.5 years older at diagnosis with AD than Caucasian children (Mandell et al., 2002). Most recently, based on ASD prevalent cases at 8 years of age, confirmed by the CDC's Autism and Developmental Disabilities Monitoring multisite network that reviewed records from multiple sources, Mandell and colleagues (Mandell et al., 2009) determined that after adjustment for confounders, African-Americans, Hispanics and other races/ethnicities were less likely to have documentation of an ASD diagnosis in their records; for Hispanics and other racial/ethnic groups, this was especially true for children with intellectual disabilities.

It appears that race differences in autism rates may stem from differences in care-seeking and clinician practices. Combined with evidence of an ASD diagnostic artifact associated with socioeconomic level and the correlation of race/ethnicity with SES, this line of inquiry seems to have a low probability of yielding true etiologic leads but can 'underscore' concerns related to access.

Place of Birth and of Residence (Immigration and Geography)

Place of birth or residence has been reported to be associated with autism. Living in an urban, as compared with rural, area is associated with a higher prevalence of autism (Gillberg et al., 1991; Lauritsen et al., 2005; Hultman et al., 2002). Because health providers tend to be concentrated in urban centers, this phenomenon is likely an artifact of greater access to qualified diagnosticians.

An effect of immigration has been reported from several parts of the world. In Denmark, children of mothers born outside of Europe (Lauritsen et al., 2005) or with non-Danish citizenship (Maimburg & Vaeth, 2006) were at increased risk; a British study found a greater risk for autism among second generation Afro-Caribbean immigrants than among other British-born children (Goodman & Richards, 1995); in Australia, children whose mother was born outside the country were at increased risk (Williams et al., 2008), with the highest risk in those from southeast or northeast Asia. In Sweden, an early study suggested that increases in autism risk in an urban area resulted from immigration (Gillberg et al., 1991). More recently children in Sweden whose mothers' birthplace was outside Europe and the United States had an elevated risk of autism (Hultman et al., 2002).

The principal environmental hypotheses that have emerged from these studies are: mothers born elsewhere may be more susceptible to unfamiliar microbial exposures in their newer place of residence; or social stresses associated with emigration and subsequent social integration may put the fetus/infant at higher risk, possibly mediated by placental enzymes involved in cortisol metabolism (O'Donnell et al., 2009).

Parental Age

Inconsistent results have been reported regarding the association between parental age and autism. A number of large studies reported an association with advanced maternal age (Bhasin & Schendel, 2007; Croen et al., 2002; Durkin et al., 2008; Glasson, 2002) and/or advanced paternal age after adjustment for maternal age (Reichenberg et al., 2006; Lauritsen et al., 2005; Croen et al., 2007; Glasson, 2002; Durkin et al., 2008). However, one found a significant inverse relationship (Burd et al., 1999) and another found neither parent's age to be predictive (Larsson et al., 2005). Investigations used variable approaches to adjusting for the other parent's age, or other factors. Interpretation of studies is hampered, in part by adjustment for variables that are on the causal pathway

or serve as intermediate markers for high risk (e.g., obstetric or fetal conditions); this approach is common and may, rather than control bias in estimated age effects, actually create bias in either direction (towards or away from the null value).

Moreover, the high correlation between advanced maternal and paternal age at procreation is difficult to disentangle and some studies lacked the statistical power to do so, despite having conducted multivariate analyses. Shelton et al., however, in a study that was far larger than any other on this topic, implemented tight control by examining each parent's age after restricting to relatively narrow age strata of the other parent. This analysis showed a consistent maternal age effect. In contrast, paternal age was influential only in younger mothers, those below 30 years of age (Shelton et al., 2010). This study thus demonstrated an independent effect of maternal age, regardless of the paternal age, and an effect of paternal age that was dependent on maternal age.

Notably, paternal age is more frequently missing than maternal age, and the analyses that mutually adjust are therefore limited to the subset of births with a nonmissing value for paternal age. If data absence is more common in younger fathers (e.g., Mouridsen et al., 1993) and less common for cases (for instance, if men on the broader spectrum who have children, do so later), then the paternal age association may be overestimated.

Most importantly, the effects of maternal and paternal age raise the issue: what is it about older mothers and fathers that is disadvantageous for the offspring? That advancing maternal and paternal age are each associated with chromosomal aberrations, low birth weight, and congenital malformations is certainly relevant (Berkowitz et al., 1990; Djahanbakhch et al., 2007; Meacham & Murray, 1994; Reichman & Teitler, 2006). Older mothers, who often have older fathers as partners, are more likely to use fertility treatments or other assisted reproductive technologies and even if conceived naturally, the ova are older and more biologically vulnerable to chromosomal aberrations. Paternal de novo mutations or epigenetic dysregulation of spermatogonia cells have been hypothesized to underlie the association of schizophrenia with increasing paternal age (Perrin et al., 2007). The ever-increasing number of spermatogonial divisions offers multiple opportunities for age-related de novo chromosomal aberrations and possible changes in methylation patterns (Sartorius & Nieschlag, 2010). Older age of fathers is associated with increased telomere length in spermatozoa. Whether these vulnerabilities for both maternal and paternal age are programmed or result from an accumulation of insults remains unclear.

Other mechanisms suggested by maternal aging include: placental insufficiency or an increased prevalence of cardiovascular conditions such as chronic or gestational hypertension, both of which could lead to hypoxia; a less favorable hormonal milieu than occurs with younger mothers; a higher body burden of toxic chemicals; and/or a less efficient development of tolerance for "nonself" stemming from age-related increased tendency toward autoimmune responses.

Specific classes of environmental exposures worthy of further investigation based on the evidence regarding parental age include reproductive technologies (see section of this chapter "Medical Factors," subsection "Medical Intervention"), endocrine disruptors and compounds that bioaccumulate or are persistent in human tissues (see section of this chapter: "Chemicals in the Environment," subsection "Endocrine Disruptor"), as well as factors influencing vascular function, or immune toxins.

Sex

One of the consistent demographic findings in autism is a higher prevalence among males as compared with females. Typically, the ratio is around 4:1, with sizeable variation from study to study (Fombonne, 2003). Mechanisms hypothesized to be responsible for this skewed sex ratio include endogenous hormones (Knickmeyer & Baron-Cohen, 2006) or epigenetic alterations such as X-chromosome inactivation (Nagarajan et al., 2008). By extension, exogenous endocrine disruptors might also play a role. An altered sex ratio at birth, favoring females, has been associated with several persistent endocrine-disrupting chemicals such as 2-, 3-, 7-, 8-tetrachlorodibenzo-dioxin (dioxin)(Mocarelli et al., 2000), and polychlorinated biphenyl ethers (PCBs) (Hertz-Picciotto et al., 2008); the PCBs are also associated with intrauterine growth restriction in males but not in females (Vartiainen et al., 1998; Hertz-Picciotto et al., 2005; Sonneborn et al., 2008). Thus, male sperm, embryos, or fetuses appear to be more susceptible to certain types of preconceptional, periconceptional, or prenatal insults, respectively. Other childhood conditions in which males are disproportionately affected are ADHD, childhood leukemia, and childhood asthma, all of which have seen increases in the last decades.

Seasonality

Seasonality of births has been well-studied for other developmental and psychiatric conditions, particularly schizophrenia (Boyd et al., 1986; Torrey et al., 1977; Parker & Neilson, 1976). An excess of winter births suggested an etiologic role for infectious agents, and indeed, a higher rate of schizophrenia was confirmed for children exposed during their second trimester *in utero* to an influenza epidemic in Helsinki (Mednick et al., 1988). Brown and coworkers reported serological evidence that maternal influenza infections in the first half of pregnancy were more prevalent for cases of schizophrenia than for controls (Brown et al., 2004).

Several research groups have examined seasonal birth patterns in autism. Two separate teams reported March and August to be months of excess births of children who developed autism. One was a case-control study in North Carolina of 810 children with autism and 768 unaffected controls (Bartlik, 1981), and another used the birth registry in Israel (Barak et al., 1995). Two other studies found excess births in March but not in August (Gillberg, 1990;

Mouridsen et al., 1994). Larger studies using more sophisticated methods found discrepant results and no evidence for a March or August excess (Bolton et al., 1992; Landau et al., 1999). A new analysis based on a very large dataset from the California DDS showed November to be a high risk birth month. Reports that focused on season rather than month gave inconsistent results (Atladottir et al., 2007; Tanoue et al., 1988), though two found winter to be a low-risk period (Konstantareas et al., 1986; Lee et al., 2008).

Methodologically, the lack of consistency in findings across studies could be a result of geographic variation in seasonality, but may also be a result of misclassification resulting from differing definitions of season, small sample sizes, and variation in lengths of gestation. With respect to the latter, if there is a critical window during the prenatal developmental period when the insult predisposes to aberrant development, then dates of conception rather than births would provide a more accurate measure of the relevant period. The finding by Lee et al. (2008) that the peak excess for multiple births was 2 to 3 weeks earlier than for singletons supports the notion that dating from conception would be less error-prone, as multiple births tend to deliver earlier than singletons. Using the California DDS data, Zerbo and colleagues found higher risks for children who were conceived in the winter months, December through March (Zerbo et al., in press).

What etiologic clues do these studies provide? Although the March birth excess is a recurrent finding, the inconsistent results underscore the need for more rigorous research, either using season of conception or through investigation of seasonally variable factors in tandem with mechanistic biologic studies. Just as parental age is a surrogate for numerous possible causal factors, seasonality represents variation in the meteorologic (temperature, rainfall), infectious, allergenic (pollen), dietary, and chemical (e.g., pesticides in agriculture and for home pest control) environments. Several of these exposures are discussed in later sections of this chapter.

Medical Factors: Infections and Immunology, Fertility Treatment, Obstetric Factors, Medications, and Vaccines

The higher risk for autism after complicated pregnancy, labor, or delivery or in association with neonatal suboptimality is a recurring theme. The literature is not, however, entirely consistent about which of these conditions or events is informative. A recent meta-analysis based on 40 investigations that evaluated a wide range of maternal factors (sociodemographic, as well as medical) concluded that evidence was insufficient for any single prenatal factor (Gardener et al., 2009). In practical terms, the origins of maternal and perinatal conditions may be ill-defined: microbiological insults, pregnancy complications, medical interventions, characteristics of labor and delivery, and infant attributes may influence each other, as well as early child neurobehavioral trajectory but

could also be influenced by aberrant CNS development. Thus, the findings presented regarding medical factors are fundamentally descriptive, yet all pertain to fetal stress, in the broad sense of the term. For this chapter, the specific medically related stressors covered are: infection; immunologic development; medical interventions for subfertility, diagnostic ultrasonography, or to facilitated delivery, medical conditions of the mother; and vaccines in childhood. The focus is on upstream factors rather than measures of infant health status such as APGAR scores or low birth weight. Table 47-2 summarizes prominent studies on maternal health conditions, both acute and chronic, as well as on medical procedures.

Infections and Immunology

Early evidence about infections as a cause of autism arose from an epidemic of rubella several decades ago. Data from two separate studies of 243 and 64 congenital rubella cases, respectively, found risks of autism between 4% and 12% (Chess, 1971, 1977; Desmond et al., 1967), in a time period when prevalences were reported at less than five per 10,000 (Fombonne, 2003). Thus, the relative risk could well have been over 100. Deykin and MacMahon conducted a case-control study comparing children with autism to their siblings, adjusting for sibship size, using interviews and medical record reviews to assess encephalitic infections. They examined the hypotheses of associations between autism and clinical infections of the mother during the gestational period, of the child in the first 18 months of life, or of another household member during these periods (Deykin & MacMahon, 1979). The mothers were more likely, during gestations of cases as compared with siblings, to have had or been exposed to rubella (RR = 3.3, p = 0.004), measles (RR = 5.5, p = 0.04), mumps (RR = 5.5, p = 0.04), or influenza (RR = 4.1, p = 0.0006). The cases themselves were more likely than their siblings, during the first 18 months of life, to have had or been exposed to mumps (RR = 2.8, p = 0.007), chicken pox (RR = 2.1, p = 0.02), ear infections (RR = 1.2, p = 0.0003), or fever of unknown origin (RR = 2.1, p = 0.0003). A comparison of medical records vs. parental reports showed differences in reporting of exposures of cases vs. siblings, but they were small, with cases sometimes more often and sometimes less often exposed; hence any bias from differential recall is unlikely to have been large. Notably, reliance on medical records alone missed a large proportion of illnesses reported by the parents; this has implications for interpretation of medical databases. Information on timing of illnesses was not available but published data suggest congenital rubella is less probable when the maternal infection occurs late in pregnancy (Peckham, 1985). Because of effective vaccination programs, most of the aforementioned illnesses are extremely rare today; however, ear infections, influenza, and unexplained fevers are still relevant. A meta-analysis of studies through March 1994 found maternal infections to be significantly associated with autism in four studies that controlled for covariates, but not in seven studies that did not (Gardener et al., 2009).

Table 47–2.

Medical factors and autism

	Major Studies*	Design	Findings**	Strengths & Limitations: Bias, Confounding	Notes
Medical Interventions in Preconception or Pregnancy					
Assisted conception	Maimburg & Vaeth (2007)	Case-control; 461 cases, 461 controls.	OR = 0.37 (0.14, 0.98).	Sample size was borderline adequate as only 10 assisted conceptions among cases. Analysis inappropriately adjusted for factors potentially influenced by the exposure: multiplicity, birth weight, gestational age, and birth defect.	Multiplicity is a common consequence of assisted conception and therefore adjustment may have strongly biased the OR.
Antenatal ultrasound	Grether et al. (2009)	Case-control; 362 cases, 393 controls.	OR = 1.06 (0.95, 1.20) for each additional scan at any time during pregnancy.	Analysis adjusted for potential confounders. Elevated risk was observed for females in relation to second trimester ultrasounds.	Number of ultrasounds may not measure the dose to the fetus based on intensity and duration of scan, and location of transducer relative to fetal tissue of concern.
Rhogam	Miles & Takahashi (2007)	Case series; diverse comparison populations, 214 cases.	OR = 1.00 (0.47, 2.16) using de novo chromosomal disorder as controls. OR = 1.02 (0.7, 1.48), OR = 0.85 (0.61, 1.27) using larger populations as controls.	Cases confirmed. Small or poorly defined comparison groups. No confounder adjustment.	Only one analysis was for anti-D immunoglobulin, with four exposed controls (i.e., statistical power was low). Race/ethnicity potentially confounded the comparison with a large control group.
Infections in Pregnancy					
Rubella	Chess (1971, 1977)	Case series; 243 cases implicit comparison with general population.	RR = 100 assuming population background prevalence of 4/10,000.	Formal diagnostic criteria not applied. Children with congenital rubella have a wide range of developmental conditions (e.g., hearing impairments, cognitive deficits, etc.), making autism diagnosis difficult.	Some of the children appeared to recover. The RR is based on only those showing no recovery.
Rubella, measles, mumps, influenza	Deykin & MacMahon (1979)	Case-control; 163 cases, 355 sibling controls.	RR = 3.3 for rubella, RR = 5.5 for measles, RR = 5.5 for mumps, RR = 4.1 for influenza.	Study used sibling controls. High proportion of obstetric records obtained for both the cases and sibling controls, and confirmation of parental report in medical records was similar for cases and sibling controls. Careful screening of confounders. Possible exaggerated p-values due to multiple siblings per family.	Well conducted. Rubella finding confirms results from case series. Consistency across viral conditions with known encephalitic sequelae could support an inflammatory mechanism. Excellent response rate and validity of data appears high, with little evidence of reporting differences for case vs. sibling pregnancies.
Miscellaneous infections	Gardener et al. (2009)	Meta-analysis of various demographic, reproductive and obstetric factors.	OR = 1.82 (1.01, 3.30 in four studies that controlled for covariates or used sibling controls. OR = 0.89 (0.56, 1.42) in seven studies that did not.	Unclear which studies or which infections were included in the calculations, whether they combined several infections from the same study, nor whether the same infections were examined in multiple studies or not.	This meta-analysis suggests maternal infections during pregnancy may play a role, but the findings are nonspecific and may include both viral and bacterial.

Table 47–2. (Contd.)

	Major Studies*	Design	Findings**	Strengths & Limitations: Bias, Confounding	Notes
Medical Conditions					
Diabetes	Hultman et al. (2002)	Case-control; 408 cases, 2,040 controls, population-based and matched on sex, year, and hospital of birth.	RR = 1.2 (0.3, 5.7).	Linked Swedish national registries for births and inpatients. Adjusted for numerous confounders such as maternal age, parity, country of birth, smoking, hypertensive diseases, etc. Unclear whether results shown were also adjusted for some downstream factors such as delivery type, birth weight, and child's APGAR score.	Population-based study. Comprehensive data on maternal medical conditions, and labor and delivery factors. Low prevalence of diabetes was main weakness. Possible bias from controlling for intermediate factors. Based on inpatient records for autism spectrum disorders, and hence may include only most severe cases.
Preeclampsia	Glasson et al. (2004)	Case-control; 465 cases, 481 sibling controls, 1,313 population-based controls.	Unadjusted analysis,*** using population controls: RR = 0.99 (0.66, 1.50).	Large study using Western Australian state medical database for 14 years, covering 90% of diagnoses. Diagnostic reports were reviewed by pediatrician, and in last few years, by pediatrician, speech pathologist, and clinical psychologist.	Similar results were found using sibling controls. Lack of control for confounders, especially parity, hampers interpretation due to likely confounding.
	Hultman et al. (2002)	Case-control; 408 cases, 2,040 controls, population-based and matched on sex, year, and hospital of birth.	RR = 1.6 (0.9, 2.9) for "hypertensive diseases," ICD8 codes 401 and 637 (essential benign hypertension, and eclampsia, preeclampsia and toxemia) and ICD9 code 642 hypertensive disorders affecting pregnancy, childbirth and the postpartum period).	Linked Swedish national registries for births and inpatients. Adjusted for numerous confounders such as maternal age, parity, country of birth, smoking, etc., but also for some downstream factors such as delivery type and gestational age.	Population-based study. Comprehensive data on maternal medical conditions, and labor and delivery factors. Possible bias from controlling for intermediate factors. Based on inpatient records for autism spectrum disorders, and hence may include only most severe cases.
	Wallace et al. (2008)	AGRE database; (n = 228). Study of predictors of severity of autism signs.	Higher scores on communication domain of ADI-R for those with: preeclampsia (2.71 pts, SE = 1.16), hypertension (2.42 pts, SE = 0.75), generalized edema (2.25 pts, SE = 0.87).	Medical histories were self-reported. Used mixed effects model to account for correlations of twins and siblings within families.	Multiplex families only. Specificity of findings for the communication but not social domain.

Labor & Delivery

Delivery: C-sections	Glasson et al. (2004)	Case-control; 465 cases, 481 sibling controls, 1,313 population-based controls.	RR = 1.83 (1.32, 2.54) for elective C-sections. No adjusted analyses were presented for emergency C-sections.	Large study using Western Australian state medical database for 14 years, covering 90% of diagnoses. Diagnostic reports were reviewed by pediatrician, and in last few years, by pediatrician, speech pathologist, and clinical psychologist. Adjusted for maternal age, birth order, birth year, threatened abortion, and fetal distress.	Sample size adequate. Appropriate control group. Systematic review of diagnoses. Potential residual confounding if birth years were not well-matched between cases and controls, especially since use of C-sections may have been rising sharply during this time period. An adjusted analysis of emergency C-sections was not presented.
	Hultman et al. (2002)	Case-control; 408 cases, 2,040 controls, population-based and matched on sex, year, and hospital of birth.	RR = 1.6 (1.1, 2.3).	Linked Swedish national registries for births and inpatients. Adjusted for numerous confounders such as maternal age, parity, country of birth, smoking, hypertensive diseases, etc., but also for some downstream factors such as child's APGAR score.	Population-based study. Controlled for confounders. Comprehensive data on maternal medical conditions and labor and delivery. Possible bias from controlling for intermediate factors. Based on inpatient records for autism spectrum disorders, and hence may include only most severe cases.
Induction of labor	Glasson et al. (2004)	Same as above.	Unadjusted analysis*** using population controls: RR = 1.40 (1.03, 1.90) using sibling controls, RR = 1.43 (1.12, 1.83) using population controls.	Same as above.	

Postnatal Medical Factors

MMR vaccines	DeStefano et al. (2004)	Case-control; 624 cases, 1,824 controls, matched on age, gender and school.	OR = 0.93 (0.66, 1.30) for first MMR vaccine before 18 months of age, OR = 0.99 (0.63, 1.55) for first MMR vaccine before 24 months of age.	Adjusted for maternal age, education, multiplicity and birth weight. Assessed timing of MMR.	Earlier vs. later MMR vaccine was not associated with development of autism.

(*Continued*)

Table 47–2. (Contd.)

	Major Studies*	Design	Findings**	Strengths & Limitations: Bias, Confounding	Notes
Postnatal Medical Factors					
MMR vaccines (con't)	Taylor et al. (1999)	Case series; 498 cases	Fold differences in mean age at diagnosis: 0.93 (0.81, 1.08) for children vaccinated after 18 months of age, 0.91 (0.79, 1.05) for children vaccinated before 18 months of age, where referents were unvaccinated.	No control group. Prevalence rates were reported but methods for calculation and definition of denominator were absent.	No comparison of those with vs. without autism. Focus, instead, was on age at diagnosis. Because it was a case series, calculation of an RR comparing incidence in children receiving vaccinations late, early or never, was not possible.
	Smeeth et al. (2004)	Case-control; 1,294 cases, 4,469 controls matched on year of birth, sex, and practice.	All children: OR = 0.86 (0.68, 1.09). Children who joined GPRD*** by 1 year of age: OR = 1.47 (0.84, 2.57). Children who joined later: OR = 0.75 (0.57, 0.97).	Blind review of medical records for vaccine status. No adjustment for demographic confounders such as parental age or social class; no adjustment for calendar time.	Large study with sensitivity analyses of timing of MMR. Blinded record abstraction. Large difference in OR for children who joined GPRD after 1 year of age (majority of children in study) suggests misclassification bias from unknown vaccinations obtained prior to joining GPRD. Confounding uncontrolled.
	Madsen et al. (2002)	Full population cohort; (n = 537,303; vaccinated n = 440,655; unvaccinated n = 96,658).	OR = 0.92 (0.68, 1.24) for autistic disorder, OR = 0.83 (0.65, 1.07) for other ASDs.	Controlled for many confounders but not for maternal age, and control for calendar time was crude. Extremely high percentage missing gestational age at delivery (51% of unvaccinated, 27% of vaccinated); method of adjustment for missingness known to bias other associations.	Large study comparing those who did vs. did not receive MMR. Unclear whether the unvaccinated varied by birth year. Possible confounding and bias resulting from analytic strategies.

*Major studies included those with at least 50 cases and 100 total subjects. However, no attempt was made to be comprehensive or complete.

**All findings shown in this table are multivariate adjusted associations, unless otherwise noted.

***For these outcomes, Glasson et al. did not report any adjusted analyses.

****GPRD = General Practice Research Database, a consortium of pediatric practices across the UK.

A study that recruited cases through the Autism Society of America found self-reports of viral infections were far more common for mothers of children with autism, as compared with mothers of controls who were participants in a previous study of perinatal complications (Wilkerson et al., 2002). Additionally, urinary tract infections distinguished case from control mothers. Key information about the control group, however, was not reported, and at the time of data collection, some of the children were well into adulthood, raising concerns about quality of long-term recall. A recent study on early childhood infections recorded in medical records showed scant evidence of differences between cases and controls, although cases were less likely, overall, to have been diagnosed with any infection in the first 2 years of life (Rosen et al., 2007). Since parents frequently do not visit a physician for mild illnesses, it is plausible that the lower incidence was a function of care-seeking behaviors. As birth order strongly influences parental health-care seeking, this variable would have been useful to explore, especially in relation to the milder infections. Genitourinary infections were more common in the case children, possibly a result of case-control differences in risk factors for urinary tract infections, most of which were not controlled.

Because of the heterogeneity of kinds of viruses associated with neurodevelopmental and psychiatric illnesses, currently it is thought that the specific micro-organism is less important than the inflammatory response it produces. This concept is supported by a number of animal studies. Experiments in rodents show that introduction of influenza infection in pregnant dams results in behavioral deficits in offspring (Shi et al., 2003), and injection of poly(I:C) or lipopolysaccharide to induce inflammatory responses produces similar behavioral aberrations with no infection (Smith et al., 2007). Some evidence indicates that earlier exposures have greater impact (Meyer et al., 2007) while other research supports mid- and late-gestational effects of immune challenges (Meyer et al., 2006).

Corresponding research in humans indicates immune dysregulation is commonly observed in autism. Neuroinflammation has been suggested to modulate cortical and cerebellar function through activation of microglia and astroglia and production of proinflammatory cytokines in some proportion of autism cases (Vargas et al., 2005). A wide range of markers of immune abnormalities has been reported in autism: alterations in plasma immunoglobulins and cytokines (Ashwood et al., 2008; Enstrom et al., 2009; Heuer et al., 2008), aberrant NK cell activity (Enstrom et al., 2009; Vojdani et al., 2008), increased mast cells (Castellani et al., 2009), maternal IgG antibodies directed against fetal brain (Braunschweig et al., 2008), proinflammatory cytokines in brain tissue (Li et al., 2009) and altered inflammatory markers in cerebrospinal fluid (Zimmerman et al., 2005). Whether early immune changes lead to neuropathology, or alternatively, deviant brain development results in immune aberrations, or possibly neither (e.g., both are downstream sequelae of a shared but unknown initiating event), remains to be delineated.

Nevertheless, these observations provide the key insight, namely, that mechanisms by which environmental exposures adversely affect CNS development might include disruption of immune developmental and maturation processes at critical junctures (Hertz-Picciotto, Park, et al., 2008). In other words, direct insult to neuronal tissue is not necessarily required, and both infectious and other agents should be evaluated in this broader perspective.

Medical Interventions

Use of assisted reproductive technology to achieve conception has been rising. In vitro fertilization (IVF) and intracellular sperm injection (ICSI) have been hypothesized to increase the risk of autism. In a large series of ICSI pregnancies resulting in 5,891 neonates, of whom 811 were followed to 3 years of age, over 10% were developmentally delayed (Palermo et al., 2008), but power was inadequate to examine autism as an outcome. Several other studies conducted to date were also underpowered to address this link (Pinborg et al., 2003; Stromberg et al., 2002). Middelburg et al. conducted a systematic review of studies of developmental outcomes of ICSI and IVF conceptions (Middelburg et al., 2008). They identified 23 reports that were judged to be of "good quality," which included rigorous criteria for a naturally conceived control group, and adequacy of follow-up and sample size. Cerebral palsy and epilepsy were frequently observed to be higher in assisted vs. natural conceptions, but only one study assessed autism (Maimburg & Vaeth, 2007). In this well-designed large study comparing 461 autism cases with matched controls, Maimburg and Vaeth reported a deficit of ICSI or IVF conceptions. However, their crude analysis (OR = 0.41) did not control for maternal or paternal age, country of origin, or plurality—four likely confounders. Their adjusted analysis (OR = 0.37) inappropriately controlled for numerous intermediate variables such as multiplicity (a direct consequence of fertility treatments), and other potentially downstream factors: birth weight, gestational age, and birth defects. As a result, both odds ratios would be expected to be biased (Cole & Hernan, 2002).

Ultrasonography is widely used to estimate gestational age, determine the number of fetuses, and screen for congenital anomalies, and the technology and equipment have undergone changes over the last few decades. Ultrasonography delivers a high frequency sound wave that can heat soft tissue, including at diagnostic levels. An HMO-based case-control study reviewed medical records to determine the number of ultrasounds taken during pregnancy and found that about 87% of women in the study had at least one ultrasound and over 20% received three or more (Grether et al., 2010). Results from fitting a logistic regression model (adjusted for potential confounders) indicated that the odds of autism did not rise exponentially as a function of number of ultrasounds taken during gestation, but second trimester scans of female fetuses were associated with an elevated risk. The possibility of a threshold response was not investigated. A challenge in

studying ultrasounds during pregnancy is the greater number of ultrasound scans performed in response to an observed abnormality.

Obstetric Conditions

Large-scale studies of obstetric factors in relation to autism have used existing medical databases from national registries, health maintenance organizations, or conglomerates of medical practices. Two major studies were from Sweden (Hultman et al., 2002) and Australia (Glasson, 2002), and a smaller one was from Denmark (Eaton et al., 2001). Hultman and coworkers drew data from the linked Swedish Medical Birth Register and Inpatient Registry to conduct a case-control study of diagnoses of "infantile autism (ICD-9 code of 299A)" (n = 408) in the years 1987 through 1994. Controls with no autism diagnosis (n = 2,040) were matched 5:1 on sex and on year and hospital of birth. Multivariate analysis was performed with several obstetric conditions, with control for certain birth and infant characteristics. A team from Australia (Glasson, 2002) similarly used the Maternal and Child Health Research Database of Western Australia which covers all births in that state's population of 1.9 million residents, and diagnoses that are made at five state centers providing services in the same region. Births in 1980 through 1995 and autism diagnoses from 1986 until 1999 were included, with earlier diagnoses reviewed by a qualified pediatric expert on autism, and later diagnoses made by a team of three (clinical psychologist, speech pathologist, and pediatrician). A total of 465 ASD cases, 481 unaffected siblings, and 1,313 population-based controls were included; maternal age and other factors were controlled in some analyses. In Denmark, two studies were conducted using national registry linkage, one with 116 cases of autism, 279 of Asperger's Syndrome, and a 10% sample of births (Eaton et al., 2001), the other with 473 cases of autism and 10 controls for each case (Maimburg & Vaeth, 2006). Diagnoses for both studies were based on ICD codes in the Danish Psychiatric Case Register.

With regard to labor and delivery, the Swedish study found Cesarean section delivery significantly more frequently in case births, OR = 1.6 (95% CI = 1.1, 2.3) (Hultman et al., 2002), and the Australian study observed this to be true for both emergency OR = 1.6 (1.1, 2.2), and elective OR = 2.0 (1.5, 2.8) procedures (Glasson et al., 2004). Nonsignificantly elevated risks for autism but not for Asperger's Disorder were associated with C-sections when adjusted for only gender and year of birth in one of the Danish studies (Eaton et al., 2004); the other study adjusted for APGAR, which could be influenced by the C-section, potentially biasing the results (Maimburg & Vaeth, 2006). In the Australian cohort, elective C-section was associated with elevated risk for autism in a multivariate model that adjusted for fetal distress, maternal age, year of birth and other factors, but emergency C-section was not. Although multivariate analyses were not conducted using sibling controls, in the univariate analysis, fewer risk factors were identified with these than with population controls, reinforcing the

view that sibling may be too similar to cases to provide valid referents. Thus, pregnancy-specific exposures may operate by intensifying susceptibility to other insults, be they inherited or environmentally induced.

Neither the Swedish nor the Australian study saw an elevated risk from preeclampsia, although hypertensive disorders were associated with a somewhat imprecise but elevated risk, OR = 1.6 (0.9, 2.9) in the former (Hultman et al., 2002). Within a sample of 228 multiplex families of children with autism in the Autism Genetic Resource Exchange (AGRE) study, hypertension, preeclampsia and edema were all associated with higher Autism Diagnostic Inventory Revised (ADI-R) communication scores (Wallace et al., 2008). Preeclampsia was not reported by Eaton and colleagues in the sample from Denmark, but placental insufficiency was strongly associated with autism in models adjusted only for gender and year of birth (Eaton et al., 2001), with similar results for "any complication."

For medications taken during pregnancy, few were examined in more than one study, effectively precluding definitive conclusions, according to a meta-analysis (Gardener et al., 2009). However, strong evidence of links to autism have been observed in small studies for thalidomide and valproic acid (Rodier et al., 1997). Fetal/infant characteristics such as low APGAR scores (Glasson et al., 2004; Hultman & Sparen, 2004; Larsson et al., 2005), breech presentation (Bilder et al., 2009), and fetal distress (Glasson et al., 2004), have been observed in autism. Current thinking regarding mechanistic implications of stress markers is that prenatal or birth hypoxia, the former being inducible by infection and the latter by C-section, may alter structural or functional features of CNS development, with permanent consequences through mechanisms such as: delayed neuronal migration (Zechel et al., 2005), degeneration and chromatolysis in the striatum (Zhuravin et al., 2006), reduced myelination (Wang et al., 2007), increased dopamine D1 receptor binding (Boksa et al., 2002), astrocytic fibroblast growth factor (Flores et al., 2002), and binding of insulin-like growth factors I and II (Boksa et al., 2006).

Vaccines and Autism

A hypothesized link between childhood vaccines and autism has stirred considerable controversy. Several distinct hypotheses have emerged. One specific conjecture is that the measles, mumps, rubella (MMR) vaccine has been a cause of autism; another is that vaccines containing the preservative thimerosal, which contains ethyl mercury, increase the risk of autism. This latter hypothesis is addressed below in the section "Chemicals in the Environment." A third theory is that the number of different vaccine antigens administered to infants is too large for some subset of children whose immune systems may not be sufficiently matured, leading ultimately to autism. Virtually no research has addressed this question. Here we synthesize the scientific literature on the MMR vaccine.

First articulated by Andrew Wakefield, who treated children for gastrointestinal symptoms, the MMR hypothesis focused on intestinal disturbances, including possible inflammation or increases in permeability that could lead to excess absorption of opioids, in the form of food-derived peptides (Wakefield & Montgomery, 1999; Wakefield et al., 1998). Various follow-up investigations have since been published, of which we present the stronger and larger ones; these did not primarily address the GI comorbidity. One ecologic analysis evaluated the relationship between rates of autism and years in which the MMR was and was not administered. Between 1980, when MMR almost completely replaced the separate measles, mumps, and rubella vaccines, and 1994, the increase in California in uptake of the combined MMR vaccine by 24 months of age rose from 72% to 82% (Dales et al., 2001). In contrast, during this same period, the rise in cumulative incidence of autism in California's DDS database, based on children born in those years and diagnosed with autism, went from just under 200 to nearly 1,200. As factors other than MMR vaccine uptake changed during this period, including the proportion of the population of affected children who were enrolled in the DDS system, conclusions from this ecologic analysis would necessarily be limited.

In Japan, the history of MMR vaccinations provided an opportunity to examine the impact of cessation of use of the MMR combined vaccine, which occurred in April 1993. After that time, the Immunization Law specified it be replaced with three separate vaccines, and that there be a 4-week period between administrations. Honda and colleagues therefore examined cumulative incidence of ASD up to 7 years of age in one Yokohama ward from 1988 through 1996 (Honda et al., 2005). Outcomes were derived from population-based screening for developmental disorders using a standardized tool at 18 and 36 months of age and summarized as annual cumulative incidence proportions. These incidence proportions rose from 1988 to 1990 while uptake of MMR declined from 70% to 34%, dropped in 1991 and 1992, and then rose higher, peaking in 1994. With a continued rise in incidence after MMR was withdrawn, the data are inconsistent with MMR having played a predominant role in the upward trajectory prior to that time. This time trend analysis, similar to other ecologic studies, presumes that other causal factors are held constant, and did not adjust for individual-level confounders.

Of studies utilizing individual-level data, a few evaluated whether cases with autism were more likely to have received the MMR; others conducted an analysis of age at vaccination to determine whether cases received their vaccinations earlier than controls or if they developed autism symptoms or regressed within a short time of the vaccinations.

CDC investigators (DeStefano et al., 2004) addressed the hypothesis that children receiving their first MMR vaccination at an earlier age (<18, <24, or <36 months old) would be more likely to develop autism, using prevalent cases aged 3 to 10 years from the population-based Metropolitan Atlanta Developmental Disabilities Surveillance Program. Controls were matched 3:1 to cases, and selected from the same school or a regular school that served the same residential area as that of a case child attending a special needs school. Age at first MMR vaccination was similar in cases and controls. Of those vaccinated *after* 36 months of age, 78% had documented developmental delays prior to 36 months of age, suggesting that age at vaccination may, for some children, be a consequence of, rather than a cause, of developmental conditions. This issue also arises in relation to thimerosal exposures, discussed in the section "Chemicals in the Environment".

The other study focusing on timing was based on a large case series of autism diagnoses in eight health districts of England among births in 1979 through 1992 (Taylor et al., 1999). Against an ongoing trend of increasing diagnoses of autism, Taylor and colleagues found no observable step-function in childhood autism incidence after introduction of the MMR vaccine. As compared with unvaccinated children, those vaccinated by 18 months of age, and those vaccinated at 18 months of age or later had similar mean ages at diagnosis, but the data did not permit examination of rates of autism. Different lag-times between the age at vaccination and age of parental concern (<1, <2, <3,…<12 month intervals) indicated a significantly higher proportion for one interval (<6 months), but not for any other in this case-only analysis. Additionally, no excess of regression occurred within 2, 4, or 6 months of receiving the MMR vaccine. In short, the results give little indication that autism diagnoses or regression clusters in specified time intervals after vaccination. Deficiencies in this study include: lack of control for factors related to age at diagnosis, such as social class (Baird et al., 2006); lack of a control group with comparable data on timing of vaccines—this was a *case-only* analysis; and, as discussed above, age at vaccination may itself be influenced by developmental status. Methodologically, this study also highlights the problem of time-to-onset analysis when onset itself is difficult to pinpoint and a common acute exposure routinely occurs shortly before typical recognition of a rare but severe disease.

The remaining studies examined those receiving vs. not receiving an MMR vaccine. Clinic records for the UK General Practice Research Database (GRPD), which contain diagnoses for pervasive developmental delay (PDD) as well as vaccination information and dates, were used to address the MMR hypothesis in a large case-control study (Smeeth et al., 2004). Abstractors were blind to the developmental outcome and up to 5 controls were matched to each case. The adjusted odds ratio for MMR was 1.47 (95% CI = 0.84, 2.57) if they joined the GPRD before their first birthday, and otherwise, 0.75 (95% CI = 0.57, 0.97). The study provides no evidence for increased risk with MMR vaccination, although potential confounders (including social class, maternal and paternal age, and birth weight) were uncontrolled, and heterogeneity by age at entry into the GPRD indicated potential bias.

In Denmark, a cohort study of all children born in 1991 through 1998 was conducted to examine associations with the MMR vaccine (Madsen et al., 2002). The authors compared vaccinated vs. unvaccinated children. Diagnoses were obtained

from the Danish Psychiatric Registry and a validation sub-study indicated that 92% of those with an autism diagnosis met the operational criteria used by the CDC in the Brick Township, New Jersey prevalence study, with the remaining 8% having other ASDs. The MMR vaccine used in Denmark was "identical to that used in the United States." The adjusted relative risk was 0.92 (95% CI = 0.68, 1.24). This study was impressive in that close to 100,000 children were in the unvaccinated group, though they were far outnumbered by those who did receive the vaccine. Individual-level data on vaccine administration was collected prospectively and independently of diagnostic information and the multivariate analysis adjusted tightly for an array of potential confounders, and did not adjust for intermediate variables, lending some confidence to the validity of results. Nevertheless, because of variable follow-up depending on year of birth, a survival analysis should have been conducted. At least 1/4 of the children were too young at the end of the study period to have a diagnosis of autism spectrum disorder, and vaccination status by year of birth was not shown. Some bias may also have been introduced by the use of an ad hoc method to adjust for the unusually large percentage of subjects with missing gestational age, which were unevenly distributed between vaccinated (28%) and unvaccinated (51%); it is known that adjustment for a "missing" category of a covariate inevitably biases results for other factors in a multivariate model (Vach & Blettner, 1991). Although this Danish study is, in many respects, the strongest investigation of MMR vaccines and autism, the potential for and direction of bias in those results is difficult to assess.

By and large, the evidence does not support the contention that MMR vaccines played a major role in the rise in autism during the 1990s. Studies comparing earlier vs. later receipt of the MMR found no differences in risk for autism. Only two studies with adequate control groups directly addressed vaccinated vs. unvaccinated children. The study from Denmark compared a very large sample of children who did not receive the MMR vaccine with an even larger group of children who did, controlled for risk factors that were antecedents of both the receipt of vaccines and the diagnosis of autism, and refrained from adjusting for intermediate variables. Methodologic concerns pertain to residual confounding resulting from crude control for calendar time (during a period of increasing diagnoses); nonuniform follow-up periods; and inappropriate comparisons involving inpatients in some years and both in- and outpatients in other years. Similar, as well as other issues regarding lack of adequate vaccination data in the children who joined the GPRD after their first birthday also limit the interpretation of the UK study of MMR. Although establishing a "null" finding (i.e., a lack of association) presents challenges from the statistical point of view, the evidence to date, which includes large studies, provides no indication that MMR vaccines, regardless of the age at administration, increase risk for autism. Nevertheless, stronger studies would be desirable to enhance conclusiveness. No studies attempted to identify susceptible subgroups of children in whom vaccines might contribute to risk of an ASD.

Chemicals in the Environment: Metals, Air Pollutants, Pesticides, and Endocrine Disruptors

Quite a number of environmental toxins affect critical CNS developmental processes. Proliferation and migration are sensitive to methyl mercury and ethanol; an organophosphate pesticide (chlorpyrifos) has been shown to influence proliferation as well as apoptosis (Rice et al., 2007). Methyl mercury and nicotine affect differentiation; several pesticides can alter synaptogenesis; and thyroid hormones or malnutrition adversely impact myelination. As the neuropathologic pathways in autism are yet to be delineated, any of these or similar observations may be relevant to autism.

As discussed earlier, besides direct insult to the CNS, another potential etiologic pathway leading to autism is via dysregulation of immune development or function. Interestingly, several classes of compounds are not only neurotoxins but also have demonstrated adverse effects on prenatal or postnatal markers of immune status, including metals, pesticides, air pollutants, and some endocrine disruptors (Dietert & Piepenbrink, 2006; Luebke et al., 2006; Hertz-Picciotto, Park, et al., 2008; Desi et al., 1986; Institoris et al., 1999; Park et al., 2008). Other mechanisms to be considered include disruption of thyroid hormones, sex steroids, or energy metabolism.

Many of the persistent organic pollutants (POPs) are endocrine disruptors. POPs are defined as meeting four criteria: *(1)* highly toxic; *(2)* stable or persistent, lasting years or decades before degrading; *(3)* transported long distances through air and water; *(4)* bioaccumulative in fatty tissue of humans and wildlife. Worldwide concern about POPs culminated in a global (intergovernmental) treaty known as the Stockholm Convention (United Nations Environment Programme, 2001); a dozen compounds were listed in the initial treaty, including nine pesticides and a few industrial chemicals or their by-products, and more have been added since that time. Although many are slated for elimination, this process is slow, and the United States, a major producer and polluter of POPs, was a signatory but did not ratify the Stockholm Convention.

In epidemiologic studies of environmental chemicals, the assessment of exposure can be quite complex. Some chemicals have extremely short half-lives of minutes or hours, while others may remain in the human body for years. Strategies to assess exposure include measurements in the environment, linkage of information from databases with emissions inventories, incorporation of data from monitoring systems for pollutant levels in given geographic areas, questions about behaviors and use of products known to contain specific chemicals, and biologic markers such as blood levels or metabolites in urine. Of critical importance for this research is the susceptible time period during which exposures can influence the development of autism. On the one hand, in the context of multifactorial etiology whereby each of multiple "hits" contributes to reducing the resilience of the fetus or child, there is no reason to preclude adverse effects at any point prior to the

full manifestation of diagnosable autism or ASD. On the other hand, if a specific target tissue is sensitive during a narrow critical window, the use of broader time intervals (because of incomplete understanding of mechanism) may hamper the ability to detect effects of relevant exposures (Hertz-Picciotto et al., 1996), as shown in a study of fetal deaths with chromosomal anomalies (Bell et al., 2001a, 2001b). Inaccurate assignment of exposure timing could be somewhat less of a problem for the POPs, especially if new sources of exposure have been eliminated, rendering temporal variability more predictable.

This section synthesizes the research base on mercury, air pollutants, endocrine-disrupting chemicals, and pesticides. Table 47-3 describes the salient studies.

Mercury

Most of the literature on metals has focused on mercury, though some reports have measured cadmium, lead, or others. A few investigations have assessed mercury emissions from industrial sources in relation to risk of autism. However, the vast majority of studies on mercury have examined thimerosal from childhood vaccines. Thimerosal is 49% mercury by weight, in the form of ethylmercury attached to thiosalicylate. Further sources of thimerosal are injections for rhesus negative (Rh-) pregnant women and personal care products (e.g., nasal sprays, contact lens solutions). Sources of *other* forms of mercury, which are major contributors to human body burdens, are fish consumption (methyl Hg), dental amalgams, and industrial emissions (inorganic Hg). No research has yet been conducted that comprehensively evaluated all sources of mercury in relation to autism. Despite in vivo metabolism to inorganic Hg, the different forms appear to have different toxicologic effects (Clarkson et al., 2003). The next subsections discuss studies of autism and thimerosal exposures in the prenatal and postnatal periods, followed by other forms of mercury.

Thimerosal in Immunoglobulin Injections to Rh- Women during Pregnancy

Several investigations in the U.S. examined whether maternal Rh- status or receipt of thimerosal-containing anti-D immunoglobulin, administered to Rh- mothers to prevent serious neurodevelopmental damage to future children, might be associated with increased risk of autism. Miles and Takahashi (2007) enrolled 305 families identified from the Autism Clinic at the University of Missouri and obtained obstetric medical records from 214 to ascertain Rh- status and receipt of Rh anti-D immunoglobulin. Childhood Autism Rating Scale (CARS) and ADI-R scores were used to confirm case status. Prevalence of Rh- status was 15.4%, very close to that expected (15.4%, 15.2%, 17.7%) based on various comparison populations, although these comparison populations were small, potentially unsuitable, and/or not well-defined. Moreover, no information was provided on race/ethnicity or other relevant demographic or medical factors. A larger and better-defined

comparison series for the thimerosal analysis would have provided more convincing evidence. This study also did not adjust for any confounders.

The investigation by Croen et al., involved 400 cases and 410 age- and gender-matched controls who were members of the Kaiser Permanente medical system for at least 2 years after birth. (Croen et al., 2008). Medical records were reviewed for Rh status, anti-D immunoglobulin, and thimerosal-containing vaccines for influenza. Unlike Miles and Takahashi, these authors adjusted for maternal age, race/ethnicity, and education, and child's sex, birth order, and plurality. The OR for Rh- status was 1.1 (95% CI = 0.7, 1.7) and for receiving anti-D immunoglobulin, 1.0 (0.6, 1.7). Rh- prevalence varied markedly by race/ethnicity, being much higher in Caucasian non-Hispanics and lower in other groups, particularly Hispanics. Since the latter were underrepresented in cases relative to controls, any bias would have been toward overestimation of the association with Rh status. Bias might also have arisen if undiagnosed cases among controls who left the Kaiser Permanente system shortly after the second birthday (before being diagnosed) were more or less likely to be Rh- than the ascertained cases, but moving a few subjects from the control to case group would have had little impact, given the size of this study.

This study would appear to be solid, if it were not for one fact, apparently not widely appreciated (Bernard et al., 2008): not all formulations of anti-D immunoglobulin contained thimerosal during the study periods. Pharmaceutical sales data (IMS, 2001) indicate that although somewhere between 31% and 51% of the market share from 1996 to 2000 was for Rhogam™, which did contain thimerosal, a similarly sized share of the market (from 44% to over 60%) was captured by BayRho™ and WinRho™ combined, both of which contained no thimerosal. Thus, a comparison across brands would have been the optimal comparison to answer the question of whether gestational thimerosal is associated with later autism in the child. Whether the medical records would be accurate with regard to the manufacturer or whether Kaiser's purchases were available is unclear, as the word "Rhogam" has come to be used generically, like the word "Kleenex," irrespective of the actual brand.

Thimerosal from Vaccines in the Postnatal Period

Thimerosal was introduced into U.S. vaccines as a preservative beginning in the 1930s. Both ecological and more rigorous epidemiologic studies using individual-level data on thimerosal-containing vaccine exposures have addressed a possible role for this mercuric compound in autism.

Three ecologic studies were conducted in Denmark, Canada, and California. Each examined time trends covering periods when thimerosal was in or had been removed from vaccines. In Denmark, the period studied was 1971 through 2000; thimerosal was used in vaccines from the 1950s until 1992 (Madsen et al., 2003). Autism rates did not begin to rise

	Major Studies*	Design	Findings (95% Con-fidence Intervals)**	Strengths & Limitations: Bias, Confounding	Notes on Interpretation of Findings
Mercury					
Thimerosal in anti-D immunoglobulin	Miles & Takahashi (2007)	Case series; diverse comparison populations; 214 cases.	OR = 0.93 (0.30, 2.89) for receipt of anti-D immunoglobulin.	Cases confirmed. Comparison groups poorly defined or of questionable validity. No confounder adjustment.	Only one analysis was for anti-D immunoglobulin, with four exposed controls (i.e., statistical power was low). Confounding likely a problem.
	Croen et al. (2008)	Case-control; 400 cases, 400 controls.	OR = 1.0; (0.6, 1.7) for receipt of anti-D immunoglobulin.	Confounders well controlled. Possible misclassification of 60% or more in the exposed category (estimated 40% PPV*** of exposure assignment).	Possible strong downward bias resulting from high misclassification, as many Rhogam manufacturers did not use thimerosal.
Thimerosal in vaccines	Hviid et al. (2003)	Full population cohort (n = 467,450) 1,227 cases.	RR = 0.85 (0.6, 1.2) for autism, RR = 1.12 (0.88, 1.43) for ASD.	Case ascertainment may have differed for exposed vs. unexposed due to changes in use of outpatients over the study period. Possible residual confounding because time was categorized in one year blocks with steep rise of autism (24% per year). Sensitivity analysis of 1991 through 1993 did not adjust for calendar time.	Brief report omitted many details. Analysis of vaccinated with and without thimerosal controls confounding by health-seeking behavior. Substantial downward bias from low ascertainment during thimerosal-exposed period. Likely residual confounding from time trend.
	Verstraeten et al. (2003)	Cohort; (n = 110,833 term infants in HMO B; other HMOs too small for meaningful analysis).	Three-month cumulative thimerosal dose: RR = 1.06 (0.88, 1.28); seven-month cumulative thimerosal dose: RR = 1.00 (0.90, 1.09).	Exclusions of infants with perinatal conditions of any type, or whose mothers had any complication of pregnancy or labor; this removed a disproportionate number with susceptibility to autism. In HMO B (the largest one), 24% of births were thereby excluded. Medical records not validated, hence case underascertainment possible.	Low birth weight, anomalies, birth hypoxia and other perinatal conditions are risk factors for autism, suggesting that the children most at risk for autism were excluded. Hence population-based estimates of thimerosal effects not possible from this analysis.
	Andrews et al. (2004)	Cohort; (n = 100,572 term infants). Hypothesis examined was early vs. late timing of vaccinations.	For each dose by 3 months of age: HR = 0.89 (0.65, 1.21); by 4 months of age: HR = 0.94 (0.73, 1.24); for time-adjusted dose by 6 months of age: HR = 0.99 (0.88, 1.12).	Compared early vs. late vaccinations, when both had thimerosal. Analysis controlled for follow-up time but not for confounders. Unvaccinated were excluded but were a small percentage of children, selection bias would be low. Significantly reduced risk was observed for general developmental delay, unspecified developmental delay, and ADD, suggesting systematic differences between those receiving vaccinations on time vs. later.	Addressed early vs. late vaccinations among those receiving three DPTs by 12 months of age. Restricted to those who received three DPT doses by 12 months of age. Unclear why other developmental delays and related conditions (Attention Deficit Disorder) show significantly lower risk in those receiving early vaccines.

Mercury

	Heron et al. (2004)	Cohort; (n = 12,956, but 6610 for prosocial behavioral problems)	Outcome at 47 months of age: HR = 1.12 (1.01, 1.23) per dose by 3 months of age; HR = 1.05 (0.97, 1.15) per dose by 4 months of age; HR = 1.03 (0.98, 1.08) for time-adjusted dose by 6 months of age. Outcome at 81 months of age: HRs ranged from 0.97 to 0.99, with all confidence intervals including 1.0.	Conducted analysis in identical manner as Andrews et al. Controlled for a wide range of potential confounders. Small study for cohort analysis of autism, hence insufficient statistical power to address autism.	Because of small sample size, did not address autism or ASD diagnoses. Instead used continuous variables on behavioral scales. Control for confounders had little impact on results.
Inorganic mercury in air pollution	Windham et al. (2006)	Case-control; 284 cases, 657 controls.	RR = 1.31 (0.91,1.88) for third quartile of Hg emissions; RR = 1.92 (1.36,2.71) for fourth quratile.	Choice of exposures was based on biologic relevance. Estimated exposures were for second year of life. Cases from the California DDS**** were confirmed by thorough record review.	Used individual-level data. Adjusted for sociodemographic factors. Relevance of exposures in second year of life is unknown. Origins of autism are likely earlier, but triggers as late as second year cannot be excluded.

Other Air Pollutants

Endocrine disruptors

Chlorinated solvents	Windham et al. (2006)	Case-control; 284 cases, 657 controls.	RR = 1.33 (0.93, 1.88) for third quartile of exposures; RR = 1.55 (1.08, 2.23) for fourth quartile.	Same as above.	Same as above.
Aromatic solvents	Windham et al. (2006)	Case-control; 284 cases, 657 controls.	RR = 0.84 (0.59, 1.20) for third quartile of exposures; RR = 1.15 (0.80, 1.65) for fourth quartile.	Same as above.	Same as above.
	Windham et al. (2006)	Case-control; 284 cases, 657 controls.	RR = 1.33 (0.94, 1.88) for third quartile of exposures; RR = 1.28 (0.88, 1.85) for fourth quartile.	Same as above.	Same as above. Notably, primary exposures to endocrine disruptors occur through food and household products, not from ambient air pollution. Many endocrine-disrupting compounds not examined by Windham et al. are ubiquitous in the home environment and disrupt thyroid and sex hormones critical to neurodevelopment. Examples include: PCBs, PBDEs, phthalates, bisphenol A.

Table 47–3. (Contd.)

	Major Studies*	Design	Findings (95% Confidence Intervals)**	Strengths & Limitations: Bias, Confounding	Notes on Interpretation of Findings
Pesticides					
Organochlorines	Roberts et al. (2007)	Case-control; 465 cases, 6,975 controls.	A priori hypotheses, exposure 7 days preconception to 49 days post-LMP: RR = 4.2 (1.7, 10.9) for fourth quartile of nonzero exposure, 500m buffer. RR = 2.4 (0.7, 8.2) for third quartiles of nonzero exposure, 500m buffer. A posteriori hypotheses, exposure days 40–95 post-LMP: maximum RR = 7.6 Above RRs for 500m buffer.	DDS**** cases not confirmed; DDS estimated at 75% complete. Adjusted for sociodemographic confounders. Adjusted for multiple comparisons. A priori hypotheses based on biologically based time windows.	Careful assessment of exposure, analysis of specific time windows and dose–response relationships. Dicofol and endosulfan were the principal organochlorines.
Pyrethroids (bifenthrin)	Roberts et al. (2007)	See above.	RR = 4.8 (no CI given) for fourth nonzero quartile, 250m buffer, exposure from LMP to delivery.	See above.	Careful assessment of exposure, analysis of specific time windows, and dose–response relationships.
Organophosphates	Roberts et al. (2007)	See above.	RR = 1.6 (no CI given) for fourth nonzero quartile, 250m buffer, exposure from LMP to delivery.	See above.	Careful assessment of exposure, analysis of specific time windows, and dose–response relationships.
	Eskenazi et al. (2007)	Cohort; (n = 372), population of mainly Latino farmworkers.	RR = 2.25 (0.99, 5.16) for 10-fold increase in maternal urinary metabolites; RR = 1.71 (1.02, 2.87) for 10-fold increase in child's urinary metabolites.	Adjusted for age, sex, breastfeeding, HOME score, income, parity, maternal intelligence, and maternal depression. High prevalence of PDD***** may suggest overreporting of signs.	Prospective study with individual urinary measurements of DAPs (dialkylphosphate) metabolites of organophosphates. Outcome was PDD subscale on the Child Behavior Checklist.

*Major studies included those with at least 50 cases and 100 total subjects. However, no attempt was made to be comprehensive or complete.

**All findings shown in this table are multivariate adjusted associations, unless otherwise noted.

***PPV = Positive predictive value.

****DDS = Department of Developmental Services of the State of California.

*****PDD = Pervasive Developmental Delay.

until 1991, and continued rising following removal of thimerosal from vaccines. A similar analysis was conducted using the California Department of Developmental Services data (Schechter & Grether, 2008) covering the period 1995 to 2007, which also found no fall-off in incidence after the removal of thimerosal from most U.S. vaccines. A Canadian study (Fombonne et al., 2006) using school-district-identified PDDs and assigning thimerosal doses based on grade level and immunization schedules for Quebec found that neither a continuous nor categorical ecologic measure of thimerosal exposure predicted autism incidence. The authors of the California study concluded, quite reasonably, that the "DDS data do not support the hypothesis that exposure to thimerosal during childhood is a *primary cause of autism* [italics added]." These studies provide evidence that a strong, predominant effect on risks for autism from thimerosal in vaccines is unlikely to have occurred.

In all three studies, the ecologic fallacy may have affected the findings because linkage between exposure and disease is not present, and hence, theoretically, cases could have been largely among the unexposed, yet the associations observed would be identical. More importantly, for time-trend studies, results can only be interpretable *when all other predictors of autism are held constant.* Since changes in ascertainment, relevant environmental exposures, and other risk factors contributing to incidence of autism are entirely plausible, ecologic studies are uninformative for assessing smaller contributions to risk from single factors.

Researchers from several countries, including Denmark, the United Kingdom, and the United States have retrospectively examined the link between thimerosal-containing vaccines in childhood and autism, using individual-level vaccine histories from medical records. Hviid et al. (2003) examined diagnoses for autism in a cohort of births spanning the period from 1990 to 1996, with follow-up through December 31, 2000. This analysis took advantage of the national Danish medical record system, whereby all vaccinations and all diagnoses can be linked. Follow-up for over 450,000 eligible children covered, collectively, nearly three million person-years and gave rise to 440 cases of autism and 787 cases of other autism spectrum disorders. During the time period of interest, only the pertussis vaccine contained thimerosal, and doses were calculated based on the number of pertussis vaccines received (1, 2, or 3) and the known composition of the formulation (50 µg of thimerosal, equal to ~25 µg of ethylmercury). Analyses adjusted for child's age and calendar period, or additionally for child's sex, place of birth, birth weight, 5-minute APGAR score, gestational age, mother's age at delivery, and mother's country of birth showed no elevated risk for autism, or for other autism spectrum disorders, regardless of the dose received. Despite control for numerous individual-level confounders, use of broad categories of calendar time against the backdrop of a steep, steady rise in incidence leaves open the possibility of residual confounding. Moreover, as described in the ecologic study by Madsen and colleagues, case ascertainment methods were inconsistent, involving inpatients only during the period prior to 1995 but both inpatients and outpatients afterward. As a result, the differential source of cases may have introduced misclassification bias.

Two major papers from the UK pertain to thimerosal from vaccines. Andrews et al. (Andrews et al., 2004) utilized a cohort of over 100,000 children born in 1988 through 1997 in a consortium of general practices in the UK. The second study, though smaller, involved an in-depth characterization of a birth cohort (Avon Longitudinal Study of Parents and Children or ALSPAC), with a broad spectrum of outcomes and covariates collected prospectively and systematically (Heron & Golding, 2004). Of the vaccines routinely administered to infants in the UK during the 1970s and 1980s, thimerosal was only used in diphtheria-tetanus-whole-cell pertussis (DTP), diphtheria-tetanus (DT), and combination vaccines containing these two, with doses similar to those used in the pertussis vaccine in Denmark. In 1990, the UK changed from a 3-, 5-, 10-month schedule to a 2-, 3-, 4-month schedule, leading to a dose of 75 µg mercury by 4 months of age in infants receiving the recommended dose on schedule.

The focus of the analysis in both investigations was to compare those with earlier vs. later receipt of thimerosal-containing vaccines. Exposure was defined as number of doses by 3 months of age, by 4 months of age, and a constructed scale for combined doses to 6 months of age. To account for wide variability in durations of follow-up, both studies appropriately performed survival analysis using Cox proportional hazards models. Andrews and coworkers (Andrews et al., 2004) found no increased incidence of autism, comparing those who received their DPT or DT vaccines earlier vs. later; the hazard ratios for autism ranged from 0.89 to 0.99. Of the nine developmental conditions examined in the consortium of general practices, only tics were significantly elevated in those with greater doses at an early age, but incidences of general developmental disorder, ADD, unspecified developmental delay, and autism were all significantly *reduced* in those who received earlier doses of thimerosal. A similar analysis in the ALSPAC study showed, among the 23 adverse developmental outcomes (with fewer than 10,000 in the cohort, autism diagnoses were too rare for analysis), the only significantly elevated risk for an adverse outcome was for poor scores on prosocial behaviors; five other significant results showed positive outcomes associated with early life thimerosal exposure (Heron & Golding, 2004). Data on potential confounding variables such as maternal and paternal age were not available in the Andrews study, and autism diagnoses were not validated, whereas in the ALSPAC study, numerous potential confounders were controlled (birth weight, gestational age, maternal education, parity, midpregnancy smoking status, breastfeeding, child's gender and ethnicity, and housing).

The authors of two studies (Andrews et al., 2004; Heron & Golding, 2004) do not comment on the unexpectedly high proportion of outcomes showing reduced incidence or improved scores. One interpretation is that early vaccines benefit several domains of neurodevelopment. An alternative

possibility is that of reverse causation. In other words, the healthiest babies would be those who were given the earliest vaccines, while vaccines may have been withheld for later administration to those not thriving or with indications of problems predictive of developmental delays. Similar to the "healthy worker effect," this may represent a "healthy vaccinee effect."

Thimerosal was used in a wider range of vaccines in the U.S., resulting in infant doses of up to 187.5µg by 7 months of age as compared with a maximum of 75µg in Denmark and the UK. The Centers for Disease Control and Prevention in the United States sponsored a retrospective study (Verstraeten et al., 2003) that took advantage of computerized databases from three health maintenance organizations (HMOs), which are combined into the Vaccine Safety Datalink. This combined database includes medical event information, specific vaccine history, including manufacturer and lot number, and selected demographic variables. Exposures were estimated from DTP, hepatitis B, and Haemophilus influenza type B (Hib) vaccines.

Only one of the three HMOs had adequate statistical power to examine the association with autism, and no significant elevation in risk was found for cumulative dose at 1 month of age, nor for doses at 3 or 7 months of age (Verstraeten et al., 2003). A considerable limitation in this study was the exclusion of a relatively large proportion of children. In the largest HMO, 24% of births were excluded on the basis of low birth weight or congenital, perinatal, or maternal complications or medical problems. Since several of these factors, and neonatal suboptimality in general, are indicators of increased risk for autism, it is possible that the authors excluded the most vulnerable children. Further concerns about the Vaccine Safety Database were discussed by an expert panel convened by the U.S. National Institutes of Health (NIH) (Hertz-Picciotto et al., 2006).

A small study of thimerosal exposure and neurodevelopmental outcomes was carried out using a subset of participants from a previously conducted randomized trial of two acellular diphtheria-tetanus vaccines in Italy (Tozzi et al., 2009), one with and one without thimerosal. With only one case of autism identified in about 1,700 children, this research was extremely underpowered and did not meet our criteria for "large-scale" epidemiologic studies.

From the public health viewpoint, it is clear that these vaccines are essential to the core mission of protecting our population from life-threatening diseases. A National Academy of Sciences panel concluded that "the evidence is inadequate to accept or reject a causal relationship between exposure to thimerosal from vaccines and the neurodevelopmental disorders of autism…." They also recommended that action to remove thimerosal from vaccines and other pharmaceutical products "might be warranted to ensure that exposures to thimerosal do not contribute to combined mercury exposures that could exceed guidelines for safe exposure." (Stratton et al., 2001). At the time of the report, there were no published epidemiologic studies examining the hypothesis that exposure to thimerosal-containing vaccines was associated with autism. By now, four studies of adequate sample size have now appeared, each of which provides evidence for a "null" conclusion. Nevertheless, none is free from serious inherent limitations.

To summarize, multiple investigations have assessed the association between thimerosal-containing vaccines given to infants and the risk for autism. The continuing trend toward increased incidence of autism, even after the removal of thimerosal from vaccines, demonstrates that the steep rise in diagnoses of the last 15 to 20 years cannot be explained by this preservative. If thimerosal has played any role, it likely has been a small one. Yet misclassification and other uncertainties in data quality, inadequate control for confounding in the analysis, and/or systematic biases in the study populations have reduced the ability of these studies to validly test the theory, underscoring the need for stronger science on this question. Although the extant literature does not rule out a contribution of thimerosal as one of many risk factors for autism, possibly acting on a susceptible subset of the population, at present there are no published studies supporting this hypothesis.

Mercury from Other Sources

Other major sources of mercury exposures include dental amalgams (inorganic Hg), industrial emissions leading to air or water pollution (elemental Hg), and fish or seafood (methylmercury). Hair Hg is known to be an excellent biomarker, consisting of about 80% organic Hg (primarily methyl) with about 20% inorganic Hg (Clarkson & Magos, 2006). An autopsy study of brain Hg levels in neonates who died of natural causes showed that either biomarker, maternal blood or maternal hair, correlates with the infant brain levels (Cernichiari et al., 1995).

Several studies have compared hair measurements of Hg in cases and controls. One group reported lower concentrations in the first haircut from children with autism (Holmes et al., 2003). However, the mean hair concentration in their control series was unusually high: 16-fold greater than the mean from the National Health and Nutrition Examination Survey (NHANES) representative sample of children 1 to 5 years of age. In fact, the vast majority of measurements on the controls were above the 95th percentile in the NHANES sample, whereas the concentrations in the children with the greatest severity of autism were very close to the national average (McDowell et al., 2004). These issues combined with absent information regarding whether cases and controls were analyzed simultaneously on the same instruments, whether the laboratory personnel were blinded, and how contamination was addressed, raise concerns about validity of the findings.

Other studies conducted measurements in specimens collected *postdiagnosis* and therefore do not directly address the role of Hg as a causal factor in autism, although differences in concentrations have been argued to indicate altered metabolism, distribution and/or excretion. However, without

quantification of and control for intake (e.g., via diet and other routes), such conclusions are not warranted. A study of post diagnosis blood concentration in children from the CHARGE (Childhood Autism Risks from Genetics and Environment Study), after adjustment for dietary and other Hg sources, observed no differences comparing children with autism to typically developing controls (Hertz- Picciotto et al., 2010).

Exposures to mercury in ambient air are discussed in the next section.

Ambient Air Pollutants

Investigators in two states have examined air pollutants in relation to autism. In an ecologic design, rates of autism were related to industrial emissions of mercury and mercury compounds in school districts in Texas (Palmer et al., 2006), but besides the problem of ecologic fallacy, incomplete confounder control likely occurred. The coefficient for mercury emissions was substantially lowered by adjustment for numbers of special education students (influenced by availability of special education classes), and addition of other socioeconomic or educational variables might have further reduced it. Also, the handling of zero or small event cells could have induced bias (Bartell & Lewandowski, in press). The large reduction in the coefficient for mercury emissions after adjustment for numbers of special education students (often influenced by availability of special education classes) suggests that inclusion of a few other socioeconomic or educational variables might have reduced the association even further. Moreover, exposure data was concurrent with autism cases (i.e., occurring when children have already reached school age and hence unlikely to be etiologically relevant since autism, by definition, develops before 36 months of age).

A second study examining emissions into ambient air was conducted in the San Francisco Bay Area (Windham et al., 2006). Analyses focused on 19 compounds having sufficient exposure variability within this region and with known or suspected developmental, neurologic or endocrine-disrupting toxicity. Using a case-control design, the authors confirmed diagnoses through an expert review of DDS case records, and selected controls from birth records, matching 2:1 to cases by county and month of birth. Residential address at the time of delivery was geocoded and linked to Census tract. Census-tract-specific average annual exposures for each compound were derived from models of Hazardous Air Pollutants (HAPs) emissions based on locations of large polluting industries, smaller area emitters, and mobile sources. Exposures for each child were ranked, and analysis compared the upper two quartiles with those below the median. Other analyses grouped compounds by structure (aromatic solvents, chlorinated solvents, metals) or mechanism (endocrine disruptors, developmental toxicants).

After adjusting for maternal age, education and race, Windham and colleagues found significantly elevated odds ratios for 3rd or 4th quartile exposures for several individual HAPs, (namely methylene chloride, trichloroethylene, vinyl chloride, cadmium, mercury and nickel) and also for chlorinated solvents and metals. Many of these exposures were strongly intercorrelated and hence the individual results require further follow-up to determine which, if any, of these compounds might play a role in autism etiology. This problem, combined with the use of long-term (annual) modeled estimates of ambient air concentrations that corresponded to postnatal year 2 or 3 of the child's life, complicate the interpretation of findings. Nevertheless, despite these caveats, the report by Windham et al. took a commendably evenhanded approach to generating useful leads about environmental causes of autism, and is a refreshing contrast to the many ecologic studies on autism that lack individual-level information on confounding factors and/or use databases with major biases (e.g., related to funding of educational services).

Volk and colleagues (2010) also conducted a study with individual level data, investigate exposure to traffic, a surrogate for air pollution rom vehicle emission. In this case-control study from California (the CHARGE study), addresses of mothers at the time of delivery or during pregnancy were geocoded and distance to the closest freeway was calculated. Those children born to mothers residing within 309 m of the nearest freeway had a 1.9-fold greater risk for autism. All cases in this study were clinically confirmed using the ADI-R and the Autism Diagnostic Obsevation Schedule. Exposures to pollutants decline to background at about 300 m from a freeway, supporting plausibility of a true association.

Pesticides

Major classes of pesticides include organochlorines (OCs), organophosphates (OPs), carbamates, and pyrethroids. Their mechanisms of action differ in the details, but many insecticides are designed to kill insects by acting directly on the CNS. The primary acute effect of OPs, used largely for cockroaches, is acetylcholinesterase inhibition, but at subacute levels, especially in the prenatal period, noncholinergic mechanisms may be most relevant (Rauh et al., 2006). Most OCs are endocrine disruptors, and many dysregulate thyroid homeostasis or have estrogenic, antiestrogenic, androgenic, or antiandrogenic activity. Several large investigations into pesticide exposures as a risk factor for autism have produced intriguing results.

Roberts and colleagues (Roberts et al., 2007) used record linkage among California's DDS system, Vital Statistics birth records and Pesticide Use Reporting System. The study population was based on births in 19 highly agricultural counties. Pesticide exposures were compared for DDS autism or ASD cases, with 15 controls matched to each case based on last menstrual period in birth records. Three time periods of exposure were examined, corresponding to neural tube closure, CNS development during embryogenesis, and the entire pregnancy period. For a total of 249 combinations of chemicals/ chemical compounds, time periods of application, and distances of pesticide application to the residential address at the time of birth, the authors compared those at the highest

quartile of nonzero exposure to the unexposed. After adjustment for multiple testing, the most significant findings were for organochlorine pesticides, with an adjusted odds ratio of 4.2 (95% CI = 1.7, 10.9) for applications during embryonic CNS development. The third-quartile exposures were elevated but not as strikingly. Dicofol and endosulfan were the primary compounds in this class. Several other associations were also significant: bifenthrin, a pyrethroid pesticide, with an adjusted OR of 4.8 (p = 0.005) for exposure at any time during gestation; and the class of organophosphates, with an adjusted OR of 1.6 (p = 0.006) for exposure at any time during gestation.

OPs are used not only in agriculture but also for home applications. Eskenazi and colleagues (Eskenazi et al., 2007) followed a birth cohort of primarily Hispanic families living in the Salinas Valley and evaluated metabolites of OP pesticides in urine collected during pregnancy and postnatally in relation to neurodevelopmental tests, including a subscale for Pervasive Developmental Disorders on the Child Behavior Check List for ages 1.5 to 5 years of age (Achenbach & Rescorla, 2000). Items resemble behaviors from the ADI-R, including: "avoids eye contact," "rocks head, body," and "unresponsive to affection." Urine specimens were analyzed for six nonspecific dialkyl phosphate (DAP) metabolites, representing the bulk of agricultural OP pesticides used in the California Salinas Valley, and previously reported to be associated with shorter gestation and abnormal neonatal reflexes (Eskenazi et al., 2004; Young et al., 2005). In this study, a 10-fold increase in total DAPs was associated with an approximate 2.2-fold higher odds of scoring in the clinical or borderline clinical range for PDD. Of 355 children, 14.4% scored above the 97th percentile on the PDD subscale, and another 29.6% were above the 93rd percentile. With a total of 44% affected, the ORs would be overestimates of the corresponding relative risks. Additionally, the high scores on the PDD subscale suggest that the administration of this subscale possibly was not reliable, and/or the translation into Spanish might not have appropriately captured the intent with regard to scoring of behaviors. Nevertheless, these findings, combined with the results mentioned above (Roberts et al., 2007) related to commercially applied organophosphates in the central valley suggest further investigation of these compounds in relation to autism or ASD is warranted.

Other supporting evidence regarding OPs comes from a comparative study of gene variants in autism family trios in Italy and North America (D'Amelio et al., 2005). OPs are detoxified by paraoxonase, an enzyme encoded by the gene PON1. Using four different statistical approaches, a significant association between autism and PON1 variants that were less active in in vitro tests was found in the North American sample but not the Italian one. This finding is consistent with a causal role for OP pesticides since they are far more widely used in North American than Italian households.

Since the banning of most organophosphates for home uses, pyrethroid and pyrethrin pesticides are increasingly used for control of household insects, recently reported to account for 17% of world insecticide sales (Davies et al., 2007). Pyrethrins are present in pet shampoos for fleas and ticks; pyrethroids, which are a synthetic version engineered for greater toxicity to insects, are widely used in household sprays and foggers for ants, flies, and cockroaches. In insects, they interfere with voltage-sensitive sodium channels (Davies et al., 2007; Shafer et al., 2005), although rodent studies also suggest glutamergic, and mechanisms GABA-mediated (Hossain et al., 2008), BDNF-gene expression changes (Imamura et al., 2006) and compromise of the blood brain barrier (Sinha et al., 2004). Pyrethroids are immunotoxic in experimental animals, causing decreased thymic weight (Garg et al., 2004; Prater et al., 2003), suppressed cellular immunity (Blaylock et al., 1995), altered macrophage, T cell and neutrophil function and lower IgG (Liu et al., 2006; Righi & Palermo-Neto, 2005) and reduced antibody production (Punareewattana et al., 2001). Two years after acute pyrethroid intoxication, patients had autoimmune disorders, deficient cellular and humoral immunity, and opportunistic infections (Muller-Mohnssen, 1999). These compounds have received little attention in human studies, but concern is raised by the presence of metabolites of pyrethroids in urine of most U.S. adults. Metabolites of pyrethroids are found in most U.S. adults (NHANES, 1999; Riederer et al., 2008).

Endocrine Disruptors

To date, little research has directly addressed any role of these compounds in autism etiology, but the critical contributions of various hormones to prenatal CNS development has led to numerous hypotheses. Many organochlorines are known to disrupt thyroid hormone homeostasis, as well as sex steroids, and the pesticides identified by Roberts & colleagues to be associated with autism (Roberts et al., 2007), endosulfan and dicofol are no exceptions. Thyroid hormones and sex steroids are of particular interest, and disruption of these endocrine systems by environmental pollutants has been studied extensively, including polychlorinated and polybrominated compounds, dioxins, pesticides, phthalates, bisphenol A, lead, and mercury. Thyroid hormones, specifically tri-iodothyronine, are required for differentiation and neuronal migration in early to mid-prenatal life, with common outcomes of hypothyroidism being mental retardation, deafness and speech problems (Porterfield, 1994). PCBs and other thyroid-disrupting chemicals have been shown to reduce levels of free and total thyroxine, inhibit sulfation, bind to thyroxine transport proteins, alter thyroid enzyme activity in the brain and/or increase levels of TSH in experimental animals (Brouwer, 1989; Brouwer et al., 1998; Crofton, 2008; Morse et al., 1993; Zoeller & Crofton, 2000; Abdelouahab et al., 2009). Roman has proposed that even a transient disruption in thyroid hormone homeostasis of a few days during prenatal development could underlie some cases of autism (Roman, 2007).

Numerous pollutants, including PCBs, dioxins, dichlorodiphenyltrichloroethane (DDT), phthalates, bisphenol A, and polybrominated diphenl ethers (PBDEs), and/or their metabolites (OH-PCBs, OH-dioxins, OH-BPA, etc.) have estrogenic, antiestrogenic, androgenic, or antiandrogenic properties

(Kester et al., 2002; Darnerud, 2008; Moore et al., 1997; Hamers et al., 2008; Meeker et al., 2009; Wilson et al., 2008). Human PBDE concentrations were found to be associated with free androgen index, as well as luteinizing hormone and follicle-stimulating hormone (Meeker et al., 2009). Baron-Cohen and colleagues have hypothesized that sex steroids, especially fetal testosterone concentrations in prenatal life, may alter autism-related behaviors and play a role in the sex ratio of autism diagnoses (Baron-Cohen et al., 2005; Knickmeyer et al., 2006). If this hypothesis is confirmed, some of the aforementioned compounds could operate through such a mechanism. PBDE concentrations in human tissues have been increasing over the last few decades (Sjodin et al., 2004). Phthalates operate as antiandrogens, and bisphenol A is estrogenic (Talsness et al., 2009). In a nationally representative sample of adults from the U.S., 92% had detectable levels of bisphenol A (Lang et al., 2008).

Lifestyle

Few studies have addressed potential risk factors such as smoking, alcohol, diet, or other aspects of lifestyle. The large-scale Swedish case-control study by Hultman et al., described above, observed daily smoking to be associated with a modest increase in risk for autism, OR = 1.4 (95% CI = 1.1, 1.8), whereas a population-based Danish study (Maimburg & Vaeth, 2006) did not find an association comparing smokers to nonsmokers based on maternal report at her first prenatal visit. The few case reports on alcohol do not represent real evidence of a link to autism, as discussed by Fombonne (2002).

Over the last few years, a number of nutritional hypotheses have been proposed for factors that might contribute to autism or explain its rise. At a fundamental level, nutritional factors have been shown to affect epigenetics, which in turn influences gene expression. Muskiet and Kemperman (2006) hypothesize that both autism and schizophrenia are influenced by early folate. Evidence cited in support of this theory comes from those exposed prenatally to the Dutch hunger, in which both schizophrenia and neural tube defects were increased, and elevated prevalence of MTHFR 677C→T homozygotes among schizophrenics. Data from the California-based CHARGE Study also indicate the use of prenatal supplements during the 3 months prior to conception or first month after conception may reduce the risk of autism (Schmidt et al., in press). Evidence also supports interactions between maternal intake of prenatal supplements and variants in folate metabolism genes. Rodier argues for an initial event occurring near the time of neural tube closure (Rodier et al., 1997). Folate may function epigenetically by ensuring sufficient methyl groups on DNA, or may promote methylation of proteins, phospholipids, and neurotransmitters in the prenatal period and beyond (Moretti et al., 2004).

Muskiet and Kemperman further postulate that these neuropsychiatric disorders are characterized by deficiency in

long chain polyunsaturated fatty acids such as arachidonic acid and docosahexanoic acid (DHA), essential in the phospholipids layer of cell membranes and critical to cell signaling. One report from the large CHARGE study (Wiest et al., 2009) and several smaller studies (Bell et al., 2000; Vancassel et al., 2001) provide supportive data regarding a deficiency of DHA in children with autism or ASD.

Another micronutrient proposed to be influential in autism etiology is zinc, which plays an essential role in preventing oxidative damage and ensuring expression of genes that direct embryonic development of the cerebral cortex and adrenal glands (Johnson, 2001).

Concern has been raised regarding reduced levels of vitamin D (Cannell, 2008). Also known as calcitriol, vitamin D is both a nutrient and a hormone. It is suggested that over the last few decades, vitamin D deficiency has increased as a result of increased use of sunscreens and reduced time spent outdoors. A remarkably high percentage of pregnant women are deficient in calcitriol (Bodnar et al., 2007). Prenatally, the vitamin D receptor appears in the brain very early in gestation, and vitamin D deficiency is associated with altered expression of proteins involved in neurotransmission, synapse formation, and calcium homeostasis (Almeras et al., 2007).

Based on the hypothesis that transient hypothyroxinemia early in gestation contributes to autism, Roman (2007) catalogs the many dietary, pharmacologic, and environmental chemical exposures that could operate through this pathway. These include soy-based flavonoids, pearl millet, and plants rich in thiocyanate, such as cabbage, cauliflower, and lima beans. Besides natural food sources, chemicals with antithyroid activity are found in tobacco smoke, many herbicides, PCBs, perchlorate, mercury, and phthalates.

Conclusion

From all the evidence gathered at this point in time, the etiology of autism appears to be highly multifactorial, complex in regard to timing of insults, influenced by susceptibility genes, and dependent on synergistic effects of combined exposures. From large epidemiologic studies, the data currently provide clues but few definitive results. The consistent increases in risk with advanced parental age might indicate a wide array of types of mechanisms. Strong associations with infectious agents, specifically viral infections during pregnancy, are intriguing; however, most of these are today quite rare because of vaccinations. The one exception is influenza. A number of investigations implicate one or another obstetric condition or medical intervention, but methodologic flaws impart the need for caution in interpretation. Studies on the MMR vaccine have not supported any major role, though more rigorous studies could enhance definitiveness of results. Investigations into thimersal have similarly shown no evidence of association with autism, but significant weaknesses in their design, and/or deficiencies in the analysis leave open the possibility of effects

in susceptible subgroups. Suggestive data on pesticides and sources of fetal stress should be pursued, including ambient air pollutants, such as from vehicle emissions. Additionally, mechanistic and toxicity studies provide the bases for future studies on a wide range of environmental chemicals, especially persistent organic compounds with endocrine-disrupting capacity. Nutritional factors also deserve serious attention.

To date, no gene has been identified that accounts for more than a few percent of autism cases, whereas linkage has been found to regions on virtually every chromosome. It is likely that the situation for environmental factors will similarly uncover dozens of factors each contributing to a relatively small proportion of cases. To the extent that the field assumes a "smoking gun," progress will appear disappointingly slow. Nevertheless, casting a wide net, linking large-scale epidemiologic investigations with state-of-the-art molecular science, "omics" or high-throughput technologies and mechanistic studies, and pursuing exploration of interactions—geneX-environment, geneXgene, and environmentXenvironment—are strategies that can be expected, with high probability, to bear fruit.

Challenges & Future Directions

- Autism etiology is multifactorial and the specific factors involved are likely quite heterogeneous, with each playing a relatively small role.
- Interactions of environmental, modifiable factors with common gene polymorphisms, or possibly sequence variants, may be involved in the vast majority of autism cases, dictating that large sample sizes are need to unravel these causes.
- Future studies should seek integration across disciplines and across mechanisms of investigation, from the molecular genetic, epigenetic, or signaling pathway to disruption of cellular or physiologic function, to the organismic, behavioral, and social levels of human responses.
- Molecular epidemiology is a particularly fruitful strategy, linking state-of-the-art bench science with large-scale human studies collecting biospecimens and a wide array of phenotypic, medical, environmental, social, and behavioral measurements.
- Attention to timing of exposures is critical, as there may be windows of vulnerability corresponding to specific mechanisms, developmental stages, or types of insult.

Environmental Exposures That Increase the Risk of Autism Spectrum Disorders

Points of Interest

- More is known about environmental risk factors for autism than for other developmental disabilities.
- The risk factors that have been established are all potent teratogens, which cause many different birth defects.
- The relative risk for each of the exposures is extremely high.
- The critical period for exposure for each environmental risk factor is during the first trimester.
- Phenotypic features that accompany the autism outcome after exposure are shared by several exposed groups and are seen in idiopathic cases and genetic syndromes, as well.

Autism spectrum disorders are unique among the conditions described in the *Diagnostic and Statistical Manual of the American Psychiatric Association* (DSM), in that several environmental exposures have been determined to increase the risk of ASDs. Although the etiology of autism is known to have a strong genetic component (e.g., Bailey et al., 1995), these environmental factors offer other avenues by which the nature of ASDs can be investigated. For example, they offer scientists the opportunity to create animal models based on exposures to risk factors, just as genetic discoveries offer the opportunity to create models by manipulating animal genotypes.

The environmental factors identified thus far account for a very small proportion of autism cases, but that does not diminish the importance of their contribution to our understanding of ASDs. The purpose of this chapter is to summarize our present knowledge of the environmental factors that are known to increase autism risk.

Rubella

Evidence and Relative Risk

The first environmental factor associated with autism was rubella infection (Chess et al., 1978; Chess & Fernandez, 1980). Because rubella exposure of the embryo has long been known to be a cause of birth defects including brain damage (Gregg, 1941; Ariens Kappers, 1957), it is hardly surprising that it might produce injuries that lead to autism. What is more remarkable is that a significantly elevated rate of autism was found using the very narrow criteria of Kanner (1943). It seems likely that the same population of rubella-exposed children, if examined with today's much broader definition of ASDs, would have shown an effect that was even more striking. However, comparing the 18 autism cases out of 243 rubella-exposed cases (Chess et al., 1978) to modern rates for autistic disorder (16.8/10,000, from Chakrabarti & Fombonne, 2001) gives a relative risk greater than 40. This is an enormous effect.

As we consider each of the known risk factors for autism, it will become apparent that each has a relative risk that is much higher than those familiar from toxicology studies. For example, the National Institutes of Health (NIH) recognizes a relative risk of 2 to 4 for the effect of smoking in increasing the risk of heart disease, and this is considered a large effect. It is worthwhile to pause here and consider what makes the risk factors for ASDs' relative risks dramatically higher. The effects of teratogens on development are different from the effects of toxic agents to which we are exposed over long periods. For example, in the case of rubella, postnatal exposure or exposure late in pregnancy cannot cause any of the permanent defects we associate with this virus. Instead, there is a brief window

during development when exposure leads to injury. This is called the critical period, and it differs for different teratogens and different defects. Notice that Chess ascertained cases exposed to rubella in an institutionalized population. That is, all the cases were severely injured. Therefore, only cases exposed during the critical period were represented in the 243 cases examined. The relative risk of 40 does not represent the risk associated with exposure to rubella at any time, or even with exposure at any time during pregnancy; it is the risk of autism among cases exposed during the critical period for severe injury. Throughout this chapter, the reader will find more examples of cases ascertained from selected groups of exposed populations. Often, there is no other way to identify exposed cases.

The reports from Chess' group did not consider the timing of exposure to rubella that resulted in autism, but critical periods for various rubella sequelae have been studied by others. Ueda, Nishida, Oshima, and Shepard (1979) investigated a sample of cases in which the time of appearance of the rash associated with the disease was known, and they described the outcome for eye defects, deafness, mental retardation, and heart malformations. They concluded that the period from the second to the fifth week postconception was associated with severe cognitive limitation, and cases with multiple defects had been exposed within the first 8 weeks. Because the autism cases reported by Chess and others all had multiple defects, it is likely that they had been exposed during the first 8 weeks postconception.

Fortunately, because of the development of a vaccine against rubella, we should no longer face the prospect of epidemics of this disease followed by epidemics of offspring with severe birth defects. As long as vaccination rates remain near 100%, this cause of autism has been eliminated.

Ethanol

Evidence and Relative Risk

In a clinic for children with Fetal Alcohol Syndrome (FAS) or Fetal Alcohol Effects (FAE), Nanson (1992) identified six who scored as severely autistic on the Childhood Autism Rating Scale (Schopler et al., 1988) in a sample of 326 cases. Each was also diagnosed with FAS, which requires facial dysmorphology, growth retardation, and dysfunction of the central nervous system. Subsequent papers (Harris et al., 1995; Aronson et al., 1997) have supported the conclusion that ASDs can coexist with FAS and perhaps with FAE. The additional cases described in these papers all shared the facial anomalies characteristic of FAS. The relative risk, based on the first study and again using Chakrabarti and Fombonne's data for autistic disorder, is over 10. Fombonne (2002) has pointed out several difficulties that make the ethanol studies hard to interpret. None is based on the kinds of diagnostic measures for autism that are commonly used today. Furthermore, FAS and FAE are very common,

so it is likely that they would occur in concert with autism occasionally by chance. However, the relative risk of 10 is still high, even with those caveats.

Rather than depending completely on the epidemiological findings, a teratologist might ask other questions to determine whether an association of ethanol exposure with autism makes biological sense. For example, "Is the critical period for FAS similar to any critical period associated with autism?" The critical period for FAS is thought to be in the third to fifth week postconception (Sulik et al., 1986). This period overlaps with the one we have just discussed for rubella, making it seem reasonable that ethanol exposures leading to FAS are occurring at a developmental stage that is sensitive to autism outcomes, as well. Another question might be, "Do children with FAS and autism share any dysmorphic features with autism after other exposures?" Yes, the facial dysmorphologies that characterize FAS (epicanthal folds, short palpebral fissures, underdeveloped maxillary region [Jones & Smith, 1973]) include features observed in autism subsequent to valproate exposure (to be discussed below). This suggests that the critical periods for autism after ethanol exposure and valproate exposure are similar. Thus, from an embryological standpoint, an FAS–autism association makes sense.

FAS and ASD Compared

Could it be that the behavioral phenotypes of ASDs and FAS are so similar that the autism diagnoses within FAS represent diagnostic substitution? First, let us consider the behavioral characteristics attributed to cases exposed to ethanol in utero. In the earliest description of FAS, based on eight severe cases in very young children (Jones et al., 1973), cognitive limitation was evident in all. Subsequent studies (e.g., Streissguth, et al., 1991) have examined a broader range of degrees of injury and included adolescents and adults, allowing a more detailed examination of cognitive abilities. The average IQ in this sample was 68, but almost half of the subjects fell in or near the normal range. Academic testing revealed that the subjects had particular difficulty with arithmetic, as compared to reading and spelling. Vineland (Sparrow et al., 1984) scores on daily living skills averaged age 9 years although the chronological age was 17 years. Socialization scores were the most affected, averaging 6 years of age. The patients in this study were not just deficient in adaptive behaviors, but exhibited a remarkable level of maladaptive behaviors. Of 31 subjects, none had a maladaptive behavior score in the insignificant range. The most common maladaptive behaviors cited were "poor concentration and attention, dependency, stubbornness or sullenness, social withdrawal, teasing or bullying, crying or laughing too easily, impulsivity, and periods of high anxiety."

After many years of recording caregivers' descriptions of the behavior of patients with prenatal alcohol injury, Streissguth, Bookstein, Barr, Press, and Sampson (1998) attempted to determine the descriptors most characteristic of offspring exposed to ethanol and evaluate descriptors for the

strength of their association with other items on the list. The result is a 36-item checklist, the Fetal Alcohol Behavior Scale, with some predictive value for identifying people exposed to maternal drinking.

This set of behaviors is a list of features of FAS/FAE, just as the diagnostic behaviors of autism are a list of features of ASDs. Starting with the behavior most highly correlated with the scale as a whole, the list includes: *(1)* overreacting to situations, *(2)* chatting with little content, *(3)* bringing up unusual topics, *(4)* demanding attention, and *(5)* not aware of consequences of actions. Of 36 items, only a few sound similar to the behaviors seen in autism. Many of the behaviors are more like the opposite of autism (e.g., likes to talk, interrupts, wants to be the center of attention, physically loving, overly friendly).

Bishop, Gahagan, and Lord (2007) have compared children with ASD diagnoses to children with FAS/FAE diagnoses, in an attempt to determine the core features of autism that separate this diagnosis from other disabilities. They used the AutismDiagnostic Inventory Revised (ADI-R) (Lord et al., 1994) and the Autism Diagnostic Observation Schedule (ADOS) (Lord et al., 2000) to evaluate sample groups of children with autism, pervasive developmental disorder, and FAS/FAE who were matched for age and full-scale IQ. The results are presented as sets of items on which the groups show great differences and ones on which they are more similar. ADI items from all domains were among those that discriminated between the groups. For example, subjects with autism were much more likely to have problems with pointing to express interest, using gestures, and imitative social play. These are from the communications domain. From the social domain, difficulties on items such as range of facial expressions, sharing enjoyment, and offering comfort were more than twice as common in children with autism as in those with FAS/FAE. The one behavior from the restricted and repetitive behavior domain with reported difficulties strongly favoring the autistic group was hand and finger mannerisms.

Direct observation with the ADOS also showed striking differences across domains for children with autism compared to the Fetal Alcohol spectrum. These included problems with eye contact, directed facial expressions, amount of reciprocal social communication, and unusual sensory interests. The authors have pointed out that even categories of behavior for which the groups seem to have similar degrees of difficulty may reflect different kinds of behavior. For example, abnormalities of group play with peers could be scored for a child who ignores the approaches of peers, or for one who is loud, bossy, and demanding (the second list is borrowed from the Fetal Alcohol Behavior Scale, described above). Bishop et al. (2007) suggest that reduced propensity for and frequency of social interactions seem to be core features of autism, but the quality of such interactions may be disturbed in too many ways to be as useful for diagnosis.

In summary, it seems unlikely that investigators could mistake the behavioral characteristics of FAS for those of autism. It seems more likely that a subset of FAS/FAE cases exhibits a different behavioral phenotype consistent with an autism

diagnosis. It remains to be seen whether that behavioral pattern arises from ethanol exposure alone, perhaps with slightly different timing, or on a different genetic background, from the more typical pattern, or whether the subset results from dual etiologies, with ethanol leading to the physical features by which FAS is diagnosed and some other factor leading to the behaviors diagnostic of autism. This author favors the view that high doses of ethanol early in pregnancy increase the risk of autism spectrum disorders.

Thalidomide

Evidence and Relative Risk

The description of autism among people exposed to thalidomide in utero (Strömland et al., 1994) is part of a remarkable study that offers a very specific time of origin for the injuries that resulted in autism. More extensive reporting of the ophthalmological results of the study can be found in work by Miller (1991) and by Miller & Strömland (1991). Work by Strömland & Miller (1993) provides a detailed description of the physical anomalies that characterized the patients. Of about 100 cases in the Swedish registry of thalidomide victims, Miller and Strömland were able to enroll 86 and personally examine them for a host of ophthalmological measures, for physical malformations, and for cranial neurological dysfunctions. In the course of their investigation, they noted four cases with obvious mental retardation and psychiatric disturbances. With the assistance of a psychiatrist, the cases with mental retardation were diagnosed as having autistic disorder, using the criteria of DSM III-R. Four cases in a sample of 86 suggest a relative risk of almost 30. However, the authors collected other data that show that the risk is even greater than this.

Each of the 86 subjects was examined for physical malformations. Strömland and Miller (1993) summarized earlier work on the specific stages of development when thalidomide results in particular physical effects. The earliest defects are those of the ears (starting at day 20 postconception) and cranial nerves, followed by those of the upper limb (starting at day 24) and then the lower limb (starting at day 27). Among the 86 cases studied in Sweden, only 17 had been injured in the earliest part of the critical period for thalidomide embryopathy, as evidenced by ear anomalies and cranial nerve dysfunctions without limb anomalies (Strömland & Miller, 1993). Each of the cases with autism had ear anomalies and cranial nerve dysfunction, indicating early exposure. One also had an upper limb effect, and none had malformations of the lower limb. Therefore, the period of injury that results in an autism outcome must be between days 20 and 24. If we use the 17 cases injured early as our denominator for our relative risk calculation, rather than including the whole thalidomide-exposed sample, then the relative risk for autism after exposure during the critical period is 140 times the risk in the general population.

For readers not familiar with the field of teratology, the finding of a very narrow window when a particular defect can arise is not unusual, but typical, of birth defects in general. In most cases we don't have supporting data to define a critical period as specific as the one in this study, but it is clear that such periods exist and that they depend on the coincidence of a particular exposure with particular events in development.

The critical period identified in this study is the time when the neural tube is closing and the first neurons are forming (Bayer et al., 1993). Those neurons are the motor neurons that make up the cranial nerve motor nuclei. The cranial nerve dysfunctions observed in the thalidomide study are evidence that some of these earliest-forming neurons were affected by the teratogen, offering another line of support to the critical period determined from physical malformations. Duane syndrome (a type of strabismus with lack of innervation from the abducens nerve to the lateral rectus muscle of the eye and reinnervation of the muscle by the oculomotor nerve) was seen in two of the cases with autism and in 24 cases altogether. Four others had some limitation of abduction. One case with autism had gaze paresis, as did six others in the total sample. Six patients had esotropia. Three of the patients with autism had palsy of the VIIth cranial nerve (the facial nerve) and 14 from the rest of the sample were affected. Abnormal lacrimation (lack of emotional tearing and/or crying to gustatory stimuli) was present in a total of 17 cases, including two of the cases with autism (Strömland et al., 1994; Strömland & Miller, 1993).

Mechanism of Action

The mechanism of action of thalidomide is not well-known. Recent hypotheses about mechanisms have focused on explaining the limb anomalies and may not explain the effects on the nervous system. It has long been known that the thalidomide-induced limb anomalies seen in primates and rabbits do not occur in rodents (Shumacher et al., 1968), but recent studies suggest that central nervous system (CNS) effects do occur in rodents (e.g., Myazaki et al., 2005; Hallene et al., 2006). Thus, it is possible that the mechanistic pathways involved in thalidomide teratogenicity may differ for different terata.

A recent series of studies in chick embryos indicates that thalidomide's disruption of limb development may have its origin in disturbances of the expression of bone morphogenetic proteins, leading to overexpression of the gene Dickkopf1, which inhibits *Wnt* signaling (Knobloch et al., 2007). Because thalidomide is a potent antiangiogenic agent (Folkman, 1995), another hypothesis has focused on the effects of the drug on angiogenic factors, such as insulin growth factor1 and fibroblast growth factor 2 (Stephens et al., 2000). Another idea is that the drug's induction of oxidative stress alters limb outgrowth by way of its effect on nuclear factor kappa B, a redox-sensitive transcription factor (Hansen et al., 2002). The authors have shown that thalidomide effects on this pathway differ between sensitive species (e.g., rabbit) and insensitive species (e.g., rat).

In summary, the Swedish thalidomide study, although carried out in humans, offers the kind of specificity and powerful conclusions usually seen only in animal studies. This is the result of many features of the study; for example, the fact that thalidomide's effects include very rare anomalies made it relatively easy to identify cases. Additionally, medical record keeping in Sweden is so thorough that exposures could be documented retrospectively. The discovery of autism among the subjects was serendipitous, but it occurred because the investigators devoted so much time to interacting with each subject and family, completing exhaustive examinations of each case. It is also a tribute to the scientific acumen of these expert clinicians that they did not confine their curiosity to their specialty (pediatric ophthalmology). It was the additional data on somatic defects and cranial nerve dysfunction that allowed them to understand the meaning of the autism cases.

Valproic Acid

Evidence and Relative Risk

All the antiseizure medications are teratogenic to some degree (reviewed in Holmes, 2002). They are frequently given in combination. The reader should be aware that these drugs tend to interfere with one another. The result is that patients taking more than one medication tend to be on higher doses of each drug than patients who are taking only one.

The first report of autism in a child exposed in utero to valproic acid (Christianson et al., 1994) appeared in the same issue of Developmental Medicine and Child Neurology as Strömland et al. (1994). The paper discusses two sibling pairs with classic features of Fetal Valproate Syndrome (Di Liberti et al., 1984; Jager-Roman et al., 1986; Ardinger et al., 1988; Kozma, 2001), such as epicanthal folds, hypertelorism, broad nasal bridge; long upper lip with flat filtrum, ear malformations, and "pinched" finger tips. One of the four children tested positive for autism. Developmental delay, and especially delay in expressive language, had been reported earlier (Ardinger et al., 1988) but those cases were not tested for pervasive developmental disorder. Soon, another case of autism in Fetal Valproate Syndrome was described (Williams & Hersh, 1997), then five more (Williams et al., 2001). One of the five had a performance IQ of 100 and a verbal IQ of 81, suggesting that the autism risk in Fetal Valproate Syndrome is not dependent on the mental retardation sometimes seen in the syndrome.

More recent studies have examined larger populations of children exposed to valproic acid in utero and offer information on the risk of autism after exposure to this teratogen. In the first (Moore et al., 2000), 52 cases were ascertained through a parent support group for children diagnosed with a fetal anticonvulsant syndrome and five came from referrals to the local genetics service. The main purpose of the study was to document and compare the dysmorphologies of the various

anticonvulsant exposures. In essence, the dysmorphologies of the valproate cases were similar to those described in the earlier case reports. Many other data were collected directly, as well, but behavioral diagnoses were ascertained from parental reports. As one might guess from the method of ascertainment, there was a very high degree of developmental delay or behavioral problems among children in the sample, with only four of the families reporting no problems.

Among the whole group, 34 had been exposed to valproate alone and 12 to valproate plus one or more other drugs. Among these 46 cases, there were three previously diagnosed with autism and two previously diagnosed with Asperger's Syndrome. There was one case with an autism diagnosis in which the individual had been exposed to carbamazepine and diazepam. Assuming that the reported clinical diagnoses were accurate, the five in 46 rate of ASDs appears to be very high. Because of the Asperger's cases, we must calculate the relative risk using Chakrabarti and Fombonne's value of 62.6/10,000 for pervasive developmental disorder (PDD) as the denominator, so the relative risk is about 17. However, in this study, with its subjects selected from a group already known to have behavioral problems, we have no way to estimate the true risk of ASDs among all children exposed to valproate in utero.

Rasalam et al. (2005) carried out a population-based study using records over a 20-year period to identify all local children known to have been exposed to antiepileptic drugs in utero. Their mothers had been referred to Aberdeen Maternity Hospital because of their high-risk pregnancies. There were 398 mothers who had 626 exposed children at the facility. From this pool, 159 mothers with 260 children agreed to participate in the study. Families were interviewed by a trained research nurse. The structured interview included questions about behavioral and social issues.

From the responses, 26 children were identified for an extensive review of their medical records, and 14 of these had indications of ASDs. The investigators accessed this group's complete records, including reports from specialists who had examined their behavior. A child psychiatrist then studied these notes for items specified in the DSM IV criteria for autism, and found that 12 met the criteria for ASD. Among those who had been exposed to valproate alone, five of 56 were positive and among those exposed to valproate alone or in combination with other drugs, nine of 77 were positive. Eight qualified for a diagnosis of autism and one for a diagnosis of Asperger's Syndrome. Comparing this rate to Chakrabarti and Fombonne's rate for PDD, the relative risk is about 19.

There may be a remaining selection bias in this study, even though it was a serious attempt to assess the whole exposed population. It seems possible that families of children with behavioral difficulties might be more likely to agree to recruitment than families of children developing normally. Unfortunately, we don't know whether this was the case, nor do we know how many children of the initial 626 children exposed to antiseizure medication were exposed to valproate. We don't know how many were lost to follow-up (their appearance in the unenrolled group does not represent a refusal of recruitment). However, assuming that the proportion exposed to valproate was the same in the unenrolled cases as in those who were enrolled, then even if we include those lost to follow-up and assume that there were no cases of ASDs in the unenrolled group, the risk associated with valproate would still be substantial. In fact, it is 7.72 with a confidence interval of 3.90 to 15.29. This is significantly different from 1.00 (no effect) at p = < .0001.

Now let us consider some other characteristics of the children evaluated in this study. For some variables, the authors describe the children with ASD diagnoses subsequent to exposure to antiseizure medications as a group, without separating out those exposed to valproic acid, but since most of the cases (9/12) had been exposed to valproate, these generalizations are of interest. The mean IQ of those with ASDs was below average, but most cases were in the normal range. No child had any evidence of regression or loss of skills. Results specific to the children exposed to valproate included: head circumference above average, a male to female ratio of 3:6, and an assortment of birth defects (e.g., strabismus, pyloric stenosis, hypospadias).

Children with autism after in utero exposure to valproate share the many dysmorphologies of Fetal Valproate Syndrome with exposed children who do not meet the diagnostic criteria for autism. Some of these features appear in other environmental etiologies as well. For example, epicanthal folds and maxillary hypoplasia are typical of Fetal Alcohol Syndrome as well as Fetal Valproate Syndrome. Strabismus and ear anomalies characterize children exposed to thalidomide as well as those exposed to valproate. These common features suggest that the critical periods for valproate teratogenicity must be similar to those for ethanol and thalidomide.

Mechanism of Action

The mechanism of action of valproic acid in teratogenesis cannot be described completely at this time, but at least two mechanisms have been identified. First, valproate is a direct inhibitor of histone deacetylase (HDAC) (Phiel et al., 2002). The HDACs have a role in the folding of chromatin, and their inhibition can unfold chromosomes, making some genes more available for transcription. Other HDAC inhibitors are also teratogenic, so there is good reason to think that this mechanism is one of the ways valproic acid alters development. It has been proposed that increases in *Wnt* gene signaling after HDAC inhibition are one of the mechanisms by which valproic acid leads to birth defects (reviewed in Wiltse, 2005).

A second mechanism, which may be related to the first (see Gurvich et al., 2005), is the ability of valproate to drive the expression of the gene, *Hoxa1* (Stodgell et al., 2006). This gene is critical to the development of the early embryo when the neural plate is developing into the neural tube, and it plays a special role in hindbrain development (Chisaka et al., 1992). Its expression is dependent on levels of retinoic acid and both high and low levels of retinoic acid are extremely teratogenic,

presumably because of their effect on the levels of *Hoxa1* expression (e.g., Means & Gudas, 1995; White et al., 2000).

A number of analogs of valproic acid have been synthesized and tested for antiseizure activity and teratogenicity (e.g., Hauck & Nau, 1989; Bojic et al., 1996). These studies have demonstrated that the antiseizure property of the drug and the teratogenic property do not share the same mechanism. Stodgell and others (2006) made use of these analogs in their studies of gene expression in rat embryos after exposure to valproate. They found that compounds with high teratogenicity had strong effects on *Hoxa1* expression, although those with no teratogenic action had no effect on the expression of the gene. Thus, the effect on *Hoxa1* may be one mechanism of action of the drug. These effects on the gene's expression can be seen only during its normal period of expression (the time of neural tube closure) and very brief periods before and after normal expression.

Animal Model

More than the other environmental factors discussed above, valproate has proven useful in the creation of animal models relevant to autism (reviewed in Arndt et al., 2006). Rats exposed to the drug around the time of neural tube closure exhibit several neuroanatomical features similar to ones reported in histological studies of brains from people with autism. For example, the rat model has low Purkinje cell counts and small cerebellar volume (Ingram et al., 2000). The same features have been reported in human autism cases (e.g., Bauman & Kemper, 1985; Ritvo et al., 1986; Bailey et al., 1998; Whitney et al., 2008; Courchesne et al., 1988).

The rat model has also been found to express a variety of behavioral abnormalities (e.g., Schneider et al., 2001; Schneider & Przewlocki, 2005; Stanton et al., 2007; Schneider et al., 2007; Markram et al., 2008). Many of the behavioral effects are in general categories of behavior that are related to autism (e.g., nociception, social behavior) but a few are in very specific behaviors known to be affected in the same way as in autism. One is a decrement in prepulse inhibition of the acoustic startle response. This was first reported in subjects with ASDs by McAlonan and colleagues (2002) and more recently by Perry and colleagues (2007). The same depression of prepulse inhibition has been demonstrated in rats exposed to valproate around the time of neural tube closure (Schneider & Przewlocki, 2005). This measure of sensory gating in the CNS could be related to failures of inhibition as seen in repetitive thoughts and actions in autism.

Eyeblink conditioning is a second very specific behavior affected similarly in both human autism and the valproic acid rat model. This basic paradigm of association learning, in which a tone is paired repeatedly with a stimulus to the eye that causes a blink until the blink occurs to the tone alone, has been studied in many neurological and psychiatric conditions. For example, children with FAE or dyslexia are severely impaired in acquisition of the conditioned eyeblink response (Coffin et al., 2005), as are people with Alzheimer's disease

(Woodruff-Pak & Papka, 1996a). People with Huntington's disease have normal acquisition of the learned response, although the timing of their blinks is abnormal (Woodruff-Pak & Papka, 1996b). In contrast to all the other conditions that have been studied, autism results in an enhancement of conditioning (Sears et al., 1994; Arndt et al., 2006). The same enhancement has been demonstrated in the rat model exposed to valproate (Stanton et al., 2001). Thus, the rat exposed to valproate around the time of neural tube closure has both anatomic and behavioral parallels to autism.

Misoprostol

Evidence and Relative Risk

Misoprostol is a prostaglandin with various legitimate uses in medicine. In South America, it is used illegally by the poor as an abortifacient. Exposure causes uterine contractions, which may or may not expel the conceptus. When the drug fails and the conceptus comes to term there is a risk of birth defects consistent with ischemia in utero (Gonzalez et al., 1998). One of these is Moebius sequence, a bilateral or unilateral diplegia of the facial nerve and the abducens nerve. Investigations of familial cases of Moebius sequence indicate that anomalies of multiple genes can produce the deficit (Verzijl et al., 1999). There is also evidence that environmental factors play a role (Lipson et al., 1989). Ischemia was suggested as a possible cause of Moebius sequence long before the teratology of misoprostol was recognized (Bavinck & Weaver, 1986). The rate of autism is high among idiopathic cases of Moebius sequence (e.g., Johansson et al., 2001).

Bandim and colleagues (2003) recruited children diagnosed with Moebius sequence in Brazil, queried their mothers regarding misoprostol use, and tested the Moebius cases for autism. In the 23 cases under study, 14 had been exposed to misoprostol, according to the mothers' statements. Among these, three met the criteria for an autism diagnosis under DSM IV. Of the nine children whose mothers denied misoprostol use, two met the criteria for an autism diagnosis. Thus, the relative risk for autism in misoprostol-induced Moebius sequence is 128. Notice that this incredible risk does not apply to misoprostol exposure in general, but only to exposures with dose and timing adequate to cause Moebius sequence. Unfortunately, at this time, we have no way to tell whether misoprotol exposure has occurred unless it has caused an obvious but rare birth defect such as Moebius sequence. The results in cases not exposed to misoprostol support earlier findings that idiopathic cases of Moebius sequence have a high rate of autism. Indeed, the 2/9 rate is just what other studies would predict. For example, the rate in the study by Johansson and colleagues (2001) was about 25%.

Why is Moebius sequence related to autism? The fact that ischemia of the brain stem appears to be the etiology of the misoprostol cases suggests that it may be the location of injury

that links the two conditions. All the mothers who reported using misoprostol in studies by Bandim et al. (2003) exposed the embryo in the sixth week postconception, so the timing is slightly later than that discussed for other teratogens that increase autism risk. Further, the proposed mechanism, ischemia, seems unrelated to the mechanisms proposed for other factors. But we know from the neurological symptoms of valproate-exposed cases and thalidomide-exposed cases that brain stem nuclei were affected and animal studies show that valproate exposure can injure the developing cranial nerve motor nuclei (e.g., Rodier et al., 1996). Thus, location of injury appears to be the one obvious common feature shared by Moebius sequence and autism associated with environmental etiologies.

What Can We Learn from Environmental Etiologies?

Early Origins and Neurobiology

The fact that all the environmental factors recognized thus far share critical periods in embryonic life (the first 9 weeks postconception) is an important contribution to our understanding of autism etiologies. Table 48-1 summarizes the critical periods for all the known environmental risk factors. At the time these studies began to appear, few scientists were thinking that autism's origins might occur so early in development. But in retrospect it seems obvious that very early injuries are the ones with the potential to explain the histology and connectivity observed in the brains of people with autism. For example, low numbers of Purkinje cells have been reported by many investigators, as discussed above, and Ingram et al. (2000), demonstrated that this condition could be reproduced in rats exposed to valproic acid during neural tube closure. Interestingly, the exposure used in this study occurred before the Purkinje cells form, so they were not injured directly. This reminds us that insults to a developing brain can have consequences for later-forming structures.

Table 48–1.
Exposure period associated with an autism outcome for five known environmental risk factors

Environmental Risk Factor	Critical Period (Postconception)
Rubella	< 8 weeks
Ethanol	2 to 5 weeks
Thalidomide	20 to 24 days
Valproic acid	3 to 4 weeks
Misoprostal	6th week

The deep nuclei of the cerebellum have been studied in a number of brains from people with autism (Bauman & Kemper, 1994; Bailey et al., 1998). The globose and emboliform nuclei were especially altered, although the dentate nucleus was less affected. These nuclei form just before the Purkinje cells (Bayer et al., 1993), again suggesting an early injury.

Rodier et al. (1996) reported a case of autism in which the superior olive was virtually absent. This very early-forming complex of nuclei (Bayer et al., 1993) is the first point in the auditory pathway where information from both ears converges on the same neurons, and plays a role in sound localization. Recently, experts on the structure examined five brains from people with ASDs and found that the medial superior olive was abnormal in every case (Kulesza & Mangunay, 2008). The normal strict orientation of the neurons was deranged, even in cases where the number of neurons appeared to be unaffected.

Early loss of neurons can alter the connections formed subsequently by other neurons. Duane syndrome, as seen in thalidomide-exposed subjects (Strömland & Miller, 1993) is a good example. Many theories of the neurobiology of autism focus on abnormalities of connections (e.g., Just et al., 2004; Kana et al., 2007), and it is easy to see how projections might go to the wrong places when tissue that provides axonal guidance to them is missing or altered. In the case reported by Rodier et al. (1996), fibers that normally go up or down the neuroaxis were seen going in all directions in the region where they would typically form a capsule around the facial nucleus. In its absence, they appear to have lost their orientation. In Bailey et al. (1998), one case of autism exhibited an extra brain stem tract never seen in controls. All these findings fit well with the idea of a disruption of development in the early embryo.

Early Origins and Early Developmental Genes

In retrospect, we now know that a number of the genes thought to play a role in autism are ones whose main or only period of expression occurs in embryonic life. These include *Engrailed 2*, which organizes aspects of early cerebellar development (Joyner et al., 1991; Kuemerle et al., 1997). Several alleles of the human gene have been shown to be associated with autism, although the causal variants have not been identified (Gharani et al., 2004; Benayed et al., 2005).

Individuals who inherit two copies of a truncating mutation of *HOXA1* have a high rate of autism, as well as deafness, vascular malformations, large head size, Duane syndrome, and facial hypotonia (Tischfield et al., 2005; Bosley et al., 2007; Bosley et al., 2008). This is called the Bosley-Salih-Alorainy syndrome (BSAS). Homozygous inheritance of another truncating mutation of the same gene (Holve et al., 2003; Bosley et al., 2008) leads to many of the same symptoms, but not autism.

Several theories of the mechanisms of action of valproate involve the *Wnt* gene pathway, and there is some evidence that

WNT2 might be a susceptibility gene for autism (Wassink et al., 2001). The involvement of early developmental genes in the etiology of autism makes the early critical periods found for teratologic risk factors seem logical, rather than surprising.

Communalities Across Etiologies

It would be exciting if all the environmental risk factors shared similar mechanisms of action, but they do not. Although their critical periods are similar, they are not exactly the same. Yet this review demonstrates that patients with these different etiologies do share many characteristics. Table 48-2 summarizes some characteristics shared across different conditions leading to autism. For example, there are some common facial features shared across several risk factors, such as malformed ears, epicanthal folds, and maxillary hypoplasia. There are dysfunctions of cranial nerves, such as strabismus and Moebius sequence.

In addition, some individuals exposed to environmental risk factors have symptoms also observed in cases with disruptions of early developmental genes. Hearing impairments are typical of rubella-induced autism, thalidomide-induced autism, and of both syndromes traced to homozygous inheritance of truncating mutations of *HOXA1*. The large head size reported in valproate-associated autism is also present in BSAS (Tischfield et al., 2005). Duane syndrome is typical of thalidomide-induced autism and of both syndromes arising from deficient expression of the HOXA1 protein.

Do idiopathic cases of autism share any of the symptoms reviewed for environmental exposure etiologies and early developmental gene etiologies? Obviously, they do. The high rate of minor craniofacial malformations in idiopathic ASDs has been recognized for many years (e.g., Steg & Rapoport, 1975; Walker, 1977). Because these can only arise during early stages of development, their presence suggests that many idiopathic cases have been subject to some early disturbance of development.

Strabismus, which we have seen to occur after exposure to thalidomide and valproate, and after homozygous inheritance of truncating mutations of *HOXA1*, has been noted to occur at elevated rates in idiopathic cases of autism as well (e.g., Sharre & Creedon, 1992). Similarly, the comorbidity of Moebius sequence or facial hypotonia with autism is seen in idiopathic cases (e.g., Johansson et al., 2001), as well as in cases associated with environmental risk factors and genetic syndromes reviewed here.

Large head size is a particularly interesting characteristic of a substantial number of people with ASDs that has received much attention. It appears that overgrowth of the brain and head begins soon after birth and tapers off in the second year of life (e.g., Courchesne et al., 2003; Dawson et al., 2007). One might speculate that postnatal overgrowth reflects some untoward influence on postnatal development occurring during the period of excessive growth. However, the fact that prenatal exposure to valproic acid also results in large head size (Rasalam et al., 2005), suggests that it may not be necessary to propose any postnatal events to account for this phenomenon. Indeed, the presence of large head size in Bosley-Salih-Alorainy syndrome proves that genetic activity altered only in the embryonic period can lead to large head size later in life. Even a single nucleotide polymorphism of *HOXA1* has been shown to be associated with the quantitative trait of head size in autism (Conciatori et al., 2004). The same polymorphism influences head growth rates in typically developing children as well (Muscarella et al., 2007). Even though large heads occur after birth, the conditions that create them may be set in motion much earlier in development.

Does Cognitive Limitation Play a Part in Environmental Etiologies of Autism?

The question has often been raised as to whether the cognitive impairment associated with many teratogenic exposures creates the apparent association of ASDs with environmental factors. In some situations, as when sample cases are collected from institutional settings, the patients are almost certain to have cognitive deficits, but this may not be true of all autism cases with the same etiology. A good example comes from two studies of autism in Moebius sequence. In the first, subjects were recruited from institutional care, and all the autism cases had cognitive limitation (Johansson et al., 2001). In the second study, subjects were recruited from families attending an international meeting of support groups for people with a Moebius sequence diagnosis (McConnell et al., 2002). In this sample, the rate of autism was slightly higher than in the first study, but more than half of the autism cases had IQs in the normal range. Among the studies of environmental exposures discussed in this chapter, several have provided data on IQ. Rasalam et al. (2005) reported IQ data for all their subjects exposed to valproate. Although the mean IQ was significantly lower in subjects with ASDs than in those without, most

Table 48–2.

Craniofacial anomalies reported in individuals with autism subsequent to four environmental exposures and one genetic syndrome

	Thalidomide	VPA	FAS	Misoprostol	BSAS
Large head size		yes	no		yes
Moebius sequence or facial hypotonia	yes			yes	yes
Duane syndrome or other strabismus	yes	yes		yes	yes
Abnormal tearing	yes			yes	
Epicanthal folds		yes	yes		
Ear abnormalities	yes	yes			yes
Hearing deficits	yes				yes
Hypoplasia of the midface or maxilla		yes	yes		

subjects with ASDs had IQs within the normal range. The four thalidomide cases studied in Strömland et al. (1994) had cognitive limitation, but a fifth case, whom the investigators were unable to recruit, was known from her records to have autism and a normal IQ. Additional data from the Brazilian misoprostol study has been shared with the author, and suggests that three of seven autism cases tested for IQ fell in the normal range (personal communication from Liana Ventura, 2009). Taken together, the available data do not rule out a role for cognitive limitation as a contributing factor in the autism rates observed after environmental exposures, but they do indicate that cognitive limitation is not a requirement for the development of autism after environmental exposures.

In summary, the discovery of environmental factors that increase the risk of autism has given us information that helps to explain many histological findings in this spectrum of disorders. An early origin for autism fits well with the issues of connectivity that seem to be part of the neurobiology of ASDs. Cases with different environmental etiologies are related to one another in symptoms and the same symptoms can be seen in some cases with known genetic etiologies. Similarly, those same symptoms often occur in idiopathic cases. Rather than being a set of rare etiologies unrelated to the much greater number of cases of unknown origin, cases associated with environmental risks appear to represent different developmental pathways to similar phenotypes.

Conclusions

The discovery of environmental exposures that increase the risk of autism spectrum disorders has provided the field with new ideas regarding the etiology of autism and new approaches to understanding its neurobiology. The idea that autism arises in early stages of development is a strong message from studies of environmental risk factors. Animal models, such as the one based on early exposure to valproic acid, promise to add to our understanding of both anatomy and behavior in autism. Comparing cases whose autism arose after environmental exposures to idiopathic cases and to some genetic syndromes suggests that different etiologies often result in similar outcomes. Not only are the diagnostic behaviors similar across etiologies, but so are some neurological and somatic anomalies that occur with increased frequency in people with autism. Although we need ways to stratify cases to advance our understanding of the genetics of autism, we also need to recognize phenotypic features that are shared by different etiologies.

Challenges and Future Directions

- It is no accident that the first five environmental risk factors identified are a virus and four drugs. It is much easier to identify these kinds of exposures and determine

dose levels for them than for many potential teratogens. Can we recognize the association between terata and exposures to agents that are widespread in the environment? This is a much greater challenge, especially when individual doses are unknown.

- Susceptibility genes that interact with environmental exposures should vary from one risk factor to another. Can we identify these genes?

Autism and Environmental Genomics: Synergistic Systems Approaches to Autism Complexity

⊞
Points of Interest

- Genomic and environmental factors work together in determining risk and severity of ASDs. Four mechanisms are highlighted:
  - Gene–environment interactions (GxE) (genetic susceptibility to environmental exposures).
  - Environmental factors causing genetic damage in germ cells (including point mutations or structural changes).
  - Environmental factors acting via heritable epigenetic modifications.
  - Genetic traits influencing environmental exposure via behavior (sometimes called *gene–environment correlation*).
- The apparently high heritability of ASDs is often misinterpreted as ruling out a large role for environmental risk factors. In fact, common, preventable environmental factors might be just as necessary as genetic factors for the occurrence of ASDs, despite high heritability, because of gene–environment interplay:
  - Heritability estimates mistakenly count gene–environment interaction as purely genetic for environmental exposures shared by twins.
  - Many genetic contributors may actually depend upon environmental exposures to have an impact, making the exposures the root cause.
  - Heritable epigenetic causes also may result from environmental exposures as the root cause.
  - Shared placentas are an environmental factor that may boost monozygotic (MZ) twin concordance and apparent heritability (through a different sort of gene–environment correlation). Genetic effects on a child's individual (nonshared) social environment (traditional gene–environment correlations) also inflate apparent heritability.

- Genetic findings in ASDs should inform research on environmental pollutants (or other risk factors) and vice versa, since genes and pollutants may have common targets. Greater collaboration, synthesis, and prioritization of risk factors based on toxicology and population attributable fraction (PAF) would be valuable. A systems and pathway-based approach, using bioinformatics and toxicogenomics tools would also benefit ASD research.

⊞
Introduction

What is "environmental genomics" and why is it important in research on autism spectrum disorders? The title of this chapter is meant to suggest that both environment and genetics are important in ASDs, and that studying the genome and environment together, in an integrated, systems approach, can drive a fruitful research and intervention agenda.

Genetics is obviously important in ASDs. But the investigation of genetic influences has run into frustrating limitations, including a realization that genome-wide association studies suffer from a high rate of false positive findings (Ioannidis, 2005; Moonesinghe et al., 2007), as well as generally modest-to-small odds ratios (typically less than 1.5) (Wellcome Trust Case Control Consortium, 2007; Allen et al., 2008; Harrison & Weinberger, 2005). In cases where larger odds ratios are suggested in autism gene candidates, the risk-associated variants are rare, so the PAF is still small, meaning that no single genetic factor has been able to account for even 50% of all cases of ASDs. Even all de novo copy number variants (CNVs) combined may be a critical factor in roughly 6% (Sebat et al., 2007) or speculatively perhaps up to 30% or more of ASDs (Zhao et al., 2007; Guilmatre et al., 2009). Genetics research is in need of new approaches that can explain and ultimately treat or prevent a larger share of all cases of ASD.

A simple focus on environmental factors alone is likewise unable to provide an adequate explanation for autism. Although various lines of evidence implicate environmental risk factors in ASDs (Institute of Medicine, 2008; Newschaffer et al., 2007; Lathe, 2006; Pessah & Lein, 2008) no specific environmental factor as yet has been verified with a large PAF. This may be because each important environmental factor mainly affects some genetic subgroup, or because many environmental factors converge upon common biological targets; either would make detection of specific culprits unlikely, because (partly resulting from sample size requirements) almost no studies of environmental factors in autism have examined risk stratified by genetic subgroup or biological mechanism of impact.

Although many research groups are still focused on either genes or environmental risk factors alone, striking progress has been made by those who study how genome and environment work together to cause disease. As explained in this chapter, they work together in several important ways, and four mechanisms are highlighted here:

> Environmental factors causing genetic damage in germ cells (including point mutations or structural changes).
> Environmental factors acting through epigenetic modifications.
> Genetic traits influencing environmental exposure via behavior (sometimes called *gene–environment correlation*).
> Gene–environment interactions (GxE).

These four general mechanisms cover a broad range of potential routes by which environmental and genetic or epigenetic factors may work together to either cause or affect the severity and phenotypic diversity of complex conditions such as ASDs. These four types of causal routes may provide a useful overarching framework for considering the many specific mechanisms that may contribute to the risk and severity of various aspects of ASDs. The advantage of this simple framework is that it calls attention to a very broad range of ways in which environmental and inherited risk factors may jointly contribute to ASDs. In particular, this perspective extends beyond narrowly defined gene–environment interaction (as discussed below), to highlight the potential importance of environment in causing de novo genetic and also epigenetic alterations, both of which have received little attention in ASD research until very recently.

There has been substantial confusion in the general public about the relative importance of environment and genetics in autism. A critical factor underlying the debate has been the widespread citation of extremely high heritability estimates. In the face of these estimates many have considered the residual role for environmental factors to be so small as not to merit serious attention. However, upon examination it becomes apparent that these heritability estimates, as well as related estimates of PAF, can be misleading and lead to erroneous conclusions about the contributions of genetics and environment (Visscher et al., 2008). In general, there is a long history

of misinterpretation of estimates of the share of cases attributable to environmental (or other) causes, as emphasized at the start of the authoritative textbook, *Modern Epidemiology*, by Rothman and Greenland (1998). As these authors point out,

> "There is a tendency to think that the sum of the fractions of disease attributable to each of the causes of the disease should be 100%… it is clear on a priori grounds that 100% of any disease is environmentally caused…. Similarly, one can show that 100% of any disease is inherited…. Many researchers have spent considerable effort in developing heritability indices that are supposed to measure the fraction of disease that is inherited. Unfortunately, these indices only assess the relative roles of environmental and genetic causes of disease in a particular setting."

The significance of this point is further developed later in this chapter, but the essential point is that a disease can be simultaneously 100% genetic and 100% environmental. Another way of putting it is that genetics may be essential, but not sufficient, to cause autism. An implication for public health is that if environmental factors are also essential, then environmental changes may be able to prevent disease or reduce its severity.

The mechanisms by which genome and environment work together in ASDs are still unclear for the most part. What is clear, however, is that the simplistic dichotomy of nature versus nurture is largely obsolete, and that both are essential.

Just as viewing genome and environment separately limits progress, a piecemeal approach to risk factors and biological avenues of inquiry may be insufficient. Given the limited findings from attempts to find single strong causes, shifting to a systems biology perspective (Kitano, 2002) (i.e., genomics and epigenomics rather than genetics, and multiple environmental factors rather than one chemical at a time) may allow us most effectively to synthesize and reconcile findings related to multiple genes and multiple environmental risk factors that seem disparate and inconsistent when considered separately. It is important to note that this does not mean ASDs should be treated as a monolithic disorder whose many and varied features can be explained by a unified set of causes. On the contrary, it is essential to recognize the heterogeneity of ASDs' features and causes (Happé et al., 2006), and a key goal should be synthesis at the population level, where various features are influenced by various causes across various individuals, forming a complete picture that accounts for the wide range of conditions.

Finally, autism research also would benefit from greater integration of findings across biological levels and areas of expertise, linking new data from genetics, toxicology, physiology, epidemiology, and other fields. The next phase of progress will require greater application of high-throughput data along with tools from systems biology and bioinformatics, to study more comprehensive sets of molecules, genomic features,

microbiota, physiological functions, cell types, brain regions, systems, and symptoms.

Part One: Mechanisms by which Genome and Environment Work Together

To help transcend the historical polarization, it will be useful to consider four ways environment and genome/epigenome can work together. These four causal routes are sketched in Figure 49-1.

Genetic Damage (E→ G→ D)

Some recent evidence has suggested that a substantial percentage of cases of autism—perhaps on the order of 6%, though some have suggested the majority of cases—may be attributable to de novo genetic changes (Sebat et al., 2007; Zhao et al., 2007). To the extent this is true, it becomes critical to determine the cause of these genetic alterations. Many authors have referred to de novo genetic changes as "sporadic" or as resulting from "stochastic processes." This may imply they occur for no particular reason or with no identifiable cause. But in fact environmental factors can cause genetic damage, and susceptibility to such damage is also influenced by nutrition (Bagnyukova et al., 2008) and by genetic factors, including genes involved in xenobiotic metabolism (Dorne, 2007) and DNA repair (Spry et al., 2007). Particularly if a substantial share of autism is attributable to de novo changes, this has important implications for etiology and possibly prevention.

DNA damage can be passed on to the next generation if it occurs in germ cells (sperm or oocytes), rather than just in somatic cells (as in cancer). The effects of germ line damage are initially seen as de novo mutations; but in subsequent generations, assuming the carrier reproduces, they are inherited and seem to be simply genetic causes of disease even if they originally resulted from environmental exposures.

Recent work suggests oxidative damage is a major cause of increased recombination and mutation in germ cells (Ohno et al., 2006). This hypothesis has profound implications for the study of genetic and environmental causes of disease, and suggests the need for research focused on environmental agents causing oxidative stress and subsequent DNA damage.

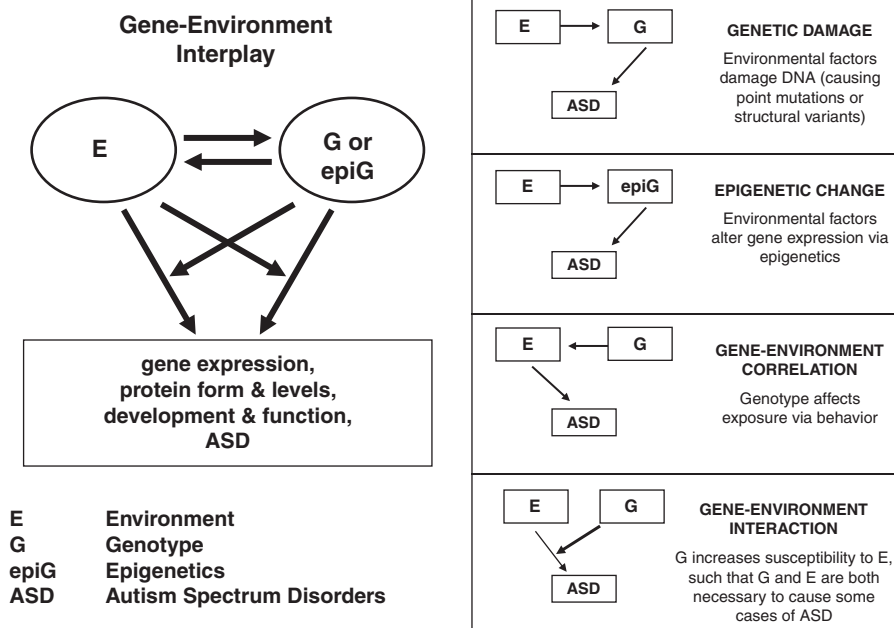
Numerous environmental factors result in DNA damage, including environmental toxicants, infectious agents, radiation, and some medications (Elespuru & Sankaranarayana, 2007). Given reported associations of ASDs with urban birth (Lauritsen et al., 2005; Williams et al., 2006), the link between urban air pollution and DNA damage may be relevant. Although hundreds of genotoxic chemicals are found in urban air samples, the components most often studied and implicated as causing DNA damage are components of particulate matter (a complex mixture of substances), particularly polycyclic aromatic hydrocarbons (PAHs) (DeMarini & Claxton, 2006; Tovalin et al., 2006). The urban environment, however, contains thousands of chemicals in addition to air pollutants, and a review of these candidates is beyond the scope of this discussion. The urban environment also differs from rural settings in terms of exposures to infectious agents and allergens in


Figure 49–1. Potential direct and interactive effects of environment, genes, and the epigenome on disease.

ways that increase risk, for example of allergies among certain genotypes (Becker, 2007; Martinez, 2007).

There are substantial gender differences in germ cell mutagenesis, in type and risk of mutation, which in cases of de novo mutations may provide clues about which parent was exposed and at what age (Crow, 2000; Eichenlaub-Ritter et al., 2007). Paternal age is a risk factor for ASDs (Croen et al., 2007; Kolevzon et al., 2007; Grether et al., 2009), and genetic damage in sperm cells does increase with the father's age (Wyrobek et al., 2006). Some recent research, though not specific to ASDs, suggests that >80% of de novo structural chromosomal abnormalities in live births are paternally derived, and most spontaneous point mutations also are of paternal origin, according to work cited by Eichenlaub-Ritter, Adler, Carere, and Pacchierotti (2007). Maternal age is a risk factor for aneuploidy (Hassold et al., 2007). Although full-blown aneuploidy does not appear to play a major role in ASDs, in one recent study 16% of 116 boys with idiopathic autism reportedly had greatly elevated rates of mosaic aneuploidy (mostly gains of the X chromosome) (Yurov et al., 2007).

Although dozens of germ line genotoxins have been identified in animal models, definitive identification of germ line mutagens in humans has been elusive for a variety of reasons (Wyrobek et al., 2007). The strongest evidence suggesting environmentally caused germ line genotoxicity in humans includes recent studies showing increased chromosomal aberrations and other forms of DNA damage in sperm following exposure to chemotherapeutic agents or radiation, and germ line mutations found in children born in heavily polluted areas following the Chernobyl accident (Wyrobek et al., 2007). Germ cell mutagens are defined and classified by the United Nations globally harmonized system (GHS) and other national approaches (Morita et al., 2006). There are well over 100 substances classified by the GHS as *Class 1B germ cell mutagens*, which are chemicals that "should be regarded as if they produce heritable mutations in the germ cells of humans." (United Nations, 2003)

A substantial body of evidence beginning in 1975 has shown that urban outdoor air pollution causes DNA damage, and more recent work has extended findings to heritable (germ line) mutations in male mice (Somers et al., 2004; Samet et al., 2004), with lower rates of DNA damage in rural areas or when urban air is first filtered to remove fine particulate matter, and these findings have been reviewed recently (Claxton & Woodall, 2007). Interestingly, DNA damage in human sperm now has been linked to elevated levels of air pollution, particularly in a high-risk GSTM1 genotype (Rubes et al., 2007), such that the preceding 90-day-average particulate matter concentration predicted elevated sperm DNA damage. Additional environmental factors including folate intake may affect susceptibility to germ line DNA damage (Boxmeer et al., 2008).

Environmental genotoxins can cause various types of point mutations, structural changes (deletions, insertions), or aneuploidy, through a variety of mechanisms (Salnikow & Zhitkovich, 2008; Schins & Knaapen, 2007; Husgafvel-Pursiainen, 2004).

Different types of environmental mutagens cause differing types of DNA changes, and to some extent leave signatures. For example, as discussed in the very useful review by Claxton and Woodall (2007), $G \rightarrow T$ base substitutions are the main type of mutation produced by PAHs and nitroarenes. Research may be able to identify certain types of DNA alterations that occur more often in autism, and this might provide clues regarding the causes of those alterations. A recent study demonstrated the great potential of genome-wide analysis of various types of genetic damage and their connection with disease, in a comprehensive analysis of multiple tumors in human breast and colorectal cancer (Wood et al., 2007), where the two cancer types had different types of mutations, interpreted as suggesting exposure to different mutagens or differences in the DNA repair process.

Epigenetic Change/Damage (E→ epiG→ D)

Inherited epigenetic (epiG) alterations may be one explanation for why genetic factors identified to date have been unable to explain most cases of ASD, despite high heritability (although rare or multiple interacting factors are also possible explanations). In fact, it is very possible that the careful regulation of gene expression and more importantly protein levels, not the DNA sequence itself, is what really matters most often in ASDs. In any event, it is increasingly recognized that gene or protein dosage, not just function, can be critical in neurodevelopment.

Epigenetic change and damage in ASDs have thus far been little studied, so their potentially important roles have not yet been elucidated. A significant role for epigenetic factors in autism has been proposed in recent years (Jiang et al., 2004), and is supported by several findings related to MECP2 and MBD1 (Hogart, 2007; Cukier et al., 2008; Allan et al., 2008; Nagarajan et al., 2006), as well as evidence that methylation is impaired in some fraction of ASD cases (James et al., 2006; Deth et al., 2008) and possibly the fact that valproic acid (a risk factor for autism and used to create an animal model of autism) causes epigenetic changes, via its action as a histone deacetylase (HDAC) inhibitor (Schneider et al., 2008; Moore et al., 2000; Khan et al., 2008). Genetic disruptions of normal epigenetic mechanisms also appear to be important in causing mental retardation (Kramer, & van Bokhoven, 2008), and their importance in the nervous system has been reviewed (Colvis et al., 2005). Knowledge is rapidly evolving in this area, and it must be noted that the practical significance of these environmental influences on the epigenome in human health and disease overall remains to be established.

A number of environmental factors are known to alter DNA methylation patterns, including certain dietary factors, such as the intake of methyl donors (folates, choline, methionine), and DNA methyltransferase inhibitors (e.g., polyphenols and perhaps isothiocyanates from plants) (Johnson & Belshaw, 2008; Edwards & Myers, 2007). Furthermore, environmentally caused genetic damage can disrupt mechanisms of epigenetic control in some cases: oxidative damage to methyl-CpG sites

on DNA has been shown to impair the ability of MECP2 to bind to these target sites (Valinluck et al., 2004).

We also note that microRNAs and other forms of ribonucleic acid (RNA) are another aspect of the genome that is relatively understudied but may be important in mediating the effects of environment (Service, 2008; Riddihough et al., 2008; Bao et al., 2007) and in ASDs specifically (Abu-Elneel et al., 2008). For example, the 15q11 to 15q13 autism locus includes a locus coding for a small nucleolar RNA (snoRNA) that regulates serotonin 2c receptor splicing (Kishore & Stamm, 2006).

A group of major studies of cancer genomics has revealed that epigenetic changes, point mutations, and copy number variants all contribute to disruption of key pathways in various types of tumors (Jones et al., 2008; Parsons et al., 2008; Chan et al., 2008; The Cancer Genome Atlas Research Network et al., 2008; Wood et al., 2007). Of particular note, the mechanism of disruption varied across tumors and genes, sometimes involving point mutations, and in other cases CNVs or altered methylation. A pathway-based, comprehensive analysis including epigenetics was essential to illuminating all relevant genes and pathways.

Strikingly, some similar findings have been reported in ASD research. Different types of defects may alter MECP2 protein levels or function in different cases, including genetic (exon or promoter mutations) and epigenetic (promoter hypermethylation) (Nagarajan et al., 2006). One study of protein and mRNA expression in frontal cortex tissue from autistic and other patients revealed that multiple pathways, including apparently both transcriptional and posttranslational mechanisms, account for variation in expression of different MECP2 transcripts within different neuronal subsets (Samaco et al., 2004). Epigenetics rather than genetics explained the majority of cases of reduced MECP2 expression in autism cases in this study, although only 14 autism cases were analyzed. More recently, a similar pattern has been observed for the oxytocin receptor gene, where promoter methylation was increased in ASD cases relative to controls, in addition to some cases of deletions involving this gene (Gregory, 2009).

A further complexity is that some individuals or families are genetically predisposed to greater epigenetic stability versus lability over time in response to environment: the amount of change in global methylation over an 11- or 16-year interval clustered within families (Bjornsson et al., 2008). This might result in a gene–environment interaction in which certain gene variants make an individual's epigenome more susceptible to environmental exposures, resulting in substantially increased risk of disease when such gene variants and exposures co-occur.

Epigenetics is a relatively new field, and the mechanisms and implications are still being explored. Epigenetic changes can act like a strange hybrid of genetic and environmental risk factors, in that they can reflect the effects of the environment but also be inherited as relatively stable multigenerational factors. This complicates the way genes and environment work together to cause disease, and is not accounted for in most models of heritability or environmental risk. If epigenetic changes are actually a frequent cause of ASDs, this will have major implications for the types of genetic/epigenetic and environmental studies that should be undertaken. Resources are becoming available to investigate these issues more comprehensively, including the Human Epigenome Project, which has been attempting to catalog genome-wide DNA methylation patterns in all major tissues (Brena et al., 2006). Genome-wide epigenetic scans are becoming feasible (Berman et al., 2009), and it is clear they will add significantly to our understanding of the full range of causes of certain diseases.

Gene–Environment Correlation (G→ E→ D)

Gene–environment correlation is the situation where genotype affects one's social environment or one's exposure to environmental risk factors. To the extent that genes influence social environment or environmental exposures, it is possible that some genes increase the risk of autism by acting via environment. In other words, environment may be mediating some of the effects of genetics on autism risk. This is an underrecognized but important route of environmental influence, and one that needs to be understood in order to appropriately interpret heritability.

Genes can influence a child's exposure to environmental factors through various mechanisms, as discussed by Scarr and McCartney (1983) and Purcell (2002). There are at least three general routes by which genes could affect a child's social environment and exposure to physical/chemical environmental factors: *(1)* parental genes affecting parental behaviors that determine social and physical environmental exposure, *(2)* the child's genes affecting the child's behaviors, altering exposure to the social and physical environment, and *(3)* the child's genes affecting the child's behaviors, in turn affecting parental behavioral responses and the social environment.

Gene–environment correlation may be important to consider in autism research. Failure to take it into account can result in incorrect estimates of heritability and an incomplete picture of the prospects for intervention. If a genotype increases risk of autism, it is generally assumed that complete prevention is impossible, at least without gene therapy. However, if the genotype is actually causing autism partly by influencing the child's environment, interventions may be able to alter that environment and prevent some or all of the harm. For example, interventions focused on parenting practices (i.e., the social environment) can improve ADHD outcomes (Nigg, 2006), despite estimated heritability of 60% to 70% or even 90% (Nigg, 2006) and twin studies that identify almost no effects of shared environment. Gene–environment interactions and/or correlations could explain such seemingly conflicting findings.

Gene–Environment Interaction (GxE → D)

The term *GxE* is used here as shorthand for gene–environment interaction. The mechanisms underlying GxE, and even the

basic definition of what is meant by GxE, are still unclear in many cases. The term *gene–environment interaction* has been used in a variety of ways, sometimes referring to biological interactions and in other cases describing statistical interactions, for example (Khoury et al., 1993). As used here, GxE refers to genetic susceptibility, where the effects of environmental exposures differ depending on genotype. Of particular interest is the case where an added environmental exposure increases the risk of disease more in a high-susceptibility genotype subgroup than in the low-susceptibility genotype.

It has become very clear from research in a variety of fields that genetics and environment clearly can and do interact (Rieder et al., 2008; Kelada et al., 2003), including in some neurodevelopmental diseases (Genc & Schantz-Dunn, 2007; Caspi & Moffitt, 2006; Thapar et al., 2007; Tsuang et al., 2004).

The possibility of gene–environment interaction in ASDs has been raised (Lawler et al., 2004; Newschaffer et al., 2002). Hints of such interaction may be starting to emerge in autism research, such as in findings related to PON1 (Pasca et al., 2008; D'Amelio et al., 2005), glutathione-related factors (James et al., 2006), immune system alterations (Enstrom et al., 2008; Ashwood et al., 2008), and pathways involving the MET gene (Sheng et al., 2010; Campbell et al., 2008).

GxE may be an important concept in ASD research for a variety of reasons:

- Studying GxE may help the field progress more rapidly in finding larger relative risk (RR) values and perhaps larger PAF values (Rutter, 2008).
- Studying GxE may identify important genes and medical intervention targets that would have been overlooked otherwise.
- Identifying environmental factors would be useful because some are avoidable or preventable in the near term, in contrast with genetic risk factors.

- Identifying genetic factors that create susceptibility to environment may enable targeted prevention efforts focused on a genetic subpopulation.

Two simple scenarios may demonstrate how genes and environment can interact to increase risk of disease. Table 49-1 shows the nomenclature used to refer to four combinations of genotype and environmental exposure, and Figure 49-2 illustrates two simple scenarios. It is critical to note that if E is ubiquitous, both scenarios appear to be simple cases of genetic causation.

Scenario 1: Gene and environment are both necessary (Figure 49-2A).

The simplest type of GxE is the case where both G and E are necessary for any impact on risk (Scenario 1).

Scenario 2: Gene simply increases susceptibility to environment (Figure 49-2B).

In this case, the risk allele (G) alone (without E) has no effect, but E alone (in the low risk genotype, g) has some effect. The combination of G and E has a much larger effect on risk than E with the low-risk genotype (g). If, for example, G controls metabolism of a toxicant, in that capacity it has no effect on ASD risk on its own, and thus it only matters when E (the toxicant) is present. E has some modest impact on ASDs in the low-risk genotype (g), but much more effect in the high-risk genotype (G).

There are, in fact, several general types of GxE, with typologies proposed by Ottman (1990, 1996) and Khoury et al. (1988). An extensive discussion of gene–environment research, including study designs and other key issues, was provided in the report, *Genes, Behavior, and the Social Environment: Moving Beyond the Nature/Nurture Debate* (National Research Council, 2006). Standard nomenclature denoting various combinations of genotype and exposure has been applied in the context of risk analysis (Cullen et al., 2008). In some cases, G and E each have direct effects on risk, apart from their interaction; in other cases only G has direct effects. Impacts on risk might be nonlinear or even nonmonotonic. It is also important to distinguish between interaction on additive and multiplicative scales. The nature of the interaction in GxE also can be expressed in the "component causes" framework (Greenland & Robins, 1986; Rothman & Greenland, 2005). These complexities have been well-covered elsewhere, albeit not in the context of autism research (National Research Council, 2006).

Toxicokinetics and Toxicodynamics

A critical research goal is to elucidate the types of mechanisms underlying GxE. It may be useful to consider two broad areas where GxE can arise: toxicokinetics (TK) and toxicodynamics (TD). Toxicokinetic variability refers to differences between individuals in the extent to which an external dose (ambient environmental concentration outside the body) results in a biologically available dose at the target organ(s). Toxicokinetics involves absorption, distribution, metabolism, and elimination

Table 49–1.

Nomenclature used to refer to four combinations of genotype and environmental exposure

Relative Risk (vs. Baseline, Which is Low-Risk Genotype and no Exposure)	g: (Genotype A: Low Sensitivity to E)	G: (Genotype B: High Sensitivity to E)
E (exposed to environmental risk factor)	gE (E has some direct effect, even in low-risk genotype)	GE (GxE means that RR is much larger among those with the high-risk combination of G and E)
e: (not exposed)	ge (baseline: no increased risk)	Ge (gene has some direct effect, even without E)

RR	g	G
E	gE: RR = 1	GE: RR >>1
e	ge: RR = 1	Ge: RR = 1

RR	g	G
E	gE: RR = 2	GE: RR = 5
e	ge: RR = 1	Ge: RR = 1

Figure 49–2. Scenarios for the interaction of gene and environment on disease risk. Explanation in text.

(ADME) of toxicants and their metabolites. Toxicokinetics has been studied intensively in the field of toxicology, and numerous models have been developed to quantify interindividual TK variability, describing how some individuals receive a larger effective internal dose for the same external exposure. Toxicodynamics, in contrast, refers to the extent to which the available dose at the target organ(s) results in adverse effects on health.

The vast majority of genes studied in autism so far are not related to TK vulnerability, partly because candidate gene studies have prioritized "brain genes" rather than genes that might result in the brain being exposed to higher levels of environmental agents or being vulnerable at lower levels of exposure (Herbert et al., 2006). Research and data in TK variability could inform the search for and analysis of potential environmental risk factors in ASDs. Research on autism's relationship with the PON1 gene that is important for organophosphate metabolism is one example (D'Amelio et al., 2005), and ASDs have been associated with two genes involved in metal metabolism (MTF1 and SLC11A3) (Serajee et al., 2004), but many other opportunities remain untapped. It is known that TK differences across the population can be caused by age, health status, infection and immune status, and genetic differences in a range of TK genes.

Genes that regulate metabolism of environmental chemicals: Numerous genes are thought to affect sensitivity to xenobiotics by altering metabolism of various compounds. These are reviewed relatively comprehensively and quantitatively by Dorne (2007).

Genetically sensitive individuals may have a given biological response or risk associated with a much lower ambient concentration of a chemical, compared with the average individual. Viewed in another way, genetically sensitive individuals may be at substantially higher risk than the average individual, when exposed to a given ambient concentration. TK variability in some major metabolic pathways may result in a twofold to even a tenfold or sometimes much

greater increase in the effective dose experienced by individuals at the high end of the population distribution of TK variability (Dorne, 2007). TD factors would provide additional variability, resulting in even greater sensitivity for some individuals.

Genes relevant to infection: There are numerous genes known to control susceptibility to infection (Kaslow et al., 2008). If infection (or the maternal immune response to infection) is a risk factor for autism, then immune defense genes may be an important determinant of autism risk. This is an avenue of investigation that appears to be untapped in autism research.

Genes involved in DNA repair: Approximately 150 human genes involved in DNA repair have been identified, and mutations in many of these are known to increase the likelihood of DNA damage and cancer (Spry et al., 2007).

Genes upregulated or downregulated in response to environmental exposures: A recent review summarized gene expression changes seen in response to multiple air pollutants, including particulate matter, diesel exhaust, secondhand smoke from tobacco, and others. Key categories of genes upregulated by exposure to multiple air pollutant mixtures included genes related to xenobiotic metabolism (e.g., CYP1B1), oxidative stress response (e.g., glutathione-related genes, heme oxygenase 1, metallothioneins), and immune response (e.g. IL-6 and IL-1b) (Sen et al., 2007).

Part Two: Methodological Pitfalls in Assessing Relative Contributions of Genes, Environment, and Gene–Environment Interactions in a Disorder with High Heritability

One of the obstacles to a serious consideration of environmental contributors to ASDs has been the high heritability

calculated for this condition, and how heritability has been misinterpreted in some cases. How can environment play a major role in autism if heritability is so high? This is a critical question that arises in discussions of research on environmental risk factors. As explained here, high heritability does not preclude a major role for environmental factors, contrary to common misinterpretations of heritability. Furthermore, there are other ways heritability may be overestimated. For these reasons, population attributable fraction is recommended as a more useful metric for describing the importance of environmental factors in ASDs.

Heritability Is Overestimated Since It Counts GxE as G, and Is Misinterpreted as Ruling out Environment

A heritability estimate describes the percentage of observed phenotypic variance that can be explained by genetic variation in the study. This generally involves taking 100% of the variance in symptoms and splitting it up between genes and environment. Such heritability estimates may be taken to imply that the "impacts" of genes and environment are separable and must sum to 100%.

In particular, twin studies overestimate heritability (and underestimate the role of environment) when genes interact with environmental risk factors that are shared within twin pairs (Nigg, 2006). To the extent a disease is caused by the interaction of genes and shared environment, the importance of shared environment is invisible in such a study design, and all the combined impact of genes and shared environment is misleadingly assigned to genes alone. The direction of bias does depend on whether shared or nonshared environmental effects are involved (Nigg, 2006). Environmental exposures shared by twins may be more common than nonshared exposures during prenatal or perinatal periods, suggesting overestimated heritability is more likely if such exposures are important sources of GxE in ASDs.

Michael Rutter has emphasized the importance of GxE eloquently (2008). GxE may be part of the explanation for the difficulty in finding obvious major causes in either genetics or environment research, despite high heritability estimates.

PAF Is a More Useful Metric for Comparing Interacting Risk Factors

Unfortunately, a heritability estimate of 90% has sometimes been misinterpreted as meaning that only 10% of cases are caused or even influenced by environmental factors. PAF is a more useful metric than heritability if the goal is to describe the proportion of disease burden that could be alleviated through research and interventions focused on a particular risk factor. PAF values estimated for various individual risk factors are not expected to sum to 100%, because the PAF values will overlap where two or more risk factors share responsibility for causation (Ezzati, 2006). Each PAF value accounts for all the cases that might be avoided if the risk

factor were removed, even if some of those cases could also be prevented by removal of a different risk factor instead. Autism research would benefit from greater use of PAF estimates.

Heritability May be Overestimated in Other Ways

In addition to GxE, another cause of overestimated heritability may be the impact of shared placentas. Monozygotic (MZ) twins usually share one placenta (*monochorionic, MC*), but sometimes have different placentas (*dichorionic, DC*). Monochorionic twins are more likely to share exposure to certain environmental factors, including pathogens, than dichorionic twins. In this regard it is notable that concordance rates for schizophrenia are higher for monochorionic than for dichorionic twins: "…concordances for MZ twins without MC markers averaged 10.7 percent. In contrast, concordances for MZ twins with one or more MC markers averaged 60 percent." (Davis et al., 1995). This suggests many MZ twins may be concordant because they share a placental environment, not just because they share genes, and heritability may be overestimated.

A heritable change caused by the environment also appears to be a genetic cause, in subsequent generations (once no longer de novo), whether via DNA sequence damage or heritable epigenetic changes. Furthermore, traits influenced by inherited epigenetic modifications appear to be genetic and add to estimates of heritability, when in reality they might result from environmental factors, and could be altered through interventions.

Gene–environment correlation may also affect heritability. It tends to bias heritability estimates upward in the case of nonshared environment, the opposite of how GxE operates. If genes influence a child's behavior and social environment in ways that in turn increase risk of developing an ASD, such environmental factors are again counted as purely genetic and inflate heritability.

Finally, heritability estimates fail to quantify any impacts that lower levels of environmental exposure would have on disease, unless such lower levels are already represented in the study sample. Estimates of the importance of environment in twin studies are limited by the amount of variance in the environment experienced by the study population. Heritability estimates take existing environmental levels and their impacts as a given, and are not designed to measure the baseline impacts of ubiquitous environmental factors.

The Need for Rethinking Heritability

Given the likelihood of GxE, environmentally caused genetic and epigenetic alterations, and other issues raised, it is incumbent upon us to rethink how we have estimated and interpreted heritability, and the roles of genes and environment, in ASDs. PAF could be a valuable metric to use more often in comparisons among risk factors in ASD research.

Part Three: Research Directions and Resources

This chapter has suggested that investigating the combined effects of multiple genes and multiple environmental influences has more potential than studying individual factors in isolation, particularly if the goal is to identify targets for intervention accounting for a larger share of all cases.

Given what is known so far, what next steps might be most productive? Several related approaches are outlined here that may speed advances in autism research, categorized using the framework of four basic causal paths developed in Part One for the ways in which genes and environmental factors may work together in autism. Although a focus on genes within environmentally responsive pathways was introduced and illustrated in Herbert et al. (2006), an expansion is suggested here, to include identifying and studying the combined impacts of both: *(A)* environmental risk factors implicated by autism genetics, and *(B)* genes suggested by environmental risk factors. In other words, genetic findings should inform the focus of environmental research, and vice versa, especially through collaborative studies of combined effects.

(A) Given a candidate autism gene or pathway, identify and study environmental factors that may relate to the key candidate gene or pathway:

1. E→ D: seek environmental factors (e.g., mutagens) that could be a cause of the observed genetic alteration.
2. E→ epiG: seek environmental factors (e.g., nutrition) causing epigenetic changes affecting gene expression (and environment-caused changes in gene expression through other mechanisms).
3. G→ E: seek environmental conditions influenced by the gene (e.g. gaze avoidance, or dietary habits).
4. GxE: seek environmental factors that could interact with the given gene or pathway (GxE), including environmental factors affecting the same pathway already disrupted and made vulnerable by the genetic variant (e.g., pollutants affecting redox status and related metabolic pathways). This approach actually can apply to more than genes or pathways—one might select any alteration found in autism (e.g., alterations in a key brain region, cell type, or biomarker), and then investigate environmental factors reported to affect this parameter. This chapter, however, focuses only on genetic changes, with reported alterations at other levels of biological organization as the starting point for investigating potential environmental factors being beyond the present scope.

(B) Given a candidate environmental factor implicated in autism, identify and study genes and ideally pathways that may relate to the key environmental factor:

1. E→ G: seek genes/pathways most vulnerable to damage by such environmental factors.
2. E→ epiG: seek genes/pathways most vulnerable to epigenetic change resulting from the environmental factor (and genes with altered expression in response to the environmental factor, through any mechanism, not just epigenetic).
3. G→ E: seek genes/pathways that might influence exposure to the environmental factor (e.g., identify any genotypes associated with urban birth or advanced parental age at conception).
4. GxE: seek genes/pathways likely to interact with the environmental factor (GxE), including:
   a. genes in the pathways acutely or permanently disrupted by the environmental factor (e.g., studying acute and permanent gene expression changes that result from the implicated environmental risk factor) or more generally any genes with known roles in some function disrupted by the environmental factor;
   b. genes controlling toxicokinetic parameters (controlling the effective dose of a toxicant resulting from exposure to a given ambient level, through absorption, distribution, metabolism, or elimination of the toxicant and metabolites, such as PON1 or glutathione-related pathways);
   c. genes influencing likelihood of maternal infection or nature of response to infection (e.g., TGFB1);
   d. genes directly affecting sensitivity of genome integrity to environment, including DNA repair genes;
   e. genes affecting genome's sensitivity to epigenetic change caused by environment (e.g., DNA methyltransferases);
   f. genes in stress response pathways in general.

Research opportunities based on the above framework are suggested below. These are followed by some brief references to new informatics resources and research methods that will be helpful in pursuing these opportunities. A conclusion reiterates the importance of shifting from a search for individual genes or single environmental contributors to genomics, combinations of environmental contributors, and systems approaches.

Genetic Implications of Environmental Findings

The environmental factors implicated in autism by studies published to date are likely to be an incomplete and biased list of candidate factors, because a discovery-based approach has not been used to identify potential environmental factors in autism.

A comprehensive, authoritative, standard database summarizing the environmental risk factors implicated in autism does not exist, although this would be a valuable resource. In the absence of such a database, the most comprehensive listing of implicated risk factors may be found in review articles and textbooks Newschaffer et al., 2007; Pessah & Lein, 2008; Lathe, 2006). Environmental risk factors implicated by at least some evidence include maternal infection, urban birth, exposure to certain heavy metals, pesticides, solvents, PCBs, and

other pollutants. Medications and treatments have also been studied as candidate risk factors, including valproic acid and the use of various anticonvulsants for other indications, thalidomide, and assisted reproductive technology. Also implicated are maternal and/or paternal age, which may in turn suggest germ line genetic damage that could partly result from environmental factors such as genotoxins. The few environmental factors implicated to date already provide some leads and suggest the types of genes that may interact with these environmental factors.

The framework discussed above should be applied to environmental findings, as a way to prioritize candidate genes, pathways, and environmental factors for further study. General principles may be useful here as well—a subset of genes can be referred to as *environmentally responsive* genes. These tend to fall in a few key functional categories: cell cycle, DNA repair, cell division, cell signaling, cell structure, gene expression, apoptosis, and metabolism (Herbert et al., 2006; Wilson and Olden, 2004).

Environmental Implications of Genetic and Pathway Findings

In contrast with environmental risk factors, there arguably do exist reasonably comprehensive databases listing the genetic risk factors implicated so far in autism (although no list can claim to include all genomic alterations actually contributing to autism). These genes are one source of information that may suggest candidate environmental risk factors (Corrales, 2009a). Some of the relevant database resources are reviewed in Table 49-2.

Belmonte and Bourgeron (2006) highlight four brain-related features that may contribute to subgroups of ASDs: excess neuronal growth and macrocephaly, abnormal neuromodulatory function, underconnectivity, and overexcitability relative to inhibition (Belmonte & Bourgeron, 2006). From an environmental vantage point, the list would be updated to include oxidative stress, immune system dysregulation, and gender-specific factors, which are environmentally modulated phenomena that may be important in a large percentage of ASD cases, since they are reported in a substantial share of ASD cases but relatively few controls (James et al., 2008; Enstrom et al., 2008). The ASD literature provides many additional clues about potential gene–environment interaction, including findings related to zinc metabolism (Faber et al., 2009; Li et al., 2003), oxytocin (Bartz & Hollander, 2008), steroids (Auyeung et al., 2008; Nakayama et al., 2007), cholesterol synthesis (Tierney et al., 2006; Zecavati & Spence, 2009), circadian rhythms (Melke et al., 2008), and key receptors and pathways including calcium channels and homeostasis (Palmieri et al., 2008; Krey & Dolmetsch, 2007; Pessah, Seegal, et al., 2008). Additionally much can be learned from studying the more extensive research on environmental factors that may influence comorbid disorders (Corrales et al., 2008).

These broad pathways or specific findings in ASDs have implications for the study of environmental risk factors.

In general, next steps in pursuing these leads could involve prioritization based on potential for a large population attributable fraction (based on exposure and risk ratio when available), replication in larger samples, and testing for gene–environment interaction in cell-based, animal toxicology, and human epidemiological studies.

Methodologies and Data

In general, biological and environmental databases are multiplying and growing very rapidly. Today, it is far easier to find data on multiple biological molecules or multiple environmental chemicals, and synthesize across databases, than it was just 5 years ago. Table 49-2 reviews some of the resources. Given the paucity of our knowledge, there is a need for discovery-based approaches, which should be applied to screen very broadly, ideally comprehensively, across the full range of genomic/epigenomic factors and environmental factors that might be involved. High-throughput methods and predictive models will be helpful in this regard, and some relevant resources such as the Comparative Toxicogenomics Database (CTD) (Mattingly et al., 2006a, 2006b; Davis et al., 2008) and the Aggregated Computational Toxicology Resource (ACToR) database (Judson et al., 2008) are already useful in compiling available information generated by these methods on gene–toxin interactions. Databases of genes, pathways, and xenobiotics can provide useful tools for network analysis of multiple factors and their potential interactions (see Table 49-2).

Methodological advances are also providing many new opportunities for ASD research. Approaches to identifying gene–environment interactions have been reviewed (Moffitt et al., 2005), and a variety of models are available. Only a very limited number of environmental factors and susceptibilities have been tested so far in such models (Corrales, 2009b), so there is great potential for advances here.

In screening the full range of potential environmental risk factors to determine which ones are worthy of further study, it will be important to consider not only potential toxicity but also the magnitude and timing of exposure. Unfortunately, exposure estimation remains a significant obstacle (Wild, 2005; Cohen-Hubal, 2009), and clearly will require ongoing attention.

Furthermore, the importance of applying a complex systems approach to studying and classifying human diseases is becoming increasingly apparent (Loscalzo et al., 2007; Wu et al., 2008; Sieberts, & Schadt, 2007). Systems biology approaches have been applied to toxicology, and models have been constructed to predict metabolism and toxicity of new chemicals, accounting for genetic variability (Ekins et al., 2006). One important methodological question is what level of detail will be most useful for modeling interactions and causal paths within networks of genes or gene–environment networks. Small to moderately sized networks of genes can be simplified and represented using binary interactions where genes turn other genes on or off, but larger predictive networks, still out of reach with current computational methods,

will require modeling that clusters genes into functional modules (Bornholdt, 2005).

Systems biology approaches are starting to be applied in the context of ASD research. For example, key signaling pathways are being identified through gene expression analysis of blood-derived lymphoblastoid cells, and are demonstrating that certain key genes or proteins (e.g., excess CYFIP1 and altered levels of JAKMIP1 and GPR155) are consistently dysregulated in autism cases caused by two entirely different causal genetic mutations (FMR1 and 15qdup) (Nishimura et al., 2007). Notably, immune response and mRNA processing were functions impacted by many of the dysregulated genes, and genes implicated in gastrointestinal disease and lipid metabolism were notably overrepresented. Other studies have also analyzed gene expression in ASDs and have implicated immune-related pathways among others (Hu et al., 2006; Gregg et al., 2008; Garbett et al., 2008). Given the influence of environment on so many of these pathways, a GxE approach to further research is strongly indicated.

Conclusion

Future discussions of genetic or environmental risk factors should be motivated by the public and clinical health importance of identifying and prioritizing among all possible contributors, and especially malleable contributors, to ASDs. From this point of view, it is important to make certain that we are turning every stone worth turning, and setting priorities rationally. This chapter has outlined how genetic and environmental factors may converge on common mechanisms pertinent to neurodevelopmental disorders, and the ways that high heritability can involve not only high genetic but also high environmental contributions. This material points toward the strong need for collaboration between genetic and environmental investigators, since this is in the best interests of both. This review has attempted to provide a glimpse of the breadth of substantive arguments for this synergistic approach, and also the many resources that already exist to facilitate it.

Both from an environmental and a medical point of view, ASDs are not only developmental disorders but also chronic conditions. For virtually all major common chronic conditions, finding clear causes, either genetic or environmental, has been difficult, raising fundamental questions about what we are trying to do (Buchanan et al., 2006). Recent systems analyses are finding that not only are there a plethora of interacting causes, but surprisingly there appear to be many core similarities among apparently different diseases (Torkamani et al., 2008). In the face of the prevalence of autism, we should remember as we seek causes that our primary purpose should be to help people with autism; our overriding goal must be to translate our findings into preventing or treating the problems associated with ASDs, and to move eventually to individualized treatments when systems assessments can be integrated into medical practice. At the population level, research should facilitate learning how to provide the greatest improvement in the largest number of cases in the shortest timeframe. This means we need to consider, of the many risk factors, which are most preventable or treatable in the near term and which have the largest impacts (high prevalence of exposure combined with high relative risk results in a high population attributable fraction). There may be important clues gained from rare factors like MECP2, certainly, but their importance at the population level is only in proportion to the extent that they may suggest actionable targets important for most cases of autism.

Michael Rutter argues that our efforts may indeed move faster if we pursue GxE effects:

"… it is very striking that the G×E effects that have been found are of moderate size and by no means are as small as the main effects of single genes considered independently of the environment. Moreover, the G×E has been found with a sample size of about 1,000. There are a variety of reasons why that is probably rather smaller than is optimal, but it does not necessarily follow that it

is necessary to move to samples of 500,000 as some geneticists have sought to argue." (Rutter, 2008)

Just as there are causes and mechanisms at multiple levels, there will be multiple levels of benefits from going forth and integrating genetic and environmental efforts. The more thorough and rapid generation of results should hasten our ability to provide treatment and prevention.

Challenges and Future Directions

- Misinterpretation of heritability estimates has created the impression that environmental factors play only a minor role in ASDs. Ongoing discussion of gene–environment interaction, mutagens, epigenetics, and gene–environment correlation could help correct any misconceptions.
- Greater collaboration across disciplines would be helpful, particularly between geneticists, toxicologists, and epidemiologists.
- Systematic review and integration across research findings from different disciplines, including PAF calculations, would be helpful in assessing priorities across possible risk factors, biomarkers, and avenues of inquiry.
- Exposure assessment and sample size are substantial obstacles to the study of gene–environment interaction, and deserve ongoing attention. Emerging exposure measurement tools will be extremely helpful, as will large cohort studies such as the National Children's Study.

Zebrafish As a Tool to Study Autism

Points of Interest

- Given the multitude of genes associated with autism and other mental health disorders, a whole animal system that can be used to screen candidate genes and potential therapeutics is in demand.
- An animal tool provides useful insight into a disorder without attempting to recapitulate all aspects of the disorder.
- The zebrafish-tool provides rapid, clear, relatively high-throughput analyses of candidate genes in an organism with high conservation in genetics and in brain development.
- Rapid and efficient manipulation of zebrafish gene expression can be easily attained by loss-of-function and gain-of-function strategies.
- Many characterized mutants and morphants can be useful in understanding nervous system development, including nervous system patterning, neural tube shaping, neuroepithelial junction formation, and neuronal differentiation.
- The zebrafish-tool can be applied to the study of autism, in circumstances where human genes associated with the disorder have been identified, where the genes are important early in brain development and where the genes have clear zebrafish homologs.

Introduction

Autism spectrum disorders (ASDs) include an array of behavioral and neurodevelopmental symptoms with considerable variation in severity and time of onset. Despite the phenotypic complexity, clear evidence indicates a strong genetic component. Recently, genes associated with autism have begun to be identified. These include common and rare gene variants (Kim et al., 2008; Miller et al., 2009; Persico et al., 2001; Steffenburg et al., 1996), as well as copy number variants (CNVs). One clear CNV associated with autism lies on chromosome 16, in the 16p11.2 interval (Christian et al., 2008; Kumar et al., 2008; Weiss et al., 2008). Consideration of the 16p11.2 interval highlights some of the challenges of analyzing ASD candidate susceptibility genes. This interval is approximately 500kb in length and includes 30 genes or putative open reading frames. Which of these genes is connected with ASDs? Is just one gene pivotal, or are several? And how can this knowledge be used to develop potential therapeutics that will ameliorate the disorder?

Two key questions must be addressed in analyzing CNVs that include many genes or in analyzing the many common or rare variants associated with ASDs. First, how can one screen through many genes to define candidates that are most closely associated with ASDs? One way is association studies using large numbers of human patient and control samples. Another way is to study homologs of human genes in an animal system. Mice display behaviors such as anxiety, hyperactivity, and enhanced spatial learning, which may describe a subset of behaviors included in ASD diagnosis and can be assayed directly for neuronal abnormalities. However, constructing and analyzing dozens or hundreds of mutations in transgenic mice is extremely cumbersome, time-consuming, and expensive. As we will discuss, the zebrafish embryo can be used as a relatively high-throughput system to assay gene function more rapidly and inexpensively than the mouse.

Second, how will knowledge of gene function lead to development of therapeutics, a major goal of autism research? Known or new psychoactive medications can be assayed for efficacy. Alternately, small-molecule screens focusing on mutations of interest as the targets may be successful. The zebrafish embryo is one of the few vertebrate systems that can be used for whole-animal, small-molecule screening, as will be discussed below.

The Zebrafish As a Tool

The zebrafish is a powerful system for the study of disease-associated gene function. In some cases, zebrafish may be a direct disease model. For example, zebrafish cancer models are proving useful for recapitulation of human cancer (Amatruda & Patton, 2008; Ceol et al., 2008). However, in the study of autism, zebrafish do not display the complex behaviors present in humans and cannot be used to recapitulate the disorder. Nonetheless, the fish can be useful for analyzing function of genes associated with autism or other mental health disorders.

We have therefore developed the idea of an *animal "tool"* as distinct from an animal *"model."* Whereas a model recapitulates the human disorder and can be used in a one-to-one fashion to study the disorder, a tool does not recapitulate the disorder. Nonetheless, a tool can be used to provide insight into the disorder. Specifically, we suggest that an animal tool can be used for its attributes, which may not be available in a more conventional model. In the case of the zebrafish, the attributes useful for analysis of genes implicated in autism and other mental health disorders include ability to perform rapid loss- and gain-of-function assays, ability to assay function of human gene variants rapidly, and ability to use embryos and larvae in chemical screens (Figure 50-1).

Zebrafish Attributes

Conservation of Brain Structure

Vertebrate brain development is highly conserved, and the zebrafish brain possesses significant structural and functional homology to the human brain (Hakryul Jo, 2005; Lowery & Sive, 2009; Tropepe & Sive, 2003). The overall organization of

Figure 50–1. Attributes of the zebrafish. See text for details. (See Color Plate Section for a color version of this figure.)

the zebrafish brain is conserved in humans. This includes, for example, the presence of ventricle spaces, many common projections in the olfactory and visual pathways, and common descending and premotor pathways (Tropepe & Sive, 2003; Wulliman, 1998). Neurulation results from neural plate movements to form the neural tube that will become the brain and spinal cord, and as indicated by fate mapping, the neural plate movements are conserved in mammals (Lowery et al., 2009; Papan & Campos-Ortega, 1999). Opening of the lumen follows, forming the ventricles, which are often abnormal in autistic patients (Hardan et al., 2001). These anatomical features make the fish an appropriate organism for studying brain development.

Neurulation: the development of the neural plate and the processes involved with its subsequent closure to form the neural tube during the early stages of embryonic development.

Husbandry and Accessibility

Zebrafish are relatively small (3–4 cm), making their husbandry relatively inexpensive. Embryos develop external to the mother, allowing accessibility to all stages of development. A single mating can yield 200 embryos, and experiments can therefore be designed to test multiple conditions with a large sample size. Development is rapid, with distinct brain regions and functional neurons developing by 24 hours post-fertilization and therefore facilitating rapid analyses. Embryos are small, approximately 0.2 mm, making relatively high-throughput assays feasible. In addition to convenience and cost benefits, large sample sizes, and ease of manipulation and analysis, a complete generation time is 3 months, which makes genetic mutant screens practical and expedient.

Imaging

Zebrafish embryos are transparent and develop externally, facilitating visualization of the brain *in vivo*, especially in conjunction with expression of fluorescent marker proteins. This feature is particularly useful to monitor the effects of loss of gene function on nervous system development. Brain structure and axon outgrowth can be captured as digital images that can be used for further analysis, including high-resolution whole-embryo images, sophisticated confocal images, and 3D reconstructions. Thus, the early consequences of changes in gene function can be studied (e.g., Gutzman et al., 2008).

Genome Project

The *Danio rerio* genome sequencing project is a collaboration between the Wellcome Trust Sanger Institute and the zebrafish community; including contributions from ZFIN, Ensembl, and Vega (http://www.sanger.ac.uk/Projects/D_rerio/). The Sanger Institute began sequencing the zebrafish genome in
2001, and the ninth annotated version is currently available on Ensembl or Vega. The Human Genome Project was assembled using a similar strategy and completed in 2003, thus it is available for comparison with the zebrafish genome (www.sanger.ac.uk/HGP/overview.shtml). In a 2000 analysis of zebrafish and human genomes, 523 zebrafish genes and expressed sequence tags (ESTs) contained mapped human orthologs (Barbazuk et al., 2000). Eighty percent of the human and zebrafish genes had conserved synteny, which was defined as two or more linked genes. Conserved syntenic regions between the human genome and the zebrafish genome suggest there may be some orthology between the species (Barbazuk et al., 2000). However, as variability in the gene sequences, gene duplications, and homologs may exist in humans or zebrafish, gene function in either organism should be analyzed more specifically. For this task, the full-length and EST sequences of interest are available for order online, and their order pages are often links from the NCBI webpage. If a human homolog can restore gene function of a zebrafish loss-of-function mutant, then there must be conservation in the function of these two genes.

Ortholog: A gene in two or more species that has evolved from a common ancestor

Homolog: A gene similar in structure and evolutionary origin to a gene in another species

Loss-of-Function Analyses

Multiple strategies can be used to create loss-of-function phenotypes including mutagen-induced screening, insertional mutagenesis, targeting induced local lesion in genomes (TILLING), zinc finger nuclease targeting, and morpholino knockdown. The choice of loss-of-function strategy depends on the specific gene. For a gene with a characterized genetic mutant, analysis of the mutant line is the most definitive way to proceed. However, most genes will not have a cognate genetic mutant, and some other strategy to ablate function must be taken. Use of antisense morpholino-modified oligonucleotides (MOs) are the most rapid and effective approach but can be used only to analyze embryonic phenotypes. Targeted mutagenesis, either by searching through random mutations (TILLING) or by use of zinc finger nucleases allow analysis of older animals, as is the case for all stable genetic mutants.

Mutagenesis Screens

Large-scale mutant screening in zebrafish, using N-ethyl-nitrosourea (ENU), has produced thousands of mutations that disrupt a wide range of genes involved in the early steps of development (Driever et al., 1996; Haffter et al., 1996; Solnica-Krezel et al., 1994). Following mutagenesis, many affected genes have been identified by a positional cloning strategy, and many mutants resembling human disease states have been useful tools to study human pathologies (Hinkes

et al., 2006; Shin & Fishman, 2002; Xu et al., 2002). Insertional mutagenesis, using retrovirus to disrupt gene sequences, has also been used to identify genes involved in early development (Amsterdam & Hopkins, 1999; Golling et al., 2002). This strategy offers the advantage of identifying the affected gene by inverse polymerase chain reaction through an associated tag at the insertion site, thus reducing cloning time. Use of stable mutants is the best way to analyze phenotypes in the adult and of enormous use in the embryo. Some mutants may be hypomorphs and retain some function, and the extent of this can be difficult to determine.

Antisense Morpholino-Modified Oligonucleotides

In zebrafish, gene expression can be knocked down using the MO strategy (Summerton & Weller, 1997), where MOs target specific mRNA at either a start or a splice site to prevent translation or to produce aberrant proteins. Morpholine rings replace the sugar-phosphate backbone of the antisense oligonucleotides, a modification that stabilizes the oligos, allowing inhibition of gene function until at least 48 hours post-fertilization. Designing the MO to the start site is beneficial if the maternal contribution of already splice-processed mRNA is a complicating factor in the experiment. However, designing the MO to target a splice site in the RNA will result in an mRNA product that can be monitored by PCR (Draper et al., 2001). Specificity of the phenotype is determined by comparison with a control MO and, most importantly, by rescue of the phenotype with injected mRNA engineered to lack the MO binding site. In our hands, rescue is achieved with at least 80% of MOs tested. The development of photo-activatable MOs provide the possibility of using MOs to achieve conditional gene silencing (Ando et al., 2001; Shestopalov et al., 2007). "Caged" MOs are synthesized with a complementary oligomer tethered to the MO by a photo-cleavable linker. Because the embryos are transparent, upon exposure to 360-nm light, the linker is cleaved and the MO is active. MOs are an outstanding tool for ablation of gene function where there is no corresponding genetic mutant. This is especially true for splice site MOs, where amount of normal RNA remaining can be monitored. Caged MOs hold enormous promise but are still under development and not commercially available at this time. MO technology is very useful for embryonic phenotypes, but beyond 48 hours of development, the MO will be diluted as cells divide and MOs cannot, therefore, be used to study adult phenotypes.

Morpholino: a molecule used to modify gene expression. MOs are an antisense technology used to block access of other molecules to specific sequences within nucleic acid.

TILLING

TILLING is a reverse genetic strategy, which involves random chemical mutagenesis (by N-ethyl-N-nitrosourea) followed

by DNA screening for point mutation of a specific target gene of interest (Skromne & Prince, 2008; Wienholds et al., 2003). After exposure to ENU, PCR using fluorescently labeled primers results in heteroduplex formation. Then, mismatch cleavage by Cel1 is used to identify rare ENU-induced mutations. TILLING can then proceed by a variety of approaches, including sequencing, agarose gels, denaturing high-performance liquid chromatography, and capillary electrophoresis (Sood et al., 2006). Using this technique, it is possible to create mutations in a gene of interest, facilitating the identification of functional or critical regions in the protein. TILLING is of proven use, especially where a null mutation is identified. A new TILLING consortium coordinates efforts in the United States, making this approach more accessible. However, it may prove difficult to isolate a mutation in a specific gene, and the lag from request to definition of the mutant may be many months.

Zinc Finger Nucleases

Zinc finger nucleases are used for targeted modification of the genome (Cathomen & Joung, 2008; Foley et al., 2009; Porteus & Carroll, 2005). These enzymes bind double-stranded DNA and cause a double-stranded break. The nuclease domain is nonspecific, but the zinc finger domain can be designed to target and bind a specific DNA sequence. Resulting double-stranded breaks are repaired by non-homologous end-joining of the DNA and can therefore be used for targeted insertions or deletions. The gene modification is transmitted through the germline, so after appropriate screening for founders of the desired modification, the transgenic fish line can be maintained and studied (Foley et al., 2009). This technique holds promise but has not been extensively proven in the zebrafish system.

Gain-of-Function Analyses

Gain-of-function analyses assess the effects of protein overexpression, or expression of a variant form of the protein.

mRNA Injection

This is the simplest gain-of-function approach, where mRNA encoding a protein of interest is injected into an early embryo and thereby expressed. Temporal control can be achieved by using a hormone inducible fusion protein (Kolm & Sive, 1995) or a tissue-specific promoter (Ju et al., 1999).

Stable Transgenics

Stable transgenic insertion can be achieved using the I-SceI restriction endonuclease, for example, which also "escorts" DNA into the chromosome (Soroldoni et al., 2009). Transgenic expression can be studied in the F0 as mosaic expression or in the F1 in case of genomic integration of the

DNA into the germ cells. The Tol2 system is a useful method for gene and enhancer trapping in zebrafish, and it can result in identification of genes that are developmentally regulated (Asakawa et al., 2008; Parinov et al., 2004). The enhancer trap system requires a transposable element such as Tol2 for random insertion into the genome, a promoter that is sensitive and can be activated by the enhancer of interest, and a reporter gene such as Gal4 or GFP (Bellen, 1999). Genes affected by the insertion can be identified by PCR amplification of genomic sequences flanking the Tol2 insertion site followed by sequencing reactions. Expression of the reporter genes in enhancer trap fish lines can be used to identify tissue-specific expression of the associated genes (Parinov et al., 2004).

Chemical Screening

The classical drug discovery approach is a screen for small molecules that bind *in vitro* to a target of interest. Such screens require a specific target, and a detailed molecular understanding of a process. Forward chemical genetics involves screening for small molecules that alter the function of a biological pathway, resulting in the induction or rescue of a specific phenotype. This approach uses a library of compounds that may be very large (~10^5 compounds) and functionally uncharacterized, or smaller (~10^3 compounds), but with annotation as to likely targets, based on preliminary assays *in vitro* or in cell lines.

Whole animals offer several advantages over cell lines for chemical screens, indicating effects on the whole animal, toxicity, and tissue specificity. Use of the whole animal can also allow the screening of processes that are not easily replicated in vitro, such as organ development. Whole-animal chemical screens are only feasible in invertebrates and in very small vertebrates. The latter include embryos and larvae of the zebrafish or the frog Xenopus, where large numbers of embryos can easily be obtained, and exclude any mammal. The zebrafish, particularly, has been used extensively in chemical screens (Macrae & Peterson, 2003; Murphey & Zon, 2006). The ease of waterborne compound application and their closer evolutionary relationship to humans make zebrafish the system of choice relative to invertebrates.

Several approaches have been developed to screen small molecules in zebrafish, taking advantage of its attributes described above (Peterson, 2008; Peterson et al., 2000; Pichler et al., 2003). Chemical screens for developmental modifiers involve arraying embryos into the wells of microtiter plates (ranging from 24– to 96-well), adding small molecules from a chemical library, and allowing development to proceed. At various stages of development, the embryos are screened visually for perturbations in the system(s) of interest. Zebrafish mutants can be screened for rescue or modulation of the mutant phenotype (Murphey & Zon, 2006), a powerful method that may be extremely useful in analysis of gene function associated with autism.

Lessons from Mutants and Morphants

Mutant Phenotypes

The embryonic zebrafish has an accessible and relatively simple nervous system, with many of its components formed and functioning as early as 24 hours post-fertilization. To help facilitate studies on the nervous system, mutagenesis screens have produced mutations that affect nervous system development. The first examples of large-scale mutagenesis screens were conducted in two independent experiments using ENU as a mutagen and produced many mutants grouped in different classes according to the affected embryonic organs (Driever et al., 1996; Haffter et al., 1996). Successively different strategies were used to produce mutagenesis by viral insertion (Amsterdam & Hopkins, 1999; Wiellette et al., 2004) or by gene trapping using the Tol2 transposable element (Kawakami, 2004). The characterization of these mutants has revealed that many aspects of vertebrate nervous system development are well-conserved in zebrafish. In this section, we describe some mutants isolated in these screens and corresponding genes that have been useful in understanding the complexity of nervous system development (Table 50-1).

Genes Affecting Nervous System Patterning

Spiel-ohne-grenzen (spg)

The mutant phenotype caused by disruption of the gene *pou2*, which is the ortholog of the human *oct4*. *spg/pou2* expression is essential for proper development of the midbrain, hindbrain, ear, and body axis (Burgess et al., 2002). *spg/pou2* functions during the establishment and maintenance of these brain regions. In addition, *spg/pou2* functions also during development of the forebrain—particularly the diencephalon—and in differentiation of the paraxial mesoderm and endoderm. In zebrafish, *spg/pou2* is the first example of a tissue specific competence factor for Fgf8 signaling (Reim & Brand, 2002).

Bozozok

The *bozozok* locus encodes the homeodomain protein Dharma, which is a regulator of cell fate determination. *boz* inhibits the Wnt pathway, aiding formation of the gastrula organizer. In the early gastrula, *boz* positively regulates the expression of Chordin and other BMP antagonists dorsally, which in turn inhibit BMP signaling and induce anterior neuroectoderm. In the late gastrula, *boz* dorsally inhibits the posteriorizing activity of Wnt

and/or other factors, whereas in the lateral blastoderm margin these posteriorizing factors transform some of the anterior neuroectoderm into more posterior neural fates. This results in specification of appropriately sized forebrain, MHB, and hindbrain anlagen in the neural plate (Fekany-Lee et al., 2000).

Parachute

The mutant phenotype is characterized by loss of the corresponding protein, N-cadherin. In zebrafish, it has a crucial role in the control of neural tube morphogenesis, maintenance of neural tube integrity by loss of neuroepithelium cell adhesion, axonal pathfinding, and neural cell proliferation (Lele et al., 2002).

Genes Affecting Neural Tube Shaping

Laminin mutants—*bashful, sleepy,* and *grumpy*—show reduced brain ventricle size relative to wild-type. Additionally, the MHB does not form normally. The *bashful, sleepy* and *grumpy* loci encode components of the extracellular matrix (ECM) proteins, Laminin α1, Laminin γ1 and Laminin β1, respectively. These genes have previously been shown to play roles during zebrafish development that include retinotectal axon pathfinding (Karlstrom et al., 1996), notochord differentiation (Parsons et al., 2002), blood vessel formation (Pollard et al., 2006), and retinal morphogenesis (Biehlmaier et al., 2007). Loss of Laminin in the basement membrane prevents normal neuroepithelial morphogenesis, particularly at the midbrain–hindbrain boundary constriction, where we have described the novel process of basal constriction (Gutzman et al., 2008; Lowery et al., 2009).

Junction Mutants

Epithelial apicobasal polarity mutants—*nagie oko, oko meduzy, heart and soul,* and *mosaic eyes*—correspond to genes previously implicated in epithelial polarity and junction formation. The *nagie oko* locus encodes the MAGUK protein Mpp5a (Wei & Malicki, 2002). *Oko meduzy* animals have a mutation in the *crb2* gene (encoding a Crumbs homolog), *heart and soul* mutants correspond to *prkci* (encoding atypical protein kinase C), and *mosaic eyes* to Epb4.1/5 (a FERM protein). The Mpp5, Crb2a, Prkci, and the FERM proteins colocalize at the apical surface of the neuroepithelium and control apical junction formation and epithelial apicobasal polarity (Horne-Badovinac et al., 2001; Hsu et al., 2006; Omori & Malicki, 2006). All these mutants have defects in neural tube midline separation, perhaps because of apicobasal polarity defects (Lowery et al., 2009).

Genes Affecting Specific Differentiated Neurons

Motionless

The mutant phenotype is caused by the disruption of a gene encoding the Mediator subunit Med12. Mutants exhibit deficits of certain neuronal subtypes, including monoaminergic neurons and cranial sensory ganglia but not GABAergic neurons. Overexpression of *mot/med12* is capable of inducing premature neuronal differentiation and an increased production of brain dopaminergic, noradrenergic, and serotonergic neurons (Wang et al., 2006). Moreover, polymorphisms of the *med12* gene in humans are associated with an increased risk for schizophrenia (Philibert et al., 2007).

Unplugged

The *unplugged* gene encodes a muscle-specific kinase (MuSK). In zebrafish, MuSK is important for motor neuron pathfinding, and it is critical for the assembly of focal synapses by cooperating with dystroglycan and also in the formation of nonfocal myoseptal and distributed synapses (Lefebvre et al., 2007; Zhang et al., 2004).

No soul

No soul encodes Foxi1, a winged helix domain-containing transcriptional regulator that is expressed in the placodal progenitor cells. Foxi1 activity is required for the coordinated expression of both neuronal fate and subtype identity genes in the visceral sensory lineage (Lee et al., 2003).

Zieharmonika

This locus encodes for enzyme acetylcholinesterase (AChE). AChE is indispensable for muscle fiber development and Rohon-Beard sensory neuron growth and survival. In absence of AChE, the acetylcholine receptor clusters at neuromuscular junctions initially assemble, but these clusters are not maintained. AChE is required for muscle fiber formation and sensory neuronal development and regulates stability of neuromuscular synapses (Downes & Granato, 2004).

Morphant Phenotypes

Morphants are animals in which gene function has been decreased by injection of a MO (Summerton & Weller, 1997). To date, most of the mutations that have been mapped are successfully phenocopied by the respective MO, making this a powerful alternate to genetic mutants, during embryonic development. MO knockdowns are rapid and effective, making zebrafish a powerful tool to study autism by selectively and easily knocking down the candidate genes emerging from genetic studies.

Recently, several risk genes for mental health disorders (including autism, schizophrenia, and mental retardation) have been intensively studied in zebrafish.

Disrupted in schizophrenia-1 (DISC-1)

The *DISC-1* gene was identified as a locus that was translocated in an extended Scottish family with psychotic illness and major

depression (Millar et al., 2000). *DISC-1* loss of function in dentate gyrus neurons causes an abnormal neurite formation (Mao et al., 2009). In zebrafish, two independent studies demonstrate different functions during fish development. In early stages of embryonic development, *DISC-1* is required for development of the forebrain by modulating the canonical Wnt pathway (DeRienzo & Sive, submitted; Brandon et al., 2009). In later stages of zebrafish development, *DISC-1* is required for normal oligodentrocytes and cerebellar neurons (Wood et al., 2009).

Reelin

There is considerable evidence for involvement of Reelin protein in autism, by association of a polymorphism in the untranslated region of its mRNA with susceptibly to autism (Fatemi, 2001). Costagli et al. have shown in the developing zebrafish embryo that reelin dynamically localizes in the central nervous system, particularly in the dorsal telencephalon and in the thalamic and hypothalamic regions, demonstrating many similarities with Reelin localization in mammals (Costagli et al., 2002).

Abelson-Helper Integration Site One (Ahi1)

Mutations in the *Ahi1* gene are correlated with Joubert Syndrome (JBTS), a developmental brain disorder characterized by autism, seizures, and mental retardation. The cerebellum and brainstem are malformed, suggesting a role for this gene in midbrain–hindbrain development (Dixon-Salazar et al., 2004; Ferland et al., 2004). Comparisons of the expression pattern between human, mouse, and zebrafish demonstrated high similarity between fish and human, showing *Ahi1* expression in the developing cerebellum that is not present in mouse (Doering et al., 2008).

Using the Fish-Tool to Study Autism

How does one put together the attributes of the zebrafish tool in a useful way to address gene function leading to autism? Figure 50-2 indicates a flowchart outlining what we consider to be a productive approach. The approach rests on the hypotheses that *(1)* zebrafish homologs of human autism risk genes can be identified; *(2)* these genes function early during brain development; and *(3)* human and zebrafish genes will show orthologous functions. We use the 16p11.2 region of chromosome 16 as an example of a set of autism risk genes to be analyzed (Weiss et al., 2008).

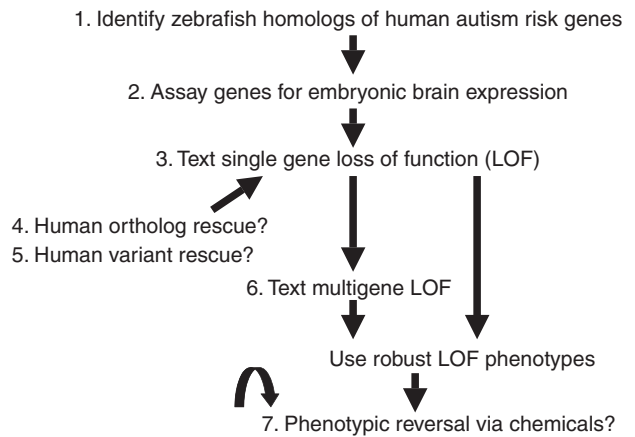
The first step is to identify zebrafish homologs of human risk genes, using information from the zebrafish and human genome projects. In some cases, there is a single zebrafish homolog, whose projected protein sequence matches closely with that of human protein. In the simplest case, this single gene is also syntenic (on a preserved chromosomal segment) in human and fish, suggesting not simply homology (sequence equivalence) but also orthology (functional equivalence).


Figure 50–2. Scheme for analysis of autism risk genes in the zebrafish tool. See text for details.

However, because the teleost genome is partially duplicated, in some cases, two zebrafish homologs correspond to one mammalian gene. These may have redundant function or may have diverged sufficiently to assume non-overlapping function (Mcclintock et al., 2002). In other cases, there may be several genes with equal levels of similarity to the human gene. In rare cases, there may be no corresponding zebrafish gene, suggesting that the human gene encodes a mammalian-specific function. How does one best decide which of two or more zebrafish genes are likely to be orthologs? One way is to ask for synteny of the location of a fish gene with human chromosome 16; however, this may not indicate similar function (Catchen et al., 2008). Another way is to address expression pattern, as genes with both similar sequence and expression pattern in fish and human are likely to be orthologous. A third level of analysis is to directly test whether the human gene can substitute for the function of the fish gene. Together with sequence identity, this last is the strongest criterion for orthology. Thus, in the 16p11.2 region, we have identified 17 genes in the 16p11.2 region with a single zebrafish homolog, three with two or more homologs and five with no fish homologs (Blaker-Lee, Gupta, & Sive, unpublished).

A second step is to assess expression patterns, where expression in the developing brain suggests genes that may function during early neurogenesis or brain morphogenesis. The third step, then, is to assess the function of each gene. The quickest way to do this is to inject MOs into the one- to two-cell embryo and assay the "morphant" phenotype at 24 to 48 hours postfertilization, after the nervous system has formed. Antisense oligos that target either the translational start site or a splice donor or acceptor site can be used. However, the latter are most useful, as successful targeting of a target almost always results in aberrant splicing, which can be monitored and quantified by reverse-transcription polymerase chain reaction (RT-PCR). Because the 16p11.2 region is generally hemizygous in autistic patients, dosage of one or more genes in this region is likely to be very important. This dosage correlation can be addressed using different amounts of injected MO to give differing amounts of normally and abnormally spliced target RNA. The splice site MO choice also ensures that maternally

stored RNAs can get the embryo through very early stages, so that only zygotic gene function is assayed, often being required at the onset of neurogenesis and brain morphogenesis.

Injection of a "control" oligo indicates MO specificity, however the key control, and the fourth step in this assay scheme, is a "rescue" experiment, which corrects the morphant phenotype to a more normal one. Thus, injection of mRNA encoding the target gene, but lacking the oligo binding site, should rescue the phenotype of the morphant. At this point, we suggest using the human homolog to perform the rescue. Not only does this confirm antisense specificity—it indicates orthology between fish and human genes. We estimate that 80% to 90% of MO oligos tested are specific—that is, resulting phenotypes will be rescued by either fish or human cognate mRNA. This sets the stage for the fifth step, which is assay of human gene variants. The functional significance of gene variants identified in autism and other mental health disorder risk genes is unclear. However, the morphant rescue assay is very sensitive and rapid, allowing analysis of scores of gene variants. Confirming the usefulness of this approach, we have shown that mutants in the *DISC-1* schizophrenia risk gene rescue the loss of function phenotype with distinct efficacy (DeRienzo & Sive, submitted). Once single-gene, loss-of-function analysis has been performed, a sixth step is analysis of synergy between 16p11.2 genes via inhibiting function of two or more. In particular, this has the potential to define whether interactions between genes in this interval may contribute to autism etiology.

Finally, a risky, but high-payoff, seventh step is to screen morphants with robust (reliable and clear) phenotypes for small molecules that can reverse morphant phenotypes. Chemical screening is well-established in the zebrafish; however, few screens have not addressed phenotypic reversal (Kokel & Peterson, 2008). Phenotypic reversal may result from changing remaining gene activity or may result from commandeering a different, compensatory pathway. Such screens can be performed using small and plentiful zebrafish embryos, where screens of similar magnitude with mammalian embryos are impossible. Such screens would be moderate throughput, of the order of several thousand compounds, pre-screened on cell lines, or purified proteins. Identification of compounds that modulate activity of a gene or pathway implicated in autism could provide important directions toward therapeutics.

We emphasize that this scheme does not try to address all manifestations of autism phenotypes but, rather, uses the fish as a tool to gain insight into aspects of gene function, which will be useful in more direct models.

Challenges and Future Directions

In conclusion, we have outlined the notion of the zebrafish as a "tool" to study the activity of genes implicated in autism and other mental health disorders. This tool will be extremely useful in meeting the challenge of assaying activity of human gene variants connected to autism. In addition, the fish provides an outstanding whole animal vertebrate system, which can be used in small molecule screens for modulation of gene function associated with autism. This attribute will be of major importance in the first steps of defining potential therapeutics that may ameliorate or reverse symptoms of autism and other mental health disorders.

Behavioral Evaluation of Genetic Mouse Models of Autism

Points of Interest

- Animal models provide essential translational tools for studying mechanisms underlying human genetic disorders and for developing treatment strategies. An effective mouse model should incorporate face validity (i.e., strong analogies to the endophenotypes of the human syndrome); construct validity (i.e., the same biological dysfunction that causes the human disease, such as a gene mutation or anatomical abnormality); and predictive validity (i.e., the analogous response to treatments that prevent or reverse symptoms in the human disease). It is essential to keep in mind that no animal model will ever fully recapitulate a uniquely human disorder such as the autism spectrum disorders (ASDs).
- Mouse models have been extordinarily useful in identifying genetic factors underlying human disorders. Reverse genetic approaches test mice with mutations in candidate genes for autism, such as the genes for engrailed 2, reelin, neurexins, neuroligins, shanks, and contactins; chromosomal deletions and duplications such as 15q11-13; and comorbid monogenic disorders such as Fragile X and tuberous sclerosis. Forward genetic approaches identify inbred strains of mice with phenotypes relevant to autism and explore mechanisms responsible for the phenotypes. Quantitative trait loci (QTL) analysis in recombinant inbred strains could lead to the discovery of novel genetic factors relevant to autism-like phenotypes.
- Because autism is diagnosed by behavioral symptoms, analogous behavioral assays are needed to phenotype mouse models of autism. The primary diagnostic symptom of autism is impaired reciprocal social interactions. Mouse social behaviors have been studied by ethologists and behavioral neuroscientists for many years. Recently, specific behavioral tasks have been developed to quantitiate simple social approach behaviors toward a novel mouse, reciprocal social interaction behaviors between two unfamiliar mice, preference for social novelty, social dominance, and tests of home cage social behaviors to model the types of social deficits seen in autistic individuals. These tasks represent the beginning of a new frontier, which has yet to be fully explored. New tasks need to be developed to study social behaviors in complex situations, subtle deficits in the social domain, Theory of Mind, and other aspects of social abnormalities that are common to ASDs. Social communication, repetitive behaviors, and restricted interests are components of the mouse repertoire for which assays are being developed to maximize relevance to the second and third diagnostic symptoms of autism.
- Although humans and nonhuman primates rely primarily on visual and auditory information to discriminate individuals, mice mainly utilize olfactory cues for the same purposes. Care must be taken to distinguish physical defects in a sensory modality from abnormalities in higher-order processing of sensory information. Although the sensory organs used to receive and transmit social cues differ between mice and humans, the critical integration and interpretation of social stimuli that appears to be problematic in autism may be processed in similar cortical regions across species.
- Mice emit vocalizations within the ultrasonic range in various social contexts and across developmental ages. Neonatal mice emit distress calls when separated from the mother. Adult mice of both sexes produce complex USV patterns in different social situations. The communicative property of USVs is under intense investigations, and the potential to use USVs to assay communication deficits in mice is being explored.

Introduction

Autism is a complex neurodevelopmental disorder with extraordinarily high heritability. Intense efforts are now focusing on identifying genetic causes of autism. Animal models provide essential translational tools to investigate hypotheses about the biological causes of ASDs, including candidate genes, synaptic and neuroanatomical abnormalities, environmental toxins, prenatal insults, and immune dysfunctions (Smith et al., 2007; Abrahams & Geschwind, 2008; Berman et al., 2008; Buxbaum, 2009; James et al., 2009; Singer et al., 2009). Robust phenotypes in model organisms offer translational tools to identify causes and to seek putative treatments for autism. This chapter discusses the most promising mouse models of autism and strategies to phenotype new genetic lines of mice.

It is important to recognize that no model system will ever fully recapitulate the uniquely human qualities of ASDs. Rather, the optimal animal model will incorporate *(1)* face validity (i.e., strong analogies to the endophenotypes of the human syndrome); *(2)* construct validity (i.e., the same causes as in the human syndrome); and *(3)* predictive validity (i.e., prevention and/or reversal of phenotypes by treatments that prevent or reverse components of the human syndrome). Because the causes of autism remain unknown, and as yet no treatments consistently improve the core symptoms, it is presently not possible to incorporate definitive construct and predictive validity into an animal model of autism. In the absence of consistent biological markers, the diagnosis of ASDs is currently based on well-defined behavioral symptoms, and animal models therefore focus on behavioral phenotypes with face validity to the diagnostic symptoms of autism. Behavioral neuroscientists are in the early stages of elaborating a set of behavioral assays with face validity to the defining symptoms of autism.

The first DSM-IV diagnostic criterion for autism, qualitative impairments in reciprocal social interactions (American Psychiatric Association, 1994; Piven et al., 1997; Lord et al., 2000; Dawson et al., 2002; Volkmar & Pauls, 2003; Lord et al., 2006; London, 2007; Landa, 2008; Rapin & Tuchman, 2008; Lord & Bishop, 2009; Volkmar et al., 2009), is perhaps the most easily modeled in rodents. Mice and rats are social species (Grant & MacIntosh, 1963; Carter et al., 1992; Young et al., 2002; Terranova & Laviola, 2005). Standard methods for scoring adult social approaches, reciprocal social interactions, nesting, sexual interactions, parental behaviors, and aggressive encounters are available in the behavioral neuroscience literature (Hofer et al., 1996; Miczek et al., 2001; Winslow, 2003; Wrenn et al., 2003; Keller et al., 2006; Champagne et al., 2007; Panksepp & Lahvis, 2007; Wersinger et al., 2007; Burgdorf et al., 2008; McFarlane et al., 2008; Scattoni et al., 2008b; Yang et al., 2009; Yang & Crawley, 2009). Our laboratory and others have developed more specialized behavioral assays using dedicated equipment to rate the types of social interactions that are most analogous to the lack of spontaneous seeking of interactions with others, lack of social reciprocity, and failure to develop peer relationships appropriate to developmental ages (Crawley, 2007a, 2007b; Crawley, 2007c), as listed in Tables 51-1 and 51-2 and described below.

Social approach is assayed in an automated apparatus that compares time that the subject mouse spends with a novel mouse versus time spent with a nonsocial novel object (Figure 51-1) (Moy et al., 2004; Nadler et al., 2004; Kwon et al., 2006; Mineur et al., 2006; Crawley et al., 2007; Moy et al., 2007; Yang et al., 2007a; Yang et al., 2007b; Jamain et al., 2008; McFarlane et al., 2008; Moy et al., 2008a; Chadman et al., 2008a; Moy et al., 2009; Yang et al., 2009, 2010; Silverman et al., 2010a).

> Sociability in our automated three-chambered social approach task is defined as the subject mouse spending more time in the side chamber with a novel mouse than in the side chamber with a novel object.

Most strains of mice spend more time with the novel mouse, representing normal sociability. Equal or less time spent with the novel mouse and the novel object would represent the absence of sociability in this task. Investigating the novel object instead of the novel mouse may be analogous to the tendency of individuals with autism to engage in nonsocial activities such as playing with one toy train, repeatedly assembling a jigsaw puzzle, excellence at a video game, rock collecting, or comprehensive knowledge of baseball statistics (Frith, 2003; Frith & Happe, 2005). Because mice investigate novel conspecifics by sniffing, an important corroborative parameter in the social approach task is significantly more time spent sniffing the novel mouse than the novel object. Sniffing is directed to the face, nose, anogenital, or other body region, depending on the relative positions of the two animals. Sniffing tends to decline after several minutes, as the subject grows familiar with the novel mouse. Mouse models displaying lack of sociability are described below and in Tables 51-1 and 51-2.

Reciprocal Social Interaction is Assayed in a Neutral Arena

> Reciprocal social interactions are scored between a pair of two age-matched mice unfamiliar to each other. Parameters scored include nose-to-nose sniffing, nose-to-anogenital sniffing, approaching from the front, following, pushing past and crawling over, as well as nonsocial behaviors such as self-grooming and arena exploration.

Behaviors exhibited by two unfamiliar age-matched mice are detected with automated videotracking equipment or rated by an observer from videotapes. The same scoring method is applicable to animals of both sexes tested at all post-weaning ages. A standard test session is 10 to 20 minutes long, a period when intense social interactions occur

Notes: An optimal model strain incorporates social deficits replicated in multiple cohorts and across different laboratories. Additional autism-like phenotypes such as unusual social olfactory or vocalization responses, repetitive behaviors, and restricted interests, along with normal physical and procedural abilities, increase the value of the strain as a model for autism. High = sociability present; Low = sociability absent; N/A = the strain has not been tested in the three-chambered social approach test.

humans. Other measures of social interaction are front approach, follow, push and crawl, and allogrooming (McFarlane et al., 2008; Yang et al., 2009). These basic, non-aggressive social behaviors are present in animals of both sexes and at all post-weaning ages, making them suitable parameters for studying developmental trajectory of social behaviors relevant to autism. Aggressive behaviors are unique to sexually mature male mice, including chasing, offensive attacking, and defensive postures. Aggressive behaviors are not as relevant to modeling the diagnostic symptoms of autism but might reflect altered social behaviors caused by genetic mutations and/or pharmacological treatments (Jamain et al., 2008; Navarro et al., 2008). An important control measure of this task is bouts of general arena exploration, locomotor activity, and
Figure 51–1. Illustration of the automated three-chambered social approach apparatus to assay sociability in mice.

general investigation toward nonsocial stimuli (Yang et al., 2009).

The second DSM-IV diagnostic criterion, qualitative impairments in communication (Lord et al., 2000; Frith, 2003; Tager-Flusberg & Caronna, 2007), may be the most difficult domain to model in rodents. The extent to which mice communicate concrete information to each other is a question that requires a great deal more investigation. As described below, olfaction is the primary sense used by mice and rats for individual recognition. However, the exact pheromonal messages being emitted by one mouse, and the correct responses to the olfactory information by the other mouse, are not yet sufficiently well-explicated in the literature to be employed as quantitative assays for communication. Besides pheromonal communication, mice also emit vocalizations in the ultrasonic range in some social situations (Maggio & Whitney, 1985; White et al., 1998; Branchi et al., 2001; D'Amato & Moles, 2001; Hofer et al., 2001; Gourbal et al., 2004; Holy & Guo, 2005; Panksepp et al., 2007; Wang et al., 2008; Scattoni et al., 2008b; Hammerschmidt et al., 2009; Scattoni et al., 2009, 2010).

> Mice emit vocalizations in the ultrasonic range in some social situations, indicating potential communicative values of USVs. Ultrasonic vocalizations emitted by pups separated from the mother and nest, and juveniles or adults during social interactions, are recorded by an ultrasonic microphone and scored for total number of calls and properties of the calls.

Pups separated from the nest emit calls that the parents use to locate the straying pup and retrieve it to the nest (Zippelius & Schleidt, 1956; Winslow et al., 2000; D'Amato & Moles, 2001; Hofer et al., 2001; Shu et al., 2005). Adult rats emit 22 kHz distress calls and 50 kHz calls during aggressive and sexual behaviors (Blanchard et al., 1991; Brudzynski et al., 1993; Panksepp & Burgdorf, 2000; Brudzynski & Pniak, 2002;

Brudzynski, 2005; Burgdorf et al., 2008). Mice communicate by emitting USVs during juvenile social interactions and during the appetitive phases of sexual behavior (Holy & Guo, 2005; Cai et al., 2006; Panksepp et al., 2007; Wang et al., 2008). Playback of recorded vocalizations during social encounters and scoring of socially appropriate responses to the calls will be needed to understand the role of USVs in rodent communication (Hammerschmidt et al., 2009).

The third DSM-IV diagnostic criterion, stereotyped, repetitive, and restricted patterns of behavior, interests, and activities (Bodfish et al., 2000; Lord et al., 2000; Cuccaro et al., 2003; Frith, 2003; South et al., 2005; Morgan et al., 2008), can be broken down into components that have analogies in the rodent behavioral repertoire. Motor stereotypies in mice and rats include high levels of vertical jumping, backflipping, circling, digging, marble burying, rearing, repeated sniffing of one location or object, barbering, excessive self-grooming, and excessive running (Creese & Iversen, 1975; Powell et al., 1999; Turner et al., 2001; Lee et al., 2002; Pogorelov et al., 2005; Korff & Harvey, 2006; Lewis et al.,
Figure 51–2. (**A**) Reciprocal social interaction test, illustrating the Noldus PhenoTyper 3000 apparatus used for videotaping pairs of mice engaged in social interactions. (**B**) A nose-to-nose sniff between two juvenile mice.

2007; Crawley, 2007c; McFarlane et al., 2008; Moy et al., 2008b; Yang et al., 2009, 2010). Perseverative patterns include the inability to change to a new search strategy, or an excessive focus on one component of a complex environment (Ralph et al., 2001; Brigman et al., 2006; Chen et al., 2007; Moy et al., 2008a). Tasks analogous to restricted interests or activities are under development, including restricted interest in a subset of holes in an open-field holeboard array (Moy et al., 2008a) and deficits in reversal learning in a T-maze task (Tanimura et al., 2008).

Analysis of multiple control parameters is essential in animal models to rule out physical and procedural abnormalities that would interfere with performance on the behaviors of interest (Crawley, 2007c). Simple physical disabilities could impair the ability of animals to conduct the procedures of the tasks that define autism-like phenotypes. For example, if a gene mutation directly affects olfactory functions, subject mice may engage in less social interaction because they are unable to detect the pheromonal cues emanating from a novel mouse. If a drug treatment induces sedation, then it is likely that impaired scores on social, communication, and exploratory tests will reflect low overall activity rather than a meaningful deficit in social approach or repetitive traits relevant to autism. Therefore, careful analyses of general health, neurological reflexes, sensory abilities, and motor functions are incorporated into the experimental design to avoid the overinterpretation of artifacts (Crawley, 2007c).

Olfactory Tasks Relevant to Studying Social Behaviors in Mice

Although humans and nonhuman primates rely primarily on visual and auditory information to discriminate individuals (Schaefer et al., 2001; Adolphs, 2002; Pelphrey et al., 2002; Hadjikhani et al., 2007; Chawarska & Shic, 2009), mice mainly utilize olfactory cues for the same purposes (Brown, 1979; Doty, 1986; Schellinck et al., 1993; Isles et al., 2001; Brennan, 2004; Keverne, 2004; Restrepo et al., 2004; Kavaliers et al., 2005; Brennan & Zufall, 2006; Arakawa et al., 2008b; Bredy & Barad, 2009). Odor cues influence a wide range of social activities in mice, including kin recognition, bond formation, mate recognition and selection, sexual maturation, inbreeding avoidance, and juvenile dispersal (Brown, 1979; Doty, 1986; Hurst et al., 2001; Hurst et al., 2005; Brennan & Kendrick, 2006; Sanchez-Andrade & Kendrick, 2009). The ability to differentiate familiar and unfamiliar individuals has advantages in many social contexts, enabling animals to form and maintain affiliative relationships while avoiding potential conspecific threats (Luo et al., 2003; Brennan & Keverne, 2004; Mombaerts, 2004; Brennan & Kendrick, 2006; Dulac & Wagner, 2006; Spehr et al., 2006).

The mouse olfactory system includes two anatomically distinct pathways (Buck, 2000; Luo et al., 2003; Brennan, 2004; Brennan & Kendrick, 2006; Kang et al., 2009; Martel & Baum,

2009). The main olfactory system consists of the main olfactory epithelium, which connects to the main olfactory bulb. The accessory olfactory system consists of the vomeronasal organ whose sensory neurons send signals to the accessory olfactory bulb. Recent advances have shown complementary roles of the main and the accessory systems. The two systems respond to overlapping social chemosignals, and both are connected to neural systems (such as the medial amygdala) that are important for social behaviors (Trinh & Storm, 2003; Baum, 2009; Kang et al., 2009).

Basic Olfactory Tests Used to Check for Anosmia (Loss of Sense of Smell)

Table 51-3 summarizes some of the widely used mouse olfactory tasks. The buried food test measures the latency to uncover a piece of odorous food, such as cookies, cereals, chocolate chips, or food pellets, which are hidden underneath a layer of bedding. The olfactory habituation/dishabituation test (Figure 51-3) measures the ability to detect and differentiate different odors. Almond and vanilla extracts (1:100 dilution) can be used as nonsocial odors, and soiled cage bedding or fresh urine can be used as social odors (Alberts & Galef, 1971; Klein et al., 1996; Yamada et al., 2001; Del Punta et al., 2002; Trinh & Storm, 2003; Woodley & Baum, 2003; Wersinger et al., 2007; Yang & Crawley, 2009). Habituation, a progressive decrease in olfactory investigation (sniffing) following repeated exposure to the same odor stimulus, indicates that the subject can recognize that identical odors are the same. Dishabituation, a reinstatement of sniffing when a novel odor is presented, reflects that the subject can differentiate a new odor from a now-familiar odor. The peaks of the habituation/dishabituation curves reflect the animal's interests in the each odor (Wersinger & Rissman, 2000; Bielsky et al., 2004; Yang & Crawley, 2009).

Social recognition, social memory, and preference for social novelty tests rely on the intrinsic tendency to investigate other individuals, especially *novel ones* (Winslow, 2003; Sanchez-Andrade & Kendrick, 2009). S*ocial recognition* is usually studied using a habituation/dishabituation task or the discrimination paradigm. For the habituation/dishabituation task, the subject is presented with a same-stimulus animal for multiple times. Then a novel stimulus animal is presented. Social recognition is demonstrated by a decline in investigation following repeated exposure to a same-stimulus animal (habituation) (Bielsky et al., 2004; Bielsky & Young, 2004; Bielsky et al., 2005; Sanchez-Andrade et al., 2005; Wersinger et al., 2007) and by a reinstatement of high levels of sniffing when a novel stimulus animal is introduced (dishabituation) (Bielsky & Young, 2004; Richter et al., 2005; Sanchez-Andrade et al., 2005; Wanisch et al., 2008). The same habituation/dishabituation presentations are employed in *social memory* tests, except that a time interval delay is introduced between presentations. For the discrimination test, the subject is given a simultaneous choice of two stimulus animals, one that the subject has previously encountered and one completely

Table 51–3.

Some basic olfactory tests relevant to investigating social behaviors in rodents

Test Category	Tests	References
General olfactory abilities	Buried food test	Crawley et al., 2007; Wersinger et al., 2007; Lu et al., 2008; Moy et al., 2009

unfamiliar to the subject. Significantly more investigation of the new-stimulus animal compared to the original-stimulus animal indicates normal recognition memory (Engelmann et al., 1995; Wanisch et al., 2008). The interval before the novel animal is introduced can be varied to study neural mechanisms of social memory. The social recognition and social memory paradigms described above can be combined into a comprehensive social olfaction test (Sanchez-Andrade et al., 2005; Sanchez-Andrade & Kendrick, 2009). In addition, the automated three-chambered social approach test, which was designed as an assay for sociability, can also be used to test social recognition, as indicated by a significant preference for social novelty. After the 10-minute sociability test in which the subject investigates a novel mouse in one side chamber and a novel object in the other side chamber, a second novel mouse is brought into the side chamber formerly containing the novel object and simultaneously presented

with the first novel mouse. More time spent investigating the new novel mouse than the original novel mouse is interpreted as the ability to differentiate the two sequentially introduced social stimuli (McFarlane et al., 2008; Moy et al., 2008b; Chadman et al., 2008).

Besides tests in which olfactory investigation is the main behavioral parameter, several paradigms evaluate scent-marking behavior (Humphries et al., 1999; Hurst et al., 2001; Hurst & Beynon, 2004; Hurst et al., 2005; Arakawa et al., 2008b; Roullet et al., 2009) or behavioral responses toward scent marks (Cheetham et al., 2007) to study social recognition. Scent-marking tasks are based on the fact that urinary odors are distinct among genetically diverse individuals and that a male mouse tends to countermark new scent marks deposited in its territory by other males (Hurst et al., 2001; Hurst & Beynon, 2004). Arakawa and colleagues (Arakawa et al., 2008a) showed that male mice gradually reduce countermarking behavior toward a repeatedly introduced stimulus mouse, and increase countermarking when a novel stimulus mouse that is genetically different from the first stimulus mouse is introduced. These findings indicate that countermarking behavior might be useful for studying the ability to discriminate different individuals based on unique molecular components contained in urinary deposits.

Odor Discrimination Tests

Social odors used in this test derive urine samples from awake or anesthetized mice, soiled bedding from a cage of group-housed mice, or nesting material from a cage of mice (Wersinger & Rissman, 2000; Woodley et al., 2004). In the non-conditioned form of the discrimination test, the subject is simultaneously presented with different social odors. More time spent sniffing one odor over the other indicates preference (Wersinger & Rissman, 2000; Isles et al., 2001; Bakker et al., 2002). Quantitation is by an observer scoring time spent
Figure 51–3. Olfactory habituation/dishabituation test, showing a mouse sniffing a cotton-tipped applicator saturated with a social odor.

sniffing each stimulus, with a stopwatch, event recorder, or videotracking software, in real time or from videotapes (Schellinck et al., 2001). In the conditioning versions of the discrimination test, subjects are first trained to associate two odors, one paired with a reinforcer (CS+) and the other one not (CS−). During the subsequent discrimination test, in which the two odors are copresented in the absence of the reinforcer, more time spent investigating the previously reinforced odor indicates the ability to differentiate the two odors (Bodyak & Slotnick, 1999; Petrulis et al., 2005; Wesson et al., 2006; Wersinger et al., 2007). Olfactometer tasks are more elaborate and sensitive discrimination tests that employ an operant chamber that delivers up to eight individual odors. The subject is trained to respond to odors paired with reinforcement versus non-reinforced odors. High levels of performance accuracy indicate the ability to differentiate odors. Delays between presentations are introduced to evaluate olfactory memory. Odorant concentrations and training schedules can be adjusted to study subtle differences in olfactory sensitivity (Slotnick & Restrepo, 2005).

Ultrasonic Vocalizations

A wide range of rodents, including mice, rats, hamsters, and gerbils belonging to the family Muridae, emit ultrasonic calls in a variety of situations. Calls have been detected from neonates at the time of birth, from pups removed from the nest, from adults during courtship and mating, and from adults during aggression and/or exploration (Bell et al., 1972; Robinson & D'Udine, 1982; Hofer & Shair, 1993; Moles & D'Amato F, 2000; Nyby, 2001; Panksepp, 2003; Venerosi et al., 2006; Moles et al., 2007; Scattoni et al., 2008b).

Separated Pup Vocalizations

Isolation-induced USVs in mice are generally 10 to 140 milliseconds in duration, with frequencies between 40 and 90 kHz. USV production follows a clear ontogenetic profile from birth through the second week of life, thus allowing longitudinal analysis during very early postnatal ontogeny. Considerable differences in this ontogenetic profile have been found among strains (Roubertoux et al., 1996). For example, C57BL/6 and BALB/c strains show peak USV rates very early, around postnatal days (PNDs) 3 to 4 (Bell et al., 1972; Robinson & D'Udine, 1982), as compared to SEC, C3H, or outbred strains, such as CD-1, which show a peak around PNDs 6 to 7 (Bell et al., 1972; Elwood & Keeling, 1982; Robinson & D'Udine, 1982; Branchi et al., 1998).

Since the early 1970s, the functional role of USVs emitted by infant altricial rodents has been a controversial issue. These calls have been interpreted as a representation of emotional state and as a communicatory act designed to elicit maternal behavior. Alternatively, USV was believed to be a byproduct of the physiological response to a thermal challenge, through laryngeal braking or an abdominal compression reaction to cold temperature (Blumberg & Alberts, 1990; Blumberg & Sokoloff, 2001). However, a considerable amount of data indicates that USV is modulated by maternal cues and reflects higher integrative processes (Hofer & Shair, 1993; Panksepp, 2003), offering evidence against the interpretation by Blumberg and Sokoloff (2001). For example, Hofer and Shair (1993) reported an immediate reduction in USVs produced by isolated rat pups when they were placed back in contact with the mother (Hofer & Shair, 1993). When rat pups were re-isolated after a brief reunion with an active or anesthetized mother, calling rate increased approximately twofold above the baseline rate measured during the first isolation. This phenomenon, called *maternal potentiation* of the separation vocalization response, indicates that the separation call does not depend exclusively on thermal factors (Hofer et al., 1994; Hofer et al., 1998). Further, qualitative changes in ultrasonic emission are detected with maternal potentiation (Myers et al., 2004).

To investigate the functional role of USVs, the emission profile has been studied by monitoring several physiological parameters, by manipulating the environmental/social context, and by characterizing maternal behavior in response to USVs. The results showed that USVs elicit approach and retrieval (Noirot, 1972; Smotherman et al., 1974; Cohen-Salmon et al., 1985; Ehret & Bernecker, 1992) and reduce attacks or rough manipulation by the dam (Noirot, 1966; Ihnat, 1995). One report demonstrated that the number of calls emitted by normal hearing pups strongly decreased when these pups were cross-fostered to deaf dams, suggesting that the number of ultrasonic calls uttered by the pups in social isolation conditions is modulated by the behavior of the mother (D'Amato & Populin, 1987). A relationship between maternal responsiveness and pup calling rate has been confirmed more recently in a study comparing C57BL/6 and BALB/c maternal responsiveness to USV (D'Amato et al., 2005).

USV analysis has been employed in several studies using mouse models of neurodevelopmental disorders (Branchi & Ricceri, 2002; Ricceri et al., 2007). In the *Ts65Dn* mouse model of Down syndrome, which carries a partial trisomy of chromosome 16 that includes the region homologous to the human chromosome 21, the ontogenetic profile of USV emissions appeared delayed by 4 days, with *Ts65Dn* mice showing a peak of emission on PND 9, as compared to PND 5 in the wild-type controls (Holtzman et al., 1996). Jimpy, a shortened life-span (PND 30) mutant line showing recessive sex-linked inheritance with a point mutation in the proteolipid protein (*PLP)* gene, displays a severe CNS myelin deficiency that is associated with a variety of complex abnormalities affecting all glial populations (Vela et al., 1998). Jimpy males produced fewer USVs than their normal male littermates, beginning at PND 2 and persisting throughout the first postnatal week (Bolivar & Brown, 1994). As observed in *Ts65Dn* mice, the USV deficit is accompanied by a delay in reaching developmental milestones, delayed body weight gain, and reduced locomotor activity. The reduced vocalization rate had

no consequences on maternal retrieval behavior (Bolivar & Brown, 1995). Oxytocin-null mice displayed a decrease in calling (Winslow et al., 2000), although exogenously administered oxytocin also decreased calling in rat pups and prairie voles (Insel & Winslow, 1991; Kramer et al., 2003). Oxytocin receptor gene KO mice showed a decrease in USV at PND 7 (Takayanagi et al., 2005), consistent with the hypothesis that oxytocin neurotransmission is necessary for the perception of social separation and the subsequent USV response. Vasopressin receptor 1b (*Avpr1b*) gene KO mouse pups showed a deficit in USVs but only in the maternal potentiation of USV paradigm (Scattoni et al., 2008b). Adult female *Avp1b*-null mutants also emitted fewer USVs during social interaction with an unfamiliar female partner (Scattoni et al., 2008b). Reeler mice, which carry a mutation in the gene for reelin, an extracellular-matrix protein involved in plasticity of dendritic spines and synaptic transmission, showed alterations in USV patterns with a clear gene-dose dependency (Laviola et al., 2006). Null reeler mice emitted fewer calls than wild-type controls, and heterozygotes emitted USVs at an intermediate level (Laviola et al., 2006) associated with body weight decreases. Vocalizations in reeler mice were reversed by prenatal exposure to an organophosphate (Laviola et al., 2006) and repeated maternal separations (Ognibene et al., 2007). *Dvl1* mutant mice deficient for *dishevelled-1*, a developmental gene in mammalian brain that regulates segment polarity in Drosophila, showed no differences in separated pup calling rate (Long et al., 2004). Mice deficient for fibroblast growth Factor 17 (*Fgf17*), a trophic factor involved in neural embryonic development and regional organization of cortical layers in cerebellum, inferior colliculus, and frontal cortex in rodents (Cholfin & Rubenstein, 2007), displayed selective alterations in the social domain, including a general deficit in USVs and decreased reactivity to social novelty in a social recognition task associated with reduced frontal cortex activation (Scearce-Levie et al., 2008).

Some of the most intriguing USV patterns are seen in mutant mouse models of human genetic disorders (Shu et al., 2005; Fujita et al., 2008; Groszer et al., 2008). Mutations in *FOXP2,* a gene that encodes the forkhead box transcription factor, was thought to be responsible for the rare disorders seen in the KE family, including verbal dyspraxia, dysphasia, and other severe language and speech disorders (Vargha-Khadem et al., 2005). Mouse pups heterozygous for *Foxp2* showed a selective decrease in USVs emitted after neonatal isolation on PNDs 6 and 10 (Shu et al., 2005). Mice with a knock-in R552H mutation in *Foxp2*, which corresponds to the human *FOXP2* R553H mutation, showed severe impairments in USVs at PND 10 (Fujita et al., 2008). These results were interpreted as supporting the role for *Foxp2* in regulating neural development and social communication. Somatic growth, somatosensory reflexes, and USVs have been examined in *Mecp2*[llox] mutant mice, a mouse model of Rett Syndrome (RTT) (Picker et al., 2006). Somatic development is similar to wild-type controls in both *Mecp2*-null male and *Mecp2* heterozygous female mice. However, beginning at PND

5, both *Mecp2*-null males and heterozygous females exhibited dramatic increases in USVs in response to social isolation. This is the earliest and most prominent sign detected in *Mecp2* mutant mice. Elevated USV levels might indicate either an altered response to social isolation or altered respiratory function, a question that has been receiving increasing attention in mouse models of RTT in recent years (Viemari et al., 2005; Ogier et al., 2007). Pharmacological studies showed that the muscarinic cholinergic agonist oxotremerine increased USVs in rat pups, and the antagonist atropine decreased USVs (Kehoe et al., 2001), offering evidence that might be relevant to the cholinergic deficits that have been reported for RTT individuals (Wenk & Hauss-Wegrzyniak, 1999). These data have translational significance, because they suggest that the early deficits noted in RTT individuals may be mimicked in the mouse models and that USVs can be used as a neonatal behavioral response to evaluate therapeutic interventions at an early age. The ontogenetic profile of USVs has been characterized in knock-in mice with a humanized mutation in the cell adhesion protein gene *Nlgn3*. Male mice with the human R451C mutation in the mouse *Nlgn 3* gene showed less USV on PND 8 than wild-type controls, whereas the emission profile in female knock-in mice was normal (Chadman et al., 2008). Developmental differences were detected between R451C knock-in mice and control groups, including slightly different rates of growth, slower righting reflexes at infancy, and faster homing responses in females (Chadman et al., 2008).

Adult Mouse Vocalizations

USVs in adult rats have been extensively described, including a 22 kHz call during stressors and aggressive interactions, and a 50 kHz call during social interactions such as sexual behaviors, juvenile interaction, and tickling (Blanchard et al., 1991; Brudzynski et al., 1993; Panksepp & Burgdorf, 2000; Brudzynski & Pniak, 2002; Brudzynski, 2005). Adult mice emit USVs with frequencies ranging from 20 to 70 kHz. The USV emission of adult mice has been primarily reported during sexual interactions (Nyby, 2001), with males responsible for most of the calls (Whitney & Nyby, 1979; Maggio et al., 1983). Unlike in rats, USVs during adult male–male encounters has not yet been extensively studied in laboratory settings (Nyby, 2001). Exposure to a female partner or to female mouse urine induces a clear USV response in adult male mice with previous reproductive experience (Whitney and Nyby, 1979; Maggio et al., 1983; Nyby, 2001; Holy and Guo, 2005; Wang et al., 2008). The quantitative analysis by Holy and Guo illustrated for the first time that the male vocalizations are characterized by temporal sequences that are specific for each individual (Holy & Guo, 2005). Female-induced male vocalization responses were reported in a study of muscarinic and dopamine receptor KO mice focused on the reward mechanisms underlying male/female recognition and sexual reward (Wang et al., 2008). USVs during adult female–female encounters have been reported by several laboratories (Maggio & Whitney, 1985; Moles & D'Amato F, 2000; Venerosi et al.,

2006; Scattoni et al., 2008b, 2010). For example, null mutation of the vasopressin *Avpr1b* gene resulted in reduced USV emission by adult females during the resident–intruder test, whereas social sniffing levels were unaltered (Scattoni et al., 2008b). Female–female calls appear to serve as communication signals, enhancing physical proximity and enabling social information gathering (Pomerantz et al., 1983; Maggio & Whitney, 1985; D'Amato & Moles, 2001; Moles et al., 2007).

A recent study reported that mouse USV was detected in adolescent C57BL/6J and BALB/cJ mice of both sexes during social interaction after 4 days of social housing followed by 1 day of social isolation (Panksepp et al., 2007). Detailed qualitative analysis revealed significant strain differences in frequency distribution of waveforms with prevalence of downward and complex sonograms in C57BL/6J mice and prevalence of upward and inverted U-shaped sonograms in BALB/cJ mice (Panksepp et al., 2007). The first generation of mice with a loss-of-function mutation in the murine *NLGN4* ortholog *Nlgn4*, which encodes the synaptic cell adhesion protein neuroligin 4, were found to exhibit deficits in reciprocal social interactions and communication (Jamain et al., 2008). Latency to start calling, upon contact with a female mouse in estrous, was 3.2 times longer in *Nlgn4*-null mutants as compared to wild-type littermate controls, and the total number of calls per session was reduced by 48% in *Nlgn4* mutants as compared to wild-type controls. These results showed that *Nlgn4* mutants were either less responsive to the social stimuli eliciting the calling or were otherwise inhibited in their propensity to vocalize.

The growing literature on USVs in mice suggests that this assay could be useful to characterize communication between the pup and the mother, and between adults of the same and opposite sex, in some inbred strains and in some lines of mutant mice. Playback experiments, in which previously recorded calls are played to a subject mouse, could be used to evaluate responses by the subject and will be necessary to determine the communicative function of various vocalizations in mice.

Mutant Mouse Models of Autism

One robust experimental approach to systematically evaluate the roles of each of the many candidate genes for autism susceptibility (Abrahams & Geschwind, 2008) is to generate mouse models with targeted mutations in genes homologous or orthologous to the human candidate gene. Table 51-1 presents a summary of autism-relevant behavioral phenotypes in some prominent genetic mouse models of autism(Silverman et al., 2010b).

Comorbidities With Single-Gene Neurodevelopmental Disorders

Growing evidence associates single-gene mutations, copy number variations, and epigenetic factors with increased risk for autism, indicating that multiple genetic pathways are involved in the disease onset. Single-gene neurodevelopmental disorders in which a high proportion of individuals meet the diagnostic criteria for autism might offer insights into the genetic mechanisms underlying autism. Fragile X Syndrome (FXS) is caused by silencing of *FMR1*, an X-linked gene that codes for the Fragile X mental retardation protein (FMRP). FXS is the most common genetic cause of mental retardation and is frequently comorbid with autism symptoms (Turner et al., 1996). As compared to wild-type controls, mice deficient for the *Fmr1* gene display impairments in reversal learning in the Morris water maze (The Dutch-Belgian Fragile X Consortium, 1994; D'Hooge et al., 1997; Bakker et al., 2002), increased startle response (Nielsen et al., 2002), increased exploratory activity, lowered anxiety (Peier et al., 2000; Yan et al., 2005), and sensorimotor gating abnormalities (Paylor et al., 2008). Social approach behavior in *Fmr1* null mice appears to be influenced by background strains on which the mutation was generated. Although KO mice generated on a B6 background (Spencer et al., 2005; Moy et al., 2009) and a B6 x FVB/NJ background (McNaughton et al., 2008) exhibited normal sociability, null mutants on a FVB/129 background were found to have deficits in the three-chambered social approach task (Moy et al., 2009). Altered social behaviors in *Fmr1* null mice have been found in other social tasks, including the mirrored chamber test, the tube test for social dominance, and direct social interaction test (Spencer et al., 2005; Mineur et al., 2006).

Rett Syndrome, a neurodevelopmental disorder caused by a mutation in the X-linked *MECP2* gene that encodes the methyl-CpG-binding protein 2 (MeCP2), is found mostly in females (Wan et al., 1999; Moretti & Zoghbi, 2006; Chahrour & Zoghbi, 2007). Individuals with this disorder are characterized by severe problems in language and communication development, muscle strength, motor functions, decreased somatic growth, mental retardation, and pronounced autism-like symptoms, including stereotyped hand movements, lack of facial expression, avoidance of eye contact, and unresponsiveness to social cues (Nomura, 2002; Chahrour & Zoghbi, 2007). Several mouse models have been generated to study the effects of *Mecp2* mutation. *Mecp2*^Flox/y mice, which have a partial loss of MeCP, exhibited motor coordination deficits, impaired learning and memory, poor nesting behaviors, and altered social behaviors in a partition test (Samaco et al., 2008). *Mecp2*^308/y mice, which carry a mutation similar to common RTT-causing alleles, showed abnormal homecage circadian activity, poor nesting behaviors, and impaired social interactions (Moretti et al., 2005). Mice with deletion of the exon 3 of the *Mecp2* gene (*Mecp2*^1lox) show increased separation-induced pup vocalizations. Genotype differences in USVs were significant on PND 5 for males and on PND 7 for females (Picker et al., 2006). Mice with a forebrain conditional KO of *Mecp2* exhibited hindlimb clasping, impaired motor coordination, increased anxiety-like behaviors, and deficits in sociability and social memory, indicating that selective loss of *Mecp2* in the forebrain is

sufficient to induce behavioral abnormalities seen in RTT (Gemelli et al., 2006).

Human chromosome 15q11-13 contains a cluster of imprinted genes essential for neurodevelopment. Lack of a functional paternal copy of 15q11-13 causes Prader-Willi Syndrome; lack of a functional maternal copy of 15q11-13 causes Angelman Syndrome (Donlon, 1988; Baker et al., 1994; Browne et al., 1997; Dykens et al., 2004; Veltman et al., 2005; Hogart et al., 2009). Strong evidence suggests duplication of the 15q11-13 region as a cytogenetic aberration in autism (Bolton et al., 2004; Dykens et al., 2004; Koochek et al., 2006; Cook & Scherer, 2008). A mouse genetic model for the human 15q11-13 duplication condition was created by generating a duplication of a conserved linkage group on mouse chromosome 7. These transgenic mice exhibited an absence of sociability and lack of preference for social novelty in the three-chambered social approach task, and perseverative behaviors in the Morris water maze and Barnes Maze tests. Pups displayed reduced maternal-separation induced USV on PNDs 7 and 14 (Nakatani et al., 2009). Two genes in the 15q11-13 region, *GABRB3* and *UBE3A*, are suggested as candidate genes for autism (Buxbaum et al., 2002; Bonati et al., 2007; Nakatani et al., 2009). Mice heterozygous for the *Gabrb3* subunit exhibit several autism-like phenotypes, including absence of sociability in the three-chambered task, poor nest-building behaviors, and stereotyped circling behaviors (DeLorey et al., 2008). These mice also display features with face validity to Angelman Syndrome, including learning and memory deficits, poor motor coordination, hyperactivity, altered rest–active cycle, (Liljelund et al., 2005; Dolen et al., 2007). Mice with a maternally inherited *Ube3a* deficiency showed impaired motor functions in a number of tests and deficits in spatial learning in the Morris water maze test (Miura et al., 2002; Heck et al., 2008).

Tuberous sclerosis is a single-gene disorder caused by heterozygous mutations in the *TSC1* (9q34) or *TSC2* (16p13.3) gene (Consortium, 1993; van Slegtenhorst et al., 1997). Besides physical dysfunctions in brain, skin, heart, kidneys, and lung; epilepsy; and cognitive impairments, tuberous sclerosis is characterized by a high prevalence of autism (25%–60%) (Wiznitzer, 2004; Napolioni & Curatolo, 2008). Mice heterozygotes for *Tsc1* and *Tsc2* displayed learning and memory impairments (Goorden et al., 2007; Ehninger et al., 2008). Male *Tsc2* +/- mice exhibited normal social approach toward an ovariectomized female novel mouse in the three-chambered task (Ehninger et al., 2008). Female *Tsc1* +/- mice exhibited reduced social interaction behaviors with a novel stimulus mouse in a neutral arena and poor nest-building behaviors (Goorden et al., 2007).

Cell Adhesion Proteins Mediating Synapse Development

Several rare mutations in genes encoding synaptic cell-adhesion molecules, including neurexins, neuroligins, contactins, cadherins, and shanks, have each been identified in a small number of individuals with autism, Asperger's Syndrome, and related neurodevelopmental disorders (Jamain et al., 2003; Laumonnier et al., 2004; Jeffries et al., 2005; Lise & El-Husseini, 2006; Autism Genome Project Consortium, 2007; Durand et al., 2007; Garber, 2007; Moessner et al., 2007; Alarcon et al., 2008; Arking et al., 2008; Jamain et al., 2008; Kim et al., 2008; Lawson-Yuen et al., 2008; Bucan et al., 2009; Gauthier et al., 2009; Sykes et al., 2009), prompting the hypothesis that the mechanisms in the early stages of synapse development contribute to the pathogenesis of autism (Bourgeron, 2007; Betancur et al., 2009; Bourgeron, 2009). Transgenic mice overexpressing neuroligin 2 displayed social deficits and high levels of repetitive jumping (Hines et al., 2008). *Nlgn2* null mutant mice displayed normal social behaviors, decreased pain sensitivity, and increased anxiety-like behaviors (Blundell et al., 2009). One line of transgenic mice with a knock-in human R451C point mutation in the *Nlgn3* gene exhibited normal social interactions and social approach behaviors, as well as normal spatial learning and memory performance (Chadman et al., 2008), whereas minor social reductions and improved performance in the spatial learning and memory task were found in another line (Tabuchi et al., 2007). *Nlgn3* null mutant mice exhibited reduced USVs by adult males contacting estrus females, normal sociability in the three-chambered task, and a lack of preference for social novelty, which might have resulted from their olfactory deficits (Radyushkin et al., 2009). The original cohort of *Nlgn4*-null mutant mice exhibited deficits in social interaction and social approach tests, as well as reduced USVs (Jamain et al., 2008). *Shank1* null mutant mice displayed hypoactivity, increased anxiety-like behaviors, and impaired fear conditioned memory but enhanced radial arm maze spatial learning and memory (Hung et al., 2008).

Signalling, Transcription, Methylation, and Neurotrophic Factors

Engrailed 2 (*EN2*) is a homeobox transcription factor that is critical for the development of the cerebellum and many serotonergic, noradrenergic, and dopaminergic nuclei (Benayed et al., 2005). *En2* null mice showed deficits in social interaction, hyperactivity, impaired motor coordination, and impaired spatial learning (Cheh et al., 2006). *FOXP2* encodes for a forkhead box DNA-binding domain. Disruption of this gene has been associated with speech and language deficits of varying severity in humans (Lai et al., 2001). Deletion and point mutations of the *Foxp2* gene has resulted in an absence (deletion) or reduction (point mutation) of separation-induced USVs in mouse pups, as well as gross developmental delays (Shu et al., 2005; Fujita et al., 2008; Groszer et al., 2008). Calcium-dependent activator protein for secretion 2 (CADPS2) is involved in the release of several trophic factors implicated in autism, such as neurotrophin 3 and brain-derived neurotrophic factor (BDNF) (Katoh-Semba et al., 2007; Sadakata et al., 2007b).

Cadps2 null mutant mice have displayed impairments in spatial learning and social behaviors (Sadakata et al., 2007a; Sadakata et al., 2007b). Phosphatase and tensin homolog on chromosome 19 (*PTEN*) is a lipid phosphatase implicated in many cancers and brain disorders (Zhou et al., 2009). Mutations in *PTEN* have been found in a small number of autistic individuals (Goffin et al., 2001; Buxbaum et al., 2007; Herman et al., 2007). Mice with a conditional *P*ten mutation in forebrain neurons have displayed impaired social behaviors, along with changes in locomotor activities, anxiety-like behaviors, increased startle responses, and impaired spatial learning (Kwon et al., 2006). Mice haploinsufficient for *Pten* have displayed deficits in sociability, which is exacerbated in mice haploinsufficient for both *Pten* and *Sclc6a4* (Page et al., 2009). *Pten* KO mice treated with rapamycin, which inhibits the signaling protein mammalian target of rapamycin complex 1 (mTOR), have displayed fewer seizures and increased social interactions (Zhou et al., 2009).

Neurotransmitters

Genes encoding the serotonin transporter, oxytocin and vasopressin receptors, and GABA receptor subunit β3 have been implicated in autism (Buxbaum et al., 2002; Lam et al., 2006; Anderson et al., 2009; Hranilovic et al., 2009). Mice null for the oxytocin gene (*Oxt*) display deficits in social memory and separation-induced pup vocalizations (Winslow & Insel, 2002; Takayanagi et al., 2005). Social approach was normal in two independent lines (Crawley et al., 2007). Mice deficient for the vasopressin receptor 1a gene (*Avr1a*) have demonstrated lower levels of anxiety-like behaviors, impaired social behavior, and intact learning and memory (Bielsky et al., 2004; Egashira et al., 2007). *Avr1b* null mutants exhibit some changes in social behaviors, including fewer USVs during social interaction with an unfamiliar partner (Scattoni et al., 2008), lower levels of aggression, and social recognition deficits (Wersinger et al., 2002). Social approach behaviors were normal in *Avr1b* null mutants (Yang et al., 2007a). *Slc6a4* null mutants displayed normal social approach behavior but a lack of preference for social novelty in the automated three-chambered task (Moy et al., 2009). Vasoactive intestinal peptide (VIP) regulates embryonic growth and development (Hill et al., 1996). Mouse dams heterozygous for *Vip* produce offspring with impairments in social behaviors that are independent of the pups' genotype (Lim et al., 2008; Stack et al., 2008).

Inbred Mouse Strain Models of Autism

Inbred strains of mice are generated by at least 20 generations of brother × sister matings to create a genetically stable line of individuals that are homozygous at greater than 99% of their genetic loci (Beck et al., 2000; Goios et al., 2007). The Jackson Laboratory, a major supplier of laboratory mice in North America, currently carries more than 400 inbred mouse strains

(http://www.informatics.jax.org/external/festing/mouse/STRAINS.shtml), among which 40 genetically diverse strains have been intensively phenotyped (Mouse Phenome Database, http://phenome.jax.org/pub-cgi/phenome/mpdcgi?rtn=docs/home). The genomes of 16 strains of JAX mice have been partially or completely sequenced (C57BL/6J,129S1/SvImJ, A/J, AKR/J, BALB/cByJ, BTBR *T⁺ tf*/J, C3H/HeJ, CAST/EiJ, DBA/2J, FVB/NJ, MOLF/EiJ, KK/HlJ, NOD/ShiLtJ, NZW/LacJ, PWD/PhJ, and WSB/EiJ) and the single nucleotide polymorphism (SNP) data of these strains are publicly available (Mouse SNP Database (http://phenome.jax.org/pub-cgi/phenome/mpdcgi?rtn=snps/door). With relevance to autism, large strain differences in social behaviors exist among commonly used inbred mouse strains (McFarlane et al., 2007; Moy et al., 2007; Yang et al., 2007b; Moy et al., 2008b; Yang et al., 2009). The intra-strain homogeneity, cross-strain diversity, and heritable nature of mouse social phenotypes make inbred mice ideal for discovering genes mediating social, communication, and repetitive behavioral traits relevant to autism. The inbred strain "forward genetics" strategy is analogous to human linkage studies for discovery of genes linked to autism (Volkmar et al., 2005; Geschwind & Levitt, 2007; Abrahams & Geschwind, 2008).

Table 51-2 summarizes and references reports of autism-like behavioral traits across a growing number of inbred strains of mice. Lack of sociability was reported in 11 strains (129/SvImJ, A/J, BALB/c, BTBR *T⁺ tf*/J, C58/J, DBA, DBA/2J, NOD/LtJ, NZB/B1NJ, SJL/J).

> BTBR T⁺tf/J is a genetically homogenous inbred strain that displays behavioral phenotypes with face validty to major symptoms of autism, including deficits in social approach and social interaction, unusual vocalization patterns, and high levels of repetitive self-grooming.

Among these, 4 strains have been tested in multiple studies. A/J, BALB/c, and BTBR consistently failed to display sociability in multiple laboratories (Bolivar et al., 2007; Brodkin, 2007; Moy et al., 2007; Yang et al., 2007 a; Yang et al., 2007b; McFarlane et al., 2008; Yang et al., 2009). A/J and BTBR displayed low scores on reciprocal social interactions (Bolivar et al., 2007), indicating good cross-paradigm consistencies in adult social behaviors for A/J and BTBR. At juvenile ages, social interaction was low in BTBR and BALB/c as compared to B6 (Panksepp & Lahvis, 2007; Yang et al., 2007a; Yang et al., 2007b; McFarlane et al., 2008; Yang et al., 2009). DBA2 exhibited sociability in two of the three studies. 129Sv/ImJ showed normal sociability in a reciprocal social interaction test (Bolivar et al., 2007) but low sociability in the three-chambered task, probably related to their low levels of general exploratory locomotion (Moy et al., 2007).

Repetitive behaviors in inbred strains of mice are conceptually relevant to the third diagnostic domain of autism. Excessive self-grooming is a prominent phenotype in BTBR and is among the most replicable findings of this strain (Yang et al., 2007a; Yang et al., 2007b; McFarlane et al., 2008; Yang

et al., 2009). High levels of self-grooming begin at early juvenile ages and remain high in adults, leading to hair loss but not skin lesions (McFarlane et al., 2008). In addition, repetitive self-grooming is observed within a social test apparatus when another mouse is present (Yang et al., 2009) and also when the subject is alone in a bare cage. Repetitive self-grooming is equally high in BTBR adults raised as pups with their own dams, cross-fostered with B6 dams, or cross-fostered with B6 dams (Yang et al., 2007b), indicating that their high self-grooming is a stable trait rather than a consequence of behavioral response to early maternal environment. Excessive spontaneous self-grooming has also been observed in several mutant mouse lines. *Sapap3* (Welch et al., 2007) and *Hoxb8* mutant mice (Greer & Capecchi, 2002) exhibit extreme self-grooming that leads to hair loss and skin injuries. *Hoxb8* KO mice also groom their cagemates, suggesting that the high levels of self-grooming in these mutant mice is not likely the result of a skin disorder that caused itching. Other repetitive and stereotyped behaviors reported in mice include water mist-induced grooming (Moretti et al., 2005), repetitive rearing (Pogorelov et al., 2005), somersaulting, jumping, leaping, tail-chasing, cage top twirling, and object chewing (Lewis et al., 2007).

Investigators often ask which inbred strain provides the benchmark scores for "normal" social behaviors, against which potential mouse models of autism can be compared. As illustrated in Table 51-2, B6 and FVB strains have consistently been found to display high social behaviors and low repetitive behaviors in all paradigms in which they have been tested.

Treatment Strategies

As described above, several robust behavioral phenotypes in mice—including low social interaction, high repetitive behaviors, and unusual patterns of communication—present reasonable face validity to the symptoms of autism (Crawley, 2007a; Crawley, 2007c). Mouse models of autism offer translational tools to evaluate potential treatment strategies. Because there are no confirmed biological markers for autism at present, but many candidate genes, models with construct validity based on candidate gene mutations may prove useful in the development of biological intervention strategies. The single-gene mutations and chromosomal copy number variants described above could become targets for pharmacological interventions and/or gene therapies (Abrahams & Geschwind, 2008; Beaulieu et al., 2008; Campbell et al., 2008; Kelleher & Bear, 2008; Bourgeron, 2009). At the time of this writing, behavioral interventions are the only effective methods to treat social deficits in autism. Intervention studies using mouse genetic models with robust autism-like phenotypes could facilitate the development of pharmacological, genetic, and behavioral treatments for autism. Table 51-4 summarizes the most promising pharmacological, genetic, and behavioral interventions in the currently available mouse models.

Drug Treatments

Pharmacological treatments, including selective serotonin reuptake inhibitors (SSRIs) and oxytocin, have been reported to modestly reduce some symptoms in individuals with autism (Hollander et al., 2000; Kolevzon et al., 2006). A recent multicenter clinical trial reported that citalopram, a prominent SSRI, produced no significant behavioral improvements and had some adverse side effects in children (King et al., 2009; Volkmar, 2009). At present, the antipsychotic risperidone, which is a dopamine receptor (D2) and serotonin ($5HT_{2A}$) receptor antagonist, is the only drug approved by the U.S. Food and Drug Administration for autism, specifically for treating the irritability associated with autism, which includes

Table 51–4.

Examples of intervention strategies in mouse models of autism

Pharmacologic Intervention	Mechanism of Action	Animal Model	Resulting Behavioral Improvements	References
2-methyl-6-phenylethynyl-pyridine hydrochloride (MPEP)	Noncompetitive antagonists to the mGluR5 receptor	*Fmr1 –/–*	Reduced susceptibility to audiogenic seizures Reduced open field hyperactivity	Yan et al., 2005 Chuang et al., 2005
			Rescued abnormal spine morphology Reversed prepulse inhibition deficits	De Vrij et al., 2008
Fenobam		BTBR	Reduced repetitive self-grooming behavio	Silverman et al., 2009
BDNF	Neurotrophin	*Fmr1 –/–*	Restored synaptic plasticity	Lauterborn et al., 2007
Rapamycin or RAD001	Inhibitors of mTOR Translational regulation	*Pten*	Reduced morphological abnormalities Improved social interaction Increased open field center time Reduced duration and frequency of seizures	Kwon et al., 2006 Zhou et al., 2007 Zhou et al., 2009

Table 51–4. (Contd.)

Pharmacologic Intervention	Mechanism of Action	Animal Model	Resulting Behavioral Improvements	References
		Tsc1 –/– (neuronal)	Increased survival rates Reduced tremors Improved gait function Improved neuronal morphology Restored myelination	Meikle et al., 2008 Ehninger et al., 2008
		Tsc1 –/– (glial)	Normalized weight gain Reduced seizure frequency	Zeng et al., 2008
		Tsc2 –/–	Reversed contextual discrimination impairment in fear conditioning Rescued spatial learning deficits	Ehninger et al., 2008
Oxytocin	Neuropeptide	*OT–/–*	Facilitated social recognition	Ferguson et al., 2001
CX546	Increases AMPA receptor activation	*Mecp2 –/–*	Improved respiratory function	Ogier et al., 2007

Genetic Intervention	Mechanism of Action	Animal Model	Resulting Behavioral Improvements	References
YAC transgene replacement *FMR1*	Cell specific expression of human Fragile X mental retardation protein (FMRP) 10- to 15-fold greater than endogenous levels	*Fmr1 –/–*	Rescued hyperactivity in open field Reversed excessive approaches in social partition task Normalized duration of social behavior	Spencer et al., 2008
			Rescued hyperactivity in open field Reduced high open field center time Reversed hypoanxiety-like phenotype in the light ↔ dark task	Peier et al., 2000
Dominant negative expression of p21-activated kinase (PAK)	Interaction with the (FMRP) Actin polymerization and spine morphogenesis	*Fmr1 –/–*	Rescued hyperactivity in open field Reduced high open field center time Reduced repetitive behavior and stereotypy Enhanced performance on trace fear conditioning task	Hayashi et al., 2007
Genetic Mutation of mGluR5	Double knockouts of Fmr1 and mGluR5 (Knockdown to 50% mGluR5 expression)	*Fmr1 –/–*	Rescue of ocular dominance plasticity Rescued inhibitory avoidance learning Rescued memory retention and acquisition	Dolen et al., 2007
Activation of *Mecp2* expression	Re-express MeCP2 using a fusion transgene activated by tamoxifen injections	*Mecp2 lox-Stop*	Improved gait Reduced tremors General poor health condition improved Reduced hindlimb clasping	Guy et al., 2007
Targeted delivery of *Mecp2* transgene	Double mutant of mice overexpressing MeCP2 in cortex crossed with Mecp2 +/– mice	*Mecp2 +/–*	Rescued open field mobility	Jugloff et al., 2008

Behavioral intervention	Mechanism of action	Animal model	Resulting behavioral improvements	References
Enriched environment	Increased spine density Increased BDNF Increased cytochrome oxidase activity	Deer mice	Reduction of stereotypy including back flipping and jumping	Turner & Lewis 2003 Lewis 2004

self-injury, aggression, and tantrums (West et al., 2009b). Although some studies demonstrated mild improvements in eye contact and other measures relevant to social behaviors after risperidone (McDougle et al., 1997; McDougle et al., 2000; Barnard et al., 2002; Chavez et al., 2006; Posey et al., 2008), other studies found minimal or no improvements in social relatedness after risperidone treatment (McDougle et al., 2005; Chavez et al., 2006). Pharmacological treatments to reverse social deficits remain to be discovered (Kratochvil et al., 2005; West et al., 2009b). In a preclinical study, it was found that mice expressing a mutant form of *Tph2*, a rate-limiting enzyme for serotonin synthesis, showed increased depressive- and anxiety-like behaviors, as well as high levels of aggressive behaviors. The depressive-like phenotypes were alleviated by treatment with TDZD-8, a pharmacological agent that inactivates Gsk3β, an intracellular signaling molecule, and by genetic inactivation of GSK3β in *Tph2* mutants. Genetic inactivation of GSK3β also reduced aggressive behaviors and increased non-aggressive social investigation in *Tph2* mutant mice (Beaulieu et al., 2008). Social recognition deficits in oxytocin KO mice were rescued by low-dose oxytocin microinjections into the medial amygdala (Ferguson et al., 2001).

Recent studies in several mouse mutant models of neurodevelopmental disorders indicate abnormal functional and structural synaptic connectivity in autism and FXS (Silva & Ehninger, 2009). This evidence prompts the hypothesis that regulators of synaptic plasticity, including metabatropic glutamate receptor antagonists (mGluRs), AMPA receptor activators, and antagonists of the mTOR, might be promising molecular targets for pharmacological interventions (Parsons et al., 2006; Hayashi et al., 2007; Ogier et al., 2007; Blundell et al., 2008; Dolen & Bear, 2008; Ehninger et al., 2008; Garber et al., 2008; Meikle et al., 2008; Silva & Ehninger, 2009; Zhou et al., 2009). In the mouse model of FXS, pharmacological treatment with 2-methyl-6-phenylethynyl-pyridine (MPEP), a potent mGluR5 antagonist, rescued behavioral phenotypes, including seizures, hyperactivity, anxiety-like behavior, PPI deficits (Yan et al., 2005; de Vrij et al., 2008), and restored deficits in synaptic plasticity and spine morphology in *Fmr1* mutant mice (de Vrij et al., 2008). An in vitro study showed that the impaired hippocampal LTP in fragile X mice was fully restored by BDNF infusion, indicating a possible mechanism for treating synaptic deficits associated with FXS (Lauterborn et al., 2007). A single intraperitoneal injection of MPEP significantly reduced repetitive self-grooming behaviors in the BTBR T+tf/J mice, the robust mouse model that displays endophenotypes relevant to all three core symptoms of autism (Silverman et al., 2010a). mGluR5 antagonists may have therapeutic potential for a variety of neurodevelopmental disorders and are in clinical trials for FXS, (Rorick-Kehn et al., 2007; Berry-Kravis et al., 2009), which has a high comorbidity with autism. Chronic rapamycin treatment normalized several neuronal morphology deficits, seizures, and alleviated social deficits in *Pten* mutant mice (Zhou et al., 2007). Treatment with rapamycin or the mTOR inhibitor RAD001 significantly increased survival, decreased tremors, and

prevented seizures in the *Tsc1* mutant mouse model of tuberous sclerosis, a single-gene disorder with a high autism comorbidity (Meikle et al., 2008). Cognitive deficits were reversed by rapamycin treatment in the *Tsc2* heterozygote mouse model of tuberous sclerosis (Ehninger et al., 2008). Treatment with the AMPA activator CX546 improved respiratory abnormalities and increased BDNF levels in the *Mecp2* mutant mouse model of RTT (Ogier et al., 2007).

Genetic Rescues

The mGluR5 receptor, one of the pharmacological targets described above, was found to be an effective target for genetic intervention. Breeding mGluR5-deficient mice with fragile X mice reduced the mGluR5 overexpression in *Fmr1* mice, and rescued several *Fmr1* phenotypes, including amelioration of audiogenic seizures and cognitive impairments (Dolen et al., 2007). p21-activated kinase (PAK) is a kinase known to play a critical role in actin polymerization and dendritic spine morphogenesis. Postnatal expression of a dominant negative transgene for PAK in *Fmr1* mice partially rescued reduced cortical LTP deficits and overgrowth of dendritic spines and partially normalized several behavioral phenotypes associated with *Fmr1* mutation, including low anxiety-like behaviors, hyperactivity, and high levels of stereotypy in an open field, as well as deficits in fear conditioning (Hayashi et al., 2007). Overexpression of human FMRP in *Fmr1* mice, using yeast artificial chromosomes, normalized the overactive social responses in *Fmr1* mice in the partition test (Spencer et al., 2008) and reversed and overcorrected several *Fmr1* phenotypes, resulting in hypolocomotion and high anxiety-like phenotypes (Peier et al., 2000).

Behavioral Intervention

Early behavioral interventions remain the most effective treatment for the symptoms of autism (Landa, 2007; Williams White et al., 2007; Dawson, 2008; Rao et al., 2008). Effective behavioral interventions have been demonstrated in two robust mouse models. Deer mice reared in standard laboratory housing have exhibited abnormalities in social behaviors and repetitive jumping (Turner & Lewis, 2003; Turner et al., 2003). Environmental enrichment ameliorated these stereotypies, improved behavioral performance on learning and memory and anxiety-related tasks, reduced seizure vulnerability, and increased BDNF levels and neurogenesis in deer mice (Powell et al., 2000; Lewis, 2004). BTBR mice reared with social B6 cagemates after weaning exhibited significant improvements in sociability as adults (Yang et al., 2010).

Challenges and Future Directions

The multiple assays described above are likely to be useful in analyzing behaviors in emerging mouse models of autism.

Methods are in place for many social tasks, measures relevant to communication, and parameters of repetitive and perseverative behaviors. The literature cited in the tables represents a growing body of literature on the generation of tasks relevant to the symptoms of autism spectrum disorders, and their applications to lines of mice with mutations in candidate genes for autism spectrum disorders.

- The second diagnostic domain, impaired communication, requires considerably more task development. Behavioral neuroscientists will need to confirm the communicative nature of olfactory and vocal cues during various types of social interactions in mice. Further methods development is needed to quantitate reciprocal scent marking, and to evaluate playback experiments for auditory communication in mice. A fundamental question is whether the very different sensory modalities used for communication in humans and mice share common cortical mechanisms for higher levels of information processing. In addition, mice may use other sensory modalities for communication, including visual cues and tactile body contact, for which assays remain to be invented. Diagnostic domains such as joint attention and Theory of Mind may be difficult to model in mice. Task development to determine whether mice display observational learning may be helpful, perhaps using methods previously developed for rats and other species (White & Barfield, 1989; Brudzynski & Chiu, 1995; Sadananda et al., 2008; Wohr & Schwarting, 2009).

- Associated symptoms of autism include mental retardation, seizures, anxiety, hyperreactivity to sensory stimuli, gastrointestinal distress, and sleep disturbances. These associated symptoms occur only in some autistic individuals and are therefore not considered diagnostic. To what extent should behavioral neuroscientists attempt to include associated endophenotypes in mouse models of ASDs? This is an open question for which animal modelers need considerable input from clinical experts. There is a technical complication in some cases, wherein mouse phenotypes relevant to an associated symptom domain would directly confound the detection of phenotypes in a core symptom domain. For example, although seizures are an associated symptom of autism, a line of mice with severe seizures may not survive to ages at which behavioral testing occurs, as seen in the GABA-A receptor unit β3 KOs, which have an approximately 10% survival rate (DeLorey et al., 2008). A line of mice with high anxiety-like traits would likely display low locomotor activity in a social environment, confounding the interpretation of low social approach scores, as seen in adult BALB/c (Brodkin, 2007). If clinical investigators strongly recommend including associated symptoms in mouse models of autism, one solution is to focus on heterozygotes in which the protein reduction is partial and the phenotype may be milder, or conditional mutants in which the mutation is neuroanatomically restricted and appears later in development, or inducible mutants in which the mutation is activated only at the time of behavioral testing. Knockdowns, using anatomically discrete gene delivery with viral vectors, and RNA silencing, represent technologies that allow highly specific expression of a mutation in a brain region of interest.

- A point that cannot be made too often is the need for replicating mouse behavioral findings. A single finding in one experiment may be spurious, as in any field of science. Experimental designs in mouse behavioral genetics must plan for at least two cohorts of mice, each of sufficient numbers of littermates for each genotype and sex (Crawley, 2007b; Crawley, 2007c). Statistical analyses must adhere to the standards in the behavioral neuroscience literature. A Two-Way or Three-Way Repeated Measures ANOVA, with subsequent *post hoc* tests such Tukey's, Dunnett's, Newman-Keuls, and Bonferroni-Dunn, determine which genotypes differ from their wild-type littermate controls. Significant findings replicated in two cohorts, and then replicated across two laboratories, will contribute the best evidence to the literature on mouse models of autism.

- As described above, a strong behavioral phenotype in a mutant line of mice offers a model system for investigating biological causes and testing treatments. Definitive biological markers for autism have not yet been identified (Carrona et al., 2008). However, several neuroanatomical abnormalities have been reported, including larger head circumference and larger volumes of some brain regions at early ages (Courchesne et al., 2001; Hazlett et al., 2005), reduced white matter and pathway connectivity (Geschwind & Levitt, 2007; Minshew & Williams, 2007; Sundaram et al., 2008), reductions in specific brain structures such as cortical minicolumns, gray matter containing mirror neurons, amygdala, and Purkinje neurons in the cerebellum (Casanova, 2006; Hadjikhani et al., 2007; Amaral et al., 2008), reduced activation of the amygdala and fusiform gyrus during social tasks (Pierce et al., 2001; Pelphrey et al., 2002), and less activation of the anterior cingulate and posterior parietal cortex during set-shift tasks (Shafritz et al., 2008). Multiple rare variants continue to emerge from whole-genome scans, association studies, and sequencing of chromosomal loci identified in linkage studies of family pedigrees (Abrahams & Geschwind, 2008; Campbell et al., 2008; Rapin & Tuchman, 2008; Buxbaum, 2009; Glessner et al., 2009; Lintas & Persico, 2009). Future investigations will determine whether similar biological markers appear in various model organisms. Experiments with animal models can be designed to reveal which of these neuroanatomical and genetic abnormalities are causal in nature—that is, which represent the mechanisms responsible for the relevant behavioral traits. When the true causes of autism are identified, then the identical mutation, neuroanatomical abnormality, neuropharmacological disruption, environmental toxin, immunological dysfunction, and other mechanisms can be

generated in model organisms. Models with face validity for the diagnostic symptoms and construct validity for the underlying causes then become valuable translational research tools to test potential treatments for autism. At present, several robust and well-replicated behavioral phenotypes in mouse models of autism spectrum disorders are available as preclinical translational tools, toward developing drugs and behavioral interventions to reverse autism-relevant traits.

Modeling Features of Autism in Rodents

Points of Interest

- A number of abnormal behaviors found in autism can be produced in rodent models. None of these behaviors are specific for autism, however.
- Human disorders caused by single-gene mutations that exhibit features of autism provide proof-of-principle for the role of genetics in autism. Similarly, studies showing that maternal thalidomide, valproate, or infection can increase the risk for features of autism in the offspring provide proof-of-principle for the role of environmental factors. Both the environmental and genetic factors can be very effectively modelled in mice.
- Certain neuropathologies that are relatively common in autism can be reproduced in rodent models.

Introduction

Animal models of many neurological diseases (Alzheimer's, Parkinson's, Huntington's, multiple sclerosis) have proven enormously useful for determining the roles of genes and environment, for understanding pathogenesis, and for testing potential therapeutic approaches. There is some skepticism, however, concerning models of psychiatric or mental illnesses (e.g., autism, schizophrenia, depression). After all, can cognitive abnormalities or language deficits be detected in animals? However, to give up on this approach would deny the application of powerful genetic and molecular tools to these critical illnesses. Moreover, animal models need not be perfect mimics of human diseases to be valuable. This is clear from the extensive and productive use of genetic mouse models for Huntington's and other neurodegenerative diseases, which do not exhibit the severe loss of particular types of neurons that characterize these disorders. The power of animal models is in

the examination of key features of a disease, and the relevance of an animal model should be judged by how well it reflects one or more features of that disease, which may include genetics, neuropathology, behavior, etiology, electrophysiology, or molecular changes.

Autism is a particularly difficult case for animal studies because it has a heterogeneous behavioral phenotype, the susceptibility genes have not been firmly identified, and it does not have a pathognomonic histology that allows definitive diagnosis. Nonetheless, autism does have generally agreed upon features that are distinctive, such as a deficit of Purkinje cells (PCs), decreased hippocampal γ-aminobutyric acid ($GABA_A$) receptors, and elevated levels of brain-derived neurotrophic factor (BDNF) and platelet serotonin (5-HT) (Palmen et al., 2004; Pardo & Eberhart, 2007; Amaral et al., 2008). There is also striking evidence for immune dysregulation in the autistic brain and cerebrospinal fluid (Pardo et al., 2006; Arion et al., 2007; Chez et al., 2007; Pardo & Eberhart, 2007; Morgan et al., 2010). Moreover, some of the characteristic behavioral features of autism can be assayed in animals, such as neophobia, abnormal social interactions, stereotyped and repetitive motor behaviors, communication deficits (ultrasonic vocalizations; USVs), enhanced anxiety, abnormal pain sensitivity, disturbed sleep patterns, abnormal eye blink conditioning, and deficits in sensorimotor gating (prepulse inhibition; PPI) (Silverman et al., 2010).

Although autism has a strong genetic basis, it is not a monogenic disorder, and thus it is not possible to establish an immediately relevant genetic mouse model, as was done with Huntington's disease. Nonetheless, there are several genetic changes that do entail an elevated risk for autism, and mouse models of these changes share some features with the human disorder. There are also several human disorders caused by single gene mutations that display autistic features and mouse mutants of these mutations display behavior or neuropathology relevant to autism. In addition, models based on autism etiology are valuable, and there are several known environmental

risk factors that are being successfully modeled in rodents. Finally, there are brain lesion models of interest. Therefore, even at this early stage of analysis, it is clear that various models can be used to study how particular genes influence certain autism endophenotypes, and how known environmental risk factors influence such endophenotypes. It will also be interesting to determine how a particular genotype influences the response to an environmental risk factor, and vice versa. There are currently very few examples of such gene-environment interactions in mouse models. This chapter discusses current genetic, environmental risk factor and lesion models. Several other authors have reviewed various aspects of animal models related to autism (Murcia et al., 2005; Tordjman et al., 2007; Moy & Nadler, 2008).

Environmental Manipulations

Thalidomide and Valproic Acid

Prenatal or early postnatal drug exposure can increase autism risk. Comorbidity of Moebius syndrome and autism support a correlation between autism and the use of the prostaglandin misoprostol, a drug historically administered for labor induction or abortion (Miller et al., 2004). Case studies of fetal alcohol syndrome also suggest that prenatal exposure to ethanol increases risk for autism (Nanson, 1992). Perhaps most clearly associated with autism, however, are the teratogens thalidomide (Stromland et al., 1994) and valproic acid (VPA; valproate) (Christianson et al., 1994). Not only can these drugs cause an array of birth defects, they also increase the incidence of autism when administered early in human pregnancy (Miyazaki et al., 2005).

The use of thalidomide led to the discovery of a window of vulnerability for the development of autism (Figure 52-1). During the 1950s and 60s, thalidomide treatment of morning sickness resulted in thousands of offspring with severe malformations. Since the timing of drug exposure leads to specific types of craniofacial defects, the defects seen in the autistic offspring could be used to determine when these offspring were exposed. In this way, vulnerability to autism was pinpointed to days 20 to 24 of gestation, the time of neural tube closure and formation of motor nuclei and cranial nerves. Importantly,

there is some evidence that idiopathic autism cases may also exhibit abnormalities in the cranial nerve nuclei and other neuropathologies that originate during fetal brain development (Schneider & Przewlocki, 2005; Palmen et al., 2004).

A few laboratories have translated maternal thalidomide exposure into rodent models. Exposure of rats to thalidomide on embryonic day 9 (E9) yields adult offspring with hyperserotonemia in the plasma (as in autism), hippocampus, and frontal cortex (Narita et al., 2002), with altered distribution of serotonergic neurons in the raphe nuclei (Miyazaki et al., 2005). These offspring also display hyperactivity in the open field and decreased learning in the radial maze (Narita et al., 2010). Exposure on E15 inhibits vasculogenesis and alters cortical and hippocampal morphology (Fan et al., 2008). Furthermore, daily maternal injection of rats from E7 to E18 yields adult offspring with altered learning and memory as measured by increased errors and latency in the Cincinnati water maze (Vorhees et al., 2001). Clearly, much more could be done with this model to establish its relevance for autism.

Because VPA retains its teratogenicity in rodents, its administration during the time of neural tube closure has proven useful as a rodent model. VPA was first introduced in the 1960s as an anticonvulsant and later as a mood-stabilizing drug for treatment of epilepsy and bipolar disorder (Markram et al., 2007). Like thalidomide, use of VPA during early human pregnancy significantly elevates the incidence of autism and the development of craniofacial defects in exposed offspring. Both case and epidemiological studies have confirmed the association between fetal valproate syndrome and autism (Hyman et al., 2006; Fan et al., 2008). Although women who are prescribed VPA for treatment of epilepsy often take the drug throughout pregnancy, it is unclear whether brain regions other than the brain stem are vulnerable to VPA insult at later stages of development (Rinaldi et al., 2007a).

> **Fetal valproate syndrome**—rare congenital disorder caused by exposure of the fetus to valproic acid during the first trimester of pregnancy; characterized by symptoms of spina bifida, dysmorphic features, musculoskeletal malformations and developmental delay

In animal studies, a single injection of VPA in a pregnant rat results in striking neuropathology and behavioral abnormalities. Offspring of rats injected with VPA show brain defects resembling those sometimes found in autism, including
Figure 52–1. Timeline of birth defects caused by thalidomide, and the critical period of vulnerability to autism. The specific dysmorphologies in the offspring depend on the precise timing of drug ingestion. The fact that autistic features were only seen in offspring of a particular set of dysmorphologies indicates that the period of thalidomide-induced autistic features corresponds to days 20–23 of human gestation. Graphic after Rodier, PM. (2000) The early origins of autism. Scientific American, *282*(2), 56–63.

reduced number of motor nuclei and PCs (Schneider & Przewlocki, 2005), hyperserotonemia, and disorganized migration of 5-HT neurons in the dorsal raphe nuclei (Miyazaki et al., 2005). Fetuses from VPA-injected mothers display hypoplasia of the cortical plate, abnormal migration of dopaminergic and serotonergic neurons, and abnormal pons pathology (Kuwagata et al., 2009). VPA is a histone deacetylase inhibitor that is thought to impede neuronal differentiation and migration by interfering with the sonic hedgehog signaling pathway.

Interestingly, offspring of rats injected with VPA on E12.5 develop behavioral abnormalities that appear before puberty,

> **Sonic hedgehog signaling pathway**—signal transduction pathway initiated by the binding of Hedgehog ligand to Patched; plays an important role in embryonic patterning and cell fate decisions

a feature that distinguishes this model from behavioral changes seen in schizophrenia (Schneider & Przewlocki, 2005). VPA offspring display lower sensitivity to pain and higher sensitivity to nonpainful sensory stimuli, which parallels reported changes in endogenous opioid systems in some autistic patients. These offspring also exhibit impaired sensorimotor gating as measured by acoustic PPI, elevated anxiety as evidenced by decreased open field exploration, increased stereotypic/repetitive activity, decreased social interaction, impaired reversal learning, altered eyeblink conditioning patterns, and enhanced fear memory processing, all of which are consistent with results in autistic children (Stanton et al., 2007; Murawski et al., 2008; Markram et al., 2008; Dufour-Rainfray et al., 2010; Roullet et al., 2010) (Table 52-1). A sexual dimorphism has been reported for some of these parameters, with abnormalities seen only in male offspring, which is also consistent with the very significant male bias in autism

Table 52–1.

Behavioral assays used in rodent models of autistic features

Behavioral Paradigm	Testing Environment	Dependent Variables
SOCIAL BEHAVIOR		
sociability	three-chambered cage with inanimate object versus social object (mouse)	time spent in each chamber; number of approaches
preference for social novelty	three-chambered cage with familiar mouse versus unfamiliar mouse	time spent in each chamber; number of approaches
ultrasonic vocalizations	empty cage; pups are briefly isolated from mothers	number of calls, frequency of calls, type of call
LEARNING AND MEMORY		
Cincinnati water maze (multiple T maze)	maze design consisting of nine interlinked T-units submerged in water; mice are trained to swim to the escape platform	latency to find platform; time spent swimming in the trained quadrant of the pool as compared to time spent in the other quadrants
Morris water maze	circular pool of opaque water; mice are initially trained to swim to visible platform and then to submerged hidden platform	latency to find platform; time spent swimming in the trained quadrant as compared to time spent in the other three quadrants
eyeblink conditioning	chamber with tone generator for administration of a series of tones (conditioned stimulus, CS) followed by a periorbital shock (unconditioned stimulus)	occurrence of eyeblink as measured by EMG eyeblink signal (conditioned response, CR); amplitude of CR; latency between CS and onset of CR; latency between CS and peak of CR
novel object exploration	brightly lit open arena; in first trial, mice are exposed to two objects; in the second trial, one of the two objects is exchanged for a novel object	investigation of novel object; time spent with the novel object
novel location exploration	brightly lit open arena; in the first trial, mice are exposed to two objects; in the second trial, one of the two objects is moved to a new location	investigation of moved object; time spent with moved object
latent inhibition	chamber with tone generator for administration of a series of tones followed by an adversive stimulus (mild foot shock)	whole body flinch amplitude; freezing in context environment and after tonal cues
SENSORIMOTOR GATING		
acoustic prepulse inhibition	cage with tone generator for administration of a series of prepulse tones followed by startle stimulus	whole body flinch amplitude; freezing
ANXIETY/LOCOMOTION		
open field exploration	brightly lit open arena	center duration, number of center entries, total distance traveled, horizontal activity, vertical activity (rearing)
amphetamine-induced locomotion	brightly lit open arena	total distance traveled, horizontal activity, vertical activity (rearing)

(Schneider et al., 2008). It will also be interesting to look for communication deficits (USVs) in this model.

Electrophysiological studies indicate that offspring of VPA-treated mothers exhibit abnormal microcircuit connectivity in the neocortex and amygdala. Exposure to VPA results in over-expression of CaMKII and the NR2A and NR2B NMDA receptor subunits in the neocortex (Rinaldi et al., 2007b). These observations are consistent with observed increases in NMDA receptor-mediated synaptic transmission and enhanced postsynaptic long-term potentiation in neocortical pyramidal neurons. Adult VPA offspring also show increased connection probability of layer 5 pyramidal cells but decreased excitability and decreased putative pyramidal cell synaptic contacts (Rinaldi et al., 2008). These results relate to MRI studies showing impaired long-range functional connectivity in autistic individuals (Just et al., 2004).

CaMKII—calcium/calmodulin-dependent protein kinase II; a member of a family of serine/threonine-specific protein kinases that is known for its role in regulating long-term potentiation

NR2A and NR2B NMDA receptor subunits—two out of several isoforms of NMDA receptor subunits that combine with other subunits to form a NMDA receptor. NR2A contains a binding site for glutamate and continues to increase in expression throughout development. NR2B contains a binding site for the inhibitor ifenprodil and is expressed mainly in immature neurons of the early postnatal brain

Recordings from neurons in the lateral amygdaloid nucleus demonstrate hyper-reactivity to electrical stimulation, elevated long-term potentiation and impaired stimulus inhibition that may contribute to the deficient fear extinction and high anxiety seen in VPA offspring (Markram et al., 2008). These results suggest molecular and synaptic alterations in VPA mice that are relevant for the alterations in amygdala morphology observed in autism (Amaral et al., 2008). Dysfunction in the amygdala may contribute to the decreased social interaction and/or abnormal fear processing characteristic of autistic pathology (Markram et al., 2008). While deficits in social play and exploration have been reported in VPA rodent offspring (Schneider et al., 2008), an important gap in the behavioral analysis of social interaction is in the analysis of social preference and USVs.

Although the mechanisms underlying the effects of prenatal VPA on fetal brain development are largely unknown, neural inflammation and gene regulation could be involved. Immunological alterations have been reported in offspring of VPA-treated mice (Schneider et al., 2008; Bennett et al., 2000), and *in vitro* studies indicate that VPA promotes astrocyte proliferation, inhibits microglial and macrophage activation, and induces microglial apoptosis (Peng et al., 2005; Dragunow et al., 2006). This is consistent with the finding that VPA can regulate epigenetic modifications through three mechanisms: inhibiting histone deacetylases, enhancing histone acetylation, and promoting demethylase activity (Chen et al., 2007). The ability of VPA to alter HOX gene expression is of particular interest, as HOXa1 is expressed during the time of neural tube closure and regulates development of the facial nucleus and superior olive (c.f., Finnell et al., 2002). Moreover, VPA treatment may actually promote neurogenesis of GABAergic neurons and facilitate neurite outgrowth (Dragunow et al., 2006). These neuroprotective effects occur after chronic VPA treatment rather than the acute exposure administered in the maternal VPA model, however (Hao et al., 2004; Ren et al., 2004).

Although maternal VPA and thalidomide exposure are responsible for only a small fraction of autism cases, the extremely high risk for autism in the offspring provides proof-of-principle for environmental influences on autism incidence. Moreover, the similarities in neuropathology and behavior between the rodent models and human autism support the utility of environment-based models for defining relevant pathways of developmental dysregulation. It will be important to extend the VPA model to mice carrying genetic variants associated with increased risk for autism, which would provide a test of the gene x environment paradigm. Interestingly, prenatal VPA exposure has been linked to altered expression of neuroligin3, a genetic susceptibility factor for autism (Kolozsi et al., 2009).

HOX—group of related genes defined by the presence of a DNA sequence known as the homeobox; they code for a class of homeodomain-carrying transcription factors that serve as regulators of embryonic development

Maternal Infection

Maternal infection is an environmental risk factor for the development of several neuropsychiatric disorders in the offspring. As is the case for schizophrenia (Patterson, 2007; Brown & Derkits, 2010), maternal viral infection is linked to higher incidence of autism by clinical, epidemiological, and case studies. Early evidence for this came from the 1964 rubella pandemic, in which the incidence of autistic features was increased more than 200-fold in the offspring of infected mothers (Chess, 1977). Case studies have linked autism to several other prenatal viral infections, including varicella, rubeola, and cytomegalovirus (Ciaranello & Ciaranello, 1995). Bacterial and protozoan infections have also been associated with autism (Nicolson et al., 2007; Bransfield et al., 2008). The most compelling evidence linking maternal infection with autism comes from a very large study utilizing the Danish Medical Birth Register. An examination of over 10,000 autism cases found a very significant association with maternal viral infection in the first trimester (Atladottir et al., 2010). In sum, the diversity of micro-organisms implicated in autism, along with the fact that several of these infections do not involve direct transmission into the fetus, suggests that the maternal immune response, rather than microbial pathogenesis, is responsible for increasing the risk for autism in the offspring (Figure 52-2). Animal models of maternal infection further
Figure 52–2. Cytokines produced by activation of the maternal immune system can alter fetal brain development. Various types of infection (bacteria, viruses, and parasites are illustrated) in pregnant rats or mice can be mimicked by injection of LPS or poly(I:C). These activate cells (pink in blue sphere) to produce cytokines (blue balls), which travel in the blood to the placenta, where they can activate cells. The cytokines can also cross the placenta into the fetal circulatory system and activate cells in the fetal brain. Illustration by Wensi Sheng. (See Color Plate Section for a color version of this figure.)

support the idea that maternal immune activation (MIA) and the production of pro-inflammatory cytokines are what unite the various types of maternal infection as risk factors for autism. There are three primary rodent models for MIA: maternal influenza infection, poly(I:C) injection, and lipopolysaccharide (LPS) injection.

Pregnant mice intranasally infected with influenza yield offspring with behavioral and neuropathological abnormalities that parallel those seen in autism. Abnormal behaviors include heightened anxiety during open-field exploration, deficient PPI, decreased novel object exploration, and reduced social interaction (Shi et al., 2003). These offspring display spatially selective PC loss in lobules VI and VII (Figure 52-3) (Shi et al., 2009), which is a common neuropathology in autism (Palmen et al., 2004; Amaral et al., 2008). There is also macrocephaly, delayed cerebellar granule cell migration, reduced Reelin immunoreactivity in the cortex, thinning of the neocortex and hippocampus, and altered expression of neuronal nitric oxide synthase and synaptosome-associated protein-25 (Fatemi et al., 2002; Shi et al., 2009). Infection on E16 or E18 causes altered expression of several genes associated with autism, white matter thinning in the corpus callosum, widespread brain atrophy, and altered levels of cerebellar 5-HT but not dopamine (Fatemi et al., 2008, 2009; Winter et al., 2008).

Because maternal influenza infection is largely confined to the respiratory tract, it is unlikely that these neurological defects are caused by direct viral infection of the fetus.

Reelin—a secreted extracellular matrix glycoprotein that regulates neuronal migration in the developing brain and synaptic plasticity in the adult brain

Nitric oxide synthase (NOS)—a class of dimeric, calmodulin-associated enzymes that catalyze the formation of nitric oxide

Synaptosome-associated protein-25 (SNAP-25)—a membrane-bound component of the neurotramsmitter vesicle release mechanism

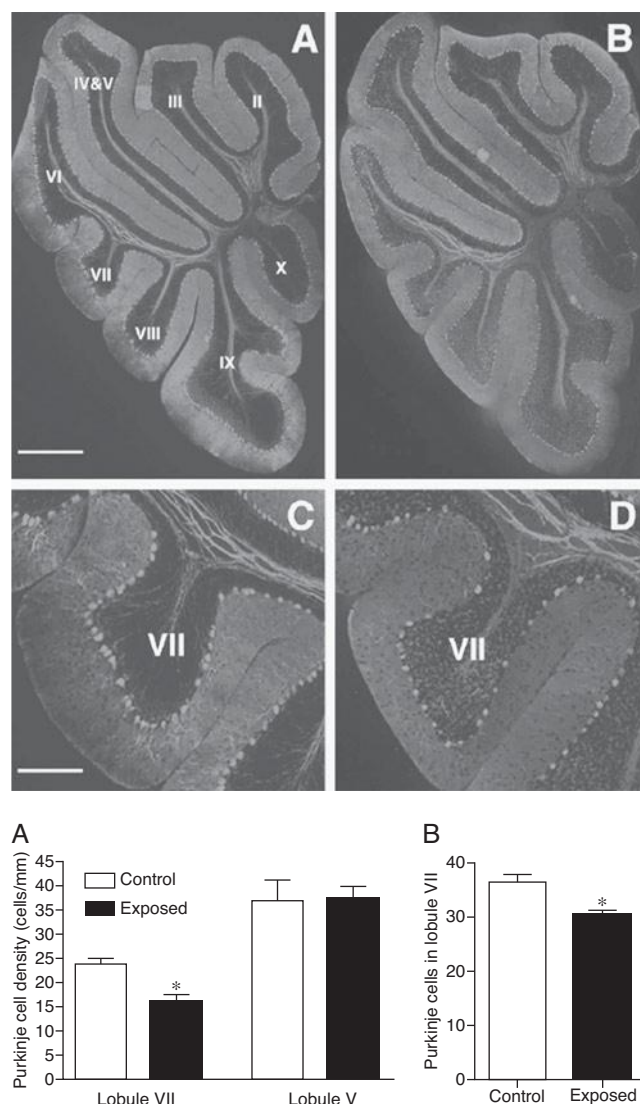
There are, however, conflicting reports as to whether viral mRNA or protein is present in fetal tissues (Aronsson et al., 2002; Shi et al., 2005). Nonetheless, the fact that stimulating the maternal immune system with poly(I:C) (mimicking viral infection) and LPS (mimicking bacterial infection) causes neuropathogical and behavioral defects in the offspring similar to those seen with maternal influenza infection supports the idea that MIA is the causative event, as no pathogen is required. Poly(I:C) is a synthetic, double-stranded RNA that generates an antiviral immune response in the absence of virus. Depending on the dosage, mode of injection (intraperitoneal or intravenous) and timing of maternal poly(I:C) administration, offspring display deficits in PPI, latent inhibition, open field exploration, working memory, social interaction and USVs, while reversal learning and amphetamine-induced


Figure 52–3. Maternal infection causes a spatially restricted Purkinje cell deficit. Adult offspring of mice given a respiratory infection with influenza virus at midgestation display a deficit in Purkinje cells in lobules VII but not in other lobules. Top: Calbindin staining of adult cerebella from offspring of control (A,C) and infected mothers (B,D) reveals a deficit in lobule VII of the latter. Panels C and D (bar = 200 μm) are higher magnification views of panels A and B (bar–800 μm). (See Color Plate Section for a color version of this figure.) Bottom: (A) Quantification of the linear density of Purkinje cells reveals a 33% deficit in lobule VII of the adult offspring of infected mothers, while no difference from controls is found in lobule V. (B) A similar, localized deficit is observed in postnatal day 11 offspring of infected mothers. Reprinted from Shi, L., Smith, S. E., Malkova, N., Tse, D., Su, Y., & Patterson, P. H. (2009). Activation of the maternal immune system alters cerebellar development in the offspring. *Brain, Behavior, and Immunity*, *23*, 116–123, with Permission.

locomotion are enhanced (Shi et al., 2003; Zuckerman et al., 2003, 2005; Lee et al., 2007; Meyer et al., 2007; Smith et al., 2007; Winter et al., 2009; Malkova & Patterson, 2010). A single poly(I:C) injection also causes histopathological changes similar to those seen in autism, including increased GABA$_A$

receptor, spatially-restricted reduction in PCs, and delayed myelination, and decreased cortical neurogenesis (Nyffeler et al., 2006; Shi et al., 2009; Makinodan et al, 2008; De Miranda et al., 2010). A cardinal pathology in schizophrenia, enlarged lateral ventricles, is also observed (Li et al., 2009; Piontkewitz, Assaf, & Weiner, 2009). In addition, there is evidence of physiological abnormalities in the hippocampus. In slices from adult offspring of poly(I:C)-treated mothers, oscillations in CA1 are less rhythmic than in controls, and CA1 pyramidal neurons display reduced frequency and increased amplitude of miniature excitatory postsynaptic currents. Differing results have been reported regarding a deficit in long term potentiation (Ito et al., 2010; Oh-Nishi et al., 2010). Interestingly, the specific component of the temporoammonic pathway that mediates object-related information displays significantly increased sensitivity to dopamine (Lowe et al., 2009; Ito et al., 2010). There are a few studies describing abnormal dopamine levels in autism (Previc, 2007), and a variety of changes in dopamine are found in the maternal poly(I:C) model (Zuckerman et al., 2003; Ozawa et al., 2006; Meyer et al., 2008a). However, whether dysregulation of the dopaminergic system is an important feature of autism is unknown. Dopamine pathology is very important in schizophrenia, where maternal infection is also a risk factor. Another finding consistent with both schizophrenia and autism is a disruption in long-range synchrony of neuronal firing. Adult MIA offspring display significant reduction in medial prefrontal cortex-hippocampal EEG coherence (Dickerson, Wolff & Bilkey, 2010).

Intraperitoneal injection—administration of material into the peritoneum (body cavity)

Intravenous injection—in mice, this is typically done through the lateral tail veins

Further supporting the role of MIA in altering fetal brain development is the use of maternal LPS injection to simulate bacterial infection. Although poly(I:C) and LPS act through different toll-like receptors, their effects on the behavior and brain pathology in offspring often overlap. For example, a single injection of LPS in a pregnant rat yields offspring with elevated anxiety, aberrant social behavior, reduced play behavior and USVs, reduced PPI, enhanced amphetamine-induced locomotion, and abnormal learning and memory (Borrell et al., 2002; Fortier et al., 2004; Golan et al., 2005; Hava et al., 2006; Basta-Kaim et al., 2010; Baharnoori et al., 2010; Hao et al., 2010; Kirsten et al., 2010), many of which parallel behaviors seen in autism. There is also evidence of hyperactivity in the hypothalamus-pituitary-adrenal axis in the LPS offspring, and some of the abnormal behaviors can be reversed by anti-psychotic drug treatment (Basta-Kaim et al., 2010), as is the case for the poly(I:C) offspring. Recall that maternal infection is a risk factor for schizophrenia as well as autism.

Histological findings include smaller, more densely packed neurons in the hippocampus, increased numbers of pyknotic cells in the cortex, fewer tyrosine hydroxylase-positive (TH+)

> **Toll-like receptors (TLRs)**—a class of transmembrane pattern recognition receptors that bind to structurally conserved molecules on microbes (pathogen-associated molecular patterns [PAMPs]); when activated by PAMP ligands, TLR signal transduction leads to the stimulation of innate immune responses

neurons in the substantia nigra, and increased TH+ cells in the nucleus accumbens (Golan et al., 2005; Ling et al., 2004; Borrell et al., 2002). Further studies indicate that changes in dendritic length, dendritic branching, spine structure, and spine density in the medial prefrontal cortex and hippocampus, suggesting dysregulated neuronal connections formed during embryogenesis (Baharnoori et al., 2008). Some of these effects, including increased cell density and limited dendritic arbors in the hippocampus, have been found in MRI and post mortem brain studies in autism (Amaral et al., 2008). Electrophysiological recordings reveal reduced synaptic input to CA1 of the hippocampus, heightened excitability of pyramidal neurons, enhanced postsynaptic glutamatergic response, and impaired NMDA-induced synaptic plasticity (Lowe et al., 2008; Lante et al., 2008). Interestingly, many of these effects are prevented by pretreatment of pregnant rats with N-acetyl-cysteine (Lante et al., 2008), which increases calcium influx when binding to glutamate receptors in combination with the transmitter. Brain imaging studies of the hippocampus and of particular neurotransmitter systems in autism have yielded inconsistent results, so no definite statement can be made about their exact roles in autism (Palmen et al., 2004).

> **Tyrosine hydroxylase**—an enzyme that catalyzes the conversion of L-tyrosine into dihydroxyphenylalanine (DOPA), a precursor for dopamine

> **N-acetyl-cysteine**—a glutathione precursor with antioxidant and anti-inflammatory properties; FDA-approved drug for treatment of respiratory conditions, renal impairment, interstitial lung disease and acetaminophen overdose

In addition to the behavioral deficits and neuropathology, the MIA models also share with autism dysregulation of immune status in the brain. Post mortem brain and cerebrospinal fluid samples from autistic individuals exhibit marked astrogliosis, microglial activation, dysregulation of immune-related genes, and high levels of pro-inflammatory cytokines and chemokines (Vargas et al., 2005; Garbett et al., 2008; Chez et al., 2007; Tetreault et al., 2009; Patterson, 2009). Although LPS itself does not cross the placental barrier, maternal LPS injections yield offspring with MHC II induction along with increased GFAP and microglial staining in various adult (Borrell 2002; Ling et al., 2004) and fetal (Paintlia et al., 2004) brain regions. While several cytokines are elevated in the placenta and amniotic fluid after MIA, mRNA transcripts for a number of cytokines are also elevated in the fetal brain following maternal LPS or poly(I:C) (Urakubo et al., 2001; Cai et al., 2000; Paintlia et al., 2004; Liverman et al., 2006; Golan et al., 2005; Meyer et al., 2008b; Elovitz et al., 2006; Hsiao &

Patterson, 2010). The importance of cytokines as soluble mediators of the effects of MIA on fetal brain development was demonstrated using cytokine knockout (KO) mice and mice injected with recombinant cytokines or cytokine-neutralizing antibodies. Interleukin (IL)-6 is necessary and sufficient for mediating the effects of MIA on the development of neurological, behavioral, and transcriptional changes in poly(I:C)-exposed offspring (Figure 52-2; Samuelsson et al., 2006; Smith et al., 2007). In a converse approach, overexpression of the anti-inflammatory cytokine IL-10 suppresses the effects of maternal poly(I:C) on the fetus (Meyer et al., 2008c). Perturbation of IL-10, IL-1, or TNFα can also significantly influence the outcome of MIA in the LPS MIA model (Girard et al., 2010; reviewed in Patterson, 2011).

> **MHC II**—major histocompatibility complex class II; cell surface protein heterodimers found on professional antigen-presenting cells; responsible for presenting extracellular peptides to helper CD4+ T cells to stimulate an immune response

> **GFAP**—glial fibrillary acidic protein; an intermediate filament protein that is used as a marker for astrocytes in the central nervous system

How cytokines induced by MIA alter the course of fetal brain development is largely unknown. The most obvious possibility is by direct action on the developing brain, as both cytokines and chemokines are key modulators of astrogliosis, neurogenesis, microglial activation, and synaptic pruning (Bauer et al., 2007; Deverman & Patterson, 2009), and some maternal cytokines have been reported to cross the placenta (Dahlgren et al., 2006; Zaretsky et al., 2004). A second possibility is that MIA alters the endocrine function and/or the immunological state of the placenta. In fact, poly(I:C) MIA increases maternally-derived IL-6 protein as well as IL-6 mRNA in the placenta. Such placentas exhibit increases in CD69+ decidual macrophages, granulocytes and uterine NK cells, indicating elevated early immune activation. Moreover, maternally-derived IL-6 mediates activation of the JAK/STAT3 pathway in the placenta, which parallels an IL-6-dependent disruption of the growth hormone-insulin-like growth factor axis (Hsiao & Patterson, 2010). Such endocrine changes could affect the development of the fetal brain and immune system, with permanent consequences. It is notable that a greater occurrence of placental trophoblast inclusions is observed in placental tissue from births of children who develop autism spectrum disorder compared to non-ASD controls (Anderson et al., 2007). Moreover, chorioamnionitis and other obstetric complications are significantly associated with socialization and communication deficits in autistic infants (Limperopoulos, 2008).

In this context, it is of interest that several studies have reported that the sera of some mothers of autistic children contain antibodies that bind fetal human, monkey, or rat brain antigens (Zimmerman et al., 2007; Braunschweig et al., 2008; Martin et al., 2008). Most relevant to this review is the

further finding that injection of such maternal sera into pregnant mice (Dalton et al., 2003) or purified maternal IgG into pregnant Rhesus monkeys (Martin et al., 2008) yields offspring with several behavioral abnormalities, including hyperactivity and stereotopies in the case of the monkeys. That something is different about the immune system of in the mothers of autistic offspring is further supported by the observation that these mothers are more likely to have a history of autoimmune disease or asthma (e.g., Altadottir et al., 2009). There is also evidence that the peripheral immune system of autistic subjects is abnormal (Pardo & Eberhart, 2007; Enstrom, Van de Water, & Ashwood, 2009). In that light it is interesting that, compared to controls, CD4+ T cells from the spleen and mesenteric lymph nodes of adult mouse MIA offspring display significantly elevated IL-6 and IL-17 responses to in vitro stimulation (Hsiao et al., 2010; Mandal et al., 2010). Furthermore, adult MIA offspring display reduced T cell responses to CNS-specific antigens, despite elevated proliferation of nonspecific T cells (Cardon et al., 2009).

Although it is commonly stated that autism can result from an environmental stimulus acting on a susceptible genetic background, there is little support for this hypothesis thus far. Thus, it is of interest that mice heterozygous for the tuberous sclerosis 2 (*TSC2*) gene display a social interaction deficit only when they are born to mothers treated with poly (I:C) (Ehninger et al., 2010). That is, this deficit is most severe when the MIA environmental risk factor is combined with a genetic defect that, in humans, also carries a very high risk for ASD. In addition, there is an excess of TSC-ASD individuals born during the peak influenza season, an association that is not seen for TSC individuals not displaying ASD symptoms (Ehninger et al., 2010).

Postnatal Vaccination

Although there is currently no convincing evidence that postnatal vaccination is a cause of autism, the occasional coincidence in the timing of routine childhood immunizations with the appearance of autistic symptoms continues to fuel public concern. The measles-mumps-rubella (MMR) vaccine is of particular interest because of the use of live, attenuated virus, but there are currently no rodent models for the effects of MMR on neural development. Moreover, many epidemiological studies have failed to substantiate a connection between MMR vaccination and autism (DeStefano, 2007).

There has been investigation of the effects of thimerosal-containing vaccines (TCVs) on neurodevelopment in rodents. Increased mercury burden from this sodium ethylmercurithiosalicylate preservative is of concern because of known neurotoxic properties of methylmercurials. One study reported that immunogenetic factors can render mice susceptible to thimerosal-induced neurotoxicity (Hornig et al., 2004). The autoimmune-prone SJL/J (H-2^s) strain developed neuropathology and abnormal behavior. However, a recent study failed to replicate the histological and behavioral results (Berman et al., 2008). This latter paper is consistent with several epidemiological studies failing to support a link between thimerosal and autism (Andrews et al., 2004; Schechter & Grether, 2008; Gerber & Offit, 2008 Price et al., 2010).

Terbutaline

The β2 adrenergic receptor is expressed early in fetal brain development, and its activation affects cell proliferation and differentiation. Terbutaline is a selective β2 adrenergic receptor agonist that is used to relax uterine smooth muscle to prevent premature labor and birth. A study of dizygotic twins found an increased rate of concordance for autism if the mother was given terbutaline for 2 weeks (Conners et al., 2005). Further implicating the β2 adrenergic receptor is the finding that certain functional variants of this gene are associated with increased risk for autism (Cheslack-Postava et al., 2007). In modeling this risk factor in rats, neonates are given subcutaneous injections of terbutaline daily, from postnatal days 2 through 5, a time meant to mimic the stage of human brain development at which the drug is given. A significant deficit in PCs was found, but no mention of any spatial restriction of this change was made. Histological changes were reported in the hippocampus and somatosensory cortex as well, including microglial activation in cortex and cerebellum (Rhodes et al., 2004; Zerrate et al., 2007). Also of interest in terms of autism is a finding of increased 5-HT turnover (Slotkin & Seidler, 2007). Behavioral analysis of this model is somewhat disappointing thus far, with female-specific hyperactivity and no change in PPI (Zerrate et al., 2007).

Genetic Manipulations

X-Linked and Autosomal Lesions

Fmr1 Knockout Mice

Fragile X Syndrome (FXS) is an X-linked condition that is the leading genetic cause of mental retardation (Hatton et al., 2006). It is caused by the loss of expression of FMRP, an mRNA-binding protein that is highly expressed in hippocampal and cortical synapses, where it regulates translation of its target mRNAs and thus plays a key role in protein synthesis-dependent functions (Bassell & Warren, 2008). It is estimated that 90% of FXS patients present some autistic-like behaviors, and that 15% to 33% meet the full diagnostic criteria of autism (Cohen et al., 1988; Bailey et al., 1998). Overall, FXS accounts for about 5% of the autistic population (Li et al., 1993). *Fmr1* KO mice display some anatomical features of FXS, such as macro-orchidism and abnormal dendritic development and morphology (The Dutch-Belgian Fragile X Consortium, 1994) and spines are altered in idiopathic autism (Zoghbi, 2003). These mice also display some core behavioral features relevant to autism, including impaired social interaction (McNaughton et al., 2008) and repetitive behaviors. Whether they display

learning and memory deficits is unclear (Dobkin et al., 2000; Frankland et al., 2004) and whether they show other autism-related symptoms such as anxiety and hyperactivity depends on the genetic background (Bernardet & Crusio, 2006). The observations that both cognitive performance and behaviors relevant to autistic traits are affected by genetic background is of interest given the genetic variability in humans and the phenotypic heterogeneity in FXS. Although overall resemblance to autism is partial, the presence of two core features of autism indicates that molecular investigation of *Fmr1* KO mice may further our understanding of the genetic etiology of FXS and autistic traits.

The signaling pathways for metabotropic glutamate receptor 5 (mGluR-5) and PAK, a kinase involved in actin remodeling and regulation of synapse structure, represent two plausible therapeutic targets for FXS and autism. A 50% reduction of mGluR-5 expression in *Fmr1* KO mice normalizes dendrite morphology, seizure susceptibility, and inhibitory avoidance extinction (Dolen et al., 2007) (Table 52-2). This supports the mGluR theory, which posits that upregulation of group I mGluR leads to exaggerated protein synthesis-dependent functions, such as long-term depression, and therefore underlies the neuropathology and behavioral traits associated with FXS (Bear, Huber, & Warren, 2004). Interestingly, postnatal inhibition of PAK in the forebrain of *Fmr1* KO mice normalizes dendrite morphology and restores locomotion, repetitive behavior, and anxiety (Hayashi et al., 2007). In addition, in a *Drosophila* model, treatment with

Table 52–2.

Amelioration (orange) or rescue (yellow) of some features of the autism-like phenotype in double mouse mutants phenotypic improvements or reversals indicate functional (direct or indirect) interactions between the targeted genes, whereas persistence of one phenotype (blue) suggests that additional genes contribute to the full phenotype. Investigation of genetic interactions provides insight into the molecular pathways underlying particular facets of autism, and may suggest novel therapeutic targets

Mouse Mutant Relevant to Autism	Rescuer Mouse Mutant	Phenotype of the Double Mutant		
		Behavior	Neuropathology	Additional Parameters
FMR1 knockout (*FMR1* KO) mice	**Dominant negative PAK transgenic mice** 40% inhibition of the catalytic activity of PAK (Hayashi et al., 2007)	Hyperactivity, stereotypy, and hypoanxiety in open field are rescued	Spine density partially restored	
		Memory deficits restored	Spine length comparable to WT Reduced cortical LTP is rescued	
	Grm5 mutant mice 50% reduction in mGluR5 expression (Dolen et al., 2007)	Exaggerated inhibitory avoidance extinction rescued	Spine density comparable to WT	Ocular dominance plasticity rescued
			Increased protein synthesis in the hippocampus is prevented	Growth increase at P30 rescued
			Audiogenic seizures attenuated	Macroorchidism not rescued
Germline *Mecp2* mutant	**Conditional BDNF-over-expressing transgenic mice** Increase in BDNF expression (Chang et al., 2006)	Improvement in the running wheel assay (locomotor function)	Neuronal activity indistinguishable from WT Modest increase in brain weight	Extension of the lifespan
Angelman syndrome mutant	**CaMKII-T305V/T306A mutant mice** Mutations in CaMKII that prevent its auto-phosphorylation (Van Woerden et al., 2007)	Rotarod performance indistinguishable from WT	Absence of audiogenic seizures	Increase in body weight rescued
			75% reduction of propensity for seizures	
		Context-dependant memory restored (hippocampal learning deficit rescued)	Long-term potentiation rescued	
		Improved water maze performance		

mGluR antagonists or protein synthesis inhibitors in adulthood can partially restore deficits in courtship behavior and improve memory (McBride et al., 2005; Bolduc et al., 2008). Two small, open label human trials based on these findings yielded promising results (Berry-Kravis et al., 2008, 2009; Paribello et al., 2010), supporting the use of FXS animal models for preclinical purposes.

Methyl-CpG-Binding Protein-Null, Mutant, and Overexpressing Mice

Rett syndrome is another X-linked disorder that causes mental retardation, primarily affecting females. It is estimated that 95% of Rett syndrome cases are caused by mutations in the methyl-CpG-binding protein (*MECP2*) gene (Chahrour & Zoghbi, 2007), leading to deficiency in this global transcriptional regulator, whose targets include BDNF. During the regression phase of the disease, affected girls display autistic-like behaviors, such as stereotypies as well as reduced social contact and communication. Association between *MECP2* variants and autism have also been reported (Loat et al., 2008). Both *Mecp2*-null mice, and mice in which *Mecp2* is deleted in mature neurons only, exhibit a neurological phenotype consistent with Rett, including hypoactivity, ataxic gait, tremor, limb-clasping, and reduced brain size with smaller neuronal cell bodies in cortex and hippocampus (Chen et al., 2001; Guy et al., 2001). BDNF levels are also reduced in comparison to wild-type (WT) animals, and deletion or over-expression of *Bdnf* in the *Mecp2* mutant brain either accelerates or delays the onset of the symptoms, suggesting a functional interaction between MECP2 and BDNF *in vivo* (Chang et al., 2006). Male mice that carry the truncating mutation, *Mecp2*[308/y], a common variant observed in Rett patients, display a milder Rett-like phenotype (Shahbazian et al., 2002). Increased synaptic transmission and impaired LTP induction is observed in the mutant mice, whereas spine morphology, BDNF levels, and synaptic biochemical composition are not altered. Behavioral deficits in these mice include enhanced anxiety in the open field, reduced nest-building, and aberrant social interactions. Genetic background modifies performance in the Morris water maze, latent inhibition, and long-term memory tasks (Moretti et al., 2005; Moretti et al., 2006). Mice over-expressing *Mecp2* also develop a progressive neurological disorder with, surprisingly, an enhancement in synaptic plasticity, motor and contextual learning skills between age 10 and 20 weeks, and, at an older age, hypoactivity, seizures, and abnormal forelimb-clasping, all of which are reminiscent of human Rett syndrome (Collins et al., 2004). These results with the various *Mecp2* mouse models indicate that this gene must be tightly regulated under normal conditions. These mice should aid in the search for genes that are regulated by MECP2 (Chahrour et al., 2008) and possibly the various behavioral abnormalities. These mice are also providing reason for optimism regarding the testing of potential treatments for Rett syndrome. In a conditional KO model, it was shown that restoring *Mecp2* expression in immature or even in mature

mice results in reversal of the disease phenotype, as measured by behavioral and electrophysiological tests (Guy et al., 2007). Thus, despite the fact that MECP2 function was disrupted during fetal and postnatal development, the disease symptoms can be reversed. In one test of a potential treatment, administration of an active peptide fragment of insulin-like growth factor 1 to *Mecp2* mutant mice extends life span, improves locomotor, heart and breathing functions, and stabilizes a measure of cortical plasticity (Tropea et al., 2009). Such results provide proof-of-principle that these mice can be used to screen candidate treatments of autism-related disorders.

Angelman and Prader-Willi Syndromes

Loss of function of maternal or paternal genes in the imprinted chromosomal region 15q11-q13 causes Angelman Syndrome and Prader-Willi Syndrome (PWS), respectively. Although clinically distinct, both syndromes are behavioral disorders presenting with some autistic traits as well as other diverse symptoms (Veltman et al., 2005). Linkage studies have also associated the 15q11-q13 locus with autism, and maternal duplications of this region account for rare cases of autism (Wassink & Piven, 2000). 70% of Angelman Syndrome patients carry large maternal deletions of 15q11-q13, and display a severe phenotype; yet, mutations in a single gene, *UBE3A*, are sufficient to cause major clinical manifestations of the syndrome. By contrast, PWS is clearly a multigenic syndrome involving 10 imprinted genes, whose individual significance in the etiology of the disorder is not yet fully clarified (Nicholls & Knepper, 2001). *UBE3A* encodes E6-AP, an enzyme that has ubiquitin protein ligase and transcriptional coactivator activities (Nawaz et al., 1999). Two different KO mouse strains with maternally inherited mutations in *Ube3a* display a phenotype consistent with human Angelman Syndrome: motor dysfunction, propensity for seizures, defective learning and memory, and abnormal electroencephalograms (Jiang et al., 1998; Miura et al., 2002). These mice also display deficits in hippocampal LTP and decreased hippocampal CaMKII activity, which may contribute to learning problems in Angelman Syndrome (Weeber et al., 2003). When crossed to mice carrying a mutation in CaMKII that prevents its autophosphorylation, the double mutants no longer exhibit the Angelman Syndrome phenotype (van Woerden et al., 2007). This suggests that increased inhibitory autophosphorylation may provide a molecular basis for deficits in LTP, motor coordination, and seizure propensity. Studies of another Angelman Syndrome mouse model, the *Ube3a*[YFP] knock-in (KI) reporter mouse, reveal that E6-AP is found in synapses and the nucleus (Dindot et al., 2008). These mice display decreased spine density, an interesting finding because altered spine morphology is observed in Rett and FXS patients, as well as in *Fmr1* KO mice (Kaufmann & Moser, 2000). Thus, the neuropathology in this KI suggests that E6-AP could play a role in spine development and synaptic plasticity. It is relevant that loss of UBE3A activity or its overexpression in *Drosophila* reduces dendritic branching and affects dendrite morphogenesis

(Lu et al., 2009). It remains to be determined whether similar neuropathology is present in the KO mouse lines and Angelman Syndrome patients and whether it contributes to cognitive dysfunction and behavioral abnormalities.

More recently, mutant mice carrying a large maternal deletion from *Ube3a* to *Gabrb3* were generated (Jiang et al., 2010). Similar to the *Ube3a* KO mice, these mutants display increased spontaneous seizure activity, abnormal electro-encephalograms, as well as impairments in learning and memory. Additional behavioral tests reveal that they display anxiety traits in the light-dark box, but no difference in pain sensitivity or in PPI. Mutant newborn pups emit more USVs than control mice. This latter observation is of interest, since Angelman syndrome patients show a happy disposition that is currently interpreted as increased signaling behavior. Relevance to autism is also possible, as increased USVs have been reported in *Mecp2* mutant and BTBR pups. However, one would expect to see fewer USVs in an autism model, given the deficits in communication in ASD. Comparative studies of the various mouse models of Angelman syndrome should yield new insights into the contribution of additional, maternally imprinted genes of this region, or biallelically expressed genes such as *Gabrb3* or *Atp10a*. Mouse models for PWS with deletion of the corresponding murine imprinted locus have been generated, but early postnatal lethality has precluded behavioral characterization (Yang et al., 1998). Among the mice engineered to carry a mutation in one candidate gene of the imprinted region, *Necdin* (*Ndn*), paternally-deficient mice display some behavioral traits reminiscent of PWS, such as skin-scraping, improved performance in Morris water maze, and reduced numbers of hypothalamic oxytocin- and LHRH-producing neurons (Muscatelli et al., 2000). Serotonergic alterations are also observed in these mice and are linked to respiratory deficiency (Zanella et al., 2008). All these findings might be relevant to autism, because repetitive self-injury, enhanced visual-spatial skills, oxytocin abnormalities, and alterations in serotonin levels have been described in autism. As with Angelman syndrome mice, *Necdin* mutant mice require further behavioral characterization.

Pten Mutant Mice

Phosphatase and tensin homolog on chromosome 10, PTEN, is a tumor suppressor that negatively regulates phosphatidylinositol 3-kinase PI3K/Akt signaling, a pathway that promotes cell growth, proliferation, and survival. Germline mutations in *PTEN* cause Cowden and Bannayan–Riley–Ruvalcaba syndromes (CS and BRRS, respectively). CS and BRRS are characterized by benign and malignant tumors in multiple organs as well as brain disorders such as macrocephaly, mental retardation, and seizure. Association between these syndromes—particularly CS—and autism has occasionally been reported (Zori et al., 1998; Goffin et al., 2001; Pilarski & Eng, 2004). Moreover, genetic screening identified *PTEN* mutations in a subset of autistic individuals who display macrocephaly (Butler et al., 2005; Buxbaum et al., 2007), an anatomical

anomaly also present in 15% to 20% of autistic patients (Lainhart et al., 2006). Of particular interest is the mouse strain Nse-cre-*Pten*^loxP/loxP, in which a *Pten* deletion is restricted to differentiated neurons in the cerebral cortex and hippocampus (Kwon et al., 2006). These mutants develop forebrain macrocephaly resulting from neuronal hypertrophy in the cortex and hippocampus. In addition, analysis of the hippocampus shows increased dendritic and axonal growth, ectopic positioning of axons and dendrites of granule neurons and elevated synapse number.

Abnormalities in *Pten*-deleted neurons correlate with enhanced levels of phosphorylated Akt and its downstream effectors, mTOR and S6. Components of the mTOR/S6K/S6 pathway are present in dendrites, where they are involved in the regulation of protein synthesis. Protein synthesis in dendrites is believed to modulate synapse morphology and function and thus is involved in synapse plasticity. These mice display behaviors reminiscent of autism, such as deficits in social interaction, exaggerated responses to sensory stimuli, decreased PPI (but only at one prepulse stimulus intensity), anxiety-like behavior in the open field, and learning deficits in the Morris water maze. However, no impairments in fear conditioning, elevated plus maze, or motor activity are observed. Increased spine density and social deficits are also observed in the *Fmr1* KO. In this context, it is relevant that ribosomal S6 kinase (S6K1), a component of the mTOR/PI3K signaling cascade, was recently identified as a major *Fmrp* kinase (Narayanan et al., 2008). Because the phosphorylation status of FMRP may govern translational regulation of its target mRNAs, upstream modulators of the mTOR/PI3K pathway such as PTEN may modulate synaptic function by affecting FMRP phosphorylation status (Bassell & Warren, 2008). Thus, FMRP phosphorylation may be affected in CS, BRRS, and also tuberous sclerosis (TSC), another human disorder associated with autism, caused by mutations in the *TSC1/2* complex. Indeed, hamartin and tuberin, the gene products of *TSC1* and *TSC2*, can inhibit mTOR (Yates, 2006). Moreover, mTOR signaling is dysregulated in the *Fmrp*-deficient mouse (Sharma et al., 2010). Taken together, these data support the hypothesis that synaptic alteration may underlie autistic-like behaviors (Zoghbi, 2003) and highlight the mTOR pathway as a key regulator of synaptic function. In addition, as in the case of the *Mecp2* mice, the *Tsc2*+/- mouse model responds to treatment in adulthood. Brief administration of the mTOR inhibitor rapamycin rescues synaptic plasticity and the behavioral deficits in the TSC model (Ehninger et al., 2009). Moreover, early phase clinical trials suggest that cognitive features of TSC may be reversible in adult humans (De Vries, 2010).

Autism Candidate Genes

Neuroligins 3 and 4

Recent findings in autism genetics have revealed several, rare causal variants that are associated with ASD (Betancur,

Sakurai, & Buxbaum, 2009). Neuroligins (NLGNs) constitute a family of transmembrane postsynaptic proteins, which, together with their presynaptic and intracellular binding partners, the β-neurexins and SHANK3, respectively, play a key role in synaptic maturation and transmission. *NLGN3* and *-4* were identified in two X-chromosome loci previously associated with ASDs (Jamain et al., 2003). Thus far, one missense mutation in *NLGN3* and four missense and two nonsense mutations in *NLGN4* have been identified in a very small number of individuals with ASDs (Jamain et al., 2003; Laumonnier et al., 2004; Yan et al., 2005), supporting the hypothesis that synaptic dysfunction is important in ASDs. Mutations in neurexin and *SHANK3* are also found in ASD probands, but whether they are involved in ASD etiology is controversial (Sudhof, 2008). There is currently no KO for *Shank3*, but a KO for *Shank1*, the closest relative to *Shank3*, was recently created. These mutants display morphological alterations in hippocampal neurons that are associated with a reduction in basal synaptic transmission, but no change in several other electrophysiological parameters (LTP, LTD, and L-LTP). Behaviorally, *Shank1* KO mice exhibit increased anxiety, impaired contextual fear memory, and, surprisingly, enhanced performance in a spatial learning task but impaired memory retention of that task (Hung et al., 2008). Additional behavioral tasks relevant to the three core symptoms have yet to be reported.

Results with *Nlgn3* and *-4* mutant mice confirm the functional significance of NLGNs in synaptic function. A *Nlgn3* KI mouse was engineered with a point mutation in the endogenous mouse gene that is identical to the relevant human NLGN-3 gene (Tabuchi et al., 2007). These mice display increased inhibitory synaptic transmission without a change in excitatory transmission, a phenotype not observed in *Nlgn3* KO mice, emphasizing the disparity between missense and nonsense mutations. It will be of interest to characterize the behavior of the KO mice to check for differential phenotypes. The augmentation in inhibitory synaptic transmission in the *Nlgn3* KI mice is accompanied by a deficit in social interaction and, as observed in the *Shank1* KO, enhanced spatial learning ability. These results are surprising because *(1)* a loss, rather than a gain of inhibition in different neural systems was hypothesized to contribute to ASDs (Hussman, 2001; Rubenstein & Merzenich, 2003), and *(2)* the individuals identified with mutations in *NLGN3* and *-4* do not exhibit potentiated learning skills. The latter observations are consistent with a report of minimal aberrant behaviors in the *Nlgn-3* KI mice (Chadman et al., 2008). Nevertheless, the results suggesting that a disequilibrium between excitatory and inhibitory synapses can affect social behavior (Sudhof, 2008) and that decreasing inhibitory transmission may be an effective therapy in some autism patients are worth pursuing. In fact, administration of the NMDA receptor partial co-agonist D-cycloserine can rescue the excessive grooming behavior in adult *Nlgn1* KO mice (Blundell et al., 2010).

Unlike humans, the rodent *Nlgn4* gene localizes to a still unknown autosome. Although there is only a 57% homology between the two species, the protein is found in synapses in both. Although *Nlgn4* KO mice display abnormalities in two of the three core autistic symptoms, reciprocal social interaction, and impaired communication, as approximated by measuring USVs, they do not display repetitive behavior or impairments in some of the other autism symptoms such as sensory ability, sensorimotor gating, locomotion, exploratory activity, anxiety, or learning and memory (Jamain et al., 2008). These observations are consistent with those seen in patients with the *NLGN4* mutation, who do not show these comorbid features. MRI analysis of the brains of *Nlgn4* KO mice show a slight reduction in size of the total brain, cerebellum, and brain stem, and some of these neuroanatomical changes are reminiscent of autism.

To summarize, several *Nlgn* models exhibit strong construct validity with the rare human mutations associated with human ASDs. Moreover, the face validity of the *Nlgn4* KO mice is fairly good at the behavioral level, but much remains to be done on its neuropathology.

CNTNAP2

One of the most validated susceptibility genes is contactin associated protein-like2 (*CNTNAP2*). This gene encodes a member of the neuronal neurexin superfamily that is involved in neuron-glial interactions and is very likely to be important in brain development (Abrahams et al., 2008b). An intriguing feature of CNTNAP2 is its enriched expression in circuits in the human cortex that are important for language development. Moreover, its expression is enriched in song nuclei important for vocal learning in the zebra finch, and feature is male-specific, as is the song behavior (Panaitof et al., 2010). In addition, (*CNTNAP2*) polymorphisms are associated with language disorders, and the expression of this gene can be regulated by FOXP2, a transcription factor that, when mutated, can cause language and speech disorders (Vernes et al., 2008). In light of these associations, it is important that recent study of the *Cntnap2* KO mouse reveals a deficit in USVs. Moreover, these mice display the other core features of autism, repetitive behavior and a social interaction deficit. They also exhibit several other features of ASD: seizures, mild cortical laminar disorganization and hyperactivity (D. H. Geschwind, personal communication).

EN2

Engrailed homeobox 1 (*EN1*) and 2 encode transcription factors expressed during embryonic and postnatal stages that regulate the development of the cerebellum. *EN2* localizes in proximity to an autism susceptibility locus on chromosome 7 (Liu et al., 2001; Alarcon et al., 2002), and genetic variations in *EN2* have also been reported to associate with ASDs (Petit et al., 1995; Gharani et al., 2004; Benayed et al., 2005; Wang et al., 2008; Yang et al., 2008), although one report could not replicate such association (Zhong et al., 2003). Although mice

homozygous for a mutation in *En-1* lack a cerebellum and die shortly after birth (Wurst, Auerbach, & Joyner, 1994), *En2* KO mice are viable and display some cerebellar pathologies resembling those reported in the brains of some autistic individuals, such as a decreased PC number, hypoplasia, and abnormal foliation (Kuemerle et al., 1997; Amaral, Schumann, & Nordahl, 2008). The juvenile KO mice display reduced social and play behaviors, and abnormal social behavior and repetitive self-grooming as adults (Cheh et al., 2006). In addition, although *En2* KO mice display normal locomotor activity in the open field, motor deficits are observed in specific tasks such as mid-air righting, hanging-wire grip strength, and rotorod. Learning and memory impairments are also evident in the water maze and modified open field with objects. At the neurochemical level, mutant mice exhibit increased cerebellar serotonin compared to controls but no alteration in dopamine levels in hippocampus, striatum, and frontal cortex or cerebellum. Thus, *En2* KO mice display face validity for autism, except for the motor deficits, which can interfere with some behavioral tests. It will be of interest to examine USVs in this model.

Serotonin

Several lines of evidence indicate that changes in serotonin signaling may contribute to autism pathogenesis. Serotonin levels in platelets are elevated in autistic patients (Cook & Leventhal, 1996), and numerous polymorphisms in genes implicated in 5-HT signaling or metabolism have been reported in autism, including the serotonin-transporter gene *SLC6A4* (*SERT*), monoamine oxidase A (*MAOA*), tryptophan 2,3 dioxygenase gene, and two serotonin receptors, 5-HT2A (*HTR2A*) and 5-HT7 (*HTR7*). Pharmacological modulation of the serotonin system using the 5-HT receptor antagonist risperidone improves ritualistic behavior and irritability of autistic children and, similarly, selective 5-HT reuptake inhibitors ameliorate repetitive thoughts and behaviors as well as mood disturbances. Conversely, depletion of tryptophan, a serotonin precursor, aggravates autistic symptoms (Hollander et al., 2005). Abnormalities in brain serotonin synthesis at different ages, as well as cortical asymmetries in serotonin synthesis, have been reported in children with autism (Chugani et al., 1997; Chugani et al., 1999). These alterations could be linked to abnormalities in cortical minicolumn organization in autism (Casanova & Tillquist, 2008). Serotonin signaling modulates various aspects of pre- and postnatal brain development (Gaspar, Cases, & Maroteaux, 2003), and some mouse lines with disruption in the 5-HT system show neuropathology consistent with those observed in autism. Behavioral changes observed in these mutants relate to mood, aggression, anxiety, depression, seizure, and learning and memory, all of which are relevant to autism.

A mouse line in which serotonin signaling is impaired is the *Dhcr7* mutant. DHCR7 (7-dehydrocholesterol reductase) is an enzyme required for the biosynthesis of cholesterol, and mice lacking functional *Dhcr7* display an increase in the area

and intensity of serotonin immunoreactivity in the embryonic hindbrain (Waage-Baudet et al., 2003). Unfortunately, *Dhcr7* KO mice die shortly after birth, precluding behavioral studies. In humans, *DHCR7* deficiency causes the Smith–Lemli–Opitz syndrome (SLOS), a disease characterized by dysmorphic facial features, mental retardation, and limb defects (Yu & Patel, 2005). Approximately 50% of patients with SLOS are also diagnosed with autism (Tierney et al., 2001). Levels of cholesterol are decreased in some idiopathic autistic children (Tierney et al., 2006), and cholesterol dietary supplementation improves autistic-like behavior of patients with SLOS (Aneja & Tierney, 2008). Presently, the mechanisms by which cholesterol deficiency affects serotonin pathways are not fully elucidated, but it is known that cholesterol can modulate the functional activity of MAO (Caramona et al., 1996) and SERT (Scanlon, Williams, & Schloss, 2001). Investigation of *Dhcr7* heterozygous mice or development of conditional mutants could further the understanding of the role of cholesterol in autism.

Bdnf-deficient mice also display alterations in the serotonin system. Signaling mediated by BDNF and its receptor tyrosine kinase (TrkB) is crucial for serotonergic neuronal development, as well as a wide variety of other neuronal functions. Variants in the *BDNF* gene have been associated with autism (Nishimura et al., 2007), and post mortem analysis of brains from autistic adults show enhanced levels of BDNF (Perry et al., 2001), whereas blood and serum levels in autism are controversial (cf. Croen et al., 2008). Various *Bdnf* or *TrkB* mutant mouse lines are available, including heterozygous null mice (homozygous KOs are not viable), conditional, and inducible *Bdnf* KO mice. Presence and severity of behavioral alterations in these mice depends on the stage at which BDNF is depleted, the brain regions targeted for BDNF deficiency, and the gender of the mutants (cf. Monteggia et al., 2004). Autistic-like behavioral impairments commonly reported are heightened aggression, hyperactivity, depression-like traits, and, in some instances, altered locomotor activity. Hyperphagia is reported in some *Bdnf* mutant lines, a finding inconsistent with autism *per se* but also observed in PWS. Despite behavioral deficits, surprisingly, dendritic morphology and GAD67 are not altered in brains from fetal and postnatal KOs (Hashimoto et al., 2005; Hill et al., 2005). In contrast, double *Bdnf +/-* x *Sert -/-* mutants display exacerbated anxiety in the elevated plus maze, greater elevation in plasma ACTH after stressful stimulus, and reduction in the size of dendrites of hippocampal and hypothalamic neurons in comparison to WT, *Sert+/+* x *Bdnf+/-* and *Sert-/-* x *Bdnf +/+* mice (Ren-Patterson et al., 2005). Because autism is often considered to be a multigenic disorder, investigation of gene/gene interaction is a logical approach.

Urokinase Plasminogen Activator Receptor Knockout Mice

Variations in the *MET* gene encoding a receptor tyrosine kinase are associated with autism (Campbell et al., 2006). Moreover, post mortem analysis of cortical tissue from

autistic individuals reveals decreased levels of MET protein in comparison to matched controls (Campbell et al., 2007). Disruption in signaling mediated by MET and its ligand, hepatocyte growth factor/scatter factor (HGF/SF), may be particularly relevant to the etiology of the disorder because, in addition to playing a key role in the CNS during development and adulthood, it is also involved in gastrointestinal repair and regulation of the immune system, two other systems that are altered in autism (Vargas et al., 2005). The PI3K/Akt pathway is one of the prominent signaling cascades activated by MET, which thereby antagonizes PTEN function. In the CNS, HGF/SF-MET signaling promotes the migration of cortical interneurons during development (Powell, Mars, & Levitt, 2001), contributes to cerebellar development and function (Leraci, Forni, & Ponzetto, 2002), stimulates dendritic growth in cortical neurons (Gutierrez et al., 2004), and induces protein clustering at excitatory synapses (Tyndall & Walikonis, 2006). Although genetic deletion of *Met* causes embryonic lethality, the KO of urokinase plasminogen activator receptor (*uPAR*), which exhibits reduced uPA activity (the protease required for the activation of HGF), is viable and displays a diminution in HGF levels and, as observed in autism, in MET levels. The *uPAR* KO mice display increased anxiety and are prone to seizures (Powell et al., 2003), features that are relevant to autism (Tuchman & Rapin, 2002). Whether these mice display deficits in any core symptoms of the disorder has not been reported. Gastrointestinal and immune pathology also needs to be assessed in these mutants.

Disrupted in Schizophrenia-1

A balanced translocation between chromosome 1 and 11 t(1;11) (q42.2;q14.1) cosegregates with schizophrenia and related disorders in a large Scottish family (St Clair et al., 1990; Blackwood et al., 2001). Disrupted in Schizophrenia-1 (*DISC1*) is altered by this translocation (Muir et al., 1995; Millar et al., 2000; Millar et al., 2001), and there is an association between variations within the *DISC* locus and autism and Asperger syndrome (Kilpinen et al., 2008). DISC1 is a scaffold protein, which, through interactions with various proteins (e.g., PDE4B, LIS1, NDEL1, NDE1, CIT, MAP1A), regulates cAMP signaling, cortical neuron migration, neurite outgrowth, glutamatergic neurotransmission, and synaptogenesis (Muir, Pickard, & Blackwood, 2008). There are a number of *Disc1* mouse variants currently available: mice carrying a truncated version of the endogenous *Disc1* ortholog, transgenic lines with inducible expression of mutant human DISC1 (hDISC1), and lines carrying N-ethyl-N-nitrosourea-induced mutations in *Disc1* (Chubb et al., 2008). Hippocampal neurons in mice with mutations of endogenous *Disc1* display dendritic misorientation and reduced number of spines, as observed in the *Fmr1* KO mice. These mice display a working memory deficit but do not show deficits in PPI or latent inhibition (Koike et al., 2006; Kvajo et al., 2008). Transgenic mice expressing hDISC1 in forebrain regions show a mild enlargement of the

lateral ventricles in comparison to WT animals, and neurite outgrowth is decreased in primary cortical neurons from these mutants. These neuropathologies are associated with altered social interaction and enhanced spontaneous locomotor activity in male hDISC1 mice and with mild impairment in spatial memory in females (Pletnikov et al., 2008). Tests assessing repetitive behavior and ultrasonic vocalizations remain to be reported. Further study of neuropathology in the various strains will also be important.

Oxytocin and Vasopressin

Neuropeptides and their associated receptors play a central role in the regulation of complex social behaviors. Several lines of evidence suggest that functional alterations in these systems may contribute not only to social deficits in autism but also to repetitive behaviors. *(1)* A reduction in oxytocin (OXT) plasma levels, associated with an elevation in the prohormone form, is observed in autistic children (Modahl et al., 1998; Green et al., 2001). Mixed results have been reported for OXT plasma levels in high-functioning adult autistic patients (Jansen et al., 2006; Andari et al., 2010). *(2)* Intranasal infusion of OXT reduces stereotyped behavior and improves eye contact, social memory and use of social information in high functioning autistic patients (Hollander et al., 2003, 2007; Guastella et al., 2009; Andari et al., 2010). *(3)* Genetic variations in OXT receptor and vasopressin receptor V1aR can be associated with autism (Donaldson & Young, 2008; Israel et al., 2008; Gregory et al., 2009). *(4)* Oxytocin receptor mRNA is decreased in post-mortem autism temporal cortex (Gregeory et al., 2009).

Current knowledge derived from studies in *Oxt* and *Oxt* receptor (*Oxtr*) KO mice underscore the subtle role of this system in aggression and anxiety. Thus, *Oxt* KO adult male progeny from homozygous crosses display high levels of aggression, whereas levels of aggression in *Oxt* KO adult male progeny from heterozygous crosses are either less pronounced or similar to WT mice, suggesting that absence of *OXT* during prenatal stages modulates the development of aggression in adulthood (Ferguson et al., 2000; Winslow et al., 2000; Takayanagi et al., 2005). *Oxt* KO female mice also display exaggerated aggression under controlled stress conditions designed to mimic the natural environment, indicating a possible interaction between the postnatal environment and the *OXT* system (Ragnauth et al., 2005). Similarly, *Oxtr* KO adult males display elevated aggressive behavior, as well as deficits in social discrimination (Takayanagi et al., 2005). *Oxt* KO adult mice nevertheless display reduced anxiety in the plus maze and acoustic startle reflex, a finding inconsistent with autism. In addition, as infants, both *Oxt* and *Oxtr* KO males emit fewer USVs in the isolation test than WT animals, which is also suggestive of decreased anxiety during maternal separation, but is also consistent with the lack of communication in ASD. The *Oxt* KO mice fail to recognize familiar conspecifics upon repeated social encounters, although olfactory and nonsocial memory are intact (Winslow & Insel, 2002). This has been interpreted as an autism-like social deficit, although

social amnesia has not been described in autism. Comprehensive neuropathology remains to be reported in these strains. Given the implications for ASD in the human findings, further study of *Oxt* mutant mice is warranted, although striking species differences are apparent for *OXT* and vasopressin, and their receptors (Insel, 2010).

Male *V1aR* KO mice exhibit deficits in olfactory social recognition and social interaction (Bielsky et al., 2004; Egashira et al., 2007). Similarly to *Oxt* and *Oxtr* KO mice, *V1aR* KO mice show reduced anxiety-like behavior in the elevated plus maze and the open field and the light/dark box, although high levels of anxiety are observed in the WT animals in comparison to other reports. No deficits in learning and memory in the Morris water maze or in PPI are detected, indicating that the face validity of this model is partial. *V1bR* KO adult females emit fewer USVs in a resident-intruder test. Although the number of USVs emitted by infant mutants is not affected during the conventional pup separation test, mutant pups fail to display maternal potentiation of USVs, which could suggest either a defect in a cognitive component or reduced anxiety (Scattoni et al., 2008). Although reduced anxiety is inconsistent with autism, V1bR antagonists could be tested to lower anxiety.

BTBR Mice

The BTBR mouse strain exhibits low levels of sociability at juvenile and adult ages, as well as abnormal social learning in the transmission of food preference test. Moreover, BTBR mice show a high level of spontaneous repetitive grooming, poor shift performance in a hole-board task, and a deficit in the water maze reversal task, which can be interpreted as the resistance to change in routine that is observed in autism (Bolivar, Walters, & Phoenix, 2007; Moy et al., 2007; Yang, Zhodzishsky, & Crawley, 2007; McFarlane et al., 2008; Moy et al., 2008). Finally, BTBR pups separated from their mother emit more and longer USVs in comparison to C57 pups (Scattoni et al., 2008). Their repertoire of vocalizations is also narrower in comparison to pups from standard mouse strains. The latter observation is significant, as human infants later diagnosed with autism make unusual vocalizations (Johnson, 2008). However, one might expect to see lower rates of USVs in pups if modeling the ASD communication deficit. Such a deficit is reported in adult BTBR mice (Wohr et al., 2010). Detailed study of the fine structure of USVs, as well as their behavioral functions in adult mice, is an important area for future studies of animal models of psychiatric disease.

A recent study indicates that BTBR mice display an exaggerated response to stress that is associated with high blood levels of corticosterone in comparison to C57 mice (Benno et al., 2009). Thus, it is not clear whether enhanced stress causes or aggravates the behavioral phenotype of these mice. Key anatomical features of BTBR mice are the absence of the corpus callosum and a reduced hippocampal commissure. These deficits correlate with impaired contextual fear memory,

which could arise from an increased susceptibility to de-potentiation. Otherwise, electrophysiological properties of hippocampal slices from BTBR (LTP, paired pulse facilitation, and basal synaptic transmission) are similar to those of C57 (MacPherson et al., 2008). Thus, several BTBR behaviors are consistent with autism, and the most striking anatomical feature in this strain is consistent with many, but not all, studies of the corpus callosum in autism (Amaral, Schumann, & Nordahl, 2008).

A difficulty with this line is that comparisons are necessarily made to other, unrelated mouse lines, and it is not clear to which line(s) BTBR should be compared. For instance, similar to BTBR mice, but unlike C57 mice, BALB/c mice display low social behavior, reduced USVs and reduced empathy-like behavior (Silverman et al., 2010). Because it is likely that there is a wide variety of genetic differences between such strains, comparing their behaviors is not equivalent to comparing behaviors and neuropathology between mutant and WT mice of the same genetic background. Nonetheless, the search for the genes causing behavioral phenotypes is ongoing, and a single nucleotide polymorphism in *Kmo*, which encodes kynurenine 3-hydroxylase, has been found in BTBR mice when compared to unrelated strains (McFarlane et al., 2008). This enzyme regulates the synthesis of kynurenic acid, a neuroprotective compound for which levels are abnormal in other neuropsychiatric diseases, including schizophrenia.

Myocyte Enhancer Factor 2 KO mice

A recent homozygosity mapping study of autism loci identified several candidate genes that are regulated by myocyte enhancer factor 2 (MEF2) transcription factors (Morrow et al., 2008). MEF2 factors mediate synapse elimination. Conditional KO of *Mef2c* at the neural stem cell stage yields mice with fewer, smaller, and more compacted neurons that exhibit what is interpreted as immature electrophysiological network properties. It is of interest that these mice display marked paw-clasping stereotypy, possibly altered spatial memory, and complex changes in anxiety tests when tested as adults (Li et al., 2008). Indeed, such behaviors resemble those observed in *Mecp2* mutants. In addition, a recent study revealed that active FMRP is required for MEF2-dependant synapse elimination, thus further pinpointing the molecular factors at play in regulating synapse number (Pfeiffer et al., 2010).

Copy Number Variations

Copy number variations (CNVs) are DNA fragments whose number is altered by deletion or duplication between various individuals. They are thought to account for a significant proportion of normal phenotypic variation within the human population (Freeman et al., 2006). Several recent studies have indicated that de novo CNVs associate with autism. Interestingly, some of the genes identified within the loci subject to CNVs in autism are related to synaptic or neuronal

activity (e.g., *SHANK3*, *NLGN4*, and *NRXN1*) (for reviews, *see* Abrahams & Geschwind, 2008a; Cook & Scherer, 2008). Thus, genome-wide investigation of CNVs might further implicate or reveal novel candidate genes in autism, for which rodent mutant lines can be developed.

Lesions

Autism is a common occurrence in children with brain lesions caused by hemorrhage or tumor (Asano et al., 2001; Limperopoulos et al., 2007). One example of this is TSC, a genetic disorder that causes benign lesions or tumors to form in many different organs, including the brain. MRI and positron emission tomography (PET) demonstrate correlations between abnormalities in the cortex and communication deficits, whereas changes in subcortical circuits correlate with stereotypies and lack of social interaction (Asano et al., 2001). Therefore, the study of autism in children with TSC and the development of animal lesion models may provide clues about autistic behavior.

> **Tuberous sclerosis complex (TSC)**—a genetic disorder that causes tumors to form in many different organs, including the brain; associated with developmental delay, mental retardation and autism and attributed to two genes: *TSC1* gene (harmartin) located on chromosome 9 and *TSC2* gene (tuberin) located on chromosome 16

Although brain lesions have commonly been used in animal models to study the circuitry underlying behaviors (Lavond & Steinmetz, 2003), interpretation of such results can be complex. First, the loss of a behavior does not prove that the lesioned brain area is the originating source for brain activity associated with that behavior. Second, lesions often damage axons passing through the brain area of interest, giving rise to erroneous conclusions about that brain region's importance in the behavior. Third, behavioral testing is necessarily performed on subjects responding to injury with various inflammatory and regenerative mechanisms whose influence on behavior is poorly understood. More recent advances in the ability to silence particular neuronal populations using genetic techniques promise much greater sophistication in unraveling the circuitry underlying behavior.

Amygdala

The amygdala has reciprocal connections with many areas, including the orbital and medial prefrontal cortex and the hippocampus, which are implicated in autism. Several post mortem studies have demonstrated amygdala abnormalities in autistic subjects, such as altered developmental trajectory and fewer neurons (Amaral et al., 2008). In case reports, children with severe temporal lobe damage resulting from viral encephalitis, tumors, or other factors developed autistic symptoms (Sweeten et al., 2002). In children with TSC,

symptoms of autism are strongly related to the presence of tubers in the temporal lobe (Gillberg et al., 1994). These findings, along with recent functional neuroimaging data, led Baron-Cohen to develop an "amygdala theory of autism" (2000), which suggests a crucial role for the amygdala in the impairment of social behavior. In addition, patients with amygdala lesions (Adolphs, 2003) and individuals with autism (Adolphs et al., 2001) appear to have similar deficits in recognizing complex emotions in facial expressions. Neonatal ibotenic acid lesion of the amygdala in the rat has been proposed as an animal model of neurodevelopmental disorders such as autism (Daenen et al., 2001; 2002a; 2002b; Diergaarde et al., 2004). In this model, animals display increased latency to play with social partners, decreased duration of contact, and hyperactivity as well as decreased adaptation and habituation to the open field, which is interpreted as locomotor stereotypy and low anxiety (Daenen et al., 2001; 2002a). Thus, excitotoxic lesions of the amygdala in the neonatal rat produce multiple behavioral abnormalities relevant to autism. This conclusion differs from that found in similar nonhuman primate studies (Amaral et al., 2003). Moreover, humans with amygdala lesions do not display deficits in social interaction like those seen in autism (Amaral et al., 2003).

> **Ibotenic acid**—a powerful neurotoxin that occurs in the mushrooms Amanita muscaria and Amanita pantherina, among others

Hippocampus

Limbic system dysfunction is fundamental to autism (Amaral et al., 2008). Neonatal ibotenic acid lesion of the hippocampus in the rat causes locomotor stereotypy in the open field test, but there are mixed results concerning deficits in social behavior early in life or in adulthood (Daenen et al., 2002b; Silva-Gomez et al., 2003) In rodent models, hippocampal lesions grossly impair memory, and autistic subjects display a selective deficit in hippocampal-dependent memory (Lathe, 2006). Because there are only a few studies analyzing social behavior in hippocampus-lesioned rats, and the damage in this area has no, or only a temporary, effect in monkeys (Amaral et al., 2003), more research is required in this area.

Prefrontal Cortex

Patients who suffer damage to the prefrontal cortex have problems in making decisions and in behaving appropriately in social situations where empathy and social and moral reasoning are appropriate (Anderson et al., 1999; Koenigs et al., 2007). There is also evidence that both the medial temporal lobe and dorsolateral prefrontal cortex are implicated in autism (Amaral et al., 2008). Moreover, lesions to the orbital and medial prefrontal cortex in nonhuman primates cause abnormal social personality expression, decision making, and loss of position within the social group (Butter & Snyder, 1972). Lesioning prefrontal cortex also provokes a decrease in positive social behaviors (grooming, huddling, and near-body

contact) and socially communicative facial, vocal, and postural behaviors, as well as an increase in inappropriate social interactions (Myers et al., 1973). Consistent with these results are ibotenic acid lesion studies of the medial prefrontal cortex in rats (Schneider & Koch, 2005). In addition, the lesion-induced disturbances of juvenile play behavior in rodents may also contribute to the social deficits observed in adult animals, because play-fighting is important for the development of communicative skills and appropriate behavioral patterns. Further work on the rodent model showed that neonatal lesion of the medial prefrontal cortex leads to reduced anxiety in the elevated plus maze, increased motor activity in open field, and, more interestingly, perseverative behavior in a reward-related test of operant behavior (Schwabe et al., 2006). This is in line with the behavioral changes reported for cerebellum lesion models.

> **Perseverative behavior**—common feature of autism, expressed as "insistence on sameness"; believed to result from the inability to understand and cope with novel situations.

Cerebellum

The cerebellum is involved not only in the regulation of motor skills but also in higher functions, including cognition, language, and emotional expression (Turner et al., 2007). Adults and children with cerebellar lesions have high social isolation, communicative disturbance, and deficits in cognitive processing (Eluvathingal et al., 2006; Limperopoulos et al., 2007). A common finding in autism is a loss of PCs (72% of cases; Palmen et al., 2004; 79% of cases; Amaral et al., 2008). Therefore, surgical or toxin lesions of the cerebellum are of particular interest in studying animal models of autism. In addition to cognitive dysfunction reported in a rat model of cerebellum lesion (Gaytan-Tocaven & Olvera-Cortes, 2004), there are two rat models displaying perseverative behavior, which is common in autism and is expressed as insistence on sameness as well as inability to understand and cope with novel situations. This kind of behavior is found in a rat model of early (P10) midline cerebellar lesion (Bobee et al., 2000). In addition, these animals display elevated spontaneous motor activity and exhibit lack of attention to environmental distractors. Unlike the autism phenotype, however, the lesioned animals are neophilic and less anxious than controls. Vermis-lesioned rats show a decreased coefficient of learning during extended training of an instrumental task, which is interpreted as perseverative behavior (Callu et al., 2007).

In sum, the lesion models support dysfunction in autism in several areas: the prefrontal cortex, the temporal lobe and the cerebellum. This may be because an early defect in the functioning of these areas of the brain alters the development of multiple other areas, however. Behavioral analysis has focused primarily on motor tasks and anxiety. These lesion models display hyperactivity and low anxiety in the open field, which is unlike the autism phenotype (Lathe, 2006). No changes, or decreased general social activity, are reported for rodent models with lesions in the amygdala, prefrontal cortex, or hippocampus. Early damage to the amygdala or the prefrontal cortex results in altered juvenile play behavior, the earliest form of non-mother-directed social behavior in rodents. Thus far, these lesion models display two types of behaviors impaired in autism—namely, a deficit in social behavior and stereotypy. It will be important to assay other types of social and communicative behavior (for example, ultrasonic vocalizations in different social contexts), as well as to compare the changes in brain pathology, biochemistry, and gene expression to those seen in autism.

Conclusions

Given that the background genotypes of the rat and mouse strains that are used for experiments are somewhat arbitrary, and that genotype is very important in autism, it is remarkable that both behaviors and neuropathology consistent with autism can be reproduced in rodents. This issue of background genotype could potentially become increasingly important as more sophisticated models incorporating human genetic variants are introduced. Although no single rodent model has yet been thoroughly studied at all levels of investigation, several models have already been explored in some depth. Among those that display face and construct validity are the maternal valproate and maternal infection models of environmental risk factors, as well as the NLGN-4, Frmr1, CNTNAP2, and MeCP2 models of genetic risk factors. Nonetheless, no model has been thoroughly investigated with all available experimental tools, including behavior, histology, biochemistry, electrophysiology, and imaging.

Challenges and Future Directions

- The fine structure of ultrasonic vocalizations, as well as their behavioral functions in adult mice, are intriguing areas for future study of potential communication abnormalities.
- Theory of mind, the ability to intuit another's thinking, is an important deficit in autism. An analogous test of empathy can be done in mice, where observing cage mates experience stressful experiences can alter the witness' responses to later tests (Langford et al., 2006; Chen, Panksepp & Lahvis, 2009). This assay should be widely tested in the available environmental and genetic models.
- To reach their full potential in mimicking the human situation, models of candidate genes should carry the variant identified in the human studies, not just a KO of the gene.
- It is now possible to test the hypothesis that the full autism phenotype may emerge from environmental risk factors acting on susceptibility genotypes.

- Multi-electrode recording, functional imaging, and immediate early gene activation studies will be important for mapping patterns of functional activity in rodent models and comparing it to fMRI data from human subjects.
- Translational, preclinical studies in several mouse models have already stimulated small clinical trials in ASD-related disorders. Although this will likely accelerate in the near future, significant species differences will undoubtedly lead to failures along the way.

Nonhuman Primate Models of Autism

Points of Interest

- Rhesus macaque monkeys live in a sophisticated social environment and use gestures of social communication, such as facial expressions, that are very similar to those used by humans. Many of these behaviors that macaque monkeys share with humans are impaired in autism.
- The neuroanatomy of the rhesus monkey brain more closely approximates that of the human brain than does the rodent brain. The frontal cortex, for example, a region that likely mediates many facets of social cognition, includes regions that are prominent in the human brain but are lacking in the rodent brain.
- Primate models based on lesions of brain regions such as the amygdala do not demonstrate construct, face, or predictive validity.
- Although few models based on known etiologies of human autism exist in the nonhuman primate, recent efforts at modeling potential immune etiologies have demonstrated provocative results.
- There is currently a great need for behavioral probes for nonhuman primate models of autism that are more sensitive to the core features of the deficit.

What Can We Learn from Nonhuman Primate Models of Human Disorders?

An animal model is defined as "an animal sufficiently like humans in its anatomy, physiology, or response to a pathogen to be used in medical research in order to obtain results that can be extrapolated to human medicine" (Merriam-Webster Online Dictionary, n.d.). Although animal models usually do not replicate all aspects of a human disorder, they do provide an experimental system to evaluate hypotheses that, for ethical and practical reasons, are impossible to test using human subjects. Nonhuman primates share many features of human physiology, anatomy, and behavior, thus making the nonhuman primate an ideal species to study a variety of human disorders (J. P. Capitanio & Emborg, 2008). For example, nonhuman primate models have revolutionized the understanding of Parkinson's disease by providing insight into the neural circuitry underlying this disorder (Burns et al., 1983; DeLong, 1990). This, in turn, led to the development of new therapies for humans such as targeted surgical ablation and deep brain stimulation (Bergman, Wichmann, & DeLong, 1990). Nonhuman primates have also played a key role in understanding the neural underpinnings of Alzheimer's disease (Wenk, 1993) and provided a model system for evaluating novel therapeutic interventions for this disorder (Lemere et al., 2004; Lemere, Maier, Jiang, Peng, & Seabrook, 2006; Nagahara et al., 2009; Tuszynski & Blesch, 2004; Tuszynski, Roberts, Senut, U, & Gage, 1996). More recently, a primate transgenic model of Huntington's disease has provided important links between the underlying cellular pathology and the behavioral symptoms of this disorder (Yang et al., 2008). Although we are in the very early stages of developing valid animal models of autism, it is likely that nonhuman primate models will play an important role in identifying biological underpinnings of autism and facilitating the development of future treatment and prevention strategies.

What Constitutes a Good Animal Model of Autism?

The strength of an animal model depends on its resemblance to the human disorder in question. Three criteria are commonly used to evaluate animal models: *(1)* Construct validity—the extent to which the model reproduces the etiology and/or pathophysiology of the disorder; *(2)* Face validity—the degree to which the model resembles symptoms of the disorder; and *(3)* Predictive validity—the extent to which treatment of the animal model provides insight into

therapeutic options for the human condition (Crawley, 2004; McKinney, 1984). The role of these three criteria in establishing animal models of autism is described in detail below.

Construct Validity

Construct validity refers to the degree of similarity between the experimental manipulation used to create the animal model and the underlying cause(s) of the human disease being studied. Construct validity of animal models of autism can be evaluated by asking the following questions: *Does the experimental manipulation stem from findings in human autism research? Does the model stem from a putative etiology of human autism?*

We suggest that for an animal model to provide a valuable contribution to autism research, it must stem from hypotheses that are directly related to the human disorder. This has proven particularly challenging for the field of autism where the underlying cause(s) of the disease for most cases remain unknown. However, as potential causes of autism are identified, animal models will play a critical role in translating results from human autism research into testable hypotheses. For example, recent research with human subjects has identified putative genetic, immunological, environmental and neurobiological markers for autism (Abrahams & Geschwind, 2008; Amaral, Schumann, & Nordahl, 2008; Ashwood, Wills, & Van de Water, 2006; Hertz-Picciotto et al., 2008; Pessah et al., 2008). Although such studies from human subjects shed light on potential biological mechanisms and plausible causes of autism, it is not possible to determine if these findings are causally involved with autism or simply an epiphenomenon of the disease. Animal models provide a means of experimentally evaluating these findings from human studies. This translational approach produces animal models with high construct validity.

Face Validity

Animal models may produce changes in gene expression, brain anatomy and chemistry, and ultimately behavior. Face validity is the extent to which these changes resemble the phenotype of the human disorder. Because autism is a behaviorally defined disorder, the assessment of face validity of animal models is currently focused on changes in behavior that resemble symptoms of autism. The following questions provide a framework to evaluate the face validity of an animal model of autism: *Is it reasonable to hypothesize that the experimental manipulation may result in behavioral changes that resemble autistic symptomatology? Are the changes in behaviors relevant to human autism? Have appropriate behavioral tests been used to evaluate behavior in this particular species? Have other factors that may influence the behavioral data been controlled for?*

For behaviorally defined disorders such as autism, it is important to relate the behavioral outcome of the animal model to the hallmark features of the human disorder. Diagnosis of autism is based on qualitative impairments in social interaction and communication, with the presence of restricted repetitive and stereotyped patterns of behavior, interests, and activities. Table 53-1 outlines the DSM-IV criteria for autism diagnosis as well as the ADOS Module 1 items that are used to diagnose autism for individuals who are pre-verbal or only produce single-word utterances. Table 53-1 also includes a list of nonhuman primate behavioral assays that can be used to assess comparable behaviors in nonhuman primate models of autism. Although some features of autism cannot be successfully modeled in animal species (i.e., language, deficits in theory of mind etc.), it is possible to examine fundamental changes in species-typical behaviors relevant to autistic symptomatology. An ideal animal model with high face validity would produce behavioral changes in the three diagnostic domains of autism: *(1)* social development, *(2)* communication, and *(3)* repetitive behaviors. However, it is important to emphasize that the goal is not necessarily to create "autistic animals." Rather, the goal is to model one or more *features* of human autism in another species so as to enable experimental approaches to understanding its biological underpinnings. Thus, it may not be realistic to expect an animal model of autism to involve behavioral changes in all three symptom domains.

This leads to the second question regarding the appropriateness of the behavioral tests that are used to evaluate the model. Face validity is enhanced by utilizing tests that tap into species-specific behaviors that are related to the symptoms of autism. This requires knowledge of autistic symptomatology, as well as an understanding of the natural behavior of the species being studied. Typical social behavior for a human child will certainly differ from typical social behavior of any model species. It is critical to keep these differences in mind when designing tests to evaluate animal models of autism. For example, diminished eye contact may be characteristic of many individuals with autism (Klin, Jones, Schultz, Volkmar, & Cohen, 2002; J. Osterling & Dawson, 1994; J. A. Osterling, Dawson, & Munson, 2002; Pelphrey et al., 2002; Swettenham et al., 1998). However, species such as rhesus macaques naturally avoid making direct eye contact because it is considered to be a threatening gesture. Thus, it would be inappropriate to use direct eye contact as a measure of social attention/interest in rhesus monkeys. Instead, we must look to other measures of social attention that reflect species-typical social interest in rhesus monkeys (i.e., trying to engage another animal in grooming, etc.). Testing behaviors that are relevant to autism and designing tests that are appropriate for the model species are critical components of creating a valid animal model of autism.

Finally, we must also control for other factors known to trigger autistic-like behaviors in laboratory animals. For example, it is well-known that restricted environments (i.e., small cages, lack of social interaction, etc.) are associated with motor stereotypies and atypical social development in a variety of species (J. Capitanio, 1986; C. Lutz, Well, & Novak, 2003). Given that atypical social development and stereotypies are

Table 53–1.

Diagnostic criteria of autism and relevant behavioral assays for nonhuman primates

DSM-IV diagnosis: six (or more) items from (1), (2), and (3), with at least two from (1), and one each from (2) and (3)	ADOS Module 1 *items included in ADOS algorithm for autism diagnosis	Comparable behavioral assays for nonhuman primate models of autism
(1) Qualitative impairments in social interaction Marked impairment in the use of multiple nonverbal behaviors such as eye-to-eye gaze, facial expression, body postures, and gestures to regulate social interaction Failure to develop peer relationships appropriate to developmental level Lack of spontaneous seeking to share enjoyment, interests, or achievements with other people (e.g., by a lack of showing, bringing, or pointing out objects of interest) Lack of social or emotional reciprocity	**Reciprocal social interaction** Unusual eye contact* Responsive social smile Facial expressions directed to others* Integration of gaze and other behaviors Shared enjoyment in interactions* Response to name Requesting Giving Showing* Spontaneous initiation of joint attention* Response to joint attention* Quality of social overtures*	Quantification of species-typical social behaviors (Bauman, M. D. et al., 2004a, 2004b) Social attention/motivation modeled after (Rudebeck et al., 2006) Neonatal facial imitation (Ferrari et al., 2006) Assessment of dominance hierarchy (Bauman M. D. et al., 2006)
(2) Qualitative impairments in communication Delay in, or total lack of, the development of spoken language In individuals with adequate speech, marked impairment in the ability to initiate or sustain a conversation with others Stereotypes or repetitive use of language or idiosyncratic language Lack of varied, spontaneous make-believe play or social imitative play	**Language and communication** Level of non-echoed language Frequency of vocalization directed to others* Intonation of vocalizations Immediate echolalia Stereotyped/idiosyncratic use of words* Use of other's body to communicate* Pointing* Gestures*	Quantification of species-typical vocalizations (Bauman M. D. et al., 2004a, 2004b) Quantification of vocalizations during separation from mother (Bauman M. D. et al., 2004a) Response to mother's vocalization (Masataka, 1985)
(3) Restricted repetitive and stereotyped patterns of behavior, interests, and activities Encompassing preoccupation with one or more stereotyped and restricted patterns of interest that is abnormal either in intensity or focus Apparently inflexible adherence to specific, nonfunctional routines or rituals Stereotyped and repetitive motor manners (e.g., hand or finger flapping or twisting, or complex whole-body movements) Persistent preoccupation with parts of objects	**Stereotyped behaviors and restricted interests** Unusual sensory interest in play material/person* Hand and finger and other complex mannerisms* Self-injurious behaviors Unusually repetitive interests or stereotyped behaviors	Quantitative assessment of repetitive and stereotyped behaviors (Bauman M. D. et al., 2008) Restricted patterns of interests (modeled after (Moy et al., 2008)
	Play Functional play with objects* Imagination/creativity*	Atypical toy play (modeled after Ozonoff et al., 2008).
	Other abnormal behaviors Overactivity Tantrums, aggression, negative or disruptive behaviors Anxiety	Activity monitoring (Martin et al., 2008) Responsiveness to fear-inducing objects (Prather et al., 2001)

hallmark features of autism, it is essential to control for these behaviors in any animal model of the disorder. Every effort must be made to raise and house animal subjects in a way that assures the development of species-typical social behavior. This includes providing adequate cage sizes, maternal rearing, and opportunities to engage in social interactions with conspecifics. Appropriate control groups are necessary to ensure that changes in behavior can be attributed to the experimental manipulation, rather than to any aspect of the experimental environment (or to a combination of the experimental manipulation and environment). Changes in behavior related to autism that are observed after selecting species-appropriate behavioral assays and utilizing proper controls result in a model with strong face validity.

Predictive Validity

The ultimate goal of any animal model is to develop a means of preventing or treating the human disorder. Predictive validity refers to treatment discoveries in an animal model that provides insight into therapeutic options for the human condition. Although we are just beginning to develop valid animal models of autism, the information gained through these models will ultimately help us move toward the goal of developing preventative strategies and/or novel therapies to reduce the incidence of autism.

Advantages and Limitations of Nonhuman Primate Models

Mouse models have certain advantages over nonhuman primate models. Mouse models can be used for a variety of approaches, including genetic manipulation, environmental manipulation, and alterations in central nervous system function (*see* Chapters 51 and 52). Mouse models are also less expensive, and because of the shorter gestation and larger litters produced by rodents, a greater number of experiments can be completed in a shorter time (mouse gestation = approximately 20 days; rhesus monkey gestation = 165-days). This allows for more extensive pilot and experimental work to be conducted with mouse models than would be practical with nonhuman primate models. Mouse models, however, are also faced with the challenges of relating the rodent brain to the human brain and rodent behavior to human behavior. Portions of the human brain, such as the prefrontal cortex, that are believed to be heavily impacted by autism, are not well-developed in the rodent brain. Given that autism is a disorder defined by changes in complex human behaviors, many of which are mediated by the frontal lobe, developing a mouse model with strong face validity has posed a considerable challenge. It is possible that a uniquely human disorder such as autism may ultimately require the use of animal species that are more closely related to humans, such as nonhuman primates. This may be particularly germane to attempts at developing new therapies. Both the advantages and the limitations of the nonhuman primate model are discussed in detail below.

Advantages

In this chapter, we focus our descriptions on research utilizing the rhesus macaque (*Macacca mulatta*), often considered to be the model species of choice for biomedical research. However, it is notable that other nonhuman primate species may also be used to study human neurodevelopmental disorders. Vervet monkeys, for example, have been used to study the complex interactions among genes, brain, and behavior (Fairbanks et al., 2004;

Fears et al., 2009) and may provide an alternative approach to modeling complex human disorders in nonhuman primates.

Compared with rodents, which are separated from humans by more than 70 million years (Gibbs et al., 2004; Kumar & Hedges, 1998), macaques exhibit greater similarity to human physiology, neurobiology, behavior, and susceptibility to diseases. This is not surprising, given that macaques shared a common ancestor with humans some 25 million years ago (Kay, Ross, & Williams, 1997) and that the macaque genome demonstrates a 90% to 93% alignment of nucleotide sequences with the human genome (Gibbs et al., 2007). The genetic similarities between humans and macaques are further demonstrated by more subtle comparisons of macaque and human genome. For example, polymorphisms in the serotonin transporter gene that have been associated with temperamental differences and susceptibility to psychiatric disorders are similar in humans and rhesus monkeys but not other nonhuman primates (Champoux et al., 2002; Lesch et al., 1997; Trefilov, Krawczak, Berard, & Schmidtke, 1999). In addition to the genetic similarities between macaques and humans, there are compelling similarities between brain and behavior that make rhesus macaques the model of choice for studying complex human disorders such as autism. The neuroanatomical and behavioral complexity of rhesus monkeys is described below in detail.

Neuroanatomical Complexity of Rhesus Monkeys

Despite the fact that the macaque monkey brain is only one-tenth the size of the human brain, the neural organization of the macaque monkey brain is remarkably similar to the human brain (Fig. 53-1). Although it is beyond the scope of this chapter to provide a detailed review of the comparative neuronanatomy of the rodent, macaque monkey and human brains, one or two examples will suffice to make the point that the macaque monkey brain is more similar to that of the human than the rodent.
Figure 53–1. Lateral surface of the (A) mouse, (B) macaque monkey, and (C) human brain. The sulci of the monkey and human have been expanded to show gyral and sulcal patterns. Although the mouse has a relatively large olfactory bulb (hidden from view on the orbital surface of the monkey and human brain), the frontal lobe by comparison is much larger in the monkey and human brain. Images courtesy of Dr. David Van Essen.

Perhaps the frontal lobe is the best regions to explore these differences. The frontal lobe has demonstrated the greatest phylogenetic advancement of any cortical area. There is substantial evidence, in fact, that the demands of living in a social environment (Byrne & Whiten, 1988; Jolly, 1966) have spurred on the evolutionary development of the nonhuman and human frontal lobes—particularly of the increased complexity of connections of these regions (Semendeferi, Lu, Schenker, & Damasio, 2002). Put simply, there are cytoarchitectonic divisions of the frontal lobe that are identifiable in the human brain and in the macaque monkey brain but are not identifiable in the mouse or rat brain (T. Preuss, 1995). As Preuss has argued (Box 53-1), based on cytoarchitectonic, connectional, and neurotransmitter distribution grounds, it is unlikely that rats have cortical homologs of the human dorsolateral prefrontal cortex that is also a prominent component of the monkey brain (T. M. Preuss, 2000). Because the frontal lobe appears to be one of the brain regions most commonly implicated in the neuropathology of autism (Carper & Courchesne, 2005), it raises the concern of whether any rodent model of autism could truly have face validity.

Others have argued that even the rhesus monkey may not be an appropriate model for the human brain. Allman and colleagues have demonstrated a unique type of cortical neuron (the Von Economo Cell [VENs]) located in medial frontal cortex of humans, all of the great ape species, four cetacean species, and African and Indian elephants (Hakeem et al., 2009). These neurons do not appear to be in the rhesus monkey brain. Allman has noted that the VENs emerge mainly after birth in humans and increase in number for the first 4 years of life. He has proposed (Allman, Watson, Tetreault, & Hakeem, 2005) that in autism spectrum disorders, the VENs fail to develop normally and that this failure might be partially responsible for the associated social disabilities that result.

Box 53–1

Comparison of the frontal cortex of the macaque monkey (A) with that of the rat (B and C). Panels B and C present two different interpretations of the organization of the rat frontal cortex. As reviewed by Preuss (2007), traditional views of the rat organization (B) identify the cortex occupying the medial wall of the frontal cortex with the dorsolateral prefrontal cortex (DLPFC) of primates. Traditional descriptions of the rat frontal cortex either make no attempt to identify homologues of the cingulate cortex (grey patterned region—medial view, panel A) or treat medial cortex as containing a mixture of DLPFC and cingulate characteristics. Preuss's interpretation (2007) shown in C, identifies the medial prefrontal cortex of rats with the medial frontal areas of primates. In particular, the areas in rats situated immediately anterior and dorsal to the corpus callosum are identified with subdivisions of the primate cingulate cortex, specifically the anterior cingulate (AC), prelimbic (PL), and infralimbic (IL) areas (grey patterned region—medial view, panel C). Under this interpretation, rats lack cortex homologous to primate DLPFC.

If this were true, neither the mouse not the rhesus monkey would be an entirely appropriate model for the syndrome. However, in a recent study of the number and size of VENs in the anterior cingulate cortex of brains from individuals with autism and typically developing controls, there were no overall differences in the number or size of VENs in the autistic brains compared to controls (Simms et al., 2009).

Social Behavior Complexity of Rhesus Monkeys

In addition to the neuroanatomical similarities with humans, rhesus monkeys also display sophisticated social behavior that resembles many features of human social behavior. Much like humans, macaques spend their lives in complex societies where survival depends on their ability to quickly and accurately interpret and respond to a variety of social signals. Macaque females from several generations live together and form long-lasting social networks or matrilines (S. Altmann, 1967; Wrangham, 1980). These matrilines are organized into dominance hierarchies where prediction of social rank is closely linked to the dominance status of kin (i.e., high-ranking mothers produce high-ranking offspring) (Bernstein & Mason, 1963; Drickamer, 1975; Missakian, 1972; Sade, 1967). This complex system of social organization requires an equally sophisticated social communication system. Much like humans, macaques use a variety of vocalizations, facial expressions, and body postures to communicate with conspecifics. The sophisticated use of social signals makes rhesus monkeys an ideal species to model complex disorders of social behavior such as autism. Moreover, the well-defined sequence of macaque monkey social development provides a rich context in which to model features of human autism.

Infant macaques must rapidly learn to interpret and produce social signals to successfully interact with members of their social group. A well-characterized sequence of social development in many ways parallels that of human infants (Figure 53-2), although at a maturational rate approximately four times faster (i.e., a 1-month-old monkey is roughly developmentally comparable to a 4-month-old human) (Suomi, 1999). Infant macaque monkeys are born with largely functional sensory systems and display an array of reflexive motor responses (Mendelson, 1982a; Mowbray & Cadell, 1962). Like human infants, infant macaques show a clear preference for face-like stimuli very early in development (Kuwahata, Adachi, Fujita, Tomonaga, & Matsuzawa, 2004; C. K. Lutz, Lockard, Gunderson, & Grant, 1998) and demonstrate a transient ability to imitate facial expression in the early postnatal period (Ferrari et al., 2006). The early developmental period of rhesus monkeys is characterized by close physical contact and frequent social interactions with their mother (C. I. Berman, 1980; Ferrari et al., 2006; Hansen, 1966; R. A. Hinde & Spencer-Booth, 1967). Around two weeks of age, infant macaques begin to explore the surrounding environment and interact with their mother's close female kin and other related offspring (C. M. Berman, 1982). Like human infants, the

Rhesus monkey
social development

0–3 Months
- Display a variety of reflexive behaviors
- Transient ability to imitate faces
- Show preference for face-like stimuli
- Averts gaze in response to stare
- Increased exploration away from mother

3–6 Months
- Produces fear grimaces
- Displays fear of strangers
- Develops ability to regulate fear responses

6–9 Months
- Peer play is most common activity
- Social grooming increases
- Transition to weaning begins
- Expression of social rank

9–12 Months
- Reduced maternal care
- Social integration into mother's network
- Birth of new sibling

Figure 53–2. Mother and infant rhesus macaques (Image courtesy of the California National Primate Research Center).

macaque infant uses the mother as a secure base and will return to her immediately if alarmed or distressed (C. I. Berman, 1980; R.A. Hinde, Rowell, & Spencer-Booth, 1964). At this critical stage of development, the infant macaque must acquire the ability to correctly evaluate social signals, particularly signals that may convey potential aggression and predict potential harm. Indeed, by age 3 weeks, infants make fewer fixations on faces of conspecifics staring at them (a potential threat) compared to faces looking away (Mendelson, 1982b; Mendelson, Haith, & Goldman-Rakic, 1982). Between 2 and 4 months of age, the infants will further develop the ability to correctly interpret and respond to potential danger by regulating their responses to direct versus indirect danger (e.g., freezing to remain undetected in the presence of danger versus producing threats when threatening stimuli are being directed at them) (Kalin & Shelton, 1989). During this time, the infants also develop a species-typical expression of fear or subordination, the fear grimace (Sackett, 1966; Suomi, 1999), and develop a fear of unfamiliar conspecifics, a behavior that is possibly akin to the "stranger anxiety" observed in human infants (Suomi, 1999).

At age 3 months, infant macaques regularly explore away from their mothers, spending approximately 50% of their time out of physical contact with her (R. A. Hinde & Spencer-Booth, 1967). Social play becomes the predominant activity between 4 and 8 months of age and is believed to facilitate development of species-typical social behaviors (Ruppenthal, Harlow, Eisele, Harlow, & Suomi, 1974). Social grooming skills also emerge around this time and play an important role in establishing and maintaining social relationships (R. A. Hinde & Spencer-Booth, 1967; Matheson & Bernstein, 2000). During the second half of the first year, infants begin to express their social rank by directing aggression to group members who are lower in rank than their mothers, while deferring to group members

who are higher ranking than their mother (Datta, 1984). The mother–infant relationship begins to transition into weaning at 5 to 7 months (Hansen, 1966). Following the birth of a sibling, macaques continue to develop more independence from their mothers and progress from infant to juvenile social behavior (Devinney, Berman, & Rasmussen, 2001).

Limitations

Despite the neuroanatomical and behavioral advantages of using nonhuman primates to model features of autism, there are important limitations to consider as well. There are certainly ethical issues that must be considered, and research involving nonhuman primates is not undertaken lightly. As described above, nonhuman primates share remarkable similarities with humans in both neuroanatomical organization and social behavior complexity. Although these qualities make them an ideal model species for human disorders, it also raises concerns with humane treatment and minimizing both the number of animals used and the kinds of procedures that are performed. As a result, nonhuman primate models of human disorder rely on very low sample sizes (usually 4–8 subjects per experimental condition). Even with these low sample sizes, research involving nonhuman primates is inherently costly. Obtaining an adequate number of subjects, providing husbandry and veterinary care, and acquiring large enclosures for housing and testing is cost-prohibitive for many investigators. Finally, it is important to recognize that progress is also much slower for nonhuman primate models. This is especially true for developmental models that require 165 days for gestation followed by years of behavioral assessments of the offspring.

In addition, not all human behaviors can be modeled in nonhuman primates. Complex behaviors associated with autism, such as theory of mind, empathy, and even imitation abilities may not be present in all species of nonhuman primates. For example, although macaques can use information about where an experimenter is looking in order to successfully "steal" an item of food (Flombaum & Santos, 2005), chimpanzees demonstrate much more sophisticated use of this social information. Through a series of experiments in which a dominant and subordinate chimpanzee compete for food, Tomasello and colleagues have demonstrated that chimpanzees not only have knowledge of what others see, they also know something about intention in action (Tomasello, Call et al., 2003). Moreover, chimpanzees also are able to draw inferences from other's behaviors, as evidenced by different reactions to behaviors that occur accidentally versus behaviors that are performed with a purpose (Call, Hare, Carpenter, & Tomasello, 2004; Call & Tomasello, 1998). Current practice, however, precludes the use of chimpanzees from invasive biomedical research.

There are also nonprimate species that may prove to be useful models of social processing. Tomasello and colleagues, for example, have found that domestic dogs can use human social and communicative behavior (i.e., pointing) to find hidden food, whereas all nonhuman primates tested (including chimpanzees) demonstrated little ability to solve the same task (Brauer, Kaminski, Riedel, Call, & Tomasello, 2006; Hare, Brown, Williamson, & Tomasello, 2002; Hare & Tomasello, 2005; Riedel, Buttelmann, Call, & Tomasello, 2006). These examples illustrate that although macaques may be the biomedical species of choice, there are important limitations to their behavioral repertoire that must be considered when designing species-appropriate tasks.

Finally, our inability to effectively utilize transgenic technologies in nonhuman primates poses another major obstacle in establishing nonhuman primate models of human disorders. Although transgenic mice models for human diseases have become common, the low efficiency of conventional gene transfer protocols has hindered the progress of developing transgenic nonhuman primates. As a result, attempts to model human diseases in nonhuman primates has been restricted to behavioral, pharmacological, cognitive, or biochemical experimental manipulations. However, as technology advances, so too does our ability to utilize genetic modification in nonhuman primates. The feasibility of applying transgenic approaches to nonhuman primates was recently established by transgene introduction of green fluorescent protein into the macaque monkey (Chan, Chong, Martinovich, Simerly, & Schatten, 2001). This breakthrough has led to the first transgenic nonhuman primate model of Huntington's disease (Yang et al., 2008). The transgenic monkeys display key features of Huntington's disease, thereby demonstrating the power of this technique in studying human disorders with a known genetic cause. Although these studies have established that genetic manipulations in nonhuman primates are possible, future work is needed to refine the techniques (Chan & Yang, 2009).

Modeling Features of Autism in Nonhuman Primates

Given that autism is a behaviorally defined disorder, current efforts to model features of autism focus primarily on inducing changes in behavior in the animal model that resemble behavioral symptoms of human autism. In the following section, we discuss current behavioral assessments used in nonhuman primate models and suggest directions to expand these behavioral assays into more autism specific probes.

Current Behavioral Assessments

One way of assessing the behavior of an animal model of autism is to observe and quantify the emergence of species-typical social and communication behaviors, while screening for the presence of atypical behaviors, such as abnormal motor patterns or stereotypies. Sophisticated analysis of behavior should include: *(1)* a comprehensive catalogue of species-typical behaviors (an ethogram), *(2)* quantitative assessments of both frequency and duration of these behaviors recorded by reliable

observers, and *(3)* assessments of subjects at different time-points in development.

This approach requires extensive knowledge of primate behavior and highly trained observers to identify and record a catalog of species-typical facial expressions, vocalizations, and body postures. In our laboratory, we have consulted with primatologists to create a catalog of 56 species-typical behaviors (M. D. Bauman, Lavenex, Mason, Capitanio, & Amaral, 2004a, 2004b; M. D. Bauman, Toscano, Babineau, Mason, & Amaral, 2008; M. D. Bauman, Toscano, Mason, Lavenex, & Amaral, 2006). The frequency and duration of these behaviors is quantified for one focal subject at a time (J. Altmann, 1974), resulting in a detailed record of the use of species-typical behaviors. In addition to frequencies and durations of discrete behaviors, observers also record the identity of the second subject and direction of the interaction (initiate or receive), thus providing insight into the appropriateness of each individual's use of social communication. In our laboratory, all observations are collected with The Observer (Noldus, 1991) behavioral data collection software by trained observers who demonstrate a predetermined interobserver concordance of better than 90%. It is important to emphasize that observers remain blind to the experimental condition of each infant for the duration of the study.

Because autism is a developmental disorder, the majority of animal models focus on prenatal or early postnatal manipulations. To screen for changes in behaviors associated with a developmental model, it is essential to monitor behavior at different time-points in development. In our laboratory, each subject is observed daily in their individual cages to screen for abnormal behaviors, weekly in their rearing groups to document the emergence of species-typical social behavior within a familiar group, and at specific time-points in development to provide more comprehensive assessments of social behavior under more challenging conditions (i.e., response to novel conspecifics, etc.).

Our current behavioral assays focus heavily on quantifying the development of species-specific behaviors and then relating these changes to human autism. By measuring the frequency and duration of macaque social signals we are able to determine whether the infant monkeys exhibit appropriate social signals at the correct developmental time-points, whether they have developed a complete repertoire of social signals, and whether they are using these behaviors in a species-typical way. We are also able to screen for the presence of atypical behaviors, such as motor stereotypies. Although this approach provides a wealth of data regarding species-typical development, it does not specifically probe for behavioral changes that are observed in humans with autism. The addition of specific probes for behaviors directly related to human autism would result in a powerful assessment of nonhuman primate models of autism.

Future Directions for Nonhuman Primate Behavioral Assessments

In recent years, rodent models of autism have undergone substantial changes spearheaded by Crawley and colleagues (Crawley, 2004, 2007a, 2007b) reviewed in Chapter 51. The result is a standardized battery of behavioral tests for rodents that focus on behaviors most directly related to autistic symptomatology. This has undoubtedly improved the quality of rodent models of autism. Future nonhuman primate models of autism will also benefit from designing behavioral probes that focus on behaviors most directly related to human autism. Indeed, the complex social behaviors exhibited by rhesus monkeys may allow them to model features of autism that are simply not present in rodent models. We are in the process of developing a series of nonhuman primate behavioral tests that can be adapted to probe for behaviors more directly related to human autism. Our strategy is to take findings from human autism research and translate these into species-appropriate behavioral tasks for our nonhuman primate models. It is fair to say that these types of tests do not currently exist because the interest in developing primate models of autism and other neurodevelopmental disorders is a relatively recent phenomenon. These behavioral assays include tests for each of the three diagnostic domains of autism:

Probes of Social Behavior Deficits Related to Autism

Recent studies have focused on two early components of social development that may be impaired in young children who go on to develop autism: *(1)* social attention and *(2)* social imitation. Many individuals with autism do not attend to salient social information (i.e., faces, eyes, etc.) in a typical fashion. For example, infants who are later diagnosed with autism look less at the face early in development compared to typically developing or developmentally delayed infants (J. Osterling & Dawson, 1994; J. A. Osterling et al., 2002; Swettenham et al., 1998). This pattern of abnormal face processing persists into adolescence and adulthood (Pelphrey et al., 2002) and may affect the ability to perceive social information (Klin et al., 2002). In addition to social orienting, individuals with autism may also have difficulty imitating the actions of others (Williams, Whiten, & Singh, 2004).

Tests of social attention and imitation that are currently used for young children could readily be modified for use in nonhuman primate models. Indeed, a test of social attention and motivation has recently been developed for rhesus monkeys (Rudebeck, Buckley, Walton, & Rushworth, 2006). Briefly, adult rhesus monkeys are placed in a cognitive testing cage where they are shown still images of salient social information (i.e., pictures of an alpha male monkey) as well as nonsocial images (i.e., objects, etc.). Social attention is measured by the amount of time spent looking at the screen, and a rough estimate of social motivation is measured by recording the amount of time it takes for the monkeys to retrieve a small food reward in front of the screen. When monkeys are presented with nonsocial images, they immediately retrieve the food reward. In contrast, monkeys delay retrieving the food reward when presented with social images. Presumably, the monkeys find the social images more interesting and choose to attend to the

social images rather than glancing down and retrieving the food reward. This task could easily be modified to assess social motivation and attention in young rhesus monkeys by creating an age-appropriate social stimulus set. This test would provide important information on how infant rhesus monkeys respond to specific probes of salient social information and provide rough assessments of social attention and motivation.

In addition to social attention, individuals with autism may also demonstrate impairments in imitation of others (Colombi et al., 2009). This combined with the discovery of "mirror neurons" in the macaque brain that fire both when an animal is in action as well as when it observes the same action by another individual has led to a hypothesis that dysfunction of the mirror neuron system might be a core deficit in autism (Iacoboni, 2005; Iacoboni & Dapretto, 2006). Recording of mirror neurons requires invasive electrophysiological experiments that are not compatible with naturalistic housing strategies. However, there are other means of evaluating imitation processing in rhesus monkeys. In the past, such experiments have been hindered by the traditional view from primate behavioral studies that apes imitate, and monkeys do not. However, it has recently been demonstrated that infant macaques possess a transient ability to imitate human facial expressions during the first week of life (Ferrari et al., 2006). This ability bears many similarities to the same abilities demonstrated in newborn humans and apes and may prove to be a sensitive assay of early imitative abilities for animal models of autism.

Probes for Communication Deficits Related to Autism

Recent developments in autism research have highlighted an infant's lack of response to their own name at 12 months as a possible developmental abnormality (Nadig et al., 2007). This study found that decreased response to name at 12 months discriminates children at risk for autism from a control group, suggesting that poor response to name may be an early feature of autism. Although it is not possible to test "response to name" in macaque monkeys, it is feasible to evaluate the infant's ability to differentiate important vocal communications. Rhesus mothers respond to separation from their infant with a species-typical "coo call," and the infants are able to discriminate maternal versus non-maternal vocalizations (Masataka, 1985). Determining whether infant monkeys respond to their own mothers coo call in a species-typical fashion may provide insight into the infants' ability to respond to salient social communication, paralleling the human infants' response to their own name.

Probes for Repetitive Behavior and Restricted Interests

Young children with autism display unusual repetitive behavior and/or restricted interests that may be modeled in

nonhuman primates. Given the overlap between motor stereotypies in human disorders and animal models, we have focused much of our attention on screening animals for the presence of any atypical motor behaviors. However, we have not screened for other aspects of repetitive behaviors that are extremely common in children with autism, such as persistent preoccupation with parts of objects or toys. Moreover, we have not developed tests to assess "higher order" repetitive behaviors that are often characteristic of individuals with autism, including insistence on sameness as well as patterns of restricted interests. It is entirely feasible to adapt tests from human autism research to probe for these behaviors in the nonhuman primate model.

For example, Ozonoff and colleagues have recently demonstrated that 12-month-old infants who are later diagnosed with autism display atypical patterns of object exploration compared to control groups (Ozonoff et al., 2008). Specifically, the infants who were later diagnosed with autism displayed more spinning, rotating, and unusual visual exploration of objects compared to individuals who were typically developing. This toy play paradigm could readily be modeled to assess lower level repetitive behaviors in infant rhesus monkeys. Higher order restricted interests could be assessed by modifying a task of novel object exploration used in young children with autism. When allowed free access to a room filled with novel toys, children with autism spend less time exploring novel objects compared to typically developing subjects (Pierce & Courchesne, 2001). These data suggest that the restricted patterns of interest characteristic of many children with autism may interfere with their ability to explore novel environments. Bodfish and colleagues have recently modified this paradigm for use in rodent models of autism (Moy et al., 2008). This paradigm could easily be modified for use in nonhuman primates.

What is the Status of Nonhuman Primate Models of Autism?

There are many possible approaches to creating an animal model of autism. Distinctions should be drawn among models that are designed to elicit behavioral symptoms, those designed to study underlying neurobiological mechanisms, and those designed to test a specific etiological theory. We have selected nonhuman primate studies from each of these approaches to discuss in detail below. Each model is evaluated based on construct, face and predictive validity to determine their value as a potential animal model of autism.

Isolate Rearing Models

We have chosen to include historical studies using isolate reared monkeys in our discussion of nonhuman primate models of autism. Although these studies were not intended as animal models of autism, the isolate rearing paradigm elicits behavioral changes in nonhuman primates that are strikingly similar to human autism. Nonhuman primates reared in isolation from

Table 53–2.
Evaluation of nonhuman primate models of autism

Nonhuman Primate Models of Autism	Construct Validity	Face Validity	Predictive Validity	Interpretation
Isolate-rearing	Moderate: requires further investigation	High	Moderate	The model exhibits high face validity because the behavioral outcome resembles many features of human autism. The construct validity is unclear—extreme social isolation may produce autistic like behaviors in children, although it is unclear how this relates to idiopathic autism. The nonhuman primate isolate-rearing model does, however, provide evidence that restricting access to social information early in development results in an animal model that in many ways resembles human autism. This lends support to current hypotheses suggesting that children who go on to develop autism are not able to obtain and process social information at critical developmental time-points. Moreover, exposing the isolate-reared monkeys to peer at specific time-points in development can "rescue" the effects of isolate-rearing. Thus, this model may provide general insight in means of rescuing atypical social development.
Neonatal amygdala lesion models	Low	Low	Not tested	Current evidence suggests that the amygdala may undergo atypical development in children with autism. However, individuals with autism do not have bilateral amygdala damage, and patients with bilateral amygdala damage are not autistic (the model has low construct validity). The behavioral outcome of neonatal amygdala lesions depends on the lesion technique, rearing conditions, and quality of behavioral observations. However, the most current evidence indicates that nonhuman primates with neonatal amygdala damage do not demonstrate autistic symptomotology early in development.
Maternal antibody model	High	Moderate	Not tested	The immunological challenge utilized in this model was derived from mothers who have produced multiple children with autism, thus identifying a putative human cause of autism (the model has high construct validity). This model has created an animal with a clear neurodevelopmental disorder (characterized by motor stereotypies) following prenatal exposure to antibodies from mothers of children with autism. Although alterations in social development were not observed in this pilot study (moderate face validity), efforts are underway to replicate and expand upon this promising model.

conspecifics will direct filial responses such as ventral clasping and nursing to their own bodies, resulting in abnormal behaviors such as self-clasping, huddling, self-orality, and rocking with stereotypic movements (Griffin & Harlow, 1966; Harlow, 1965; Harlow & Zimmermann, 1959). Even more striking, nonhuman primates reared in complete isolation for the first 6 months of life fail to develop species-typical social behaviors (Harlow, 1965; Harlow, Dodsworth, & Harlow, 1965) as evidenced by their failure to initiate or reciprocate play and grooming behaviors (Harlow & Harlow, 1962; Harlow & Harlow, 1965; Harlow, Rowland, & Griffin, 1964) and by their inability to respond to a variety of species-specific social signals (Mason, 1960). In addition to the deficits in social behavior, restricted rearing or housing practices are also associated with abnormal behaviors, such as self-directed (Champoux, Metz, & Suomi, 1991) and self-injurious behavior (C. Lutz et al., 2003).

Deficits in social and communication development, combined with the presence of self-directed repetitive behaviors, in many ways parallels symptoms of human autism. This is not at all to suggest that restricted rearing practices are a common cause of autism. We know that children with autism are not raised in substandard conditions. If anything, parents and therapists put forth heroic efforts to create an environment that will help a young child with autism acquire social and communication skills. It is, however, possible that extreme social deprivation conditions such as those found in substandard orphanages, may predispose children to develop autistic like behaviors. A 1999 study by Rutter and colleagues reported that 6% of 111 children adopted from Romanian orphanages showed autistic-like patterns of behavior between 4 and 6 years of age (Rutter et al., 1999). The findings by Rutter suggest that early deprivation of social stimuli may alter brain development and result in behavioral symptoms that resemble autism.

The parallels between primate deprivation studies and autistic-like behaviors associated with substandard human orphanages warrants further discussion as a possible animal model of autism. Both the isolate reared nonhuman primate studies and the reports of children raised in substandard orphanages indicate that there are critical periods of development when social interaction is required to develop species-typical social behavior.

If social interaction is withheld during these critical periods, the resulting behavior resembles autistic symptomatology. Clearly, social interaction is not intentionally withheld from children who go on to develop autism. However, it is possible that autism is caused by a failure to develop the neural circuitry required for infants to attend to and engage in social interaction during these critical periods. Thus, a disruption in the neural circuitry required to engage in early social interactions may mimic the effects of early social deprivation. Indeed, Schultz and colleagues have proposed that early abnormalities in visual attention mediated by the amygdala result in an inability to identify salient signals, which in turn alters overall development of social perception and knowledge of others (Schultz, 2005). Another hypothesis argues that a primary deficit in social motivation mediated by dopamenergic reward systems underlies early inattention to social signals that is characteristic of autism (Dawson, Webb, & McPartland, 2005; Dawson et al., 2005). Either a disruption in processing capabilities or a deficit in social reward systems could conceivably lead to an inability to attend to social information early in development. The same brain systems that mediate these behaviors in human children may be altered in the nonhuman primate rearing models. Thus, there is a potential similarity between isolate rearing and the underlying cause(s) of human autism; however, more research is needed to determine the construct validity of this model.

In addition to high face validity, the nonhuman primate isolate rearing studies may also demonstrate high predictive validity by providing valuable insight into therapeutic interventions. Subsequent studies of the isolate reared monkeys revealed that recovery of social behavior was possible under specific circumstances. Although young isolate reared monkeys exposed to age-matched peers showed only limited recovery of social responses, it was later shown that 6-month-old isolates exposed to much younger monkeys achieved almost complete recovery of social behaviors (Harlow & Suomi, 1971). The authors suggested that the younger monkeys posed no threat to the isolate reared subjects, thus allowing the isolate reared monkeys to "learn" species-typical social behaviors as the younger monkeys passed through their own stages of socialization. Interestingly, peer-mediated play has also been used as an effective social intervention for young children with autism (Rogers, 2000). In peer-mediated therapies, typically developing peers are taught to initiate play behaviors using common play materials and activities (Odom & Strain, 1986; Oke & Schreibman, 1990). This approach has proved effective in increasing the social interactions in young children with autism, thus demonstrating another parallel between human autism and the primate isolation research.

Amygdala Lesion Models

In the early 1990s, much attention was focused on the potential role of amygdala pathology in autism. This "amygdala theory of autism" was based on several findings: (1) reports of abnormal cell density in the amygdala of autistic brains (M. L. Bauman, 1991; M. L. Bauman, Filipek, & Kemper, 1997); (2) atypical patterns of amygdala activation in human subjects with autism (Baron-Cohen et al., 2000; Baron-Cohen et al., 1999); and (3) a putative animal model of autism resulting from neonatal amygdala damage in rhesus monkeys (Bachevalier, 1994, 1996).

The nonhuman primate model of autism developed by Bachevalier and colleagues was based primarily on a study of six peer-reared monkeys that received aspiration lesions of the amygdala within the first postnatal month (Bachevalier, 1994). When placed in social dyads at age 2 months, the neonatal amygdala-lesioned infants showed less overall activity, exploration, and social behavior initiation than age-matched controls. At age 6 months, activity levels were relatively normal, but social interactions were reduced in amygdalectomized infants compared to the controls. The authors also reported that more extensive lesions of the medial temporal lobe, including the amygdala, hippocampus, and ventromedial temporal cortex produced a more profound effect on social interactions, including lack of social skills, flat affect, and increased stereotypic behaviors. Given that impaired social communication and a lack of social interest hallmark features of autism, the authors proposed that lesions of the medial temporal lobe, specifically the amygdala, might provide an animal model of autism (Bachevalier, 1994, 2000).

The studies by Bachevalier et al. were some of the first attempts to use the nonhuman primate to model features of autism. It is possible, however, that the behavioral changes in these monkeys may have been influenced by unintended collateral damage of neural tissue surrounding the amygdala and/or by the restricted rearing practices that were employed. To address the potential limitations of the Bachevalier study, our laboratory designed a series of experiments to evaluate the effects of more selective neonatal amygdala lesions on the development of socially reared rhesus monkeys. We utilized the injectable neurotoxin ibotenic acid which selectively removes neurons, while sparing surrounding cortex and fibers of passage (Meunier, Bachevalier, Murray, Malkova, & Mishkin, 1999). Unlike the Bachevalier subjects that were reared with access to peers only, we raised our subjects with their mothers and provided them daily access to larger social groups consisting of several mother–infant pairs and an adult male. This semi-naturalistic rearing strategy facilitates the development of species-typical social behavior and decreases the presence of abnormal repetitive behaviors. We predicted that if the amygdala is a core component of the social brain, then removal of the amygdala early in development would profoundly alter fundamental features of social behavior, including social attention and the ability to produce and interpret social signals. However, if these core features of social behavior remain intact following amygdala damage, then it is reasonable to conclude that the amygdala is not essential for the development of fundamental aspects of social behavior.

In our studies, 24 rhesus monkeys were given selective ibotenic acid-induced lesions of the amygdala or hippocampus

or a sham lesion procedure at age 2 weeks. We then observed the social development of these animals during the first year of life by systematically quantifying social interactions with their mothers, familiar peers, and novel peers. When observed at age 3 months, the amygdala-lesioned monkeys spent the same amount of time nursing and in contact or proximity with their mothers as did control or hippocampus-lesioned subjects (M. D. Bauman et al., 2004a). There were no differences among the experimental groups in the frequency of mother–infant behaviors, and none of the infants engaged in maladaptive behaviors in the first year of life, such as self-clasping, crouching, rocking, or motor stereotypies, which are indicative of abnormal social behavior development (J. Capitanio, 1986). After the amygdala-lesioned subjects were weaned from their mothers at age 6 months, they continued to develop a species-typical repertoire of social behavior (M. D. Bauman et al., 2004b). They were observed successfully interacting with members of their social rearing group, with familiar conspecifics at ages 6 and 9 months, and with novel conspecifics at age 1 year. These studies demonstrated that infant macaques with neonatal amygdala lesions are able to *(1)* form filial bonds; *(2)* develop a species-typical repertoire of social behavior; *(3)* display interest in conspecifics; and *(4)* interact with conspecifics in various social contexts.

Although the amygdala-lesioned subjects developed fundamental aspects of social behavior, they differed from control and hippocampus-lesioned subjects in some significant ways. The most striking abnormality of the amygdala-lesioned subjects was their inappropriate fear behaviors in various contexts. We observed that amygdala-lesioned subjects produced fear behaviors more frequently than control or hippocampus-lesioned subjects during social interactions with both novel and familiar social partners (M. D. Bauman et al., 2004b). We have proposed that through its mediation of fear, the amygdala plays a modulatory—rather than essential—role in social processing. It is plausible that the absence of social interaction observed by Bachevalier was not the result of "autistic-like" symptomatology but rather the result of abnormal social fear response that is characteristic of amygdala-lesioned monkeys. This explanation is consistent with the view that the amygdala is not essential for fundamental aspects of social behavior, such as producing social signals and interacting with conspecifics. However, the amygdala may indirectly modulate social behavior by detecting danger within a social context and orchestrating an appropriate behavioral response.

Observations of these animals are ongoing, and we have observed additional changes in their behavior over time. For example, the amygdala-lesioned subjects are lower ranking in their social groups compared to hippocampus-lesioned or control subjects (M. D. Bauman et al., 2006). Interestingly, both the amygdala- and hippocampus-lesioned subjects developed repetitive behaviors in the second year of life (M. D. Bauman et al., 2008). The emergence of stereotypies after a period of relatively normal development bears some resemblance to developmental disorders, such as autism, where abnormal behaviors may become apparent or worsen following seemingly typical developmental trajectory.

In spite of these later changes in behavior, the absence of pronounced social deficits or repetitive behaviors early in development indicates that neonatal amygdala lesions do not result in an animal model of autism with high face validity. To produce a model with high face validity, we would have expected to see pronounced changes in social behavior and communication by the time the monkeys reached age 12 months (roughly equivalent to a 4-year-old human). Moreover, the construct validity of an amygdala lesion model is questionable. Although there is compelling evidence for structural and functional amygdala abnormalities in individuals with autism (K. M. Dalton, Nacewicz, Alexander, & Davidson, 2007; K. M. Dalton et al., 2005; Schumann & Amaral, 2005; Schumann et al., 2004), complete amygdala lesions do not replicate this pathophysiology. Likewise, human subjects who do suffer from bilateral amygdala damage display subtle deficits in social processing but clearly are not autistic (Adolphs et al., 2005; Adolphs & Tranel, 2003; Adolphs, Tranel, & Damasio, 1998; Adolphs, Tranel, Damasio, & Damasio, 1994; Adolphs, Tranel, Damasio, & Damasio, 1995). The low construct and face validity of the neonatal amygdala lesion model would argue against this approach as a valid animal model of autism.

Maternal Auto-Antibody Model

Converging evidence indicates that immune dysfunction may play an important role in a subset of autism cases (van Gent, Heijnen, & Treffers, 1997). Some patients with autism demonstrate abnormalities and/or deficits of immune system function, including inappropriate immune response to pathogen challenge (Ashwood, Anthony, Torrente, & Wakefield, 2004), recurrent infections (Stern et al., 2005), peripheral immune abnormalities (Ashwood et al., 2003; Croonenberghs, Bosmans, Deboutte, Kenis, & Maes, 2002; Singh, 1996) and neuroinflammatory responses in the central nervous system (CNS; Vargas, Nascimbene, Krishnan, Zimmerman, & Pardo, 2005). In addition to general immune system dysfunction, recent evidence suggests that certain forms of autism are associated with autoimmune conditions (Ashwood & Van de Water, 2004). Autoimmunity occurs when the immune system inappropriately identifies and reacts to "self" components. Several studies have also reported that autoimmune disorders are more common in family members of individuals with autism compared to typically developing controls (Comi, Zimmerman, Frye, Law, & Peeden, 1999; Richler et al., 2006; Sweeten, Bowyer, Posey, Halberstadt, & McDougle, 2003). Moreover, antibodies directed against CNS proteins have been found in the sera of children with autism (Cook, Perry, Dawson, Wainwright, & Leventhal, 1993; Plioplys, Greaves, Kazemi, & Silverman, 1994; Singh & Rivas, 2004; Singh, Warren, Averett, & Ghaziuddin, 1997; Singh, Warren, Odell, Warren, & Cole, 1993; Todd & Ciaranello, 1985).

In addition to the presence of auto-antibodies in individuals with autism, recent evidence raises the possibility that

maternal auto-antibodies to fetal brain tissue may play a role in a subset of autism cases (Vincent, Dalton, Clover, Palace, & Lang, 2003). Antibodies from serum of mothers who have children with autism have been shown to react to antigens on lymphocytes from their affected children (Warren et al., 1990). Given that antigens expressed on lymphocytes are also found on cells of the CNS, these authors proposed that aberrant maternal immunity may be associated with the development of some cases of autism. In support of this, the presence of antibodies against brain tissue was recently identified in the serum of a mother whose child has autism (P. Dalton et al., 2003), and Van de Water and colleagues have identified a common pattern of auto-antibody production to fetal brain tissue in the serum of mothers who have two or more children with autism (Braunschweig et al., 2008). Collectively, these studies suggest that an atypical maternal antibody response directed against the fetal brain during pregnancy may be present in a subset of autism cases.

Although evidence for pathogenic maternal antibodies is very suggestive, it is not feasible to establish a causal relationship in human subjects. Animal models are needed to evaluate the effects of prenatal exposure to potentially pathogenic antibodies. A preliminary rodent model of developmental disorders reported behavioral abnormalities in mice prenatally exposed to serum from a woman whose children have autism and other developmental disorders (P. Dalton et al., 2003). Similarly, Martin et al. (Martin et al., 2008) recently published a study on the effects of exposing gestating rhesus monkeys to IgG class antibodies obtained from human mothers of multiple children with autism. Behavioral observations of monkeys prenatally exposed to purified IgG from mothers of children with autism revealed more whole body stereotypies than both untreated control monkeys and monkeys prenatally exposed to purified IgG from mothers of typically developing children. Importantly, the increased stereotypies were observed consistently across several different testing paradigms over a 7-month period. These testing situations are described in detail below.

One month following weaning, each subject was observed for behavioral differences either while alone or while paired with a familiar conspecific from their social rearing group. Behaviors were scored in real time using a catalog of normal and abnormal behaviors commonly displayed by rhesus monkeys. Results demonstrated significantly higher frequencies of whole-body stereotypies in the maternal autism IgG treated monkeys compared to the control IgG treated and control untreated monkeys in both solo and paired conditions. When the subject was engaged in a particular stereotypy for more than 6 seconds, an extended stereotypy was scored. Significant differences were observed in the frequency and duration of extended stereotypies when animals were in the paired condition. A similar pattern of whole body stereotypies was also observed during dyadic interactions with unfamiliar conspecifics. One month following the pairings with familiar peers, monkeys were removed from their social groups and placed with one of four unfamiliar monkeys in the same large testing enclosures. Once again, results demonstrated a higher frequency of whole-body stereotypies in the maternal autism IgG

treated monkeys compared to control IgG treated and control untreated monkeys.

In addition to these three behavioral settings, the autism IgG-exposed monkeys produced an increased number of midline crossings (an indication of hyperactivity) in the mother preference task that is administered over the first 4 days following weaning. In this task, infants are provided access to their mothers or to another familiar adult female. The species-typical response is to identify the location of the mother and then to remain in proximity for the remainder of the trial. In contrast, the autism IgG-treated animals demonstrated significantly more cross-cage pacing and did not settle in proximity with their mothers. Finally, all animals in this pilot study were fitted with actimeters that measured activity throughout 3 weeks of testing. No differences in activity were detected when the animals remained in their social groups. However, during the individual housing condition, the autism IgG-treated group demonstrated significantly higher levels of activity than the control group.

These preliminary data indicate that prenatal exposure to IgG class antibodies from mothers of children with autism alters the behavioral development of rhesus monkeys. Profound stereotypies were observed in several behavioral settings across 7 months of testing. In addition to these striking results, this study provides evidence for the feasibility of examining the effects of potentially pathological maternal antibodies in nonhuman primate models. Although these results are provocative, it is clearly premature to consider these findings indicative of an animal model of autism. We are currently conducting a larger-scale study attempting to replicate the results of this pilot study. We are also aware that repetitive stereotypies only represent one facet of autistic symptomatology. We have thus far not observed robust deficits in social behavior and communication in the pilot animals. Thus, we may have succeeded in modeling one feature of autistic symptomotology rather than the entire disorder. It is also noteworthy that repetitive behaviors are not specific to autism. Indeed, motor stereotypies are a common feature of many developmental disorders, including Rett syndrome and mental retardation (Berkson, 1983; Berkson, Gutermuth, & Baranek, 1995; Bodfish, Symons, Parker, & Lewis, 2000; Wales, Charman, & Mount, 2004). Despite these limitations, we find the results obtained from the pilot study promising for several reasons:

1. The model demonstrates high construct validity. The proposed model comes directly from families of children with autism. The immunological challenge utilized in our pilot study was derived from mothers who have produced multiple children with autism, thus identifying a putative human cause of autism.
2. The model demonstrates moderate face validity. At the very least, this immunological model has created an animal that demonstrates one of the core features of autism (motor stereotypies). Given the prevalence of repetitive behaviors across a wide range of neurodevelopmental disorders, this research may provide

important information regarding the neurobiology of abnormal repetitive behaviors.

3. There is a potential for high predictive validity. If we are successful in replicating and extending the findings from our pilot study, we foresee important clinical implications. The focus of concurrent studies is to identify the relevant fetal brain auto-antigens. This would allow us to use the identified auto-antigen to break tolerance, establish the behavioral model, and extend this immunological model using immunomodulation to alter the developmental outcome of the infants. These future studies may provide directions for treatment of human mothers. For example, screening for brain-directed antibodies may provide an indication of risk factors for women who intend to become pregnant. This information may be particularly important to women who have had previous children with autism since the probability of having a second child with autism is substantially higher than risk for a first child with autism. More importantly, the detection of brain-directed auto-antibodies may lead to therapeutic interventions that may decrease the risk of producing children with serious neurodevelopmental disorders.

Conclusions

It is likely that future animal models will play an important role in evaluating the biological underpinnings of autism and facilitating the development of future treatment and prevention strategies. The validity of animal models is based on: *(1)* construct validity (degree of similarity between the experimental manipulation and the underlying cause of the human disease), *(2)* face validity (the extent to which the resulting model resembles the phenotype of the human disorder), and *(3)* predictive validity (treatment discoveries in an animal model which may provide insight into therapeutic options for the human condition). Nonhuman primates closely resemble humans in both sophistication of social behavior, (e.g., they use facial expressions for social communication) and neural organization, (e.g., they have all of the regions of the frontal lobe identified in the human brain), thus making the nonhuman primate an ideal species to model features of autism. Coe and colleagues (Short et al., 2010; Willette et al., 2010) have recently capitalized on these similarities by including assessments of both behavior and brain development in nonhuman primate models of prenatal exposure to infection. While these studies were not specifically proposed as animal models of autism, their findings demonstrate the power of pairing sophisticated behavioral assessments with structural MRI to systematically evaluate the effects of a prenatal insult on both brain and behavior development. Future efforts to evaluate the validity of nonhuman primate models will require increasingly sophisticated behavioral probes that are sensitive to the core features of autism, as well as research tools, such as eye tracking and functional neuroimaging, that bridge the gap between human and animal studies.

A current limitation to the development of additional primate models of autism is the dearth of convincing evidence on specific etiologies of autism. Assuming this information will be forthcoming in the near future, it will also be essential to develop behavioral probes for nonhuman primates that are sensitive to the core features autism. With these developments, the nonhuman primate can provide a valuable test bed for evaluating preventative measures and innovative treatments.

Challenges and Future Directions

- Developing nonhuman primate models of autism with high construct validity (e.g., models that stem from hypotheses that are directly related to causes of the human disorder).
- Improving face validity of nonhuman primate models by developing assays of nonhuman primate behavior that are relevant to symptoms of human autism.
- Establishing collaborative efforts between rodent and nonhuman primate models of autism to make use of the unique advantages each approach offers.
- Translating results from nonhuman primate models into preventative strategies and/or novel therapies to reduce the incidence of autism.

Autism as a Disorder of Functional Brain Connectivity

Points of Interest

- Autism is not localized to a single place in the brain, but rather is a neural systems level disorder.
- Cortical Underconnectivity Theory proposes that the connectivity between frontal and posterior brain areas is compromised in autism, lowering the communication bandwidth between these regions. The underconnectivity is manifested as aberrant white matter (measured with MRI morphometry and diffusion tensor imaging) and reduced synchronization of brain activity between frontal and posterior areas.
- The reduced availability of frontal areas in autism may lead to increased reliance on posterior areas, particularly visual areas.
- Cognitive and other behavioral intervention programs may be able to strengthen the connections among relevant brain areas by training in thought processes that require frontal-posterior collaboration. The use of explicit instructions and selective reinforcements would be a starting point in such programs designed for children with autism.

"During the last couple of years, I have become more aware of a kind of electricity that goes on between people. I have observed that when several people are together and having a good time, their speech and laughter follow a rhythm. They will all laugh together and they talk quietly until the next laughing cycle. I have always had a hard time fitting in with this rhythm, and I usually interrupt conversations without realizing my mistake. The problem is that I can't follow the rhythm." Grandin (1995, pp. 89–92)

The above words from Temple Grandin provide lucid testimony of how casual social interaction in daily life is alien territory for people with autism. The complex nature of the

functioning of the world, especially the social world, is enigmatic to people with autism just as the disorder itself is intriguing to families and researchers. Whereas human interactions are the products of a carefully orchestrated symphony of understanding and accessing minds, the conductor of it, the human brain, carries out this coordinated venture with utmost precision and with regular rhythm. Temple Grandin points out that she can't follow the rhythm of human interactions, but what lies beneath the struggle is a brain trying to keep up with the symphony. This chapter is about how the brain coordinates the orchestra of cognitive and social functions, the symphony of the organization and the functioning of the brain, and how an aberrant brain communication system in autism produces thought processes and behaviors that are atypical.

The symptoms of autism are extremely widespread such that it manifests itself as a multidimensional (social, cognitive, linguistic, and information processing) disorder. Researchers, especially neuroscientists who study autism, have long been in the hunt for finding the dysfunction of a single region in the brain that could explain the complexities of autism. The commonly asked, although implicit, question is, "Where in the brain is autism located?" Obviously, there has been no single convincing answer to this question. Considering the complexity, breadth of symptoms, and the intriguing nature of autism, any attempt to localize the disorder to a single cortical structure seems unlikely to succeed. Studies seeking such localized abnormalities have not demonstrated a consistent pattern of brain dysfunction in autism (Jacobson et al., 1988; Sears et al., 1999; Piven & Arndt, 1995). On the other hand, this difficulty in finding a single structural culprit in autism attests to the complex nature of the disorder and calls for an explanation at a more comprehensive and global level. A relatively novel approach to answer the questions related to the neural basis of autism would be to consider the brain as a system of coordinated components, a network in which different parts function together collaboratively to

accomplish a goal. This approach to studying the brain in autism has resulted in a theory called the Cortical Underconnectivity Theory of autism (Just et al., 2004), according to which, the communication between frontal and posterior brain regions is impaired in autism, negatively affecting the coordinated network functioning during task performance. In other words, the brain is functionally and structurally underconnected in autism, particularly when complex cognitive and social functions are processed. In this chapter, we will discuss cortical underconnectivity as an emerging theory of autism and its potential implications at the neural and behavioral domains. In addition, we will also relate the underconnectivity theory to various other neuropathological findings in autism research.

Cortical Underconnectivity Theory of Autism

The performance of any task is associated with the co-activation of multiple cortical and subcortical regions, and successful task performance depends on the effective integration of neural output from the distinct brain regions involved (Tononi, Edelman, & Sporns, 1998). This integrative functioning of cortical regions may be compromised in individuals with autism. According to the Cortical Underconnectivity Theory (Just et al., 2004), autism is a cognitive and neurobiological disorder marked by underconnectivity among cortical regions that results in a deficit of integration of information at the neural and, therefore, cognitive levels. The first-discovered indication of the underconnectivity was the reduced synchronization between the functional MRI (fMRI)-measured activation in co-activating cortical areas, referred to as *functional underconnectivity* (See Box 54-1). More recent elaborations of the underconnectivity theory localize the functional underconnectivity to frontal-posterior synchronization (Just et al., 2007), relate the underconnectivity to properties of cortical white matter, and construe the underconnectivity as a limitation on frontal-posterior bandwidth. Bandwidth is a critical factor in the performance of a computational network, referring to the amount of information that can be transmitted between the nodes of the network per unit time. Neuroimaging research has been very clear that human thought involves a network of cortical areas whose activity is coordinated (Just & Varma, 2007), and that coordination has to be based on inter-regional communication, using the white matter tracts that provide the anatomical connectivity.

The fMRI findings emerging in the last few years indicate that the synchronization between frontal and posterior areas is lower in autism in many diverse tasks, such as sentence comprehension (Just et al., 2004), verbal working memory (Koshino et al., 2005), executive functioning (Just et al., 2007), attribution of mental states to animated shapes (Kana et al., 2009), visuomotor coordination (Villalobos et al., 2005), visual imagery in sentence comprehension (Kana et al., 2006),

response inhibition (Kana et al., 2007), processing of fearful faces (Welchew et al., 2005), discourse processing (Mason et al., 2008), and working memory for faces (Koshino et al., 2008). In brief, functional imaging studies are providing evidence of underconnectivity in the distributed networks of cortical centers that subserve the core symptoms in autism, including social cognition, language comprehension, and reasoning. The synchronization across time-points is independent of the absolute levels of activation in the two areas, and vice versa, so the fMRI findings of functional underconnectivity are providing an entirely different and richer account of the coordination of activation across brain areas.

A particularly interesting case of underconnectivity occurs in people who are just relaxing when their brain goes into what is called *a resting state* or a *default mode*. Even in that state, the degree of synchronization between the frontal and posterior parts of the default mode network is lower in people with autism (Cherkassky et al., 2006). This result shows that the brain characteristics of autism are manifest not just when a person is performing a particular cognitive or social task, but even when they are just relaxing. The brain marker of underconnectivity in autism is present in the resting state.

The common finding of cortical underconnectivity across all of the studies mentioned earlier highlights the pervasiveness

---

Box 54–1
Measurement of functional connectivity

Functional connectivity (the temporal correlation of brain activity in spatially separated areas) can be measured by several different approaches. In our approach, it is usually computed separately for each participant, as a correlation between the activation time-course averaged over all of the activated voxels in each member of a pair of activated regions of interest. In our approach, the following steps are used: *(1)* Functional regions of interest (ROIs) are manually defined on the group activation map to encircle the main clusters of activation. A sphere is defined for each cluster (with a radius of approx. 8–14mm) that best captures each cluster of activation in the activation map. *(2)* The time-course of the fMRI signal from each ROI is extracted from individual subjects' data based on the normalized and smoothed images. The activation time-course is based on the mean activation level of only the activated voxels within the ROI (minus their baseline level established during "rest" periods). *(3)* The functional connectivity between two ROIs is computed as the correlation between their activation time-courses, which is then converted to Fisher's "z"-score to test for statistical differences. Further analyses can be carried out by grouping the ROIs into different sets of ROI pairs (such as frontal-parietal pairs, or temporal-occipital pairs, etc.) to compare the functional connectivity between autism and control groups for a given set of ROI pairs. It is in the frontal-posterior pairs where the functional connectivity has usually been found to be lower in autism during the performance of high-level tasks.

of the frontal-posterior undersynchronization of brain regions in autism. In addition to the findings from brain imaging studies, results of several behavioral studies of autism provide evidence for an information processing style relying on reduced frontal-posterior integration and coordination. For example, people with autism are not impaired when processing the meaning of individual words (Eskes, Bryson, & McCormick, 1990; Frith & Snowling, 1983) but have difficulty in integrating the meaning of different words in a sentence (Goldstein, Minshew, & Siegel, 1994). In these cases, the trouble seems to be not at the level of comprehending individual word meanings but at the level of integrating these word meanings to form a more complex representation. This type of focusing on unintegrated components may stand in the way of comprehending complex linguistic discourse (such as irony, metaphor, ambiguity, and puns) and understanding complex social situations (such as face processing, gaze processing, and joint attention), all of which require a coordination among the psychological processes that operate on the components of a larger array of information. At the same time, the focus on the processing of components of an array may be advantageous when the properties of the larger array may interfere with processing of a component (as might occur in finding an embedded figure whose presence is occluded by the larger array). The Cortical Underconnectivity Theory attempts to explain not only the deficits in autism but also the relative sparing of some functions.

Underconnectivity theory also provides an alternative framing for previous theories of autism, providing a link between the behavioral characteristics of autism to the underlying biological substrate. For example, both the weak central coherence theory (Frith, 1989; Happe & Frith, 2006) and the enhanced perceptual functioning proposal (Mottron et al., 2001; 2006) emphasize that people with autism have difficulty integrating parts of information into a meaningful whole. Underconnectivity theory also predicts this weak coherence among ongoing processes, by virtue of poorer communication and collaboration among brain areas associated with such processes. The complex information processing deficit approach (Minshew et al., 1997) attributed autism to a fundamental inability in handling information in complex tasks requiring abstraction. Tasks that are considered more complex typically require more participation of frontal areas, and the postulated underconnectivity to frontal areas would account for the impaired performance in such tasks.

Cortical Underconnectivity Theory is also in agreement with other neural models such as the temporal binding deficit hypothesis of autism (Brock et al., 2002). According to this hypothesis, it is the impairment of temporal binding *between* local networks that results in the deficits found in autism, whereas temporal binding mechanisms *within* local networks may be intact or possibly enhanced. Binding entails communication, and an impairment in communication will impair binding. Overall, the theme of several cognitive and neurological theories points to an underlying deficit in cortical connectivity in autism.

The Generality and Specificity of Underconnectivity

Investigations into the generality and specificity of the manifestation of underconnectivity in autism have found that underconnectivity is more pronounced in the communication to and from the frontal lobe. Again, one area of difference in functional connectivity found between autism and control participants is between frontal and parietal networks. Frontal-parietal underconnectivity has been reported in executive functioning (Just et al., 2007), in visual imagery in sentence comprehension (Kana et al., 2006), in a response-inhibition task (Kana et al., 2007), and in working memory for faces (Koshino et al., 2008). Hence, the theory posits that the communication bandwidth between frontal and posterior cortical regions is lower in participants with autism than in typical participants.

Reduced functional connectivity is not confined to a particular domain or task but is likely to be a general phenomenon at least across the neural systems involved in high-level cognition. At the cognitive level, the demand for communication between frontal and posterior regions is greater in relatively complex tasks, such as problem-solving, working memory, attribution of mental states, and language comprehension.

By contrast, functional connectivity within and between the relatively posterior brain areas has been found to be intact or sometimes superior in people with autism. This intact functional connectivity is centered mainly in the occipital-parietal areas (e.g., Villalobos et al., 2005). The higher connectivity in autism, seen mainly in the visual or visuospatial brain areas, is not surprising considering the behavioral findings of relative preservation of visuospatial ability in autism (Shah & Frith, 1983; Caron et al., 2004, Ring et al., 1999; Mottron & Burack, 2001). People with high-functioning autism might resort to an information processing style that is less reliant on frontal participation and more reliant on posterior visuospatial processing. In this perspective, this is not an information processing style chosen as a preference by people with autism but a brain systems adaptation to reduced frontal input. It is possible that people with autism have difficulty in solving tasks that have high cognitive and social processing demands that are normally accomplished with the involvement of frontal regions, and to compensate for this limitation, they rely on visuospatial processing that draws more on posterior cortical regions.

Informational connectivity with the frontal lobe may be impaired in autism because of several structural and functional abnormalities found in this region (discussed later in this chapter). These structural and functional abnormalities might be the underlying problem that results in underconnectivity between the frontal lobe and other regions in autism (although other causal interpretations cannot be dismissed). In the following sections, we will discuss how the autistic brain responds to cortical underconnectivity and

also how structural abnormalities in autism might affect functional connectivity.

How Does the Autistic Brain Adapt to Underconnectivity?

If autism is characterized by decreased frontal-posterior communication bandwidth, then one might expect to see concomitant adaptations in cortical functioning. Just et al. (submitted) propose a computational model of an executive functioning task that accounts for the some of the autism brain activation findings in fMRI studies. One of the main contributions of the model is the insight it provides into how a bandwidth constraint could bring about a consequent adaptation. The model is instantiated within a computational theory of the cortical neuroarchitecture, 4CAPS, which characterizes cognitive functioning as the emergent product of the collaborative activity of a set of co-activating brain centers that are in communication with each other (Just & Varma, 2007). In the autism model, the bandwidth limitation is implemented as a limitation on the amount of information that can be communicated per unit time between any frontal center and any posterior center. (This limitation could result from compromised structural integrity of some of the white matter tracts that carry the communication [Keller et al., 2007].) In addition to modeling the decreased frontal-posterior bandwidth, the model also implements an increase in parietal autonomy in autism. This adaptation may arise in response to the decreased frontal-parietal bandwidth. In particular, the task that the participants were performing was a visuospatial problem-solving task (Tower of London), which evokes substantial frontal and parietal activation. Because the input from the frontal center is slow in coming (because of the bandwidth limitation), the system, in some straightforward cases, proceeds to make a move in the task without the benefit of the frontal input. In effect, this adaptation accords greater autonomy to the parietal centers.

More generally, the cortical infrastructure of thought could adapt to a lower frontal-posterior bandwidth by relying less on collaboration with frontal nodes and instead functioning more autonomously of the frontal nodes. This would be an instance of a resource limitation exerting a shaping influence on the functional architecture of the network.

The proposal of greater reliance on posterior cortical regions in autism is reflected in the brain activity observed in autism. Several fMRI studies have shown a decrease in frontal activation in autism with an increase or no difference in activation in posterior regions, such as parietal and occipital areas (e.g., Ring et al., 1999; Kana et al., 2006; Kana et al., 2007; Koshino et al., 2005). Another possible form of adaptation in autism to frontal-posterior underconnectivity is higher connectivity between other pairs of other regions, such as cortical and subcortical regions (Mizuno et al., 2006). It is extremely likely that whatever the initial biological impact that autism imposes on the brain, the subsequent development and learning in the dynamic brain system establishes widespread adaptations to the system.

Structural and White Matter Correlates of Functional Underconnectivity in Autism

Could the functional underconnectivity in autism (the limited frontal-posterior bandwidth) result from an underlying structural abnormality? Structural limits on communication between regions in the brain may cause computational changes to evolve to deal with a pattern of reduced connectivity. Two different MRI-based methods have been used for the investigation of structural abnormalities in autism: (1) MRI morphometry examining the volumes of various gray and white matter structures and (2) diffusion tensor imaging (DTI) to examine the structural integrity of white matter. As mentioned earlier in this chapter, some of the autism volumetric results have been inconsistent. However, one of the more consistent volumetric findings is the abnormality in brain volume in autism. For example, an increase in brain size (Aylward et al., 2002; Piven et al., 1995) with substantial size difference in early development (Courchesne, Carper, & Akshoomoff, 2003; Sparks et al., 2002; Courchesne et al., 2001) has been reported in autism. The greater brain size in early childhood in autism might well be related to compromised interconnectivity between specialized neural systems, giving rise to a more fragmented processing structure (Herbert, 2005; Schultz, 2001).

Another relatively consistent morphometric finding in autism is the smaller size of the corpus callosum (Vidal et al., 2003; Hardan et al., 2000; Manes et al., 1999; Piven et al., 1997; Egaas et al., 1995). Because the corpus callosum is a major white matter tract, an abnormality of its volume may be an index of a more general compromise of white matter. Such white matter abnormalities may contribute to diminished functional connectivity patterns in autism. In a comparison of structural and functional measures of cortical connectivity, we reported that across individuals with autism, the lower frontal-posterior functional connectivity (i.e., lower synchronization) was correlated with the (relatively reduced) size of the corpus callosum (Just et al., 2007; Kana et al., 2006). The findings suggest the possibility that in autism, the compromised properties of the white matter (measured indirectly in terms of corpus callosum size) constrain the communication between frontal and posterior regions (measured by the functional connectivity). By contrast, in control participants, the white matter is assumed not to constrain the normal range of functional connectivity, and accordingly, there is no correlation between corpus callosum size and functional connectivity in control participants. Later in this section, we will further discuss the role white matter structures may play in functional connectivity.

Underconnectivity theory brings to light the role of the frontal cortex by postulating its impaired communication with the rest of the cortex. (Impaired executive function theory [Hughes et al., 1994; Pennington et al., 1998] and impaired complex information processing theories of autism [Minshew et al., 1997] are also suggestive of a compromised role of frontal cortex.) Evidence concerning brain structure is consistent

with this emphasis. Abnormalities such as delayed maturation of the frontal lobe (Zilbovicius et al., 1995), increased frontal cortical folding (Hardan et al., 2004), anatomical shifting of major sulci in the frontal lobe (Levitt et al., 2003), localized enlargement of the frontal lobe (Carper & Courchesne, 2005), and maldevelopment in minicolumns in the frontal cortex (Buxhoeveden et al., 2004; Casanova et al., 2002) have been reported in autism. White matter abnormalities have also been reported in the radiate compartment of the frontal lobe (Herbert et al., 2004).

The structural abnormalities of the frontal lobe raise interesting questions about the causal pathway through which underconnectivity enters into autism. It may be that abnormalities in the white matter connecting frontal to posterior areas are the primary cause and that the changes in frontal gray matter are a consequence of its inability to communicate normally with posterior parts of the brain. This causal account stands in contrast to (and is difficult to empirically distinguish from) the possibility that the primary abnormality is in the frontal gray matter, an abnormality that leads to decreased attempts to communicate with posterior areas, which in turn may lead to less use of frontal-posterior white matter tracts and hence to their deterioration. Because the system develops dynamically, with interplay between gray and white matter, it is difficult to determine which facet is primary and which is a consequence.

Taking into consideration several structural abnormalities observed in the frontal lobe in autism, Courchesne and Pierce (2005) have suggested that the connectivity *within* the frontal lobe may be excessive, disorganized, and inadequately selective, whereas connectivity between frontal cortex and other systems may be poorly synchronized, weakly responsive, and informationally impoverished. The frontal cortex may be functioning abnormally in itself, or it may be abnormal in its interaction with posterior collaborating centers. Abnormal interaction could result from a failure to develop, modify, or prune various connections during the development of the neuropil (Zilbovicius et al., 1995). In brief, the structural and developmental abnormalities in the frontal lobe may contribute to underconnectivity in autism. The prefrontal cortex, an area that has been consistently implicated in the etiology of behavioral disorders, has profuse afferent and efferent axonal connections with multiple neocortical, subcortical, and limbic regions (Fuster, 2001; Mesulam, 1985). Several of these connections are reciprocal and provide the anatomic substrate for the prefrontal lobe to temporally coordinate its functioning with other cortical areas in performing functions like language, problem-solving, and memory. Results of functional MRI studies have consistently reported atypical activation and synchronization of brain areas (especially frontal-posterior) in autism during the performance of higher cognitive functions.

The findings of abnormalities in brain structures in autism suggest that the connectivity between cortical regions could be altered in autism in several ways (Boddaert & Zilbovicius, 2002). Findings of delayed maturation of frontal lobe circuitry in autism (Zilbovicius et al., 1995), decreased functional connections within the cerebral cortex and between the

cortex and subcortical regions (Horwitz et al., 1988), and abnormalities of the dentato-thalamo-cortical pathways (Chugani et al., 1997) suggest that connection abnormalities could be the basis of autism.

Another facet of structural abnormality in autism is related to the integrity of the white matter fibers. Widespread white matter volumetric abnormalities (increased volumes in some areas and decreased volumes in other areas) have been found in individuals with autism (Herbert et al., 2003), indicating connectivity disruption. A recent DTI study of autism involving a large sample size and a wide age range (Keller, Kana, & Just, 2007) demonstrated reductions in the structural integrity of white matter, measured by fractional anisotropy (FA), in the corpus callosum area and in frontal lobe areas near the corpus callosum in child and adult participants with autism. FA of water diffusion refers to the directional selectivity of the random motion of water molecules within a tissue (Basser, 1994; Pierpaoli & Basser, 1996). Lower FA values may reflect decreased fiber density, reduced myelination of fiber tracts, or less directionally coherent organization of fibers within a voxel (Basser, 1995; Pierpaoli & Basser, 1996; Beaulieu, 2002), all of which could reflect decreased anatomical connectivity in autism. At least one study (Ben Bashat et al., 2007) found increased FA in two young children with autism spectrum disorder (ASD). However, the age range in that study was 1.8 to 3.3 years, which is around the same time increased brain volume is first seen in ASDs. Our study as well as others (e.g., Barnea-Goraly et al., 2004) used children older than age 8 years, and the results show reduction in FA in ASD.

Note that the white matter abnormalities in autism include not only smaller white matter volumes in some regions but also larger white matter volumes in other regions (Herbert et al., 2002; Courchesne et al., 2001). For example, Carper et al. (2002) found both frontal and parietal increased white matter volumes in children with autism compared to typically developing children.

Based on studies of white matter differences in autism, several researchers have recently proposed disconnection as a key characteristic of autism, such as Belmonte et al. (2004), Courchesne & Pierce (2005), Herbert et al. (2004), and Rippon et al. (2006). This proposal converges with the findings of functional connectivity abnormalities in autism (Just et al., 2004). The findings of morphometric abnormalities, white matter abnormalities, and aberrant activation in complex tasks in autism all suggest that autism is a neural systems disorder that involves the development of abnormal systems connectivity.

Microstructural Abnormalities in Autism and Their Relation to Cortical Underconnectivity

The lower frontal-posterior functional connectivity observed in autism in multiple social and cognitive tasks could possibly result from several underlying microstructural abnormalities.

Earlier we discussed one such possibility: abnormalities related to the structural integrity of white matter. In addition, several early neurodevelopmental processes (such as neuronal migration and axonal pathfinding) could be abnormal. The period of initial cortical plate formation in the human telencephalon is 7 to 10 gestational weeks; neuronal proliferation, 8 to 16 gestational weeks; neuronal migration, 12 to 20 weeks; and development of six-layered cortex, following migration (Volpe, 2001). Neuronal migration abnormalities have been reported in post-mortem cases of autism (Bailey et al., 1998). Developmental alterations in axon number, axon pathfinding, synaptogenesis, and subsequent pruning of axons could result in abnormalities in white matter tracts involving selective disruption of both long-range as well as local connections (Geschwind & Levitt, 2007). Thus, the alterations found in functional and structural connectivity in the autistic brain could be the consequence of at least one neurodevelopmental process.

Abnormalities associated with glial cells may also play a role in maldevelopment of brain structure and connections. Specialized glial cells called *oligodendrocytes* support neurons by creating an insulating myelin sheath around some axons, increasing its bandwidth by a factor of 10. If these cells were in some way underfunctioning, they could fail to adequately build up the myelin sheath that enables higher-bandwidth transmission of information through bundles of axons and provides connectivity between cortical centers. Evidence of astroglial and microglial activation and neuroinflammation in gray and white matter (in samples taken from the middle frontal gyrus, anterior cingulate gyrus, and posterior cerebellar hemispheres) have been found in studies of autistic postmortem cases (Vargas et al., 2005). Glial cells are also involved in neural migration, structural formation of the minicolumn, minicolumn function, and apoptosis (Marin-Teva et al., 2004). Defects associated with the organization of minicolumns in autism could be the result of abnormalities in neuronal migration. Migration abnormalities could alter the fundamental vertical organization of the minicolumns, which would lead to fractionated and incompletely or aberrantly formed minicolumn vertical circuitry, as well as an imbalance between excitation and inhibition within and between minicolumns (Courchesne et al., 2005). Minicolumn abnormalities (more numerous and abnormally narrow minicolumns in frontal and temporal cortex) have been reported in autism (Casanova et al., 2002). This would create an abundance of short connective fibers relative to long ones, which may indicate a deficiency in long distance (inter-regional) connectivity.

Yet another possibility is that abnormalities in neurochemistry could lead to abnormal brain development. Studies using magnetic resonance spectroscopy have been helpful in examining the brain neurochemistry in autism. Regionally specific reductions in N-acetylaspartate (NAA; an amino acid present predominantly in neurons and axons [Baslow, 2003] that impacts the neuronal integrity) have been reported in autism. Some of the regions with NAA reduction include cingulate gyrus, temporal gray matter, frontal and parietal white matter, hippocampal-amygdaloid complex, and cerebellum (Friedman

et al., 2003; Hisaoka et al., 2001; Levitt et al., 2003; Otsuka et al., 1999). Several researchers have proposed that dysfunction of another amino acid, glutamate, could be of etiological relevance to autism (Carlsson, 1998; Polleux & Lauder, 2004; Rubenstein & Merzenich, 2003). Glutamate plays an important role in neurodevelopmental processes, including neuronal migration, differentiation, axon genesis, and plasticity (Coyle, Leski, & Morrison, 2002). Thus, irregularities in brain neurochemistry could be a potential factor in the abnormal development of connections and, hence, atypical brain functioning in people with autism.

Relevance to Intervention and Training

With converging findings of brain connectivity abnormalities emerging in the field of autism research, an obvious question, especially from parents, families, and educators, is how this new understanding of brain function in autism might lead to a potential remedy or treatment program. The effectiveness of behavioral training programs in modifying brain function has been documented previously in studies of stroke patients using constraint-induced therapy (Taub, Uswatte, & Morris, 2003; Liepert et al., 2000) and in children with reading disability using instructional training (Temple et al., 2003; Meyler et al., 2008). The main target of such an approach in autism would be the improvement of communication among brain areas or improving the strength and integrity of white matter fibers connecting various brain regions. One possible treatment research direction is to develop a training regimen in a task that requires extensive repeated frontal-posterior communication, as many executive tasks do. Functional and structural brain imaging techniques could assess the brain activation, functional connectivity, and white matter connectivity before, during, and after training. One study that provided 100 hours of intensive remedial reading instruction over 6 months to 8- to 10-year-old children who were poor readers produced a reliable increase in the structural integrity of their white matter in a region that had shown lower-than-normal integrity prior to the intervention (Keller & Just, 2009). Specifically, DTI measures showed improvement of the white matter after behavioral remediation treatment. Moreover, the amount of white matter improvement in an individual child was correlated with the amount of improvement in their reading performance, indicating the relevance of the white matter change to the cognitive functioning. These remediation findings in children who were poor readers are a promising harbinger for ameliorating connectivity deficits in autism with analogous therapy programs.

Cognitive and behavior-based intervention programs can attempt to strengthen the connections among relevant brain areas. The use of explicit instructions and selective reinforcements would be a starting point in such programs. For example, one of the key findings in the domain of face processing is that people with autism tend not to look at the

eye region or the whole face but focus on isolated features, such as the mouth or ear. Such an isolated or detailed processing style would mean a failure to view the face in an integrated and holistic manner, which typically would be facilitated by the coordinated functioning of the face processing area in the brain and the frontal regions and emotion-related regions. For example, the connections among the fusiform face area (face perception), amygdala (emotion), and inferior frontal gyrus (semantic coding) may play a role in processing face information within a social context. However, in autism, the fragmented processing style is accompanied by weaker functional connectivity among these regions (Koshino et al., 2007), suggesting that in autism, there may be a lack in coordinating different types of information about a face. Intervention programs that encourage integrated, coordinated processing could possibly improve the connectivity. And to the extent that a particular neurobiological substrate of underconnectivity is eventually identified (say, possibly, oligodendrocyte activity), pharmacological agents could be developed to regulate that activity. More generally, deeper scientific understanding of the nature of autism inherently provides new clues for possible therapeutic approaches.

Conclusion

Cortical Underconnectivity Theory provides a compelling framework for explaining the cognitive and behavioral impairments in people with ASDs. The theory explains not only the deficits of people with autism (cognitive, social, and complex language) but also their strengths (visuospatial processing). The theory also provides accounts for many of the phenomena prior theoretical accounts of autism have focused on, such as the complex information processing deficit, executive dysfunction hypothesis, and the theory-of-mind account. The underconnectivity theory encourages the design of training programs for children with autism that focus on targeting and improving the cross-communication between different areas of the brain.

Challenges and Future Directions

- **Developmental studies:** Because autism is a developmental disorder, the connection abnormalities found in autism might either be a disruption of previously connected regions or a failure in the normal development of connections among the regions (Geschwind & Levitt, 2007). Future studies might focus on longitudinal as well as cross-sectional studies examining connectivity across different age groups. Functional MRI and DTI studies at very early ages in autism (DTI studies are quite possible in infancy), as well as at later stages, can trace the developmental trajectory of cortical connectivity in autism in comparison to control groups.

- **Novel measurement techniques:** Functional connectivity in autism has been examined mainly by the use of functional MRI. Because functional connectivity measures the synchronization of brain activation, future studies and some in progress will use techniques such as magnetoencephalography (MEG) and electroencephalography, which both have much higher temporal resolution than fMRI. As of now, there are very few MEG studies in the field of autism. In addition, the measures of functional connectivity can be supplemented by measures of white matter integrity (using DTI) and brain neurochemistry (using magnetic resonance spectroscopy). Furthermore, using these varied approaches in conjunction with each other may provide an enriched characterization of cortical connectivity in autism.

The Extreme Male Brain Theory of Autism: The Role of Fetal Androgens

Points of Interest

- There are sex differences in neuroanatomy, neural function, cognition, and behavior in the general population.
- People with ASD show an extreme of the typical male profile in terms of empathy and systemizing.
- Whether such hyper-masculinization is evident at the level of neuroanatomy and neural function in ASD remains to be tested.
- Fetal testosterone (fT) is known from animal research to play an organizing role in brain development.
- fT associated with individual differences in eye contact, vocabulary development, empathy, systemizing, attention to detail, and autistic traits in typically developing children.
- It remains to be tested whether fT is elevated in children who go on to develop an ASD.

Autism and Asperger Syndrome (AS) are autism spectrum disorders (ASDs). The diagnosis rests on the presence of difficulties in reciprocal social interaction and communication, along with strongly repetitive behavior and unusually narrow interests (A.P.A., 1994). The prevalence of ASD is currently estimated to be 1% (Scott et al., 2002). Autism spectrum disorder is biased toward males (Fombonne, 2005) with a 4:1 (male:female) ratio for classic autism (Chakrabarti & Fombonne, 2001) and 8:1 for AS (Scott et al., 2002). Classic autism and AS differ in terms of the presence of additional learning difficulties and language delay (in classic autism only). Autism spectrum disorders are neurobiological and genetic (Stodgell et al., 2001), but the specific factors responsible for the higher male incidence in ASDs remain unclear. One possible factor is that ASDs may be an extreme of the male brain (Baron-Cohen, 2002).

The Extreme Male Brain: Psychology

The extreme male brain (EMB) theory of autism is an extension of the empathizing-systemizing (E-S) theory of typical sex differences (Baron-Cohen, 2003). The latter theory proposes that females, on average, have a stronger drive to *empathize* (to identify another person's thoughts and feelings and to respond to these with an appropriate emotion), whereas males, on average, have a stronger drive to *systemize* (to analyze or construct rule-based systems) (Baron-Cohen, 2003). Evidence relevant to this is as follows: Individuals with ASD score higher on the systemizing quotient (SQ), an instrument on which typical males score higher than typical females (Baron-Cohen et al., 2003; Auyeung et al., 2006; Wheelwright et al., 2006). Individuals with ASDs have intact or superior functioning on tests of intuitive physics (Baron-Cohen et al., 2001; Lawson et al., 2004), a domain that shows a sex difference in favor of males (Lawson et al., 2004). Individuals with ASDs are faster and more accurate than controls on the Embedded Figures Task (EFT), a task on which typical males perform better than typical females (Shah & Frith, 1983; Jolliffe & Baron-Cohen, 1997). The EFT requires good attention to detail, a prerequisite for systemizing. All of these are relevant to systemizing.

On the empathizing quotient (EQ) (Baron-Cohen & Wheelwright, 2004), individuals with ASDs score lower than control groups, whereas typical females score higher than typical males (Baron-Cohen & Wheelwright, 2004). Individuals with ASDs score lower than typical males on the "Reading the Mind in the Eyes" task (Baron-Cohen et al., 1997), the Social Stories Questionnaire (Lawson et al., 2004), on tests of recognizing complex emotions from videos of facial expressions or audios of vocalizations (Golan et al., 2006), and on the Friendship and Relationship Questionnaire (which tests the importance of emotional intimacy and sharing in relationships)

(Baron-Cohen & Wheelwright, 2003). All of these are tests of empathy. On the Childhood Autism Spectrum Test (CAST) (Scott et al., 2002; Scott et al., 2002), boys score higher than girls (Williams et al., 2008), and children with ASDs score higher than controls (Williams et al., 2005). On the autism spectrum quotient (AQ) (Baron-Cohen et al., 2001a), individuals with ASDs score higher than those without a diagnosis (Baron-Cohen et al., 2001). Among controls, males score higher than females (Baron-Cohen et al., 2001; Baron-Cohen et al., 2006; Auyeung et al., 2008), a finding that has been reported cross-culturally (Wakabayashi et al., 2004; Wakabayashi et al., 2006; Wakabayashi et al., 2007; Hoekstra et al., 2008). Similar results have been found using the Social Responsiveness Scale (SRS), finding that individuals with an ASD diagnosis score higher than typical males, who in turn score higher than typical females (Constantino & Todd, 2005). All of these are measures of autistic traits.

The Extreme Male Brain: Biology

Characteristics of neurodevelopment in autism may also represent an exaggeration of typical sex differences in brain development (Baron-Cohen et al., 2005). For example, there is larger overall brain volume in males during childhood (Giedd et al., 1996), and in ASDs, this may be even more extreme (Courchesne et al., 2004). There is greater growth of the amygdala in males during childhood (Merke et al., 2003), and in ASDs, this may be even more extreme (Sparks et al., 2002). The posterior section of the corpus callosum is thicker in females than males (Jancke et al., 1997) and in ASDs is even thinner than is typical (Herbert et al., 2004). These are all volumetric measures of the brain. Using fMRI, typical females show increased activity in the extrastriate cortex during the EFT and increased activity bilaterally in the inferior frontal cortex during the "Reading the Mind in the Eyes" Test compared to typical males (Baron-Cohen et al., 2006). People with ASDs show even less activity in each of these regions during these tasks (Baron-Cohen et al., 1999; Ring et al., 1999). Parents of children with ASDs also show hyper-masculinization of brain activity (Baron-Cohen et al., 2006), suggesting that this may be part of the broader autism phenotype. These are all functional neuroimaging measures of the brain. It remains important to identify the biological mechanisms that cause such sexual dimorphism. One possible biological mechanism is the effect of fetal testosterone (fT) (Geschwind & Galaburda, 1985), reviewed in the next section.

The Role of Fetal Testosterone in Brain Development

Fetal gonadal hormones (including the androgens [e.g., testosterone, dihydrotestosterone], estrogens [e.g., estradiol,
Figure 55–1. The Empathizing-Systemizing Model of Typical Sex Differences. The main brain types are illustrated on axes of Empathising (E) and Systemising (S) dimensions (numbers represent standard deviations from the mean). Balanced brain (Type B); female brain (Type E), male brain (Type S); the extreme Types E and S lie at the outer borders. According to the 'extreme male brain' theory of autism, people with ASD will generally fall in the darkest region. Modified with permission from Baron-Cohen, S. (2002). The extreme male brain theory of autism. *Trends in Cognitive Science, 6*, 248–254.

estrone, estriol], and progestins [e.g., progesterone]) lead to the differentiation of the male and female phenotype (Fuchs & Klopper, 1983; Tulchinsky & Little, 1994; Kimura, 1999; Hines, 2004). If androgens and the androgen receptors are present, the male genital phenotype will develop. If not (as seen in Complete Androgen Insensitivity Syndrome), the female genital phenotype will develop (Jost, 1961; Jost, 1970, 1972; George et al., 1992). Fetal gonadal hormones are essential for sexual differentiation of both the body and the brain (Goy, 1980; Fitch & Denenberg, 1998). In what follows, we summarize some key points in this process. Three surges in testosterone levels are known to occur. The first surge is between weeks 8 and 24 of gestation (Collaer & Hines, 1995; Baron-Cohen et al., 2004; Hines, 2004). Most of the prenatal androgen effects occur between 7 and 12 weeks of gestation (Rommerts, 2001). Then, after birth, a second peak in circulating testosterone occurs in human male infants. Usually the levels remain in the pubertal range for a few months and then drop to the barely detectable levels observed in childhood by age 4 to 6 months (Smail et al., 1981). Finally, the third surge is associated with puberty. Individuals vary both in the levels of hormones to which they are exposed and in their sensitivity

to those hormones. Variations in androgen responsivity (caused by mutations in the human androgen receptor gene) can result in complete insensitivity to androgens (and thus female differentiation) or to infertility and minor undervirilization (Casella et al., 2001). The timing of hormonal effects influences whether effects are organizational or activational (Goy, 1980). Organizational effects produce *permanent* changes in the brain (Phoenix et al., 1959) and are most likely to occur during early development when most neural structures are becoming established. The discovery of such organizational effects of fT came from animal research (mostly rodents), and to date, these have only looked at neuroanatomy or limited aspects of behavior (spatial ability and mating). Activational effects occur later and are associated with concurrent changes in circulating hormone levels (Kimura & Hampson, 1994; Cooke et al., 1999).

Fetal Androgens Affect Brain and Behavior: Evidence from Rare Medical Conditions

Although animal research provides strong evidence for the effect of hormones in development, the direct manipulation of hormones in human fetuses is unethical. Instead, researchers have studied people, in whom for medical reasons the sex hormones are higher or lower than expected for a person's sex (Money & Ehrhardt, 1972). Two examples are *Congenital Adrenal Hyperplasia (CAH)* and *Complete Androgen Insensitivity Syndrome (CAIS)*. Congenital Adrenal Hyperplasia is a condition in which an enzymatic defect (usually caused by mutations in the gene coding for 21-hydroxylase) results in high levels of adrenal androgens, beginning very early in gestation. It has an incidence of 1 in 10,000 to 1 in 15,000 live births (Grumbach et al., 2003). Females with CAH differ from unaffected females (their siblings or age- and sex-matched controls) in spatial orienting, visualization, and targeting (Resnick et al., 1986; Hampson et al., 1998; Hines et al., 2003b). Females with CAH are also more likely than controls to be left-handed (Nass et al., 1987), although the difference is small and inconsistent. Females with CAH are more interested in male-typical activities and less interested in female-typical activities (Ehrhardt & Baker, 1974; Berenbaum & Hines, 1992; Berenbaum & Snyder, 1995; Berenbaum, 1999; Hines et al., 2004). Girls with CAH score lower than sex-matched controls on measures assessing empathy, intimacy, and the need for close social relationships (Mathews et al., 2009; Helleday et al., 1993; Resnick, 1982; Kuhnle & Bullinger, 1997). Individuals with CAH showed higher levels of language and learning difficulties than unaffected family members (Resnick et al., 1986). All these changes can be interpreted as masculinization.

Complete Androgen Insensitivity Syndrome is a second example of a rare medical condition affecting prenatal endocrine responses. It occurs when there is a complete deficiency of working androgen receptors. It is an X-linked recessive disorder and hence occurs more often in genetic males.

Prevalence is between 1 in 20,000 and 1 in 60,000 live male births. At birth, genetic male infants with CAIS are phenotypically female, despite an XY complement, and are usually raised as girls. At puberty, breasts develop under the influence of estrogen derived from testicular androgens. Diagnosis usually takes place when menarche fails to occur (Nordenstrom et al., 2002; Grumbach et al., 2003). In studies, gender identity has not differed between genetic males with CAIS and control women (Quadagno et al., 1977; Hines et al., 2003a). Individuals with CAIS perform in a female-typical fashion on tests of visuo-spatial ability (Money et al., 1984).

These findings suggest that two X chromosomes or functioning ovaries are not required for feminine-typical psychological development in humans and highlight the role of androgen receptors in influencing masculine-typical psychological development. However, existing studies have not examined all sexually dimorphic aspects of neurobiology and cognition in these populations. Therefore, one cannot rule out an effect of X-chromosome genes or ovarian hormones on some aspects of sex-typical neurodevelopment.

Fetal Androgens Affect Brain and Behavior: Evidence from Amniotic Fluid Testosterone

Another approach to testing if fetal androgens affect brain and behavior is to measure fT in amniotic fluid obtained during routine diagnostic amniocentesis. An advantage of this approach is its timing. It is typically performed during the second trimester of pregnancy (usually 14–20 weeks of gestation) that coincides with the serum testosterone peak period in male fetuses. Several studies have documented a large sex difference in amniotic androgen levels (Judd et al., 1976; Dawood, 1977; Robinson et al., 1977; Nagami et al., 1979; Finegan et al., 1989). The origin of androgens in amniotic fluid is the fetus itself. Hormones enter the amniotic fluid via diffusion through the fetal skin in early pregnancy and via fetal urine in later pregnancy (Judd et al., 1976; Schindler, 1982). Testosterone obtained in amniotic fluid is thought to be a good reflection of the levels in the fetus (van de Beek et al., 2004) and represents an alternative to direct assay of fetal serum that would be unnecessarily invasive. In the Cambridge Fetal Androgen Project, children whose mothers had amniocentesis during pregnancy (but who were otherwise typically developing children) were followed-up after birth at ages 12, 18, 24, 48, and 96 months (Baron-Cohen et al., 2004). Evidence that amniotic testosterone affects cognitive development includes the following. Fetal testosterone is inversely associated with eye contact in males at age 12 months (Lutchmaya et al., 2002). Fetal testosterone is inversely associated with size of vocabulary development at ages 18 and 24 months (Lutchmaya et al., 2002). Fetal testosterone is inversely associated with quality of social relationships, and positively associated with narrow interests, at age 48 months (Knickmeyer et al., 2005). Fetal testosterone is inversely

associated with empathy at ages 48 and 96 months (Chapman et al., 2006; Knickmeyer et al., 2006). Fetal testosterone is positively associated with "systemizing" at age 96 months (Auyeung et al., 2006). Fetal testosterone is positively associated with performance on the EFT, as a measure of attention to detail, at age 96 months (Auyeung et al., submitted). The effect sizes in these studies range from 0.2 to 0.4. Because all of these domains of behavior (eye contact, language development, quality of social relationships, narrow interests, empathy, systemizing, and embedded figures/attention to detail) show sexual dimorphism and may be hyper-masculinized in ASDs, it raises the question as to whether fetal testosterone plays a role in the development of autism. In the final section, we review evidence that androgens—especially fetal testosterone—may play a role in autism or autistic traits.

The Role of Sex Steroid Hormones in Autism Spectrum Disorders or Autistic Traits

Evidence that supports a role for hormones in the development of ASDs is preliminary and includes the following: Androgen-related medical conditions such as polycystic ovary syndrome (PCOS), ovarian growths, and hirsutism occur with elevated rates in women with AS and in mothers of children with autism (Ingudomnukul et al., 2007). Girls with CAH have a higher AQ score than their unaffected sisters (Knickmeyer et al., 2006c). Children with AS and children with classic autism have lower 2D:4D ratios than typical developing children (Manning et al., 2001; Milne et al., 2006). The ratio of the second digit to the fourth digit (2D:4D ratio) is lower in men than in women. The 2D:4D ratio is fixed by week 14 of fetal life (Garn et al., 1975) and is influenced by testosterone (Manning et al., 2002). This suggests children with ASD have been exposed to higher amounts of androgens. A subset of male adolescents with autism show hyper-androgeny, or elevated levels of androgens, and precocious puberty (Tordjman et al., 1997). Delayed menarche has also been found in females with AS (Knickmeyer et al., 2006; Ingudomnukul et al., 2007). Puberty timing reflects hormonal programming of the hypothalamic-pituitary-gonadal axis during gestation (Grumbach & Shaw, 1998).

Left-handedness and ambidexterity are more common in typical males (Peters, 1991) and individuals with autism (Gillberg, 1983). Body asymmetries are related to prenatal sex hormones and breast or testis size on the left versus right sides of the body are related to cognition (Kimura, 1999). Fetal testosterone is implicated in left-handedness and asymmetric lateralization (Fein et al., 1985; Satz et al., 1985; Soper et al., 1986; McManus et al., 1992). The typical male brain is heavier than the female brain, a difference that partly results from fT exposure (Hines, 2004). Individuals with autism have even heavier brains than typical males (Hardan et al., 2001). Amniotic fT levels are positively associated with higher scores

(indicating greater number of autistic traits) on the CAST and on the child autism spectrum quotient (AQ-C) (Auyeung et al., 2008). These findings are consistent with the fetal androgen theory of autism, although the ultimate test of this theory will require testing between fetal testosterone and clinically diagnosed ASDs. The latter will require much larger samples than have previously been tested.

It is important in a review chapter such as this to summarize criticisms of the fetal androgen theory of ASDs. First, if autism is an extreme of the typical male behavioral profile, why do people with ASD not show high levels of aggression or a strong interest in competitive sports? We suspect this criticism reflects a misunderstanding of the different roles that fetal as opposed to current (circulating) testosterone play. The latter may well affect aggression and competitiveness, but fetal androgens may selectively affect very different aspects of cognition such as attention to detail and empathy. This remains to be tested. Second, given that testosterone interacts with multiple systems in the body, why single it out for a special role? We acknowledge that if fT plays a role in ASDs, it is likely to do this in complex ways, as testosterone modulates neurotransmitters (such as GABA) as well as peptide hormones (such as oxytocin), to name just two examples. Understanding such relationships will require testing of multiple systems within the same experiment. Third, given that amniotic testosterone is currently only studied in humans via amniocentesis and only 6% of pregnant women undergo amniocentesis, does this not lead to potentially biased samples? We acknowledge this bias but would note that currently this is the only ethical way to study fT because amniocentesis itself carries a risk of inducing miscarriage (in 2% of cases) and so cannot be justified purely for research on a randomly selected, and therefore representative, sample of pregnant women. The main risk of bias comes from higher maternal age because this is one reason why women are referred for an amniocentesis (being older than 35 years old). For this reason, maternal age is entered as a variable in the regression analysis. All fT effects that have been found remain significant after removing any variance because of maternal age.

A further criticism is that if sex differences in the population are only found when one compares equal numbers of males and females, and if studies of ASDs tend to be biased toward males, is the extreme male brain theory really just a reflection that ASDs affect more males than females? This is a valid concern, but it is interesting that where it is possible to compare equal numbers of males and females with ASDs, typical sex differences are absent, which argues against any risk of circularity. Also, when fT effects are found on behavior, these are seen *within* sex, not just when the sexes are combined. This suggests these are hormone effects rather than a redescription of sex differences. Finally, Skuse and others have pointed out that sex-linked neural and behavioral phenotypes could emerge not just because of hormone effects but genetic effects. We agree that fT is only one of many mechanisms that are likely candidates for giving rise to such sex differences, and indeed our recent candidate gene study identified 10 genes

involved in the sex steroid hormone pathway that were nominally associated with either autistic traits, empathy, or an ASD (Chakrabarti et al., 2009).

Conclusions

The higher incidence of autism in male individuals might provide important clues to the etiology of the condition, which has been described as an "extreme of the male brain" (Baron-Cohen, 2002). The studies reviewed here suggest that prenatal testosterone could be involved in the sex differences in key areas of behavior in the general population (social development, language development, empathy, systemizing, and attention to detail) and to the male vulnerability to autism. These studies suggest that variations in fetal testosterone are related to individual differences in cognition and behavior in typically developing children, but caution needs to be taken when extrapolating these results to individuals with autism. Our ongoing collaboration with the biobank in Denmark that has thousands of amniotic samples will enable a test of the fetal testosterone theory in clinically diagnosed cases of ASD.

Challenges and Future Directions

- Testing the fetal testosterone theory in relation to diagnosed ASD will require tens of thousands of amniotic samples because only 1 in 100 of these are expected to go on to develop an ASD.
- It is an assumption that amniotic testosterone reflects testosterone levels in the brain, but this remains untested.
- Ethically, if it were established that in ASD there are elevated fetal testosterone levels, this does not mean a treatment implication is to block fT, as fT is likely to be involved in many systems, not just the development of autistic traits.

The Mirror Neuron System and Imitation

Points of Interest

- Mirror neurons provide a functional matching between a motor response during the action of the self and a perceptual response to the actions of others.
- Mirror neurons have been recorded in many different areas of the primate brain as well as in songbirds.
- The functional properties of mirror neurons suggest that they are relevant to imitation, a pervasive form of learning and nonverbal communication and affiliation.
- Brain imaging studies have also revealed reduced mirroring responses in patients with autism.
- The reduced mirroring responses in autism have behavioral relevance, because they correlate with the severity of the condition.
- Mirroring responses may be used as biomarker of intervention efficacy.

Imitation is a pervasive form of learning and transmission of culture and has been strongly associated with higher cognitive functions in humans, such as language and the ability to understand other minds (Hurley & Chater, 2005). Reports on imitation deficits in children with autism date back to at least the early 1950s (Ritvo & Provence, 1953). For many years, however, these early findings had little impact on the research on autism. Recently, interest on imitation deficits in patients with autism has been revived by the work of Rogers and Pennington (Rogers & Pennington, 1991). At the same time, recent neuroscience discoveries have revealed neuronal mechanisms that seem ideally suited for imitation. Inevitably, these two lines of research recently merged and provided the first wave of data on the neural mechanisms of imitation in patients with autism.

Cellular Mechanisms of Mirroring

Macaques: Hand-and-Mouth Actions

Less than 20 years ago, depth electrode recordings in macaques demonstrated unexpected sensory properties in neurons located in motor areas and thus discharging—as expected—while the monkey performed a variety of actions. The unexpected sensory properties of some of these motor neurons were such that the neurons would also fire at the sight of someone else's action (di Pellegrino et al., 1992). Thus, the properties of these cells were as if the monkey was watching her own actions reflected by a mirror. Hence, because the discharges of these neurons seem to "reflect" the perceptual aspects of actions of others onto the motor repertoire of the observer, they were called *mirror neurons* (Gallese et al., 1996).

The initial recordings of mirror neurons were obtained in motor areas that coded for hand-and-mouth actions (di Pellegrino et al., 1992; Gallese et al., 1996; Rizzolatti & Craighero, 2004). Neurons in these cortical areas code for a variety of goal-oriented hand actions, such as grasping, holding, manipulating, tearing, bringing to the mouth, and so on. They also code for a variety of mouth actions, such as biting and sucking, and even communicative actions such as lip-smacking, a facial gesture of positive valence. For many years, recordings on mirror neurons have been restricted to two specific brain regions coding these kinds of actions. However, a recent wave of studies has revealed mirroring neural mechanisms in a variety of brain areas and for other kinds of actions, as discussed below. This recent wave of studies has suggested that neural mirroring is not restricted to specific brain regions and specific actions but, rather, may represent a widespread functional mechanism for learning and social interactions.

The mirror neurons for hand-and-mouth action that have been more heavily studied have been divided in two main categories: *strictly congruent* mirror neurons and *broadly congruent* mirror neurons (Rizzolatti & Craighero, 2004). Strictly congruent mirror neurons (approximately one-third of all recorded hand-and-mouth mirror neurons) discharge for the same action, either performed or observed (e.g., a precision grip—i.e., a hand-grasping action using only two fingers to grasp a tiny object). Broadly congruent mirror neurons (approximately two-thirds of all recorded mirror neurons) do not discharge for the same action during action execution and action observation but, rather, for similar actions achieving the same goal or for logically related actions—for example, the observation of placing an object (say, on a table) and the action execution of grasping it. The fact that broadly congruent mirror neurons outnumber strictly congruent ones is important, because it gives the mirror neuron system enough flexibility to be critically activated during a variety of social interactions. Although imitation is a fundamental human ability and it is critical for social interactions, it is often also useful not to imitate others but rather act in a complementary fashion (Newman-Norlund et al., 2007). Furthermore, a flexible imitative behavior does not necessarily result in copying faithfully all aspects of an action. Sometimes it is useful to copy only some elements of an action and creatively integrate those elements with one's own motor repertoire. Broadly congruent mirror neurons seem ideal cells to support these flexible forms of imitation.

Furthermore, mirror neurons seem to code action-related information in a fairly abstract way. Very often, in real-life situations, we are not able to observe the actions of other people in their entirety, because many objects may occlude our sight. Indeed, mirror neurons are able to code observed actions even though the action is not fully in sight. They are also able to discriminate between an action and its pantomime even when both action and its pantomime are visually identical. Indeed, if a screen occludes, in part, the sight of the animal, and the animal observes a human experimenter reaching behind the screen, then the cell will discharge when the animal knows that there is a graspable object behind the screen but will not discharge when the animal knows that there is no object to be grasped behind the screen (Umiltà et al., 2001).

Mirror neurons are able to code the actions of other people even in absence of visual stimulation. Actions are often associated with sounds (footsteps, clapping, breaking peanuts, etc.). We are typically able to recognize the actions of others by simply listening to those sounds. In monkeys, mirror neurons fire at the sound of an action (say, breaking a peanut) even when the action is not seen at all (Kohler et al., 2002).

Taken together, the properties of mirror neurons suggest that these cells provide a fairly abstract coding of the actions of others. The most compelling evidence in support of this interpretation is a study that, by adopting a clever experimental design, demonstrated that mirror neurons are able to discriminate between two identical grasping actions associated with different intentions (Fogassi et al., 2005). In this study, which

included control conditions not described here, the presence or absence of a container indicated whether the experimenter was going to grasp food and place it in the container (grasping-for-placing) or was going to grasp food and eat it (grasping-for-eating). At the sight of the grasping action (i.e., well before observing what happened after grasping), the majority of mirror neurons discharged differentially for grasping-for-placing and grasping-for-eating, whereas only a minority discharged equally for both conditions. Most mirror neurons discharged for grasping-for-eating, although some preferred grasping-for-placing.

The experiment on coding intentions suggests that mirror neurons may actually code more the goal of the action than the action itself. A dramatic demonstration of this concept has been provided by a recent study (Umiltà et al., 2008). Monkeys were trained to grasp with normal pliers (i.e., requiring finger closing for grasping) and "reverse pliers" that required finger opening (a completely opposite finger movement!) for grasping. Mirror neurons discharged at the sight of the grasping actions with both normal and reverse pliers, confirming that these neurons code the goal of the grasping action rather than the finger movement itself. This finding also suggests that mirror neurons can rapidly change their functional properties, a concept that has potentially important implications for treatment, because it suggests that it may be possible to improve the functions of mirror neurons in patients with a deficit in the mirror neuron system (*see* below).

Two recent studies on grasping mirror neurons have demonstrated new properties in this neuronal population. Approximately half of the cells recorded in one of these studies (Caggiano et al., 2009) had preferential discharges for observed grasping actions in specific sectors of space. Some neurons discharged only for observed actions that occurred in the peri-personal space of the monkey (the space surrounding the body of the animal), whereas others discharged only for observed actions that were performed in the extra-personal space of the monkey (the sector of space outside the peri-personal space). The encoding of the space sectors in which the observed actions occur is also dynamical. If a transparent panel is interposed between the monkey and the observed action, an action in peri-personal space becomes unreachable by the monkey, although the action is still visible. Thus, from a pragmatic standpoint, this action is in extra-personal space, although it occurs near the body of the observing animal, because the animal cannot intervene on it. Mirror neurons coding for peri-personal space actions stop discharging when an action near the body is observed through a transparent panel. In contrast, mirror neurons coding for extra-personal space actions start discharging for peri-personal space actions when the actions are observed through a transparent panel that makes it impossible for the monkey to act on the observed action (Caggiano et al., 2009). Taken together, these findings suggest that the functional properties of mirror neurons allow an analysis of the actions of other people in terms of potential interactions with them.

However, one of the potential problems with premotor neurons that fire at the sight of somebody else's actions is that

we might find ourselves imitating others all the time. This behavior is not desirable. A recent study in monkeys has revealed one of possibly many mechanisms of control of unwanted imitation (Kraskov et al., 2009). Some mirror neuron for grasping discharged when the monkey performed the grasping action but completely suppressed their activity during grasping observation. This suppression of activity in these mirror cells may represent a neuronal mechanism of control of unwanted imitation during action observation.

Macaques: Other Types of Mirror Neurons

Recently, a variety of mirroring responses in single neurons was recorded in cortical areas that code for reaching and ocular movements. In dorsal premotor cortex, neurons discharge when the monkey makes reaching movements toward a target by using a cursor and when the monkey observes the same cursor, operated by the experimenter, reaching the target (Cisek & Kalaska, 2005; Cisek & Kalaska, 2004). A similar finding was reported in a later study recording from both dorsal premotor cortex and primary motor cortex (Tkach et al., 2007). In addition, this later study demonstrated that watching the cursor movement in absence of the target did not elicit any discharge in the mirror cells, suggesting again a primary coding of the action goals in these cells. An even more recent study has confirmed that the primary motor cortex contains mirror neurons for reaching movements (Dushanova & Donoghue, 2010).

In the lateral intraparietal area (LIP), there are mirror neurons for ocular movements and attention. These neurons discharge both when the monkey gazes in the preferred direction of the neuron and when the monkey observes another monkey gazing in the preferred direction of the neuron (Shepherd et al., 2009). These mirroring mechanisms for ocular movements may be important neural mechanisms for shared attention.

These recent studies demonstrate that mirror neurons are not restricted to the areas coding for hand-and-mouth movements in which they were originally discovered by the group of Rizzolatti. Neural mirroring may be a pervasive mechanism in the primate brain, facilitating social learning and social interactions. An important evolutionary question involves whether neural mirroring is restricted to primates. Imitative vocal learning in songbirds is an obvious case to start investigating this question.

Audio-Vocal Mirror Neurons in Songbirds

The concept that communication requires a correspondence, or common code, between the sensory and motor codes representing the signal is not new (Liberman & Whalen, 2000; Liberman & Mattingly, 1985; Liberman et al., 1967; Liberman et al., 1957). In neural terms, the most compelling implementation of such a concept would be to establish this correspondence at the level of single cells. A recent study has demonstrated that neurons in the swamp sparrow forebrain provide a precise auditory-vocal correspondence, displaying nearly identical patterns of activity when the songbird is listening to the birdsong and when the songbird sings the birdsong. Importantly, the disruption of auditory feedback during singing does not alter this pattern of activity, demonstrating that this activity is of motor nature (Prather et al., 2008). Furthermore, the neurons displaying these functional properties input onto anatomical structures in the avian brain that are known to be important for learning.

Similar results have also been obtained in the juvenile zebra finch (Keller & Hahnloser, 2009). The demonstration of auditory-vocal mirror neurons in songbirds is important, because it suggests that neural mirroring may be a parsimonious, optimized neural mechanism for action-perception coupling that the evolutionary process exploits at many levels. If this is true, a question that naturally follows is whether mirroring is also anatomically and functionally pervasive. Recent depth electrode recordings in humans suggest that this is indeed the case.

Mirror Neurons in Humans

The typical practice of neuroscience is to study cellular mechanisms in animals and neural systems in humans. Neural systems in human are generally studied by investigating the behavior of patients with brain lesions and by using a variety of methods in healthy subjects and in patients, including brain imaging and brain stimulation techniques. Why do neuroscientists use animal models to study cellular mechanisms in the brain? There are two primary reasons. First of all, the study of cellular mechanisms is highly invasive and cannot be performed in humans unless rare clinical opportunities allow it. Second, it is assumed that the cellular mechanisms observed in animal models are mostly preserved in humans. Hence, the animal data have inferential validity with regard to cellular mechanisms in humans. For example, visual-cortical cells such as the simple and complex visual cells discovered by Hubel and Wiesel in the cat (Hubel & Wiesel, 1959; the authors received the Nobel Prize for Physiology and Medicine for this work; this was the first time that neurophysiologists received the award) have never been recorded in humans. However, there is no visual neuroscientist that challenges the notion that such cells are also present in the human brain. Indeed, when brain imaging data fail to show results compatible with the presence of such cells in the human visual cortex, the scientists interpret the findings not as a challenge to this notion but only as suggesting some limitations of brain imaging techniques (Boynton & Finney, 2003).

Curiously, mirror neurons have been treated quite differently, especially among non-neuroscientists. For mysterious reasons, the existence of mirror neurons in humans has been challenged on the grounds that mirror neurons had been recorded only in animals and not in humans and that brain imaging cannot unequivocally establish their existence in the human brain. The discussion of this issue is an oddity in neuroscience debates. This argument had never before been made,

and hopefully it won't be made in the future. Indeed, it is quite irresponsible to challenge the inferential validity of neurophysiological data in animals, because such position undermines the ethical grounds of performing neurophysiology on animals. Although the recent report on individual mirror neurons in humans (Mukamel et al., 2010), recorded with depth electrode in patients with epilepsy, should end such a peculiar debate, it is important not to forget how irresponsible it has been to raise this issue, given the potential policy consequences of such an odd claim.

The proof of the existence of mirror neurons in humans is actually a relatively trivial achievement. The conceptual advancement of the data obtained with depth electrodes in humans is that these cells seem to be located in many neural systems. But let's first look at the results of this study (Mukamel et al., 2010). The action potentials of more than a thousand human neurons were recorded in a series of 21 patients implanted with depth electrodes. The patients were implanted to localize precisely the focus of epilepsy, such that only pathological brain tissue—and not healthy tissue—was subsequently removed during surgery. The location of the implanted electrodes was obviously determined only on the basis of clinical considerations. Thus, the modified clinical electrodes that were also able to record action potentials from individual neurons (for clinical purposes the electroencephalography [EEG] signal is obviously the key) were not located in human brain areas that were homologs of the macaque brain areas where mirror neurons had been recorded by monkey neurophysiologists. During the days preceding the localization of the epileptic focus (which generally happens when the patients seize), the patients were tested while performing and observing grasping actions and facial emotional expressions and also while performing some control tasks. Mirror neurons were found in the medial frontal cortex (in an area called the supplementary motor area [SMA], a brain area important for movement initiation and selection) and in the medial temporal cortex, a brain structure important for memory processes. These are brain areas where mirror neurons had not been previously recorded.

Taken together, the new human data and the recent monkey data suggest that the function of the mirroring neural mechanism depends on the functions of the neural system in which mirror neurons are embedded. The critical feature, and the common denominator, of mirror neurons is the functional matching between a motor response for actions of the self and a perceptual response to the actions of others. The mirror neurons initially recorded in areas coding for the goals of hand-and-mouth actions most likely mirror the goal of the action. The mirror neurons in SMA most likely mirror movement initiation. Mirror neurons in the medial temporal cortex most likely mirror the memory trace of executing the observed actions. Thus, when the patient performs the action, medial temporal cells encode the memory trace of making a grasping action. When the patient observes someone else performing the action, that memory trace is re-activated by the firing of the neuron. Thus, neural mirroring provides a pervasive and rich mapping of the actions of others onto our own actions and the experiences associated with performing them.

Because the mapping between the actions of self and others provided by mirror neurons is so rich, there must also be mechanisms of control and differentiation between actions of the self and actions of others. The depth electrode recordings in humans has revealed that a contingent of mirror neurons had opposite firing rate changes during action execution and action observation. The majority of this subset of mirror neurons increased their firing rate during action execution and suppressed entirely their activity during action observation. This pattern of activity, as for the mirror neurons recorded in monkeys with the same pattern of activity (Kraskov et al., 2009), may help inhibiting unwanted imitation. However, another function of these cells, especially the ones located in the medial temporal lobe, may be the important distinction between the actions of the self and the actions of others.

Mirroring Neural Systems and Their Role in Imitation

From Single-Unit Recordings to Brain Imaging

The neural systems for imitation in humans are typically studied with techniques that cannot record the activity of individual neurons but, rather, measure the integrated activity of large populations of cells, as in EEG, magnetoencephalography (MEG), and transcranial magnetic stimulation (TMS), or changes in blood flow and blood oxygenation that are thought to be related to changes in large populations of cells, as in positron emission tomography (PET) and functional magnetic resonance imaging (fMRI). An alternative way of studying the neural correlates of imitation is by investigating the effect of brain lesions, which also obviously involves a large number of neurons. The classical approach is the neuropsychological study of imitation deficits in patients with either naturally occurring lesions or surgical resections. A more recent approach has been the use of repetitive TMS to induce transient "lesions" in the stimulated brain areas and measure the resulting behavior.

A fundamental issue here is obviously how to translate the findings from single-cell recordings to the investigation of neuronal ensembles. The practice of interpreting human brain imaging data on the basis of single-cell neurophysiological data in nonhuman primates is well-established and has been adopted since the very early days of brain imaging. The exciting proliferation of fMRI experimental designs and analysis methods, however, has promised to circumvent this practice, which relies heavily on the scientists' interpretation of the imaging data on the basis of neuronal properties described in the animal literature. The hope was that these new brain imaging techniques would provide more "objective" measures of activity in specific neuronal populations.

This was indeed the promise of adaptation paradigms in fMRI. Adaptation fMRI paradigms exploit a neurophysiological

property exhibited by many neurons—that is, the habituation to repeated presentation of the same stimulus or to repeated execution of the same action. The general idea of fMRI adaptation paradigms is that by using clever experimental designs, it is possible to image the action potentials of a specific neuronal population that discharge selectively for specific stimuli or during specific actions, even though fMRI obviously does not have the technical capability of imaging single neurons (Tootell et al., 1995). Although the idea was clever, it relied on insufficient knowledge of the neuronal mechanisms of adaptation (Bartels et al., 2008). Indeed, the changes that adaptation induces in the adapting neuron appear to happen at the level of its input, rather than its output, thus making it impossible to claim that fMRI adaptation can image the action potential activity of specific neuronal populations. For example, direction-selective adaptation in visual direction-selective neurons occurs in specific sectors of the receptive field of the adapting neuron and not throughout its receptive field (Kohn & Movshon, 2003). This seemingly odd finding can only be interpreted as showing that the changes in neuronal activity that determine adaptation occur in early visual neurons that input onto the adapting direction-selective neuron. Indeed, these earlier visual neurons are known to have smaller receptive fields than motion-direction selective neurons. Furthermore, neurons that are not selective and discharge equally for two stimuli (e.g., stimulus A and B) still show adaptation for repeated presentation of stimulus A or stimulus B but do not show adaptation for successive presentation of stimulus A followed by B or vice versa (Sawamura et al., 2006). The most likely explanation of this phenomenon is that the nonselective but adapting neuron receives separate inputs from neurons responding to stimulus A and B and that adaptation most likely happens at synaptic level (once again, at input level). This is extremely important for two reasons. First, it demonstrates that adaptation and neuronal selectivity do not go together, even though the basic assumption of fMRI adaptation is that they must go together to make the results interpretable. Second, it makes a specific type of adaptation, repeatedly adopted to test for the existence of mirror neurons in humans—the so-called "cross-modal adaptation—substantially untestable.

Although there is no evidence yet that mirror neurons adapt, many fMRI studies have used the adaptation paradigm to test for mirror neuron responses in humans. In light of the absence of evidence for adaptation in mirror neurons and in light of the neurophysiological evidence discussed above that suggest that the changes producing adaptation occur at the input level, rather than at the level of action potentials of the adapting neuron, the choice of fMRI adaptation designs applied to the study of mirror neurons is already odd. At any rate, one of these early papers made the argument that mirror neurons should adapt not only for performing or observing repeatedly the same action but also for cross-modal adaption—that is, performing and then observing the same action, or vice versa. Cross-modal adaptation in mirror neurons should occur because these cells respond selectively to

the execution and observation of the same action (Dinstein et al., 2007). However, as we have seen above, selectivity and adaptation do not go together, making this assumption problematic. Furthermore, if adaptation happens at synaptic level, cross-modal adaptation in mirror neurons is difficult to obtain, because the neuron most likely receives input from frontal areas during action execution and from visual areas during action observation. Indeed, four studies using fMRI adaptation during execution and observation of actions (Dinstein et al., 2007; Chong et al., 2008; Lingnau et al., 2009; Kilner et al., 2009) have consistently demonstrated adaptation for repeatedly executed and for repeatedly observed actions, but the results of cross-modal adaptation have been inconsistent. One study failed to show cross-modal adaptation (Dinstein et al., 2007), two studies demonstrated cross-modal adaptation only in one condition (and they were inconsistent with each other!) (Chong et al., 2008; Lingnau et al., 2009), and only one study (admittedly, the most carefully designed of the whole series) demonstrated cross-modal adaptation for both the executed action following the observed one and vice versa (Kilner et al., 2009).

Another emerging trend in human functional brain imaging is the use of multivariate statistics (or classifiers) to look for reproducible patterns of brain activity over cortical areas. With this approach, patterns of activity in some trials presenting, for example, stimulus A are expected to correlate with patterns of activity in other trials also presenting stimulus A but not with patterns of activity in trials presenting stimulus B. This technique has produced beautiful studies of visual perception (Haxby et al., 2001). However, those studies applied this method to areas in which many neurons exhibit similar neurophysiological properties—that is, they are characterized by what is called "population coding." It makes sense that pattern recognition methods demonstrate robust results in these areas, given that in these areas a large number of neurons have similar responses. As we have seen in the section on single neuron recordings in monkeys, mirror neurons are only a subset of neurons in the brain areas in which they are recorded. It is almost inevitable that pattern recognition methods fail to reveal mirroring responses in paradigms of action execution and action observation, whereby action execution and action observation are assumed to yield similar patterns of activity. When these analysis techniques are coupled with an adaptation paradigm, a negative result must be expected, and indeed it has been reported (Dinstein et al., 2008). The significance of this negative result, however, is extremely limited. Furthermore, classifiers are inherently difficult to interpret even when positive results are obtained, as discussed in detail elsewhere (Bartels et al., 2008).

Given that spiking activity (the firing of neurons—i.e., their action potentials), local field potential (which is currently believed to represent the integrated synaptic input), and blood oxygenation level dependent (BOLD) fMRI signals tend to go together in many cases (Logothetis et al., 2001) (although dissociations have been observed, showing that BOLD and local field potential (LFP) tend to be coupled more than BOLD

and spiking activity; Logothetis & Wandell, 2004), a much more effective strategy to investigate mirroring properties of human brain areas using fMRI is by manipulating specific parameters that are known to activate mirror neurons selectively while keeping constant some other parameters. This strategy has indeed produced a series of successful studies that have revealed the strong links between human mirror neuron areas and imitation.

Brain Imaging and Transcranial Magnetic Stimulation Data on Human Imitation

In an early fMRI study of human imitation, we based our prediction on the BOLD activity of human brain areas containing mirror neurons and on the single-cell recordings performed in the monkey with depth electrodes. Those data have indicated that mirror neurons discharge more vigorously during action execution compared to action observation. Indeed, the firing rate increase of mirror neurons during action observation is approximately half the firing rate increase during action execution. Thus, we predicted a higher BOLD increase compared to baseline during action execution than during action observation. Furthermore, given that during imitation subjects are both seeing and performing the action, we also predicted that the BOLD increase during imitation should approximately be the sum of the BOLD increases measured during action execution and during action observation. The fMRI results obtained in an experiment on imitation and observation of finger movements confirmed these predictions. Two areas of the human brain, the inferior frontal cortex and the anterior part of the posterior parietal cortex, displayed the predicted pattern of activity (Iacoboni et al., 1999). Furthermore, these areas corresponded fairly well (in anatomical terms) with the areas of the monkey brain in which mirror neurons were originally recorded. These results indicated not only homologies between the monkey and the human mirror neuron areas but also that these areas are important for imitation.

In a subsequent study, we tested whether the activity in the two human brain areas we had previously identified was modulated by action goals. Developmental psychology data have suggested that imitation in children is especially tuned to imitating the goals of other people's actions (Bekkering et al., 2000). In an fMRI experiment, we adopted a paradigm that was previously used in the developmental psychology experiments. The results demonstrated that among the two previously identified brain regions, the inferior frontal area was particularly sensitive to imitating the goal of the action (Koski et al., 2002). Indeed, a later study also demonstrated that this region codes the intention associated with the observed action, rather than the action itself (Iacoboni et al., 2005; Figure 56-1).

The inferior frontal area identified in these two imaging studies on imitation overlaps with the posterior part of Broca's area in the left hemisphere, a prominent brain area for language. This overlap is theoretically important. After the discovery of mirror neurons in macaques, it had been suggested that these cells may represent neural mechanisms that are the evolutionary precursors of neural systems for language (Rizzolatti & Arbib, 1998). Indeed, the macaque brain area in which mirror neurons were originally discovered is believed to be the homolog of Broca's area in the human brain (Rizzolatti & Arbib, 1998). Thus, our fMRI studies, which demonstrate mirror-like patterns of activation during imitation experiments in Broca's area, seem to corroborate the evolutionary hypothesis of mirror neurons as neuronal elements precursors of neural systems for language in humans. However, activation of a language area in a nonlanguage task in a brain imaging experiment may be ambiguous. Indeed, brain imaging gives us only correlational information between brain activity and behavior. In principle, an activation of a language area during
Figure 56–1. Mirror Neuron Areas and Intention Understanding. When subjects observe the same grasping action associated with different intentions (as suggested by the context in which the action is embedded), mirror neuron areas activate differently. Grasping the intentions of others with one's own mirror neuron system. *PLoS Biology, 3*(3), e79), the frontal mirror neuron area in humans is less active for a grasping action with no context and maximally active for a grasping action embedded in a context that suggests drinking. In this study (Iacoboni, M., Molnar-Szakacs, I., Gallese, V., Buccino, G., Mazziotta, J. C., & Rizzolatti, G. [2005].

a nonlanguage task may simply represent covert verbalization during the task. This alternative explanation is rather unlikely, because there is no apparent reason why subjects should covertly verbalize a little during action observation, a bit more during action execution, and even more during imitation (the pattern of activity we measured in the posterior part of Broca's area). At any rate, we decided to test the relationships between Broca's area and imitation directly by using repetitive TMS over the posterior part of Broca's area while subjects were imitating finger movements. The rationale behind this experiment was to produce a transient "lesion" in the posterior part of Broca's area to test whether its functioning is essential to imitation. To control for nonspecific effects, subjects also performed a visuo-motor control task and were stimulated in a control site. The results demonstrated a selective impairment for imitation but not for the control visuomotor task only when subjects were stimulated over the posterior part of Broca's area but not when they were stimulated over the control site (Heiser et al., 2003). These data demonstrate a causal link between activity in the posterior part of Broca's area and imitation, ruling out that the activation in imaging studies represented epiphenomenal activity.

In the monkey, neurons in the superior temporal sulcus (STS) demonstrate visual properties similar to the visual properties of mirror neurons. They respond to the sight of object-oriented actions and more generally to biological motion (Perrett et al., 1989; Jellema et al., 2000; Puce & Perrett, 2003). The STS neurons, however, are only higher-order visual neurons, do not activate during action execution, and thus do not have mirror properties. However, given their visual properties, they likely feed visual information into the fronto-parietal mirror neuron system. Indeed, there are well-established anatomical connections between STS and the posterior parietal mirror neuron area (Seltzer & Pandya, 1994). The brain imaging studies on imitation and action observation we have performed in the last 10 years have confirmed the role of human posterior STS in visual processing of observed and imitated actions (Iacoboni et al., 2001; Koski et al., 2002; Koski et al., 2003; Iacoboni et al., 2004; Iacoboni et al., 2005; Molnar-Szakacs et al., 2006; Kaplan and Iacoboni, 2006). Taken together, the imaging studies on human imitation suggest a core neural circuitry for imitation composed of three major cortical areas: the STS, the posterior parietal human mirror neuron area, and the inferior frontal human mirror neuron area. Within this circuitry, the processing of information necessary for imitation is likely implemented as follows: the STS provides a higher-order visual description of the action to be imitated and the parietal mirror neuron area is concerned with the copying of the detailed motor aspects of the action, whereas the inferior frontal mirror neuron area codes the goal of the action. When the imitative action is planned, an efferent copy of the imitative action is sent back to the STS, where there is a matching process between the visual description of the action and the prediction of the sensory consequences of the planned imitative action. If there is a good matching, then the imitative actions are executed. If not, then

appropriate corrections are implemented until a good matching is achieved (Iacoboni, 2005). This core neural circuitry for imitation is presumed to interact with other neural systems to facilitate social cognitive skills. For example, there is evidence supporting the hypothesis that the interactions between the core neural circuitry for imitation and the limbic system are important for empathy, as we will see in the next section.

The Face of Empathy

Many notable authors have emphasized the links between imitation and empathy (de Montaigne, 1575; Smith, 1759; Poe, 1982; Nietzsche, 1881; Wittgenstein, 1980). More recently, quantitative studies have established strong correlations between the tendency to automatically imitate others during social interactions (a phenomenon known as "The Chameleon Effect") and the tendency to empathize, to be concerned about the mental and emotional states of others (Hatfield et al., 1994; Chartrand & Bargh, 1999). The relationships between imitation and empathy suggests strong functional interactions between the core neural circuitry for imitation and classical emotional brain areas belonging to the limbic system, such as the amygdala. Anatomically, these structures are connected in the primate brain through the dysgranular sector of the insular lobe (Augustine, 1996). A plausible hypothesis about the interactions between the neural circuitry for imitation and limbic areas during imitation that leads to empathy is as follows:

1. Neurons in STS code the higher-order visual description of facial expressions, actions, and body postures of other people.
2. This information is sent to the fronto-parietal mirror neuron areas that initiate the imitative process.
3. Signals from the mirror neuron areas are sent—via the insula—to limbic areas.
4. The activity in the limbic areas triggers the mental and/or emotional states often associated with those actions and/or facial expressions—for example, smiling.

This plausible series of neural events has also a neural counterpart during simple observation of the facial expressions, actions, and body postures of other people. Indeed, mirror neurons also fire during the mere observation of the actions of others. This firing can, in principle, initiate a similar cascade of neural activations that may lead to an inner imitation of the facial expressions, actions, and body postures of other people and eventually also to empathy for others by simulating the emotional states associated with the facial expressions, actions, and body postures of other people.

To test this model, we performed an fMRI experiment in which subjects were asked to observe and to imitate facial emotional expressions. The model makes two general predictions: First, during both observation and imitation, there should be activation of the core neural circuitry for imitation (STS and fronto-parietal mirror neuron areas), of the insula, and of limbic structures such as the amygdala. Second, during
Figure 56–2. Neural Circuitry for Empathy. When subjects imitate or observe facial emotional expressions, they activate a complex network of areas. The activity in areas highlighted in yellow correlates with behavioral scales of empathy and social competence, suggesting that this neural circuit may represent a biomarker of sociality in humans. (See Color Plate Section for a color version of this figure.)

imitation, the activity throughout this large-scale neural network should be higher than during observation, if it is triggered by mirror neuron areas: indeed, mirror neuron areas had displayed this pattern of activity in our previous brain imaging experiments. The brain imaging results supported both predictions (Carr et al., 2003), suggesting that one way of empathizing with others is through bodily enactment of the actions of others or through the simulation of such enactment (during observation only; Figure 56-2).

This study described a large-scale network with functional properties that may plausibly explain the links between imitation and empathy. The lack of behavioral data correlating the tendency to empathize of the experimental subjects with the activity in this large-scale network, however, made it impossible to test more stringently the hypothesis that the functional properties of this network are important for empathy. A series of subsequent brain imaging studies, in both adults and children, and both from our lab and others labs, have tested and supported this hypothesis by providing strong correlations between the empathy scores of the experimental subjects and activity in mirror neuron areas (Kaplan & Iacoboni, 2006; Gazzola et al., 2006) and also in the insula and amygdala (Pfeifer et al., 2008).

The Mirror Neuron Hypothesis of Autism

Because mirror neurons have been implicated in a variety of functions that are cornerstones of social behavior, some authors have hypothesized that autism may be associated with a mirror neuron dysfunction (Williams et al., 2001). Evidence in support of this hypothesis has been obtained in different labs and using different methods. Some studies have shown anatomical differences between subjects with and without autism in mirror neuron areas (Hadjikhani et al., 2005).

Other studies have shown EEG differences in the suppression of the mu rhythm (Oberman et al., 2005), a parameter taken to reflect mirror neuron activity (Hari et al., 1998). A MEG study has demonstrated that cortical activation during imitation is delayed in Asperger's Syndrome (Nishitani et al., 2004). Using fMRI and our paradigm on imitation of finger movements (Iacoboni et al., 1999), another group also found differences between subjects with and without autism in levels of activation in mirror neuron areas (Williams et al., 2006).

We used fMRI to test the hypothesis that the large-scale neural network composed of mirror neuron areas, insula, and limbic areas whose activity correlates with empathy (and other parameters of social competence) is impaired in patients with autism. Two groups of children were studied with fMRI while the children were both observing and imitating facial emotional expressions, as in the previously described study. One group was composed of typically developing children (TD) and the other was composed of children diagnosed with autism spectrum disorder (ASD). The brain imaging data revealed indeed that the group of children with ASD had reliably less activity in mirror neuron areas, insula, and amygdala during both imitation and observation of facial emotional expressions. Furthermore, and probably even more compellingly in support of the hypothesis that this circuitry is critically impaired in the ASD group, we found a correlation between the activity in these areas and the severity of the disease, as assessed by widely used scales. This correlation was such that the more reduced the activity in these areas (and especially so in mirror neuron areas), the more impaired was the social functioning of the subject (Dapretto et al., 2006).

Taken together, the correlations between brain imaging data and behavioral scales suggest that mirror neuron areas, the core neural circuitry for imitation, and even more broadly the large-scale network that includes also insula and limbic structures, may represent biomarkers of sociality. Future studies, especially if coupled with successful interventions, as briefly discussed in the conclusions, will further explore this exciting hypothesis.

Before concluding, however, it is important to address some criticisms to the mirror neuron hypothesis of autism. Despite the wealth of neurophysiological and brain imaging data supporting this hypothesis, some behavioral studies that demonstrated that children with ASD can understand action goals (Hamilton et al., 2007) dismissed the brain data and concluded that the "broken mirror" hypothesis of autism must be wrong (Southgate & de C Hamilton, 2008). This criticism rests on the assumption that there is a one-to-one correspondence between behavior and brain systems, so that one can infer the functioning of brain systems on the basis of human behavior. The behavioral data, however, can be easily explained with the idea that tasks can be successfully performed in many different ways, adopting different cognitive strategies and using different neural systems. Indeed, a recent study demonstrates that subjects with ASD understand the intentions of others' actions by relying on contextual and

object semantic cues, whereas subjects without ASD rely on the observed motor behavior (Boria et al., 2009). These are two rather different strategies indeed, most likely relying on different neural systems.

Conclusions

To conclude, a potential application of the neuroscience studies discussed in this chapter is a wider use of imitation-based interventions in children with autism. Indeed, such interventions are already underway, and the preliminary results are rather promising (Ingersoll, 2010; Ingersoll et al., 2007; Ingersoll & Gergans, 2007; Ingersoll & Schreibman, 2006). The social behavior of subjects with autism undergoing relatively simple interventions based on reciprocal imitation between the patient and the therapist (indeed, these techniques can be taught to the parents of the children) ameliorates visibly (Ingersoll, 2010; Ingersoll et al., 2007; Ingersoll & Gergans, 2007; Ingersoll & Schreibman, 2006), thus promising to be an effective intervention.

Challenges and Future Directions

- Integrate single-unit data and brain imaging data on neural mirroring.
- Use activity in mirror neuron areas as a biomarker predicting the effectiveness of interventions.
- Make brain imaging laboratories more patient-friendly so that more data can be gathered in more naturalistic settings of imitation and action observation.

Information Processing and Integration

Points of Interest

- The autistic brain is characterized by abnormal network architecture (increase in short-range connections and decrease or perturbation in long-range connections) and abnormal network recruitment.
- Network disruptions in autism manifest as intact or enhanced low-level information processing and dysfunctional or disengaged complex information processing.
- Deficits in complex information processing affect all domains of perception and cognition.
- Diagnostically salient social abnormalities may arise in combination with, or even partially as a consequence of, disordered perceptual processing.
- Some of these antecedent network abnormalities appear to be familial traits.

Developmental Disorders and Neural Information Processing

Much like the people whom it seeks to understand, autism research is prone to a sort of "weak central coherence," with a multiplicity of hypotheses targeted at particular systems or levels of analysis. The most vexing problem often is not identifying the observational details but assembling these details into a single, coherent theory. The challenge of autism research is that its work has been fractionated within many separate models of dysfunction, reflecting the many separate perspectives and approaches of cognitive and systems neuroscience that have been brought to bear on it. These models only now are beginning to be combined. Focusing on autism's social deficits, some have characterized autism as a dysfunction in a cognitive module for "theory of mind" (ToM), the ability to think in terms of social partners' beliefs and desires

(Baron-Cohen et al., 1985, 2002). Others explain both social and nonsocial phenomena as consequences of a more general dysfunction of executive control (Hill, 2004), shifting and distribution of attention (Allen & Courchesne, 2001), "central coherence" of gestalt or global-level percepts (Frith & Happé, 1994; Happé & Frith, 2006), or an enhancement of local processing, often at the expense of engaging intact global-level processing (Mottron et al., 2006). Although each of these theories seems to contain at least a piece of the picture, the process of putting these pieces together has begun only recently (Belmonte et al., 2004b; Mottron et al., 2006).

In science, as in any human endeavor, what is discovered is constrained by what is looked for. All too often, experiments are framed so as to confirm or to refute hypotheses within one theoretical framework. ToM studies show deficits in tasks of attributing false belief (Baron-Cohen et al., 1985), executive function studies show deficits in tasks of planning (Hughes et al., 1994) and inhibition of prepotent responses (Ozonoff et al., 1994), attention studies show slowed shifting (Courchesne et al., 1994a) and abnormal distribution (Townsend & Courchesne, 1994; Burack, 1994) of attention, studies of central coherence show facilitation on tasks of perceptual disembedding (Shah & Frith, 1993; Plaisted et al., 1998), and perceptual studies show enhanced discrimination of first-order stimuli (Plaisted et al., 2003; Bertone et al., 2003, 2005). Each of these foundational results has been individually confirmed by further explorations, but each has remained largely unintegrated with other findings.

Significantly, within each of these domains of exploration, there is very appreciable variance in behavioral and physiological measures: many children with autism pass tasks of first-order or even second-order belief attribution (Frith & Happé, 1994); deficits in executive function vary across task paradigms, executive subdomains, and individuals (Hill, 2004); attention varies between abnormally narrow "spotlight" and abnormally broad distributions (Townsend & Courchesne, 1994); central coherence as measured by the Embedded

Figures Test varies substantially within the autism population and, in fact, correlates with similarly variable performance on ToM tests (Jarrold et al., 2000); and perceptual variation in motion coherence thresholds is very large, with a third of the autism population within the normal range (Milne et al., 2002; Belmonte, 2005). Despite this richness of variance within perceptual and cognitive domains, with a few notable exceptions (e.g., Jarrold et al., 2000), the covariance structure between domains remains unexplored. Linking these investigations is important because in illuminating pervasive abnormalities of neural information processing that span cognitive domains, one can explain how these domains normally relate to one another computationally and developmentally—in both abnormal and normal developmental contexts (Valla et al., 2010).

Recent theoretical constructions of autism have converged on the notion of a systems-level dysfunction in neural computation (Belmonte et al., 2004a, b), one whose interactions with normal programs of brain and cognitive development may result in perturbations at many levels of processing. Autistic deficits in complex social and communicative skills are comparatively well-studied, as these deficits are the most obvious, the most diagnostic, and the most debilitating. However, the relevance of abnormalities at lower levels of function (Rogers & Ozonoff, 2005) ought not to be ignored, as perturbations at these simpler, more tractable levels of processing may offer insights at the systems level. In particular, correlation between behavioral and physiological studies of sensory and attentional phenomena on the one hand, and complex social cognitive processes on the other, may illuminate abnormal modes of development in which a systems-level abnormality perturbs both low and high levels of processing, and/or abnormal developmental cascades in which dysfunction at low levels of processing perturbs activity-dependent development at higher levels. Support for the notion of such multilevel cascades of perturbed development comes from the success of interventions addressing rapid auditory sequence processing in language and communication disorders (Tallal et al., 1996, 2004; Fitch & Tallal, 2003), from studies of schizophrenia demonstrating deficits in early sensory processing (Butler & Javitt, 2005; Uhlhaas & Silverstein, 2005; Butler et al., 2007) and relating auditory frequency discrimination to deficits in affect recognition (Leitman et al., 2007) and visual size discrimination to deficits in ToM (Uhlhaas et al., 2006), from physiological studies of autism suggesting compensatory processing for dysfunctions in early sensory and attentional computations (Belmonte & Yurgelun-Todd, 2003) and behavioral studies linking joint attention to ToM and pretense (Charman, 1997), and even from studies of normal development and aging showing that deficits in automatic, early processing evoke downstream, compensatory abnormalities in later, more effortful stages of neuro-cognitive processing (Townsend et al., 2006). In each of these instances, what seems on face an alteration of higher-order cognition is seen to be related to, and in some cases a consequence of, perturbations at lower levels of processing.

Abnormal Complex Information Processing in Autism

The beginnings of a conception of autism as abnormal complex information processing arose from neurological evaluations of children with autism (e.g., Minshew & Payton, 1998). Many of the characteristic behavioral abnormalities in autism (e.g., seizures, mental retardation, and deficits in higher-order cognition and complex behaviors) are consistent with abnormal function of association cortex and cerebral gray matter. At the same time, autism is not characteristically associated with deficits in sensorimotor cortex (e.g., cerebral palsy, blindness, deafness). These findings led Minshew et al. initially to conclude that autism was characterized by an intact sensorimotor cortex but an abnormal association cortex.

Further, many children with autism have no difficulties learning new words (supporting the hypothesis that autism is not the result of focal brain dysfunction) and are quite capable of repeating words or phrases (e.g., in immediate echolalia) but seem to have problems with comprehension and the production of novel, spontaneous expressive language. These observations suggest that dysfunction in autism results primarily from an abnormal development of brain connectivity, affecting functional relationships between association cortex and sensorimotor cortex. This neuropsychologically driven view of autism as a disorder of neural connectivity has garnered support from physiological data and is consistent with therapeutic views of autism as a disconnection between cognitive and affective systems (Greenspan et al., 2001).

This integrative, neural-systems view of autism differs fundamentally from theories that have posited a single core deficit in some specific domain or sensory modality (Minshew et al., 1997), such as empathizing, executive function, ToM, or central coherence. In this view, the domain-specific deficits integral to the diagnostic triad of autism become manifestations of a general deficit in complex information processing. Autism then can be characterized by an abnormal balance between decreased or perturbed long-range connectivity and perhaps enhanced local connectivity. This perturbation of *neural* connectivity is reflected in *cognitive* connectivity, manifesting as intact or enhanced abilities in simple perceptual or cognitive tasks and deficits in complex cognitive tasks.

Deficits and Superiorities Beyond the Triad

Because autism is behaviorally defined, it is not surprising that many investigations of autism begin by examining those behaviors that are most diagnostically relevant. However, mature cognition is but the endpoint of a process of interactive specialization during which complex cognitive capacities emerge from simpler antecedents (Johnson et al., 2002). Thus, profound and pervasive deficits in social communication could be secondary to more primary neurological

abnormalities. Systems-neuroscience models attempt to avoid this pitfall by seeking a broader, underlying abnormality in information processing in general.

Minshew et al. (1997) evaluated this hypothesis of complexity-dependent deficits by giving 33 adults with autism and age-matched controls a battery of neuropsychological tests to assess performance in nine domains: attention, sensory perception, motor skills, simple language, complex language, simple memory, complex memory, reasoning, and visual-spatial skills. Typically developing controls demonstrated better performance in the domains of motor skills, complex language, complex memory, and reasoning. The groups were indistinguishable in the domains of attention, sensory perception, simple memory and visual-spatial skills. The autism group demonstrated significantly better performance in the simple language domain.

The pattern of decreased performance in complex domains with intact or enhanced performance in relatively simple domains strongly supports the complexity-dependent information processing deficits hypothesis. However, a deficit in complex information processing could be expected also to produce abnormalities beyond the diagnostic triad. This prediction was confirmed by a later, large study, which found that individuals with autism develop postural control later than typically visual input with auditory or tactile information (Bonneh et al., 2008), or to combine ongoing cognitive developing children and do not attain the level of function observed in typically developing adults (Minshew et al., 2004). In further support of abnormal complex information processing, these authors found that the unusual postural development was related to a decreased ability to integrate visual, vestibular, and somatosensory information. This theme of a lack of ability to combine processing with visual input from direct gaze (Chen et al., 2010) has been cited in studies of "low-functioning" autism and has been elaborated by a recent finding of an autistic deficit in combining visual and proprioceptive feedback during a motor control task (Haswell et al., 2009). In general, autism seems marked by a lack of ability to integrate or to shift focus rapidly among distinct perceptual channels—for example, information from distinct sensory modalities (Akshoomoff & Courchesne, 1992), distinct spatial locations (Townsend et al., 1996), or even distinct perceptual channels within a sensory modality (e.g., speech content vs. speech prosody; Courchesne et al., 1994a)—and by a lack of ability to integrate such perceptual information with ongoing cognitive processing; thus individual perceptual and cognitive processes may be intact but not coordinated with each other, a realization that carries significant implications for psychological and educational therapies (Chen et al., 2010).

Minshew and colleagues repeated their initial neuropsychological profile of autism by giving 112 children (56 individuals who met diagnostic criteria for autism, 56 age- and IQ-matched controls) a similar battery of tests (Williams et al., 2006). The findings were similar in that the autism group showed decreased performance in the domains that put greater demands on information processing and integration. Unlike results from the earlier study, the children with autism did not show decreased performance in the reasoning domain or increased performance in the simple language domain. Additionally, the children with autism showed decreased performance in the sensory perception domain. Such age-related performance differences highlight the importance of understanding autism as a developmental disorder and the need to examine early stages of development to investigate its etiology.

Neurobiological Foundations of Autistic Information Processing

Just as many theories of autism have posited a single core deficit in a single domain, anatomical investigations of autism have tended to focus on localized neurobiological abnormalities. Previous research has identified specific, focal abnormalities in the brain stem (Hashimoto, 1995; Rodier et al., 1996), amygdala (Aylward et al., 1999), hippocampus (Aylward et al., 1999; Saitoh et al., 2001), cerebellum (Courchesne et al., 1988; Murakami et al., 1989; Courchesne, Townsend, & Saitoh, 1994b; Hashimoto, 1995), parietal lobes (Courchesnet et al., 1993), temporal lobes (Redcay, 2008), and frontal lobes (Carper & Courchesne, 2000; Courchesne et al., 2001; Sparks et al., 2002; Aylward et al., 2002). However, only recently have explanations begun to be offered as to how all of these anatomical abnormalities might be related, both to each other and to the complex symptomatology of autism.

This synthesis is complicated by autism's developmental nature. Many of the studies identifying specific abnormalities, whether in biology or behavior, have pragmatically investigated adult or adolescent populations. However, such an approach is ill-equipped to distinguish between a core deficit and a compensatory mechanism. As suggested earlier, many of the behaviors diagnostically essential to autism may, in fact, be secondary dysfunctions resulting from adaptive processing strategies that help normalize cognition (Belmonte et al., 2004b). Maintaining restricted interests, for example, can be an effective strategy for keeping a chaotic and unmodulated sensorium somewhat predictable and therefore cognitively tractable (Belmonte, 2008), and in fact childhood repetitive behaviors correlate with childhood fears and anxieties even in the context of normal early development (Evans et al., 1999). Any satisfying explanation of the etiology of autism must include developmentally early structure and function in the autistic brain.

Network Perturbations of Neural Information Processing

Twentieth-century neuroscience was marked by great successes at single-variable problems. Human and animal studies elucidated the effects of focal lesions affecting single brain

regions and identified those regions with circumscribed cognitive capacities, resulting in clinical and basic understandings of focal brain disorders such as well-characterized frontal and temporal aphasias, parietal hemi-neglect, and medial temporal anterograde amnesia. Nearly coeval with these advances in the understanding of isolated brain regions came an understanding of the effects of isolated genes: errors in single genes give rise to well-characterized brain disorders as diverse as Huntington's disease and Rett Syndrome. As difficult as these problems were to solve, they were in some sense the low-hanging fruit. Twentieth-century, univariate neuroscience has been supplanted by the multivariate, integrative neuroscience of the twenty-first century, and the canonical multivariate neuroscientific problems are complex neuropsychiatric conditions that perturb networks of cooperating cognitive capacities, networks of communicating brain regions, and networks of interacting genes. Single-gene dysfunctions (e.g., Fragile X Syndrome [Pieretti et al., 1991], Timothy Syndrome [Amir et al., 1999], or the aforementioned Rett Syndrome [Splawski et al., 2004]) may mimic multivariate disorders, in that they involve dysfunctions in single genes whose protein products interact with many other genes and/or proteins, either by regulating transcription (Rett Syndrome and *MECP2*) or translation (Fragile X Syndrome and *FMR1*) or by perturbing the kinetics of ubiquitous cellular signaling mechanisms (Timothy Syndrome and *CACNA1C*). In these specific cases, however, what is in one sense a single-gene disorder is more proximally the result of network perturbations affecting the many genes and proteins whose regulation is directly or indirectly disrupted. In the general case, then, complex neuropsychiatric conditions arise from multiple interacting genetic factors—and, no doubt, environmental ones too.

Human cognition, including scientists' cognition, operates by constructing fetishes, in the anthropological sense of the term. That is, we think by attaching meanings to concrete artifacts that function as symbols. In the domain of neuroscience, these artifacts are brain regions, genes, proteins. Because our minds are structured for symbolic manipulations, it's easy for us to think of the anatomy of a piece of the brain or the structure of a gene or a protein. It becomes more difficult to wrap our heads around a problem, however, when the problem is defined not in terms of concrete objects but in terms of abstract networks. This preference for the concrete— ironically, given scientists' descriptions of autism's detail-oriented perception and trouble with abstraction—is why neuroscience and neuroscientists still enjoy pretending that complex disorders boil down to single brain regions in fMRI studies or to single susceptibility genes. The true picture certainly is more complicated: fMRI studies that show neatly delimited activations may be looking only at the major node or nodes within distributed networks of functional anatomy, and genetic studies that associate autism with a single allele may be looking only at an entry point to a complex graph structure of genetic interactions. Univariate projections of these complex networks are useful insofar as they provide such entry points from which the rest of the network connectivity graph can be explored.

The complexity-dependent pattern of deficits and intact or enhanced abilities, then, is the result of abnormal networks, both at the genetic and neuronal level. The topic of networks of interacting genes is covered elsewhere in this volume and will be reprised briefly at the end of this chapter. For now, the focus will turn to networks of interacting neurons. Work in the fields of graph theory and dynamical systems theory can be applied to neural networks to provide useful insights.

Dynamical Systems Theory. Mathematically defining the behaviors of networks is of interest to researchers in many fields, including physics, mathematics, and computer science (and increasingly, neuroscientists), and many of their insights are particularly relevant to neurobiology. Three concepts especially applicable to the brain are *(1)* synchronicity, *(2)* "small-world" networks, and *(3)* "scale-free" networks. (For a more thorough review, *see* Strogatz, 2001.)

Synchronicity is the extent to which oscillators in a network are related in terms of frequency and amplitude. Kuramoto (1984) discovered that a fairly simple mathematical equation can predict the number of edges that must be added to a collection of oscillators before some of the oscillators in that network synchronize. As the number of "edges" (connections) in the network increases past this connectivity threshold, more and more "nodes" (cells or columns or functional regions, depending on one's anatomical level of analysis) synchronize until the network is fully interconnected and all of the nodes are oscillating in unison. A biological example of a fully synchronized network is the sinoatrial node (Peskin, 1975). In this "natural pacemaker," even if the cells are not initially synchronized, the networked structure of the node causes the cells to synchronize over time.

"Small-world" networks are characterized by short average path lengths and high clustering. A classic example of a small-world network is the network of co-authors within a given discipline (e.g., Strogatz, 2001), where authors are the nodes and collaboration on a paper defines the edges—that is, if A and B have written a paper together, then (A, B) is an edge in the graph structure. Authors that are affiliated with the same institutions tend to be co-authors on each other's papers, creating many intramural edges (clustering). When researchers from different institutions collaborate, a shortcut is created between these institutional clusters (short path length). In a neurobiological context, small-world networks are interesting because it has been argued that such networks might have been selected for as an adaptation to a sensory-rich environment.

The "degree" of a node is the number of edges (connections) attached to that node. **"Scale-free" networks** have mostly low-degree (sparsely connected) nodes but a few

high-degree (densely connected) nodes, or "hubs" (Barbási & Albert, 1999). These high-degree hubs can act as gateways for the shortcuts of a small-world network, and so many networks exhibit both small-world and scale-free properties. Scale-free networks are particularly interesting because they are resistant to random failure: intact function of neural and cognitive networks does not depend on the functional integrity of any particular subgroup of neurons. On the other hand, scale-free networks are very susceptible to targeted attacks—that is, if a hub is disrupted, then the entire network could be disrupted (Albert, Jeong, & Barbási, 2000; Barbási, Albert, & Jeong, 1999; Cohen, Erez, ben-Avraham, & Havlin, 2000). These properties may hold important implications for the developmental role of frontal-lobe hub abnormalities in autism.

The Brain As a Network

A great deal of research has shown that the nervous systems in biological organisms follow a scale-free and small-world organizational scheme. This characteristic holds even for relatively simple organisms such as the worm *Caenorhabditis elegans* (Strogatz, 2001). Before recent developments in neuroimaging, neurologists were positing small-world structural networks (using different terminology) based on lesion studies. Mesulam (1990) proposed that behavior and cognition arose from a collection of parallel distributed processing networks in the brain, each comprising several "widely separated and interconnected local networks." Using data gleaned from lesion studies, it was possible to identify the cortical and subcortical regions (local networks) necessary for a given behavior or cognitive task. Importantly, this work helped to highlight the fact that an observed deficit in some complex emergent capability could be arrived at from multiple, distinct mechanistic pathways (i.e., insult to any of the relevant hubs—highly connected cortical areas—could produce downstream disruption of the entire network).

With the advent of new technologies, it has become possible to begin to examine these systems in healthy individuals, allowing researchers to investigate normal variation in neural and cognitive networks. More recent research has directly shown that the human brain also follows a small-world organizational scheme at several levels of analysis (e.g., Supekar, Musen, & Menon, 2009). Many have argued that the human brain is also a scale-free network (e.g., Heuvel et al., 2008), although some are not convinced (Achard et al., 2006). Regardless, few would argue with the assertion that the vehicle by which diverse cortical and subcortical areas collaborate is synchronization. As discussed above, the synchronicity of a network depends in part on the connectivity of the network. *Connectivity*, however, is an overloaded term, susceptible to various theoretical definitions and to various experimental measures. Special care must be taken to specify the type of connectivity being discussed.

The Confusion of *Connectivity*

At a gross level, one can make a distinction between *structural connectivity* (i.e., nodes and edges of the network are physical structures) and *functional connectivity*, wherein the nodes are still physical structures, but the edges of a functional network are statistical relationships (usually measures of correlation or covariance). Functional connectivity, for its part, can be defined in raw terms of the degree to which one neuron or one neural assembly activates another or in terms of the degree to which information is transferred between neurons or neural assemblies. The first sense of this term—that of simple co-activation—is easily captured by statistical measures of correlation or covariation between two spike trains or two electroencephalography (EEG) or fMRI time series. The second sense is more complex and often of greater practical import. The capacity of a neural assembly—or of any computational system—to represent information depends on the number of distinct states in which it can exist. For example, a railway signal in operation can exist in three distinct states conveying three distinct pieces of information: red (stop), amber (caution), and green (go). The information-theoretic measure of entropy is a quantitative measure of this tendency of a computing system to exist in multiple states. This discussion will avoid mathematical definitions, focusing instead on the intuitive concept.

Consider, as a simplified example, the representation of information on a whiteboard. Each patch of the whiteboard can be either filled or unfilled by ink from a marker. In normal use, the whiteboard has a very high entropy because there are many possible distinct configurations (states) of filled or unfilled patches, and these many configurations each can represent characters or graphics. In the case where the marker dries out, however, the board is left with only one state—all white. Entropy is consequently zero, and no information can be represented. This case is analogous to that of pathologically weak neural connections in which neural assemblies remain in an all-off state regardless of the inputs with which they're presented. In the converse case where the marker bleeds all over the board the moment it touches the surface, again there is only one state, this time all black, and again the entropy is zero. This case is analogous to that of pathologically strong neural connections in which neural assemblies activate at the drop of a hat and remain activated. From this simple example, it can be seen that connectivity in terms of information transfer is not necessarily the same as connectivity measured in terms of mutual activations: the greatest degree of mutual activation evokes the least information capacity. In particular, overconnectivity at a neural level (or in general at the level of relatively local cell assemblies) may evoke underconnectivity at a cognitive level (Belmonte et al., 2004a)—a relationship that may be very significant for autism, as we shall see.

Entropy also exists in structural networks. Recall that for small-world networks, there exists a connectivity threshold for synchronicity. In a network whose connectivity is below this

threshold, none of the neurons will synchronize. At the other extreme, a network whose connectivity greatly exceeds this threshold could become entirely synchronized. As in the case of the malfunctioning marker board, such a network loses its selectivity. Rather than pairing activation patterns with distinct stimuli, the overconnected network responds indiscriminately to any stimulus.

A growing body of research has found that individuals with autism exhibit abnormalities in functional (task-related and resting-state) networks as well as structural networks (Noonan et al., 2009), characterized by an increase in short-range, small-scale connections at the expense of long-range, large-scale connections (Courchesne et al., 2007; Hasson et al., 2009; Kennedy & Courchesne, 2008; Minshew & Williams, 2007). These findings lend support to the notion that disruptions in the finely tuned balance between underconnectivity and overconnectivity, perhaps associated in some cases with an imbalance at the neural level between inhibition and excitation (Rubenstein & Merzenich, 2003) may produce the wide-ranging symptomatology of autism spectrum conditions.

Further evidence for disordered neural networks comes from the investigations of abnormal neural structure and function associated with autism. The cortex of the autistic cerebellum contains abnormally few Purkinje cells and granule cells (Williams et al., 1980; Ritvo et al., 1986; Bauman & Kemper, 1985; Bauman & Kemper, 1994), which could allow disinhibition in the cerebellar deep nuclei causing downstream overexcitation of the thalamus and its cerebral cortical projections. At a cerebral cortical level, one report has noted that densities of dendritic spines in autism are generally increased (Hutsler & Zhang, 2010), although this increase occurred with an idiosyncratic anatomical distribution in different individuals: on average across individuals and across the several anatomical regions sampled, autistic spine densities exceed non-autistic densities; however, this relationship has been pinned down to a single region only in the case of output layer 5 in temporal cortex (Brodmann area 22). An increase in spine densities at the neural level is consistent with abnormalities of information transfer at the computational level of analysis, and the idiosyncratic distributions are consistent with similar individual variations in patterns of functional activation detected by fMRI in contexts of motor (Müller et al., 2001), visuomotor (Müller et al., 2003), free viewing (Hasson et al., 2009), and face perception tasks (Pierce et al., 2001) and suggest an interaction between individual experience and a systems-level perturbation of some general mechanism for synaptic plasticity or learning. Notable in this connection is the raft of recent results on autism-associated disorders, suggesting that alteration of activity-dependent synaptic plasticity may be one route into the neural computational differences that can produce autism (Kelleher & Bear, 2008; Sharma et al., 2010; Hoeffer & Klann, 2010); these results begin with Fragile X Syndrome but may generalize to other autism-associated pathophysiologies.

Finally, because brain networks exhibit at least some scale-free properties, and thus should be resilient to randomly located failures within the network but not to failures at network hubs, another crucial question is whether individuals with autism demonstrate structural or functional abnormalities of the hubs of networks that subserve behaviors associated with autism, both within and beyond the diagnostic triad. Based on the current literature, the answer appears to be "yes." When shown pictures of eyes and asked to infer mental states, individuals with autism show enhanced activation of the superior temporal gyrus, accompanied by reduced activations in prefrontal and medial temporal areas (Baron-Cohen et al., 1999). Further, the connectivity between extrastriate visual areas and prefrontal and temporal areas normally associated with inferring mental states is reduced. When given the Embedded Figures Test (a task that relies on visually separating local details from a gestalt whole), individuals with autism show enhanced activation of ventral visual areas in the occipital cortex, despite reduced activations in parietal and prefrontal areas (Ring et al., 1999). When viewing faces, activation in the fusiform gyrus is reduced, yet areas outside the "face area" of the fusiform gyrus (Pierce et al., 2001), including inferior temporal gyrus (Schultz et al., 2000) and peristriate cortex (Critchley et al., 2000), show enhanced activation.

Prefrontal cortex (PFC) plays an important role in many higher-order cognitive functions. Gilbert et al. (2008) found that individuals with autism showed task-specific atypical recruitment of medial PFC during an executive function task; of the many areas examined in the study, medial PFC was the only area that distinguished between the autism and control groups. The same result has been obtained in the case of a task of auditory change detection in which anterior cingulate activation nearly completely differentiated autism-spectrum and non-autism-spectrum boys (Gomot et al., 2005) and in the case of a complex task of visual attention, in which boys with autism spectrum conditions did not differentially activate anterior cingulate cortex as a function of task complexity and showed a delayed and prolonged activation of dorsolateral prefrontal cortex (Belmonte et al., 2010), echoing at a physiological level many behavioral findings of long latency to disengage and to shift attention (e.g. Courchesne et al., 1994a; Townsend et al., 1996, 1999; Belmonte, 2000; Landry & Bryson, 2004)—a phenomenon that constitutes one of autism's earliest behavioral signs (Zwaigenbaum et al., 2005). Significantly, many of the clinically unaffected siblings of children with autism spectrum conditions show attentional function intermediate between that of normal and autism spectrum groups and a typically autistic time-course of delayed and prolonged differential frontal activation when attention-demanding and less demanding task conditions are compared (Belmonte et al., 2010), suggesting that this delayed frontal discrimination may be a familial endophenotype permissive, but not determinative, of autistic development.

In autism, it seems, perception and cognition are driven in a bottom-up manner, with stimulus discrimination depending on early activation of posterior cortical regions subserving sensory and perceptual organization (e.g., Belmonte & Yurgelun-Todd, 2003) and frontal discrimination being

brought to bear only much later (Figure 57-1), often too late for the demands of timed tasks that require quick-response decisions. This pattern stands in contrast to the physiology of nonautistic perception and cognition, in which discrimination is driven strongly and early by top-down signals from frontal cortex. Despite this strong difference between autistic and nonautistic populations, at an individual level it becomes somewhat more difficult to distinguish autistic and nonautistic people on the basis of brain physiology: in fact, the degree of delay in differential frontal activation correlates with psychometric measures of autistic traits, not only in those with autism spectrum disorders but also in their clinically unaffected siblings, even in unrelated children without any autism spectrum conditions in the family! It may be the case, then, that this dimensional variation in the degree of frontally based, top-down information processing represents a continuum of cognitive variation in all human beings, autistic or not.
Figure 57–1. Top-down cognition in non-autistic individuals, bottom-up cognition in those with autism spectrum conditions. fMRI time-courses from prefrontal cortex (right middle frontal gyrus) and posterior, sensory-driven cortex (right posterior intraparietal sulcus at its junction with transverse occipital sulcus) illustrate that non-autistic children (red) respond rapidly to a difficult perceptual problem with additional frontal activation. In those with autism spectrum conditions (blue), this differential frontal activation is muted, delayed, and prolonged so far past the end of the experimental trial that it is of no use in rendering a response decision. Those with autism spectrum conditions seem rather to depend on bottom-up signaling from early activation of posterior cortices. Clinically unaffected sibs (magenta) of those with autism spectrum conditions manifest a similarly delayed and prolonged time-course of differential frontal activation, and a frontally driven, top-down activation of posterior cortex but not the autistic, bottom-up, early peak in posterior cortical activation. Reprinted with permission from Belmonte et al. (2010). Visual attention in autism families: "unaffected" sibs share atypical frontal activation *Journal of Child Psychology and Psychiatry*, *51*, 259–276, published by Blackwell Publishing on behalf of the Association for Child and Adolescent Mental Health. (See Color Plate Section for a color version of this figure.)

What may differentiate clinically affected and unaffected individuals, then, is the developmental translation of this dimensional, anatomically localized abnormality, within the frontal connectivity hub, to a more generalized, categorical degradation of functional connectivity throughout the brain: autism spectrum probands manifest this whole-brain connectivity degradation, whereas unaffected siblings do not (Belmonte et al., 2010)—or at least not to any similar degree (Figure 57-2). Future longitudinal studies of younger sibs at risk for autism spectrum conditions may usefully examine this question of the relationship between familial frontal-lobe abnormality and anatomically generalized disruption of functional connectivity.

Connectivity in Autism

To identify abnormalities in connectivity, it is essential to understand connectivity in typically developing individuals. For more than a decade, resting-state fMRI has been applied to investigate functional connectivity in humans. The first of this work applied low-frequency (<0.1 Hz) fluctuations in BOLD signal to identify functionally connected areas of motor cortex, which were later shown to be associated with motor function (Biswal et al., 1995). More recently, this method has been employed to assess the resting-state "default" network in healthy adults.

A recent study employing resting-state fMRI distinguished a "salience network" and "cognitive-control network" in healthy adults (Seeley et al., 2007). The "salience network" comprises superior temporal pole, anterior insula, and paracingulate and anterior cingulate cortices, with functional connections to temporal, parietal opercular, dorsolateral PFC, and subcortical areas, including parts of the thalamus, hypothalamus, extended amygdala, striatopallidum, substantia nigra, and periaqueductal gray. Activation of this network, specifically dorsolateral PFC and dorsal anterior cingulate cortex (ACC), correlates with reported levels of anxiety prior to scanning. The "executive-control network" comprises left frontoinsular areas and lateral PFC and dorsomedial PFC, with subcortical functional connections extending into anterior thalamus and dorsal caudate. Activations in this functional network are positively correlated with performance on a cognitively demanding task (the Trail Making Test).

Cherkassky et al. (2006) compared the resting-state functional networks in autism and control groups and found that both networks comprised similar areas, but the autistic resting-state network was less strongly connected. In another study (Just et al., 2004), subjects were asked to read and answer questions about sentences. Individuals with autism showed greater activations in left lateral superior temporal areas (classically defined Wernicke's area) and reduced activation in left inferior frontal gyrus (classically defined Broca's area). They also exhibited reduced functional connectivity between the two regions, indicating reduced synchronization between
Figure 57–2. Functional connectivity among 76 brain regions (38 bilateral pairs) in children with autism spectrum conditions, clinically unaffected sibs of children with autism spectrum conditions, and unrelated non-autistic children. The axes are lists of brain regions; a colored dot indicates a statistically significant correlations between fMRI time-courses in the indicated region pair. Although no difference survives correction for the large number of multiple comparisons, when measures are collapsed across all regions pairs, the non-autistic and sib groups are statistically indistinguishable in their degrees of overall functional connectivity, whereas both groups are highly significantly distinct from the autism spectrum group. Reprinted with permission from Belmonte et al. (2010) Visual attention in autism families: "unaffected" sibs share atypical frontal activation. *Journal of Child Psychology and Psychiatry, 51*, 259–276, published by Blackwell Publishing on behalf of the Association for Child and Adolescent Mental Health. (See Color Plate Section for a color version of this figure.)

the broad cortical areas termed Broca's and Wernicke's. Cortical networks appear to demonstrate small-world and scale-free properties. Achard et al. (2006) defined a functional network with 90 cortical and subcortical regions. This network satisfied small-world criteria, with highly connected hubs located mainly in association areas of neocortex. They contrasted this "core" with the "periphery" of paralimbic areas that were less highly connected. By employing diffusion tensor imaging (DTI), they also identified white matter tracts underlying these functionally connected cortical regions. Moreover, these small-world anatomical networks closely mirror those already identified in cat and macaque cortex.

More recently, van den Heuvel et al. (2008) applied a similar methodology to investigate resting-state functionally connected networks in 28 healthy adults. They found small-world and scale-free characteristics in their voxel-based analysis and identified potential hub regions in bilateral anterior cingulate cortex, bilateral superior temporal lobe, bilateral thalamus, and bilateral posterior cingulate cortex. A follow-up study by DTI and fMRI confirmed that anatomically connected cortical areas on either end of well-known white matter tracts (e.g., genu and splenium of the corpus callusom, bilateral fronto-occipital, and parietal fasiculi) also exhibited functional connectivity (van den Heuvel et al., 2009).

Until quite recently, there have been almost no studies examining how functional networks in the brain change developmentally. Understanding the developmental trajectory of typically developing individuals is important because of the developmental nature of autism. Following the precedent set by Mesulam (2000), Supekar, Musen, and Menon (2009) parcellated the brain into five regions: primary sensory, subcortical, limbic, paralimbic, and association. Assaying differences between children and young adults with respect to small-world characteristics of these functional networks as

defined by resting-state fMRI, they found that resting-state functional networks exhibit small-world properties (high clustering and low average path length) in both adults and children. However, the adults exhibited increased functional connectivity for cortico-cortical connections relative to children. These developmental changes in functional correlation were also related to changes in anatomy. DTI revealed that the child group was characterized by a greater number of short-range structural connections. In the adult group, these short-range connections were fewer and long-range connections became much more prevalent. Further, functional connectivity between anatomically close brain regions was greater in children than in adults, whereas functional connectivity between distant regions (whether measured by Euclidian distance or fiber-tract length) was greater in adults than in children. Supekar et al. concluded that normal development is a dynamic processes, wherein the brain is initially (at least by age 6 years) overconnected, both structurally and functionally. Subsequent pruning and rewiring reduce short-range structural and functional connections and increase long-range connections. Future anatomical and physiological studies of autism can usefully address, longitudinally or even simply cross-sectionally, this issue of the developmental relation between short-range and long-range connectivity.

These developmental abnormalities of connectivity may relate to more commonly measured developmental abnormalities of tissue volume. Because of the timing of diagnosis, little is known about autistic brain volume perinatally. By the second year of life, however, white matter and gray matter volumes have increased relative to typically developing controls (Courchesne et al., 1999; Ben Bashat et al., 2007). White matter increases, driven by premature myelination in frontal regions (Ben Bashat et al., 2007) are most pronounced in later developing, anterior regions of the brain, specifically in frontal

and temporal lobes but not the posterior occipital lobe (Carper & Courchesne, 2005; Carper et al., 2002; Courchesne et al., 2001, Hazlett et al., 2005; Sparks et al., 2002). Gray matter development follows a similar pattern, with early overgrowth in frontal and temporal lobes but not in the occipital lobe (Bloss & Courchesne, 2007; Carper et al., 2002, Hazlett et al., 2006; Keats et al., 2004; Palmer et al., 2005). Later decreases in gray matter volumes are evidenced by cortical thinning and abnormal white matter development in frontal, temporal, and superior temporal areas in adults with autism (Hadjikhani et al., 2006; Lee et al., 2007). These changes are especially relevant to the connectivity paradigm; some have suggested that the developmental trajectory of brain volume is more strongly linked to performance on cognitive tasks than measures of static brain volume (Shaw et al., 2006).

This issue of brain size is important because it constrains the ratio of short-range to long-range anatomical connections. An increase in long-range connections is associated with a smaller brain, both in the context of brain imaging of normal adults (Lewis et al., 2009) and in a computational model based on anatomical observations of autism (Lewis & Elman, 2008). This relationship is thought to have been established evolutionarily because it helps to maximize cellular efficiency and to minimize conduction delays (Ringo, 1991; Ringo et al., 1994; Lewis et al., 2009). An increase in overall brain volume should be accompanied by an increase in short-range, intra-hemispheric, and cortico-cortical connections and a reduction in long-range and inter-hemispheric connections. Thus, it should come as no surprise that autism is marked by a reduction in corpus callosum volume (e.g., Egaas et al., 1995; Alexander et al., 2007; Just et al., 2007) and abnormal white matter growth specific to short-range connections such as the corona radiata and intrahemispheric corticocortical connections (Herbert et al., 2004). Such an increase in local structural connectivity could degrade the signal-to-noise ratio of those networks by pushing the interconnectedness of the neurons too far past their synchronization threshold—a possibility consistent with the strong comorbidity of autism and epilepsy (Ballaban-Gil & Tuchman, 2000).

Manifestations of Abnormal Information Processing in Autism

These long-range connections, especially to and from frontal and parietal areas, are essential for large-scale networks subserving the unique computational complexities of social cognition, such as the resting or "default" network and the oft-cited "mirror neurone system" (Courchesne et al., 2007). Large-scale networks that additionally involve parietal areas have been postulated to mediate perspective-taking, both in a physical visuo-spatial sense and in a social ToM sense (Frith & Frith, 2006). Autism is often conceptualized from the perspective of cognitive modularism as though it were a selective deficit in a module for ToM, the ability to represent others' beliefs

and desires as separate from one's own and to act on such separable representations. However, this exclusive conceptualization in terms of ToM cannot explain autism's characteristic pattern of superiorities and deficits in nonsocial domains, such as those described by the notion of "weak central coherence" (Frith & Happé, 1994). Key to unifying autism's social and nonsocial symptoms domains is understanding autism as a *developmental* condition—developmental not only in terms of its nosology but in terms of its etiology, in which complex social cognitive traits may unfold from more subtle abnormalities in simpler, nonsocial capacities, or in which both social and nonsocial symptoms may arise from common disruptions at the level of the underlying neural systems and substrates on which these capacities are built and refined as development proceeds. Thus, although autism's social and communicative deficits are its most obvious, most diagnostic, and most debilitating symptoms, they are not necessarily its most etiologically primary.

A possible computational connection between ToM or perspective-taking in general and the more sensory and perceptual qualities of weak central coherence is provided by a reframing of perspective-taking as the translation of egocentric into allocentric perspectives (Frith & de Vignemont, 2005). In this view, the core computational issue is described not in social terms but in the more perceptual terms of the transformation of egocentric coordinates (those centered on the observer) to allocentric ones (those centered on the surrounding space—whether concrete physical or more abstract social space—and those who occupy it). This unifying view has links, too, with the notion of enhanced perceptual function in autism (Mottron et al., 2006) in that imagining an allocentric perspective demands suppressing one's own, veridical, perceptually immediate, and salient egocentric perspective on the world (Belmonte, 2008). Whereas this replacement of a detail-oriented, disconnected veridical percept with a more abstract, bound, and contextualized symbolic representation was described by Frith and Happé (1994) in the context of autism as "central coherence," Trope describes exactly the same concept as "level of construal" (Liberman & Trope, 2008) and relates it to the concept of psychological distance, which spans both simple spatial or geometric distance and social distance. In normal subjects, the spatial distance from which events are perceived is associated with more social and abstract forms of psychological distance such as perception of goal-directedness and use of abstract rather than concrete language (Fujita et al., 2006). Thus, autism's social, linguistic, and perceptual abnormalities may be all pieces, related to each other computationally in the same way in which less extreme variations in these abilities are inter-related in typically developing people.

Studies of complex cognitive traits tend to place experimental control at odds with ecological validity, and it usually is experimental control that wins. A simple Posner attention paradigm, for example, is a very specific assay for the disengagement, shifting, and engagement of attention, but its repetitive trials may so fail to engage the experimental subject's interest and excitement that the experiment fails to measure

the levels to which these capacities are engaged in everyday behavior. Many investigators are attempting to find a way between the horns of this dilemma of experimental control versus ecological validity by embedding well-controlled stimuli in more naturalistic contexts (e.g., Valla et al., 2010).

A 2009 study (Cohen et al.) has helped to elucidate how social and spatial perspective-taking might be differentiated neurologically. Five adults with pharmacoresistant epilepsy (but not autism) were asked to provide responses that required either spatial or social perspective-taking. Four of the subjects had presurgical electrodes implanted on the surface of temporal cortex, and the fifth subject had a lesion in pSTS. The individual with a lesion to pSTS was significantly slower and less accurate at the social perspective-taking condition. Additionally, the four individuals with intracranial electrodes demonstrated significantly greater gamma power over pSTS during social perspective-taking as compared to spatial perspective-taking. These results suggest that pSTS is an important component of a cortical network utilized to assess the desires of others.

Gamma: frequencies greater than 30 Hz. Gamma power has been suggested as an electrophysiological indication of perceptual binding (Engel & Singer, 2001).

STS has also been implicated in the identification of biological motion in a point light display (PLD; Blake et al., 2002). Individuals with autism seem able to identify actions but have difficulties identifying and describing emotion in the biological motion depicted by PLDs (Moore, Hobson, & Lee, 1997; Hubert et al., 2007). A biological explanation for this surprising result may come from two recent fMRI studies that examined subjects' abilities to identify intact and scrambled PLDs (Herrington et al., 2007; Freitag et al., 2008). The intact versus baseline condition produced reduced activations in middle temporal gyrus and, in Freitag et al., was accompanied by increased activations in postcentral gyri, left hippocampus, and middle frontal gyrus. Moreover, it seems that individuals with autism may be recruiting a different neural network to identify intact human movements in PLDs. Freitag et al. compared intact and scrambled conditions and found that controls activated a network involving bilateral frontal, temporal (especially STS), and parietal areas, as well as insula and basal ganglia. The autism group did not demonstrate such widespread activations. Rather, they seemed to rely on the parietal-temporal junction and frontal areas in the left hemisphere and limbic areas and thalamus in the right hemisphere. Given that autism is associated with a reduction in the white matter tracts that lie next to parietal-temporal junction and STS (Barnea-Goraly et al., 2004), biological motion abnormalities in autism provide one further example of how atypical behavior associated with autism is related to atypical recruitment of an abnormally structured brain.

Point light display (PLD): a collection of moving points of light representing points on a single moving figure. These can be generated by attaching markers to important joints on actors.

Abnormal cortical recruitment was also found in a recent study examining functional networks during adult subjects' viewing of a film clip (Hasson et al., 2009). Whereas typically developing controls exhibited a consistent activation pattern relative to the film, subjects with autism manifested neither the same activation pattern as the controls nor the same activation pattern as each other. However, subsequent analysis revealed that the observed differences in the autism group (both between groups and within group) arose because of idiosyncratic fluctuations in cortical activity in the individuals with autism. In other words, typically developing adults recruit similar cortical areas that exhibit similar activations across time during the passive viewing of a film. Individuals with autism exhibit the same pattern, but it is obscured by superposition of idiosyncratic activations throughout this network, including high-order areas and primary sensory cortices. High test–retest reliability for these idiosyncratic activation patterns indicate that they are not transient abnormalities. Rather, these findings suggest that autism is marked by individually unique neural networks. Such idiosyncrasies help explain why one of the most consistent findings in autism research, regardless of the methodology or variables of interest, has been a much greater variance in the autism group than in controls.

Atypical cortical recruitment is not limited to the visual domain. For example, a recent fMRI study used a self-paced sequential finger-tapping paradigm to examine online cortical motor function in 13 right-handed children with high-functioning autism and 13 right-handed control children (Mostofsky et al., 2009). Although the behavioral results did not differ, the autism group demonstrated reduced activations in contralateral and ipsilateral anterior cerebellum relative to controls, with increased activations in posterior supplementary motor area (SMA). The functional connections between bilateral thalamus and SMA were also reduced in the autism group. The researchers noted that because the demands of the motor task were driving the correlations below "rest-level," it was likely advantageous for the individuals with high-functioning autism to treat SMA and right and left thalamus as independent processors.

This decreased connectivity may also help explain why individuals with autism seem to rely to a greater extent on proprioceptive feedback, rather than visual feedback, for updating and modulating motor programs. In a recent study (Haswell et al., 2009), individuals with autism were asked to move a lever hidden by a horizontal screen toward a target animal on a monitor in front of them. By applying force orthogonally to the intended direction of movement, it was possible to assess reliance on visual feedback and proprioceptive feedback. The individuals with autism relied much more strongly on intrinsic (proprioceptively defined) coordinates. Moreover, increased reliance on proprioceptive feedback was correlated with higher scores on the SRS and the Reciprocal Social Interaction Score on the ADOS-G, as well as greater impairment on the Physical and Neurological Examination of Subtle Signs (PANESS). PANESS scores are interesting because they not only distinguish children with autism (Jansiewicz

et al., 2006) but correlate with increased white matter volume in left motor cortex (Mostofsky et al., 2007).

Perception in Autism

Across modalities, abnormal connectivity in autism manifests as intact or enhanced perception of simple stimuli with deficits in perception of complex stimuli. Further, individuals with autism seem to preferentially recruit computationally early stage information processing centers. It is important to note that for our purposes, a stimulus is more "complex" if it requires the recruitment of a greater number of interacting functional capacities. For example, Bertone and colleagues (e.g., Bertone et al., 2003) use luminance-defined (additive contrast) and texture-defined (multiplicative contrast) visual stimuli. The luminance-defined stimuli are "simple" because they can be processed in V1, whereas texture-defined stimuli require the integrative capacities of V5.

Individuals with autism show deficits in complex motion processing, as evidenced by abnormally high perceptual thresholds for coherent motion (e.g., Spencer et al., 2000). These findings have been taken by some to indicate that autism is characterized by a "dorsal stream vulnerability" because of impairments in abilities subserved by the magnocellular pathway (Spencer et al., 2000; Milne et al., 2002), possibly because of a decreased signal-to-noise ratio. However, as Bertone and Faubert (2006) have noted, these results could also be explained in terms of complexity-dependent deficits. When using computationally simple first-order and computationally complex second-order tasks, individuals with autism demonstrate decreased performance only on second-order motion perception tasks (Bertone et al., 2003). More recently, Pellicano et al. (2005) have found deficits in global motion coherence in autism with intact low-level (e.g. subcortical areas, thalamus) flicker sensitivity in the dorsal stream, suggesting that magnocellular function is relatively unaffected. Abnormally "noisy" networks may affect the ability of individuals with autism to perform integrative tasks, which might manifest only during complex, higher-order tasks (Minshew & Williams, 2007; Simmons et al., 2009).

Further evidence for complexity-dependent visual processing abnormalities in autism comes from research into contrast sensitivity. Some studies have found intact dynamic (Bertone et al., 2005; Pellicano et al., 2005) and static (Behrmann et al., 2006; de Jonge et al., 2007; Milne et al., 2009) contrast sensitivity in individuals with autism. Yet two studies have found that autism is associated with a higher contrast threshold for second-order stimuli (Bertone et al., 2003, 2005). Contrast sensitivity seems to be intact for dynamic first-order stimuli (Bertone et al., 2003) and enhanced when first-order stimuli are static (Bertone et al., 2005). These results were recently replicated in a small population of unaffected 6-month-olds whose older siblings had been diagnosed with autism (McCleery et al., 2007), suggesting that complexity-dependent

perceptual processing may be an endophenotype of autism. This constellation of intact or enhanced perception of simple visual stimuli with decreased perception of complex visual stimuli could serve to differentiate between autism spectrum conditions (extending to clinically unaffected family members) and related neurodevelopmental disorders such as Fragile X Syndrome (Bertone et al., 2006).

Autism is associated with both hypersensitivies and hyposensitivities (e.g., Bogdashina, 2003) to a wide variety of stimuli. Moreover, these unusual sensitivities may interfere with an individual's ability to communicate, as in the case of the potential effect of cross-modal extinction (Bonneh et al., 2008) on perception of multimodal social and nonsocial stimuli. Given reports of unusual sensory sensitivities in autism, sensory gating might be expected to be disrupted. Yet people with autism spectrum conditions have intact auditory (Kemner et al., 2002) and audio-visual (Magnée et al., 2009) P50 suppression (a hallmark of sensory gating). A 2008 study (Orekhova et al.) did find impaired auditory P50 suppression but only in a low-IQ autism subgroup. Further, in the low-IQ subgroup only, P50 suppression was correlated with mean spontaneous gamma power, implicating abnormal perceptual binding. Because the studies that found intact P50 suppression did not include low-IQ subjects, these results suggest that relatively simple sensory gating may be disrupted only on the extreme end of the autism spectrum.

Consistent with the complexity-dependent hypothesis, some studies have found enhanced early stage perception in autism. For example, in an auditory mismatch study, N1 latency was reduced (Ferri et al., 2003). When viewing Gabor patches, autism has recently been associated with earlier, exogenous activation of right posterior intraparietal sulcus (Belmonte et al., 2010) and reduced P1 latencies and earlier alpha-band peaks (Milne et al., 2009). In Milne et al., P1 latency was significantly negatively correlated with CARS score, suggesting that the severity of autistic symptoms may be associated, more generally, with faster low-level information processing.

Milne and colleagues (2009) also found that the individuals with autism exhibited a less specialized visual processing network. They used Gabor patches with four different spatial frequencies. For the higher frequencies, the control group showed increased gamma power. This stimulus-dependent increase was depressed in the autism group, suggesting that at least for contrast sensitivity, individuals with autism possess a network with reduced entropy—that is, one that responds indiscriminately strongly to all types of inputs.

Not surprisingly, reduced selectivity (resulting from connectivity-driven reductions in network entropy) has been observed in several other EEG studies. If children with autism are asked to respond to an auditory stimulus, their P3 is abnormally distributed into occipital areas associated with visual processing (Kemner et al., 1994). In the same population, novel visual stimuli, even if they are task-irrelevant, reliably produce an enhanced N2 response (Kemner et al., 1994). In autistic adults, the evoked P1 response is either

overgeneralized to stimuli far away from an attended location or unusually enhanced at the attended location (Townsend & Courchesne, 1994). Finally, during attentional shifts between hemifields, individuals with autism show indiscriminate activations, rather than spatially specific augmentation of the visual steady-state potentials observed in typically developing populations (Belmonte, 2000). These unusual evoked responses are consistent with primary sensory areas that suffer from degraded signal-to-noise ratio, perhaps resulting from overconnectedness of local structural and functional neural networks.

Networks of Neurons, Networks of Genes, and Proteins

A brief discussion of autism genetics is appropriate to the topic of autistic neural information processing insofar as the same network issues arise. Autism genetics, like autism physiology, has suffered from the distraction of twentieth-century, univariate approaches. Single-gene studies of complex neuropsychiatric disorders are valuable insofar as they highlight points of entry into networks of interacting genes, but it is these network-level disruptions that are the meat of the matter. The risk for autism arises not only in the protein product of an individual gene but, rather, in that protein product's many interactions with other genes and proteins that themselves carry individual differences. Many of these interacting susceptibility alleles vary greatly in their prevalance between distinct populations. For example, the G/T SNP rs3813034 in the 3' UTR of *SLC6A4* has been selected for the T-allele in African and European populations but for the G-allele in Asian (Chinese, Japanese, and eastern Indian) populations (Guhathakurta et al., 2008), and in the case of *RELN*, 16% of Indians but only 6% of Europeans carry an expanded sequence of 11 or more CGG repeats in the 5' UTR (Dutta et al., 2007). These are but two examples of a phenomenon that is likely widespread among populations and among individual autism risk factors. Because autism susceptibility or protection alleles individually produce only small increments or multiples of risk, we can expect that the risk level and perhaps even the very identity of an allele as an autism risk factor, within a specific population, may depend on the population-genetic context consisting of all the genes with which that putative risk factor interacts. Contrasts between genotypically and (endo)phenotypically well-characterized populations from different regions or other stratifications (e.g., castes; *see* Reich et al., 2009) therefore may have much to say about the nature of the genetic networks involved in autism susceptibility or protection. Candidate-gene studies in eastern Indian populations, for example (Dutta et al., 2007, 2008; Guhathakurta et al., 2008, 2009; Sen et al., 2010), have revealed tantalizing contrasts, both positive and negative, with findings from the more often studied populations of Europe and North America. Why is it germane, and important, to talk about genetics in the context

of a chapter on information processing? As we hope that this brief discussion has shown, genetic networks and their associated environmental factors cannot be separated from their effects on neural networks. The answers to autism, and to other complex neurodevelopmental disorders, will come from an integrative style of neuroscience and an integrative sort of neuroscientist that deals in both these domains.

Conclusion

During the past decade, the neurobiological study of neuropsychiatric disorders has benefited from this new focus on connectivity between brain regions (Frith, 2003; Fusar-Poli & Broome, 2006). In particular, the systems-level dysfunction in autism has been characterized as a network perturbation possibly comprising abnormally strong and undifferentiated connectivity within local networks and a resultant failure to develop normal patterns of long-range connectivity among brain regions and among cognitive subsystems (Brock et al., 2002; Belmonte et al., 2004a; Courchesne & Pierce, 2005). This idea is consistent with an emerging collage of autism susceptibility genes that perturb neural connectivity by altering neuron numbers, synaptic structure, or neurotransmission (Belmonte & Bourgeron, 2006)—many of which may be responsible for dimensions of normal as well as abnormal cognitive variation (Ronald et al., 2006a, b; Valla et al., 2010)—and has been supported by functional imaging results in autism demonstrating abnormally strong activation within brain regions that subserve low levels of processing along with abnormally weak activation within higher-order, integrative regions (Belmonte & Yurgelun-Todd, 2003) and abnormally weak functional connectivity between brain regions (Just et al., 2004; Belmonte et al., 2010), as well as by anatomical studies of high local and low bridging white matter volume (Herbert et al., 2004) and low-diffusion anisotropy in white-matter regions subserving integrative processing (Barnea-Goraly et al., 2004).

The recency of interest in neural connectivity in autism arises in the context of the historical focus of neuroscience on single-variable problems. Science as a matter of course directs its enquiries toward well-framed and tractable hypotheses in which one independent variable is manipulated while all other factors are somehow held constant. Historically, this single-variable focus has produced great advances in the understanding of the effects of brain lesions (in which a single anatomical structure is silenced) and single-gene disorders (in which one gene is silenced or gains function). Complex neuropsychiatric conditions, however, are anything but single-variable problems. In autism in particular, the one truth that has become clear from decades of study is that this behaviorally defined condition converges from many possible etiological factors and combinations thereof and diverges into a welter of endophenotypic variability (Belmonte et al., 2004b). The lesion model is as poor a one as the single-gene

model for understanding developmental disorders, as the experience-expectant maturation of any one brain structure depends on its receiving properly patterned inputs from the structures with which it communicates, and thus a perturbation of any one region becomes a perturbation of the entire network of interacting brain regions (Johnson et al., 2002), just as variants in a collection of genes combine to produce emergent variation in networks of interacting genes (Belmonte & Bourgeron, 2006). Instead, research into autism ought to proceed with the understanding that the ultimate etiological explanation of autism will involve complex genetic processes that produce unique brain anatomy and associated unique function, and that the very same genetic factors that underlie autism also produce a broad range of cognitive diversity in the nonautistic population and many cognitively beneficial traits in people with autism spectrum conditions. An eventual prevention and cure for autism will succeed insofar as it can ameliorate autistic deficits while preserving autism's unique, detail-oriented perceptual insights and confer the social and communicative abilities that will allow people with autism to share those insights with the broader social world (Belmonte, 2008). This volume, then, should more properly and generally to be titled not "Autism Spectrum Disorders" but "Autism Spectrum Conditions"— for the autism spectrum encompasses a wide range of phenotypes and may well turn out to be inseparable from the state of being human.

Challenges and Future Directions

- Distinguish between dimensional and categorical aspects of autism spectrum conditions.
- Investigate what factors affect bifurcation between diagnosis of autism and subclinical autistic traits (both additional risk factors in clinical populations and protective factors in nonclinical populations); develop targets for preventive treatments.
- Investigate how systems-level abnormalities of the neural computational substrate might give rise developmentally to diagnostic characteristics of autism; characterize covariation of low-level and high-level perceptual and cognitive abnormalities in autism spectrum conditions.
- Characterize the developmental relationship between short-range and long-range structural and functional connectivities in autism spectrum conditions.
- Integrate univariate conceptions of autism into multivariate, multilevel constructs.

Commentary

Francesca Happé

Translation Between Different Types of Model

Inspired by the chapters in this section, the present commentary discusses possible relationships and interplay between animal models and neurocognitive accounts of autism spectrum disorders (ASD). It begins with a recap of types of validation possible for animal models in general. After brief comments on construct and predictive validity in models of ASD, face validity is discussed at a number of distinct levels. Face validity concerning behavior or symptom pattern has been the primary focus for this behaviorally diagnosed spectrum of conditions. What should be the aim of animal models of ASD focused on behavioral face validity? At least two possible approaches exist; to attempt to model the full syndrome (as advocated by Tordjman et al., 2007, for example), or to identify and target "fractionable" elements, ideally intermediate phenotypes, which need not be unique to ASD. These different approaches are discussed, and evidence is presented for fractionating the triad of ASD characteristics. Lastly, possible contributions from cognitive theories to animal models of ASD are considered.

Assessing Animal Models: Different Types of Validity

As several authors in this section (e.g., Yang, Scattoni, Chadman, Silverman, & Crawley, Chapter 51) remind us, animal models can be assessed in terms of three broad types of validity: "face validity" or analogy to human syndrome, "construct validity" or similarity of cause or pathogenesis, and "predictive validity" or similarity of prevention, reversal, or treatment effects. In our ongoing ethical consideration of the use of animal models, a clear rationale and justification of validity is imperative.

In human conditions where the genetic basis is known, such as Fragile X or Rett syndrome, **construct validity** can be achieved simply in, for example, knockout mice. In the case of

ASD, as Hsiao, Bregere, Malkova, and Patterson point out (Chapter 52), the etiology is unknown, and so establishing construct validity is a huge challenge. That ASDs are highly heritable is not disputed: twin and family studies (reviewed elsewhere in this volume) suggest heritability as high or higher than for any other developmental disorder (although see Corrales & Herbert, Chapter 49, for cogent arguments about why heritability estimates might be inflated by, for example, unknown gene-environment interaction or placentation effects). The genes involved in vulnerability in most cases of ASD are as yet unknown (Abrahams & Geschwind, 2008). In a small minority of cases of ASD, a known chromosomal abnormality will be identified, or a rare single gene mutation. Such cases are the focus of much investigation, for example mouse models of FraX are studied to illuminate ASD, because of the raised rate of ASD in FraX children. Such research (e.g., Spencer, Graham, Yuva-Paylor, Nelson, & Paylor, 2008) has highlighted the important influence of the genetic background on which the knockout is made. This reminds us that in the human case, too, the identified single gene mutation may not be the sufficient cause of the individual's autism, even in this small minority. Similarly, the causal role of raised copy number variation (CNV) in autism (e.g., Sebat et al., 2007), and other psychiatric conditions, has been debated (e.g., Joober & Boksa, 2009).

Animal models are key to exploring putative *environmental* causal factors in ASD. These, which include in utero factors such as exposure to neurotoxins (e.g., valproic acid), maternal infection (e.g., rubella) or maternal autoantibodies, are well described in the Chapters in section VII, by Hertz-Picciotto, Rodier, and Corrales and Herbert (Chapters 47, 48, and 49, respectively). Rodier and Hertz-Picciotto highlight similarities between the study of environmental factors and the study of genetic contributions to ASD: extremely rare cases with known cause (e.g., thalidomide) may shed light on some final common pathway of effect relevant to ASD more widely, but apart from these only rather weak links can be made to many hundreds of possible environmental factors.

Animal models are vital for testing the causal role of environmental factors associated with autism in epidemiological studies (reviewed by Hertz-Picciotto, Chapter 47). As the authors in section VII note, however, even identifying reliably associated environmental risk factors is complicated by the likely gene-environment interaction—that is, only some individuals will be vulnerable to the key environmental factors (or, genetic vulnerability will only be seen in certain environments). This requires studies stratifying environment by genetic group or vice versa. Since, at present, we know neither the key environmental factors nor the key genetic factors, one might be forgiven for a certain pessimism about discovering the causes of autism "bottom up." Corrales and Herbert suggest, however, that the study of biomarkers that aggregate multiple environmental risk factors would be one way forward in the absence of knowledge of specific teratogens (Chapter 49). Animal models exploring gene-environment interaction will be essential; seeing how a particular genetic variant develops under different environmental circumstances may elucidate not only causal mechanisms of pathology but also possible paths of intervention.

The process of translational research is, ideally, one of iteration between clinical/human and nonhuman/lab work. **Predictive validity** is often tested, for example, by looking at the effect of clinically useful drug treatments on animal models of disorder. In the case of ASD, it is striking that there is no targeted drug therapy known to affect the core symptoms. Drugs may be given for aggression, anxiety, self-injury, and so forth, but no drug has been shown to alter social, communication, or repetitive/restricted behavioral aspects of the core phenotype. While this may change in the years ahead (note for example, recent work suggesting improved social processing during oxytocin administration, reviewed by Posey, Erickson, & McDougle, 2008), the most effective interventions for ASD to date are behavioral and educational (see Rogers & Wallace, Chapter 61; Kasari & Locke, Chapter 66; and others in this volume). These have not been "back-translated" into animal models relevant to ASD—although it is notable that social effects of maternal deprivation in monkeys can be reversed in some cases by peer contact (as discussed in Bauman & Amaral, Chapter 53). The effects of specific educational "environmental enrichment" deserve to be studied at the neuronal and epigenetic levels. It is interesting that individual differences, for example, in drug response within an inbred strain are typically regarded as "noise" in the data—whereas a clinical perspective might find drug nonresponders of particular interest. Even within inbred strains of lab animals (whose members are genetically identical), clear behavioral differences can be seen by handlers, in, for example, social hierarchy and cage stereotypy. These presumably reflect gene-environment interaction and epigenetic effects, important for understanding clinical heterogeneity.

The study of treatment effects highlights an important aspect of ASD that animal modelers need to note; developmental course. Studies of genetically at-risk infants, through the baby sib projects now underway in several centers (see

Zwaigenbaum, Chapter 5, this volume), are providing more accurate information about how ASDs unfold. Animal models, and particularly possible future animal models of treatment effects, need to capture the profile of typically unexceptional very early development, followed by first signs of reduced social orienting (e.g., turn to name, preferential gaze to face, and eye contact) around 9–12 months. Recent research also suggests nonsocial symptoms emerging relatively early, such as peculiar visual exploration of objects (Ozonoff, Macari, Young, Goldring, Thompson, & Rogers, 2008) and repetitive behavior (Watt, Wetherby, Barber, & Morgan, 2008). Regression, ranging from relatively sudden "loss" of skills to increasing divergence from the typical developmental trajectory, appears to be common throughout the spectrum (see Ozonoff, Heung, & Thompson, Chapter 4, this volume).

Importantly, however, some individuals with ASD make good progress in later childhood or adulthood, and compensation can be dramatic, at least within structured and "scaffolding" settings. Thus the demands of the environment importantly modify the presentation of ASD—in line with gene-environment interaction effects discussed above (and in detail in Corrales & Herbert, Chapter 49, and Hertz-Picciotto, Chapter 47). Since laboratory conditions typically strive to limit "noise" due to variable environment, limited environmental variance may mask relevant genetic variance in animal models. Similarly, quantitative genetic research with humans has shown the snowballing effect of gene-environment (G-E) correlation; that many environmental factors are "heritable" in the sense that genetically influenced traits evoke and search out certain sorts of environments (see review by Jaffee & Price, 2007). If lab animals have little chance to seek out, choose, or influence elements of their environment, these G-E correlation effects (and hence heightening of heritability) will not be seen. Lastly, the final part of the developmental trajectory, that is, old age in ASD, has barely been charted and remains a key area for future research. Tracing brain changes during aging in putative animal models of ASD may give clues for future clinical studies of ASD in old age.

The remaining type of validity, **face validity**, has perhaps been the main focus for discussion of animal models: is autism a quintessentially human condition? Could a mouse, for example, ever be "autistic"? However, face validity can be examined at a number of levels, much as Morton and Frith's (1995) causal modeling framework suggests any condition can be described and explained at behavioral, cognitive, and biological (neural, genetic, etc.) levels. Thus, for example, face validity of an animal model of the *neuropathology* of autism would depend on the homology between the human and model neural organization. While no single or sufficient neuropathology has been identified as causal in ASD, better-replicated brain features include reduced Purkinje cells in the cerebellar vermis, accelerated brain growth in infancy, and increased platelet serotonin, as well as the more recent suggestion of abnormal long-range connectivity—all of which are discussed in contributions to the present volume. Each of these could be interestingly modeled in nonhuman animals

(see Chapter 52, by Hsiao et al.). Blaker, DeRienzo, and Sive's chapter on the use of the zebrafish to investigate ASD (Chapter 50), also reminds us that an "animal tool" may shed light on human pathology *without* approximating a match to the human disorder.

Face validity has received most discussion, however, in relation to the behavioral level, perhaps because autism is a behaviorally defined diagnosis. Here it is pertinent to ask, what should be the focus for animal modelers seeking behavioral face validity? Should the aim be to mimic the full syndrome of ASD (as advocated by, for example, Tordjman et al., 2007), or to focus on one symptom of the disorder (e.g., Miczek & de Wit, 2008)? In the next section, I'd like to suggest that useful pointers may come from studies of ASD and ASD-like traits in human quantitative genetic studies.

The "Fractionable Triad"?

Autism is only diagnosed in the presence of qualitative impairments in social and communication skills, and rigid and repetitive behavior/interests (RRBI). However, when one looks outside core autism, it appears that the "autistic triad" is not monolithic but rather "fractionable" (Happé, Ronald, & Plomin, 2006). Four types of evidence are relevant to summarize here (for fuller discussion of the "fractionated triad" view, see Happé & Ronald, 2008; Mandy & Skuse, 2008; and for a contrary view, Constantino et al., 2004). First, studies of ASD-like traits in the general population suggest that traits reflecting the three parts of the triad are only moderately correlated; correlations in middle childhood in large samples of twins (N > 6,000) suggest correlation coefficients around .3 or .4 (e.g., Ronald et al., 2006). Even in a sample meeting diagnostic criteria for an ASD (autism, Asperger's syndrome, or atypical autism; N = 189), social and communication impairments correlated around .5, and each correlated with RRBIs around .2 (Dworzynski, Ronald, Happé, & Bolton, 2009). Second, twin modeling suggests genetic influence on each of the triad traits is largely distinct and nonoverlapping with genetic influences on the other traits (genetic correlations range from less than .2 to .5; Ronald et al., 2006).

Third, many children can be found in the general population who have parent-reported levels of impairment as high as do children with ASD diagnoses, but in just *one* area of the triad. Taking the most impaired 5% in the Twins Early Development Study (TEDS) sample at age 8, the expected and actual overlap of difficulties can be examined. Clustering of difficulties is seen (Wing & Gould, 1979), with many more children falling into the two- and three-impairments groups than would be expected by chance co-occurrence alone (1.9% rated as showing 2 impairments across the three areas versus expected 0.75%; 0.7% rated as showing impairment in all three areas, plus 0.5% with preexisting diagnosis of ASD, versus expected rate of co-occurrence by chance 0.0125%). However, the largest numbers of impaired children (10% in total) remain those who have difficulty in only *one* area (social,

communication, or RRBI) from the ASD triad. Item analysis does not suggest any qualitative difference between the behaviors prompting high impairment scores in these "single impairment" groups compared with children (with or without existing diagnosis of ASD) showing the full triad of difficulties (Happé & Ronald, 2008). Further study using cognitive tests would be informative, and one might hypothesize that using cognitive rather than behavioral probes will lower still further the interrelation between the different aspects of ASD.

Lastly, these results from the general population and twin analyses (which should be viewed in the light of contrary findings from, e.g., Constantino et al., 2003, using a different measure of social skills), find support from quite independent research on the broader autism phenotype. Family studies have shown that relatives of ASD probands show elevated rates of subclinical ASD-like traits, and may show difficulties in just one area of the triad (e.g., rigid traits without social difficulties, or vice versa; Pickles et al., 2000; Szatmari et al., 2000). This suggests that distinct genetic contributions, underlying separate parts of the ASD triad, are contributed by different relatives, coming together in the proband to make the particular "catalytic" mixture that is ASD. It is interesting in this regard that recent genetic work has made a distinction between "familial" versus "de novo" cases of ASD (see, e.g., Abrahams & Geschwind, 2008). It may be that the fractionated triad view proposed above holds true primarily for familial ASD—and that phenotypic and genetic correlations between aspects of the triad will be higher in de novo cases and even lower in familial cases than those values reported above.

On the basis of these four types of data, the fractionated triad view would suggest that animal models of *specific* aspects of ASD (e.g., social abilities/difficulties), ideally of valid intermediate phenotypes, is likely to be the most helpful approach, and that modeling of the full syndrome or symptom profile is unnecessary and possibly unhelpful.

Using Cognitive Accounts to Help Refine the Behavioral Phenotype

One of the challenges to establishing behavioral-level face validity of an animal model is that the manifestation of the core symptoms in ASD is so heterogeneous, as reflected in the use of the term "spectrum." Thus, social impairment is not a simple lack of sociability, and social approach can range from aloof to "active-but-odd," with eye contact, for example, varying from avoidant to staring. Similarly, communication impairment is not "just" delay or lack of spoken language, but lack of compensation with communicative gesture, and abnormal pragmatics even in the face of excellent vocabulary and perfect syntax. Rigid/repetitive interests and activities also vary widely, ranging from rocking, to spinning objects, to abstruse fact collection. It is probably also important to note the "fractionation" within RRBIs apparent in, for example, factor analytic studies (e.g., Lam, Bodfish, & Piven, 2009). One facet of these varied manifestations is that some aspects of development are

found to be at age-typical or even superior levels in ASD. Thus our models (animal or otherwise) need to allow for uneven profiles of skills. For example, models of social impairment in ASD need to allow for attachment to parent that appears to be no different from that of other children of the same developmental level (Rutgers, Bakermans-Kranenburg, van IJzendoorn, & Van Berckelaer-Onnes, 2004). Similarly, while intellectual disability is strongly associated with ASD, a good model of ASD would allow for typical or superior levels of intelligence alongside specific social difficulty. In this context, it is exciting to see possible mouse models with areas of *superior* ability: faster eye blink conditioning in the valproate model (reviewed by Rodier, Chapter 48); enhanced spatial learning/water maze in some knockout mouse models focused on autism candidate genes (reviewed in Hsiao et al., Chapter 52).

A second challenge in considering behavioral face validity of ASD models is the essential ambiguity of behavior. Consider, for example, a knockout mouse who fails to explore his environment. This single measure of behavior could reflect several alterative underlying factors: for example, high anxiety, difficulty switching attention from current focus, or sensory sensitivities. Another model animal who fails to approach a conspecific may do so due to reduced social interest, but might instead be demonstrating abnormally high interest in nonsocial aspects of his environment, or misrecognition of dominance or aggression cues. Behavior alone is ambiguous: is self-injury in a nonverbal child with ASD well modeled in an animal who shows excessive self-grooming? Do cage stereotypies in animals capture anything relevant to repetitive coin spinning in a young adult with ASD?

Cognitive theories help make sense of behavioral ambiguity and heterogeneity, by positing and testing core processing abnormalities. They draw together apparently disparate behavioral manifestations to triangulate on latent cognitive factors that may be invariant but displayed through a range of manifestations across ages and ability levels. Do these accounts offer any promise to those using animal models to understand the causes of ASD? Animal models are vital for testing the causal status of putative biological (including environmental and genetic) factors, which cannot be manipulated in studies with human participants. By contrast, cognitive level theories typically do not *need* animal models for testing their hypotheses, and cognitive factors can be manipulated through good task design (what Frith has called the method of "fine cuts"; Frith & Happé, 1998). However, cognitive theories may be useful in the process of so-called reverse translation, by, for example, suggesting novel behavioral assays. Bauman and Amaral highlight the need for behavioral probes sensitive to the core features of ASD in animals (Chapter 53). Cognitive accounts may help with this. For example, Klin, Lin, Gorrindo, Ramsay, and Jones (2009) found insensitivity to biological motion and increased sensitivity to audiovisual synchrony in toddlers with ASD. Since preferential attention to biological motion can be found in a variety of species (Johnson, 2006), this might prove a useful focus for behavioral assays of animal models—although perhaps only at certain stages of development.

Another strand of cognitive accounts takes as its focus the uneven profile of skills and difficulties, as well as the narrow focus of interests in ASD. Several current theories suggest superior featural processing in ASD (e.g., weak coherence, Happé & Frith, 2006; Happé & Booth, 2008; enhanced perceptual functioning, Mottron et al., 2006; enhanced discrimination/reduced generalization, Plaisted, 2001). While there is debate as to the precedence of global versus local processing in nonhuman animals (using classic paradigms such as Navon hierarchical figures, e.g., Goto et al., 2004), these accounts provide plenty of scope for developing novel behavioral assays for animal models. For example, the superior eye for detail that in ASD appears to contribute to distress at "tiny" changes, might in an animal model be probed by recognition or habituation paradigms incorporating minor featural changes. Baron-Cohen's recent work on hypersensitive perceptual discrimination (Baron-Cohen et al., 2009) would suggest that a mouse able, for example, to discriminate odors more sensitively than is typical, might be of interest in relation to ASD.

Considering superior featural processing in ASD also illustrates again the importance of cognitive theory and the potential ambiguity of behavior alone. For example, recognition memory for faces is poor in ASD (e.g., Blair, Frith, Smith, Abell, & Cipolotti, 2002). A candidate behavioral homologue in the mouse might be conspecific identity recognition by smell, since olfaction is the key sense in this species. Testing social sniffing behavior is a good probe, then, if your cognitive model of ASD is that identity recognition is disrupted secondary to a primary lack of social interest. However, if face processing is disrupted in ASD because of a featural processing bias (as suggested by reduced inversion decrement for faces), olfactory recognition may not be an appropriate assay.

The fractionated triad account, which suggests that different aspects of the phenotype have distinct and separable cognitive (as well as etiological) underpinnings, also promotes the study of aspects of ASD that are not necessarily unique to ASD. This is relevant to cognitive accounts of nonsocial features of ASD, such as the executive dysfunction account (see, e.g., Hill, 2004, for review). One criticism of this account has been that executive impairments are seen in a number of other clinical groups (e.g., ADHD), who do not show the striking social deficits seen in ASD. This was taken as detracting from the dysexecutive account of ASD because executive impairment could not explain the core social difficulties. However, on the fractionated triad account, executive dysfunction may be critical to ASD, even if it overlaps entirely with that seen in ADHD, because it is the *combination* of deficits that gives ASD its particular flavor and manifestation, not necessarily the uniqueness of any one of its components. This should be encouraging for researchers developing animal and other causal models of ASD: what has been discovered about response selection and action in response to novelty (e.g., Eagle, Bari, & Robbins, 2008), whatever the target clinical group or disorder, could prove relevant to understanding RRBI in ASD. The implication is that, for example, the lack of social impairment in the primate maternal autoantibody model of ASD, described by Bauman and Amaral in Chapter 53, in no way detracts from the importance of their

successful modeling of stereotypies— and that the latter need not be specific to ASD to be highly informative.

Consideration of the executive dysfunction account also raises an important point about animal models. In human clinical groups, notably in those with acquired frontal lobe damage, there is often a significant discrepancy between performance on tests and adaptive functioning in real life (Mesulam, 1986; Shallice & Burgess, 1991). That is, tests may fail to capture real-life difficulties, because of the structured nature of tests, the reduction of timing demands, or the scaffolding of generative skills by the test situation. Similarly a verbal and intelligent child with ASD may be seen at his best in one-to-one discussion with a clinician, but appear very much less well adapted in the unstructured context of the school playground. Common tests of, for example, mouse social skills often do not extend beyond interacting with one or at most two peers, which may not tap complex naturalistic interaction. Yang et al.'s Chapter (51) discusses possibly more sensitive methods such as home cage observation of sleeping in a huddle.

It is notable that the theoretical models included in this section explicitly bridge and merge cognitive and neural data. Thus, Kana and Just (Chapter 54) link cognitive work showing good featural processing and poor integration of information, with neuroimaging data on functional and structural connectivity. Further links could be made to animal models; for example, Rinaldi, Perrodin, and Markram (2008) have reported abnormal frontal (hyper)connectivity in a valproate model of ASD. Baron-Cohen and colleagues (Chapter 55) propose high fetal testosterone as a factor influencing both superior featural processing and inferior social cognition in ASD. Iacoboni (Chapter 56) links the somewhat complex results on imitation deficits in ASD (for evidence and argument contra the mirror neuron account of ASD see Hamilton, Brindley, & Frith, 2007; Southgate & Hamilton, 2008) to single cell recording work in monkeys showing the existence of mirror neurons that link action recognition and production.

With their clear links to biological cause, these models would seem well placed to inspire animal models. It is interesting, however, that each appears to attempt to explain the whole of the autism symptom profile, in contrast to the suggestion from the fractionated triad hypothesis discussed above. Kana and Just suggest that "reduced functional connectivity is not confined to a particular domain or task, but is likely to be a general phenomenon at least across the neural systems involved in high-level cognition"—which would seem to predict a monolithic rather than fractionable triad of impairments in ASD (Chapter 54). In addition, a strong interpretation of their account would seem to render impossible the high intelligence seen in some ASD individuals. Abnormal functional connectivity is also not specific to ASD (e.g., dysconnection explanations of schizophrenia; Stephan, Friston, & Frith, 2009)—which is not a problem if it forms only one part of the neurocognitive underpinnings of the disorder (see above), but is problematic if proposed as a sole explanation for the full triad of symptoms.

Baron-Cohen et al. (Chapter 55) describe a sequence of findings linking fetal testosterone to both reduced social/ communicative skills (e.g., less eye contact in boys at 1, lower vocabulary at 2, poorer social relationships and empathy at 4 years) and increased RRBI (more narrow interests at 4, higher "systemizing" ratings and EFT at 8 years). This contrasts with the prediction from the fractionated triad view, and the finding that ASD-like social difficulties can be found without accompanying RRBI traits, in the general population and in relatives of those with autism. Clearly animal models could be useful in testing the fetal testosterone account of ASD: if the "origin of fetal testosterone in amniotic fluid is the fetus itself" (Baron-Cohen et al., Chapter 55; but see Gitau, Adams, Fisk, & Glover, 2005 for positive correlation between maternal and fetal plasma testosterone levels), establishing the causal effects of high testosterone in utero will require experimental manipulation in randomized designs. Such research seems especially promising in light of Corrales and Herbert's (Chapter 49) reminder that some environmental factors (e.g., toxins, oxidative stress) differ in their effects by gender.

Do Animal Models Need to Consider *Associated* Features?

There are a number of behavioral and cognitive features strongly associated with ASD that are not part of the diagnostic criteria (discussed by Yang et al. in relation to practical difficulties with some animal models). These include epilepsy, intellectual disability, sensory abnormalities (sensory fascinations and sensory sensitivities), anxiety, and savant skills. All of these are found at greatly raised rates in ASD groups compared to other populations, but are neither universal nor specific to ASD. Should these associated features form part of the target for models of ASD, be they animal models, theoretical neurocognitive accounts or models of environmental factors?

At least some of these associated features show the interesting pattern that, despite high prevalence in ASD probands, they are not found at elevated rates in the first-degree relatives of those with ASD—i.e., they do not appear to be part of the broader autism phenotype. Thus epilepsy, seen in up to 30% of those with ASD, is not increased in rate in parents and siblings of ASD probands compared to the general population (e.g., Mourisden et al., 2008). How should we interpret this pattern? It would seem that epilepsy, and perhaps also intellectual impairment, arise only in the context of the full triad of impairments, but do not accompany individual parts of the triad. Anderson (2009) has suggested this pattern marks out "emergent" traits, arising from multiplicative effects between several genetic and/or environmental factors. Such "emergent phenomena" ("those phenomena that are sensitive to a particular configuration of risk alleles, factors, or traits", Anderson, 2009, 25) may be far harder to model than core features of ASD. Anderson also refers to the mirror image of emergence— submergence, where a typical developmental feature or skill fails to develop because one or more of the multiplicative collection of factors necessary for its development is disrupted. Such a process would be open to disruption from a large range

of possible causes, since it involves many coacting healthy systems, contributing to one final common pathway. On a more optimistic note, Anderson points out that remediation of such an emergent process might be tractable: "The potential for small changes to produce large non-linear effects on emergent phenotypes is exciting and should provide impetus to this area of research" (2009, 25). In this regard it is interesting that Yang et al. (Chapter 51) report that environmental enrichment can not only reduce stereotypies in lab-reared deer-mice, but also improve learning and reduce seizure vulnerability.

Cognitively inspired twin modeling may be helpful in unpicking possible relationships between core and associated features of ASD, and in turn guide animal models of genetic and environmental effects. For example, Vital, Ronald, Wallace, and Happé (2009) have explored parent-reported special abilities (in music, math, art, or memory), because of the greatly raised rate of special skills in ASD (Happé & Frith, 2010). Their study in typically developing twins showed significant phenotypic and genetic correlation between reported special abilities and ASD-like RRBI traits (Happé & Vital, 2009). One implication of this might be that animal models of the RRBI part of the triad should search for signs of superior skills, memory and/or discrimination of stimuli.

Another possibility is that some of these associated features are secondary or downstream effects of core aspects of ASD. For example, work by Hallett and colleagues, again using twin modeling, has suggested that individual differences in ASD-like traits and in internalizing (anxiety and depression) in the general population are not linked by shared genetic effects, but over time show phenotypic links (Hallett, Ronald, Rijsdijk, & Happé, 2010). Thus, children's social and communication difficulties at age 7, for example, predict their traits of anxiety and depression at age 12, even controlling for their original level of internalizing at 7 years. In principle, downstream effects might not be key targets for animal models, unless the hypothesized "domino effect" is one that could be itself modeled closely enough to allow conclusions concerning relevant clinical intervention. For example, it has been suggested that low measured IQ in ASD may reflect downstream effects of lack of social insight (affecting social routes to skill and knowledge acquisition, despite good general processing efficiency as reflected in short inspection times; Schueffgen, Happé, Anderson, & Frith, 2000); since socially mediated learning is so much more important for human infants than probably any other species, this domino effect is better studied (and ameliorated) in clinical/cognitive studies than in animal models.

Conclusions

Cognitive accounts of autism have an important part to play in the search for the etiology and neural basis of this puzzling condition. Not only can intermediate phenotypes aid genetic research (and thereby the search for environmental factors), and inspire neuroimaging studies, they may also provide new behavioral assays for animal models. Twin modeling suggests that the different aspects of the ASD triad are "fractionable," and this might encourage the study of isolated aspects of the phenotype (e.g., social cognition), and of aspects that may not be unique to ASD. Translation from "bedside to bench" and back is needed, to create real cross-talk between those studying ASD through genetic, epidemiological, animal modeling, neuroimaging, cognitive, and clinical methods.

Applied Behavior Analysis and Early Intensive Behavioral Intervention

Points of Interest

- Applied behavior analysis (ABA) is a discipline of research and practice within the helping professions. ABA interventions are implemented in many settings, with many different clinical and nonclinical populations.
- ABA interventions for individuals with autism spectrum disorders (ASD) primarily involve strategies based on operant conditioning, such as systematically reinforcing target behaviors and teaching individuals to distinguish between different cues in their environments.
- In both research and practice settings, ABA interventions are routinely evaluated with single-case experimental designs in which each individual serves as his or her own control.
- One ABA intervention format, discrete trial training (DTT), is designed to help individuals with ASD master new skills rapidly by breaking down instruction into a series of short, simple learning units, each of which lasts only a few seconds and has a clear beginning and end. Other ABA intervention formats are more loosely structured and are used to promote generalization from the teaching situation to everyday settings.
- Research suggests that when implemented intensively (20–40 hours per week) and early (beginning prior to age 4 years), ABA may enable some children to make significant gains in IQ and other standardized test scores.
- Many studies indicate that ABA interventions can help individuals with ASD learn new skills, but these studies have involved small numbers of subjects, most of whom are young, developmentally delayed, or both. Thus, larger studies that include a broader range of individuals with ASD are needed.

ABA draws on principles of learning theory to help people learn new skills and overcome behavior problems (Cooper, Heron, & Heward, 2007). ABA has become an important intervention strategy for persons with ASD, but, more generally, it is an applied science and profession that is practiced in diverse contexts. Examples include general and special education at all grade levels (Heward et al., 2005), psychotherapy for a variety of behavioral disorders (Woods & Kanter, 2007), safety programs at job sites and other locations (Geller, 2001), management of business organizations (MacWhinney, Redmon, & Johnson, 2001), and interventions to promote health and well-being (Cummings, O'Donahue, & Ferguson, 2003).

In ABA, the term *applied* refers to a focus on socially relevant outcomes (Baer, Wolf, & Risley, 1968). For individuals with autism, ABA practitioners and researchers (referred to as behavior analysts) have emphasized outcomes such as moving out of institutions into the community (Lovaas et al., 1973), entering general education classes (Lovaas, 1987), strengthening relationships with typically developing peers (Strain & Schwartz, 2001), and enabling caregivers to become effective teachers for their children (Johnson et al., 2007).

The term *behavioral* in ABA reflects an emphasis on measurable outcomes. Behavior analysts consider any action that can be measured to be a behavior (Baer et al., 1968). Thus, the defining features of ASD (problems with reciprocal social interaction, limited social communication, and intense repetitive behaviors or narrow interests) are all considered behaviors. Associated features of ASD, such as delays in cognitive and self-help skills, are also viewed as behaviors. Because internal states such as thoughts and feelings are associated with observable actions such as verbalizations, facial expressions, and body language, they too are deemed to be behaviors.

Analysis indicates that decisions about interventions derive from a systematic data-based evaluation. Data collection usually involves direct observations that are repeated on multiple occasions with the same individual over time. These observations are often supplemented by assessments of the acceptability of interventions and outcomes to consumers and caregivers (Wolf, 1978), as gauged from ratings or interviews.

⬚
Key Concepts

Behavior analysts recognize that ASD are biological syndromes and that research on genetic and neurological etiologies is necessary to advance understanding of the disorder (Smith, McAdam, & Napolitano, 2007). However, they also believe that it is possible to develop effective interventions without knowing the precise etiologies of ASD (Lovaas & Smith, 2003). They posit that whatever the etiologies turn out to be, the biological functioning in individuals with ASD leads them to be "ill-fitted" to typical environments (Bijou & Ghezzi, 1999; Lovaas & Smith, 1989) and that environmental modifications can promote behavior changes that improve their functioning and quality of life.

ABA emphasizes careful assessment of how environmental events influence the behavior of an individual. ABA studies show that many significant events involve operant learning, which occurs in all humans and many other organisms. This kind of learning takes place when an antecedent event sets the occasion for a behavior and a consequent event either increases or decreases the likelihood that the behavior will occur again. An antecedent event is a change within the individual or in the external environment that occurs just prior to the behavior and acts as a trigger. A *consequent event* is a change that immediately follows the behavior. Consequent events that increase behavior are called *reinforcers*; consequent events that decrease behavior are said to result in extinction. For example, when an individual with ASD sees a peer (*antecedent event*), she may make eye contact and say "Hi." If the consequence is a smile and praise from the peer (a reinforcer), the student is likely to greet the peer in the future. However, if the peer walks by without acknowledging the greeting, the student may not greet the peer on subsequent occasions because the behavior was not reinforced. Behavior analysts use the term *three-term contingency* to describe this relationship among the antecedent, behavior, and consequence.

Behavior analysts note that humans can acquire a three-term contingency without experiencing it directly. Through modeling, an individual learns a contingency by observing others. Thus, an individual with ASD might be taught how to make greetings by watching two people greet each other. In rule-governed behavior, the individual is merely told about the antecedent–behavior–consequence relationship. For example, a person with ASD might learn greetings by hearing an instructor explain, "When you greet others, it's important to make eye contact and say 'Hi' or 'Hello' to show you're interested." In equivalence class formation, an individual may learn that stimuli are associated with one another even if they have never been presented together. If an individual finds out that the spoken word "ball" corresponds to a picture of a ball, and that this spoken word also corresponds to the written word "ball," he is likely to associate the picture with written word, despite never being taught this association (Sidman, 1994).

As individuals learn new three-term contingencies, it becomes important for them to discriminate among antecedents. Discrimination learning involves giving different responses to different antecedents. For example, if a teacher holds up a ball and asks "What is it?," the correct response is to say "ball." However, if the teacher holds up a cup and asks "What is it?," the correct response is to say "cup" (and not "ball"). To help individuals make discriminations, behavior analysts systematically use prompting procedures such as providing physical, gestural, or verbal guidance to perform a behavior in response to an antecedent. Prompts are gradually reduced and eventually eliminated as the individual masters the discrimination. Throughout this instruction, correct responses may be reinforced immediately.

In ABA, an establishing operation (EO) is an event that alters the reinforcement value of a consequence. An EO also may alter the frequency of behaviors that the individual uses to obtain the consequence. For example, placing a favorite toy in sight but out of reach may increase both the reinforcement value of the toy and the rate at which an individual requests the toy. This situation creates opportunities to expand the individual's communication skills in ways such as requiring the individual to add more words to the request or to coordinate the request with eye contact. Systematic use of EOs is a central component of the incidental or "naturalistic" teaching approaches described in the next chapter.

Another common ABA procedure is task analysis, which consists of breaking down a complex skill into its component steps. For example, most self-help skills require completion of a series of steps. To wash hands, an individual must turn on the water, place her hands under the tap, apply soap, rub her hands together, and so on. Once behavior analysts have identified the steps, they can teach the skill with chaining procedures, in which steps are taught separately and subsequently linked together; and shaping, in which successive approximations of a behavior are taught (e.g., drying hands more and more completely).

Application of Applied Behavior Analysis Concepts to Autism Spectrum Disorders

In all, behavior analysts emphasize a rather small number of key concepts—mainly, the three-term contingency (antecedent–behavior–consequence), reinforcement, discrimination learning, and a handful of others. To behavior analysts, this short list has the virtue of parsimony (Lovaas & Smith, 1989). To many others, however, it seems too reductionistic to give an adequate account of ASD and support appropriate interventions (Greenspan, 2000). One reason for skepticism is that although most ABA concepts apply to humans and nonhumans alike, the defining features of ASD involve difficulties with skills that are unique to humans, such as reciprocal communication, creativity, and social interaction.

Behavior analysts have attempted to describe these difficulties in ABA terms. In ABA, communication is a particular kind of operant learning referred to as *verbal behavior* (Skinner, 1957). From this perspective, communication can be classified

into different categories based on its function. In ABA terminology, mands include requests, questions, commands, and advice whose primary controlling variable is an EO, such as deprivation. For example, either stating a request or having a tantrum to obtain a favorite object could be a mand in which the reinforcer is receiving the object from another person and the establishing operation is lack of access to the object. Communication that occurs in the presence of a nonverbal discriminative stimulus is called a tact. Opinions, observations, replies to many questions, and verbal reports are all examples of tacts. Intraverbals are another class of communication that consist of verbal responses to a verbal discriminative stimulus, as occur in conversations between two people. An autoclitic is a unit of verbal behavior that clarifies or alters the meaning of other verbal behavior. Examples include plurals and verb tenses, which specify the number and timing, respectively, of other sentence structures and words such as *not*, which reverse the meaning of phrases.

From this perspective, many individuals with ASD make frequent mands, but the mands tend to be limited in variety or complexity (or both). Other classes of communication (tacts, intraverbals, etc.) may occur less often or may be inappropriate to the situation. (In ABA terms, the antecedents may differ from the antecedents for communication by typically developing individuals). The analysis of verbal behavior has had a strong influence on ABA interventions for enhancing communication skills (e.g., Bondy, Tincani, & Frost, 2004; Sundberg & Michael, 2001).

Creativity is defined in ABA in terms of fluency (number of responses), originality (novelty of responses), variability (differences between responses), flexibility (use of a stimulus for multiple purposes), and divergent thinking (problem solving) (Neuringer, 2004). By reinforcing responses with these characteristics, ABA practitioners seek to increase creativity (e.g., Lee, McComas, & Jawor, 2002).

Social interaction similarly can be characterized in terms of discriminative stimuli and reinforcers. For example, joint attention, which is an area of particular difficulty for young children with ASD, involves sharing an experience with another person (Mundy & Crawson, 1997). An example is looking at an adult, then looking at a toy, and then looking back at the adult. From an ABA standpoint, joint attention requires that the adult and toy each function both as discriminative stimuli and as reinforcers (Dube et al., 2004). ABA teaching methods for systematically establishing these functions may increase joint attention (Whalen & Schreibman, 2003). For older and more advanced individuals with ASD, problems with social interaction are often attributed to a lack of "theory of mind" (Baron-Cohen, 1995). That is, they struggle to explain, predict, and interpret the behavior of people in terms of mental states such as desires, beliefs, feelings, and thoughts. To behavior analysts, this problem may reflect an inability to detect social cues or a limited repertoire of responses to those cues.

Behavior analysts suggest that individuals with ASD tend to have learning styles that contribute to their difficulties in communication, social interaction, and overly repetitive or restrictive activities. For example, stimulus overselectivity, which is the tendency to focus on only one element of a complex antecedent, may interfere with generalizing communication skills to novel situations (Wilkerson & McIlvane, 1997), establishing joint attention, and detecting social cues (Koegel & Koegel, 2006). Inability to form equivalence classes may impede acquisition of abstract concepts (Wilkerson & McIlvane, 1997). A need for consistent, immediate reinforcement may deter individuals with ASD from engaging in social situations, which often have unpredictable outcomes (Bijou & Ghezzi, 1999).

In sum, relying on just a few concepts, behavior analysts have offered descriptions of the defining features of ASD. Of course, the adequacy of these descriptions is open to debate, but they have provided the basis for a large number of intervention studies, to which this chapter now turns.

Research Methods

Although other interventions such as psychotropic medications are also tested scientifically, a distinctive feature of ABA is that the same methodology is routinely used in both research and applied settings. This methodology is largely one of single-case research design in which individuals serve as their own controls, and interventions are evaluated for each person to whom they are applied (Bailey & Burch, 2002). Typically, the design involves comparing a baseline phase in which individuals receive no intervention to one or more intervention phases, with data collected continuously through all phases. If the behavior improves relative to the baseline phase each time that the intervention is introduced, one can conclude that the treatment may have produced this improvement. If the behavior does not improve, the intervention is refined or changed.

One single-case methodology is the alternating treatment design, also called a multi-element design (Barlow & Hersen, 1984). In this design, intervention is implemented on alternate days or sessions; on the other days or sessions, there is no intervention. This design is used when the effects of an intervention are expected to occur immediately. It also can be deployed as an assessment tool. For example, in a procedure called analog functional analysis, different experimental conditions are presented in an alternating treatment design to identify factors that may be maintaining a problem behavior. As an illustration, Ahearn et al. (2007) examined vocal stereotypy displayed by four children with autism. Following a standard functional analysis procedure developed by Iwata et al. (1994), participants' rates of vocal stereotypy were compared across four conditions, each of which was implemented in 5-minute sessions. In the alone condition, the participant was left by him- or herself. In the play condition, the participant was given the opportunity to play freely with toys. In the attention condition, the participant again played with toys,

and the experimenter provided attention to the participant whenever the participant engaged in vocal stereotypy. In the demand condition, the experimenter made routine requests of the participants but withheld requests for 15 seconds in response to participants' stereotypy. Figure 58-1 presents data for one participant, Mitch. Each line in the figure corresponds to one of the four experimental conditions. The data reveal that Mitch's stereotypy occurred with the greatest frequency during the alone condition. This funding suggests that intervention strategies such as arranging the environment to minimize unstructured, alone time might be effective. The remaining participants showed different patterns in their data, indicating that appropriate interventions for them might not be the same as those for Mitch.

When an intervention might take longer to have an impact, the alternating treatment design may not be suitable, but another option is the reversal design, in which a baseline of several sessions, days, or weeks is followed by an intervention, followed by a return to the baseline phase, and so on. A reversal design can yield particularly strong evidence that an intervention causes behavior change for an individual participant (Barlow & Hersen, 1984). For example, Anglesea, Hoch, and Taylor (2008) used a reversal design to test an intervention for slowing down three teenagers with ASD who ate too rapidly. During the baseline condition, participants wore the pager, but it did not vibrate. During the intervention condition, the pager vibrated at 10- to 30-second intervals. Figure 58-2 shows data for one participant, Mark. As indicated in the figure, the baseline condition (pager prompt absent) was in effect for seven sessions, followed by six sessions of the intervention condition (pager prompt present), back to the baseline condition for another seven sessions, and finally back to the intervention condition for seven sessions. The black line shows the average number of seconds that Mark took to consume each bite during the session, whereas the gray line shows the total number of bites per session.
Figure 58–1. Example of an alternating treatment (multi-element) design. Percentage of observation intervals with stereotypic behavior for Mitch across four experimental conditions: Alone, Play, Attention, and Demand. Reprinted with permission from Ahearn, W. H., Clark, K. M., MacDonald, R. P. F., & Chung, B. I. (2007). Assessing and treating vocal stereotypy in children with autism. *Journal of Applied Behavior Analysis, 40*, 263–275. © Society for the Experimental Analysis of Behavior, 2007.

It can be seen that, going from the first baseline condition to the first intervention condition, Mark's time to consume each bite greatly increased, and the number of bites decreased. When he returned to the baseline condition, he reverted to the rates he had shown during the first baseline condition. However, re-introduction of the intervention replicated the gains made in the first intervention condition. This result
Figure 58–2. Example of a reversal design. Total eating time in seconds and number of bites to consume target foods for Mark across sessions. "Pager Prompt Absent" is the baseline condition. "Pager Prompt Present" is the intervention condition. Reprinted with permission from Anglesea, M. M., Hoch, H., & Taylor, B. A. (2008). Reducing rapid eating in teenagers with autism: Use of a pager prompt. *Journal of Applied Behavior Analysis, 41*, 107–111. © Society for the Experimental Analysis of Behavior, 2008.

demonstrates that the vibrating pager was effective in bringing down Mark's rate of eating.

Although useful for testing whether an intervention alters an already acquired behavior, alternating treatment and reversal designs are usually not appropriate for evaluating interventions intended to teach new skills. Such interventions should produce long-lasting increases in skill levels rather than gains that disappear as soon as intervention is withdrawn. A single-case methodology that allows for testing of more permanent effects is the multiple baseline design, which involves having two or more baseline phases that are of varying lengths and then applying treatment to one baseline at a time (Barlow & Hersen, 1984). For example, Betz, Higbee, and Reagon (2008) incorporated a multiple baseline design to evaluate an intervention for increasing peer interactions in three pairs of preschool children with autism. The intervention involved teaching each participant to follow a schedule that consisted of a series of photographs depicting games. The study included four phases: baseline, teaching, maintenance, re-scheduling (when the sequence of photographs was varied), and generalization (when new games were introduced). Figure 58-3 displays the results. The thinner line represents the percentage of intervals during which interaction occurred. The heavier line depicts the percentage of intervals during which instructors provided prompts for interaction. The first pair, Ali and Dillon (top of Figure 58-3), rapidly increased their rate of peer interaction and maintained this increase for the remainder of the study. At the same time, the rate of prompting decreased. A similar pattern emerged for the second pair, Brady and David (middle of Figure 58-3). This pair also participated in a reversal probe session during which the photographic activity schedule was removed (between the re-sequencing and generalization phases, as indicated in Figure 58-3). They seldom interacted during that session and thus appeared to depend on having the schedule available. However, they did interact during novel games in the generalization phase (with the schedule present). The third pair, Nathan and Jackson (bottom of Figure 58-3), also made gains when they were taught to follow the schedule. Overall, then, the schedule increased interactions across all three pairs of children with autism. Moreover, gains endured over time and extended to novel games, provided that teachers continued to provide a schedule.

Despite their extensive use in ABA, single-case designs remain somewhat controversial. Many psychologists and educators regard such designs as rigorous tests of the efficacy of an intervention. The clinical psychology division of the American Psychological Association suggests designating interventions as evidence-based if there are either two randomized clinical trials (RCTs) or a series of nine or more independent, well-designed single-case studies (Chambless & Hollon, 1998). The Council on Exceptional Children requires only six such studies, but with more stringent methodological benchmarks (Horner et al., 2005). Some investigators use single-case designs to evaluate interventions that originated outside of ABA (e.g., Rogers et al., 2006).

In contrast, criteria for identifying evidence-based medical interventions characterize single-case experiments as weak forms of evidence, on a par with uncontrolled case studies (Guyatt et al., 2008; Higgins & Green, 2006). According to this perspective, single-case experiments offer little more than anecdotal information, and other methodologies—particularly RCTs—are necessary to establish an intervention as evidence-based.

A working group that was convened by the National Institute of Mental Health proposed a middle ground (Smith et al., 2007; *see also* Reichow, Volkmar, & Cicchetti, 2008). The group noted that single-case experiments have greater methodological rigor than case studies because they provide continuous measures of the outcome variable and systematic replication of intervention effects. The group also suggested that there are some circumstances under which single-case experiments might stand alone as evidence for an intervention, but other circumstances under which it would be important to conduct further evaluations in RCTs. Single-case studies are best suited for evaluating the immediate effects of a specific intervention on a particular behavior for an individual participant. As such, they often suffice for testing interventions such as procedures to teach a new self-help skill. However, they may need to be followed by RCTs if it is important to look at more long-term and global outcomes, test combinations of interventions or compare alternate interventions, or evaluate outcomes across large groups of participants. For example, it might be useful to compare ABA interventions for problem behavior to psychotropic medication or to a combination of ABA and medication. Also, it might be informative to put together a package of ABA interventions to increase peer interactions and assess outcomes on general indices of social functioning such as reductions in core features of autism and increases in the quality of friendships and relationships with family members (Smith et al., 2007).

Applied Behavior Analysis Intervention Strategies

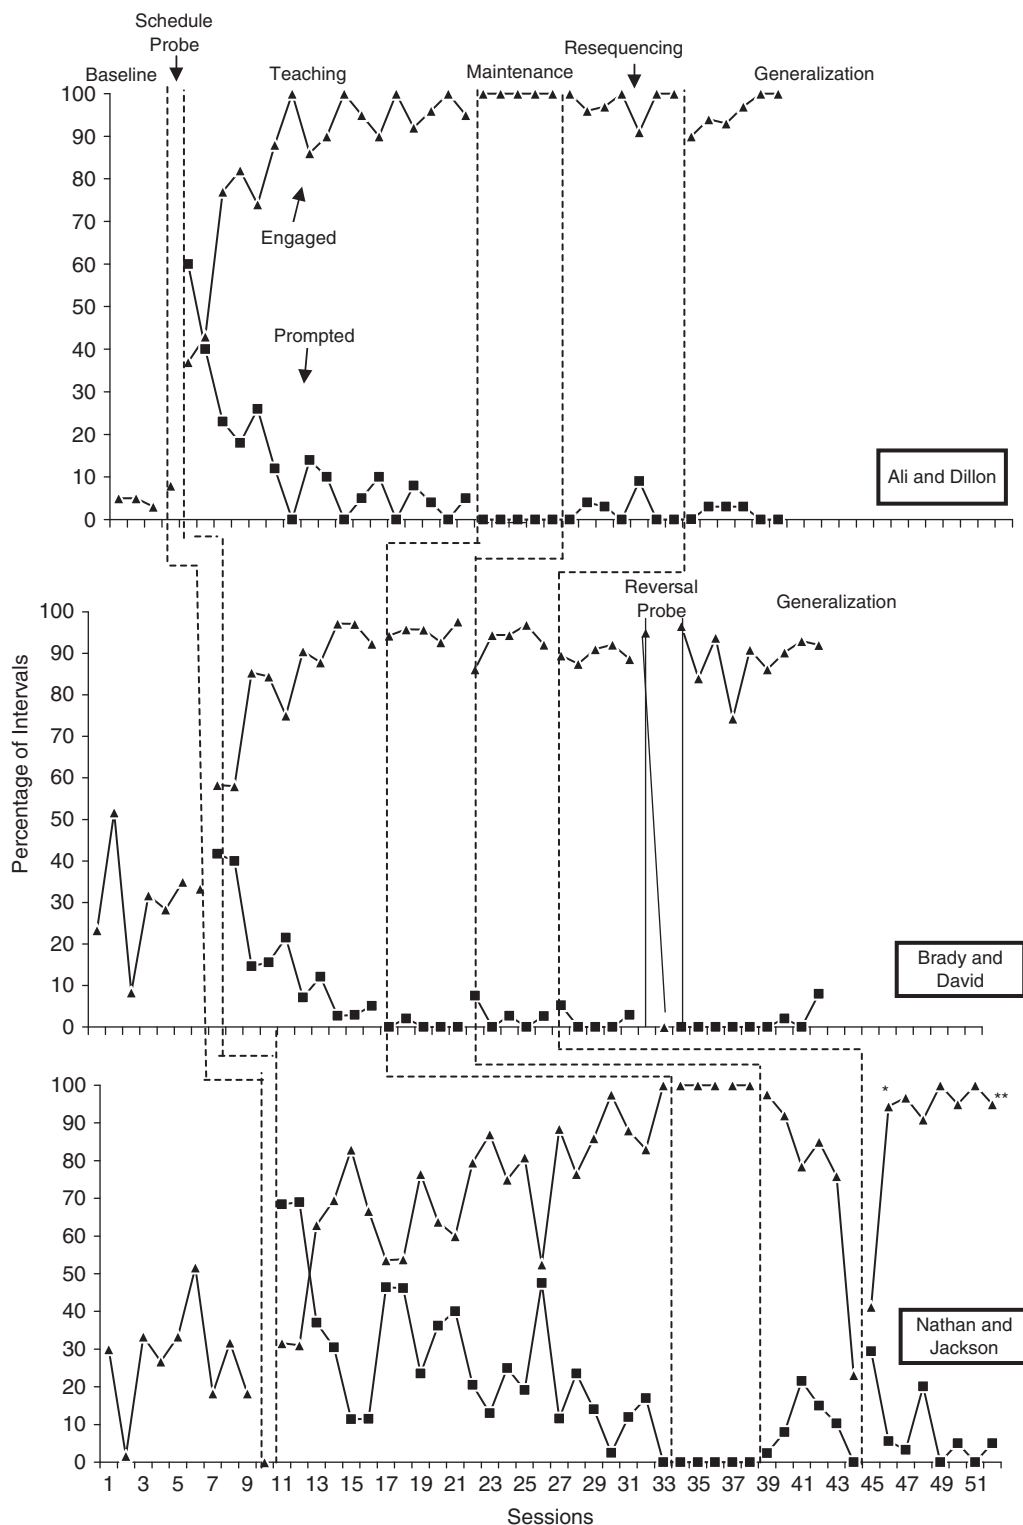
Many ABA interventions for individuals with ASD have support from multiple single-case studies. These interventions focus on either overcoming behavioral deficits (increasing the skillfulness or frequency of a behavior) or reducing behavioral excesses (decreasing the rate or severity of challenging behavior). Interventions for overcoming behavioral deficits range from highly structured teaching methods to more loosely structured methods and incidental teaching in which instruction is embedded in the context of everyday activities. (Incidental teaching methods are described in more detail in Chapter 59.) Interventions for reducing behavioral excesses are based on an assessment of antecedents that may trigger a behavior and consequences that may reinforce it. The focus is mainly on preventing the occurrence of such behavior, but it


Figure 58–3. Example of a multiple baseline design. Results of the joint activity schedule intervention for Ali and Dillon (top), Brady and David (middle), and Nathan and Jackson (bottom). The intervention is introduced in the teaching phase and extended across subsequent phases of data collection. Reprinted with permission from Betz, A., Higbee, T. S., & Reagon, K. A. (2008). Using joint activity schedules to promote peer engagement in preschoolers with autism. *Journal of Applied Behavior Analysis, 41*, 237–241. © Society for the Experimental Analysis of Behavior, 2008.

is usually also necessary to consider how to respond when the behavior is displayed.

Discrete Trial Training

An especially distinctive ABA intervention is discrete trial training (DTT), which is a highly structured teaching format characterized by *(1)* one-to-one interaction between the practitioner and the child in a distraction free environment; *(2)* clear and concise instructions from the practitioner; *(3)* highly specific procedures for prompting and fading; and *(4)* immediate reinforcement such as praise or a preferred toy for correct responding (Smith, 2001). As a learner masters a new skill in DTT, interventionists aim to promote generalization of the skill to everyday environments by systematically loosening the format. For example, they may conduct sessions in many different settings, vary the instructions, reduce the frequency of reinforcement, and spread out the times when they ask the learner to practice the skill.

DTT is commonly implemented to shape new behaviors that were not previously in the repertoire of an individual with ASD, such as new speech sounds or motor skills. It is also emphasized in discrimination learning tasks such as imitating actions performed by another individual, matching identical objects or pictures to each other, labeling objects expressively or receptively, comprehending language concepts such as opposite pairs (e.g., big/little) and prepositions, and completing cognitive or preacademic tasks (e.g., counting objects or sequencing pictures).

DTT has been found to be effective in many single-case experiments (Goldstein, 2002) and outcome studies of early intervention programs in which DTT is a primary intervention procedure (reviewed later in this chapter). Behavior analysts offer several reasons why DTT may work (Smith, 2001). First, it breaks the continuous flow of social interaction into separate units that have a clear beginning and end (Newson, 1998). This simplification may help individuals with ASD—particularly those who are young or developmentally delayed—to learn the basic structure of an interaction between two people. Also, the trials have a predictable structure, and DTT sessions often involve repeating an instruction multiple times while systematically reducing prompts. This format may fit the preference that many individuals with ASD have for routine over novelty. In addition, DTT often involves breaking down a skill into small steps and teaching steps individually. Such an approach may be consistent with the detail-oriented learning style of individuals with ASD. Further, because each trial is relatively short (usually 5–20 seconds), DTT affords a large number of learning opportunities, thereby promoting rapid acquisition of new skills. Finally, the one-to-one instruction allows close monitoring of an individual's progress and careful tailoring of the instruction for the individual (Smith, 2001).

However, DTT also has important limitations (Smith, 2001). Because it requires setting up a tightly controlled environment with very specific cues, prompts, and instructional materials, skills may not generalize from DTT to everyday settings such as home or school even after interventionists systematically loosen the format. In addition, because it involves having children with ASD respond to cues from the interventionist, children may not initiate the use of skills that they acquire in DTT. Also, DTT is labor-intensive in that it consists of one-to-one instruction with the interventionist continually providing cues.

A more general concern is that DTT differs in many respects from the kinds of situations in which most children learn social and communication skills (Koegel & Koegel, 1995; Prizant & Wetherby, 2005). During the toddler and preschool years, most typically developing children learn these and other skills in the context of playful routines with caregivers, interactive games with peers and adults, make-believe activities, and independent exploration (Prizant & Wetherby, 2005). They seldom learn from being drilled. Moreover, typically developing children often learn by initiating activities to which others respond, rather than the other way around, as occurs in DTT. Although structured teaching becomes increasingly important as children grow older, unstructured times remain crucial for their development (Elkind, 2001).

For behavior analysts who rely on DTT, however, the differences between DTT and typical learning situations are precisely the point (Smith, 2001). Children with ASD present for treatment because, to varying degrees, they have been unsuccessful in learning social and communication skills in the same way that other children do. Although it sometimes may be possible to help individuals with ASD by finding or creating teachable moments during everyday activities, it may be necessary at other times to design an environment that better suits their learning styles (Lovaas & Smith, 1989).

DTT remains a central component of many long-established ABA programs, particularly for young children with ASD (Stahmer, Collings, & Palinakas, 2005). It is used in all comprehensive ABA programs that have been described in a manual and tested in published, controlled outcome studies of toddlers and preschoolers with ASD (cf. Rogers & Vismara, 2008). However, research indicates that it can be less effective than incidental or naturalistic teaching approaches (described in the next chapter) under some circumstances (Delprato, 2001), and outcome studies of comprehensive ABA models that place a greater emphasis on such approaches are currently underway. Also, as discussed, the highly structured format of DTT has both advantages and disadvantages. Therefore, DTT is not a standalone intervention for individuals with ASD. Rather, it needs to be implemented in conjunction with other intervention methods (Smith, 2001). In addition, there may be individual differences in how children with ASD respond to DTT as compared to incidental teaching. For example, Sherer and Schreibman (2005) found that although some children with ASD responded well to incidental teaching, others did not and might have fared better in an intervention program that emphasized structured teaching such as DTT.

Other Structured Intervention Methods

Other structured intervention methods in ABA have a more flexible format than DTT but still involve having the interventionist set the agenda, choose the skills to be taught, and provide direct instruction to the individual with ASD. One extensively studied set of approaches is called *peer-mediated social skills training* (Strain & Schwartz, 2001). These approaches involve coaching typically developing peers on how to engage individuals with ASD in social interactions and then having the peers and individuals with ASD play or work together in pairs or small groups. Research indicates that peer-mediated social skills training can significantly increase the rate of social interaction (McConnell, 2002) and also can be used to promote learning of academic skills (Kamps et al., 1999). Another set of approaches involves teaching individuals with ASD to follow a script, then fading out the script and systematically cuing individuals to use the script in appropriate contexts. A script might consist of a series of related conversational statements that the individual with ASD can make when talking with another person about a topic, a sequence of role-playing or make-believe activities, or a succession of actions involved in completing a self-help skill or activity of daily living. There are a variety of formats for presenting scripts. In video modeling, two or more models act out the script, and it is recorded for repeated viewing by the individual with ASD. A meta-analysis of single-case studies indicated that video modeling qualifies as an evidence-based intervention for enhancing skills in the areas of social communication, self-help, and on-task behavior during instructional activities (Bellini & Akullian, 2007). Alternatively, modeling can be provided in vivo, and some research indicates that this approach also can be effective in promoting skill acquisition (e.g., Coe et al., 1990). Additional formats for presenting scripts include pictorial schedules, in which each picture corresponds to a part of the script (McClannahan & Krantz, 1998), or simply written words or picture symbols (McClannahan & Krantz, 2005). A number of single-case studies support the use of pictorial schedules or written scripts to promote social communication and independent completion of activities of daily living (McClannahan & Krantz, 2005).

Interventions to Reduce Challenging Behaviors

Behavior analysts hypothesize that in most instances, challenging behavior is maintained (often inadvertently) by reinforcement from environmental or physiological events such as attention from others, opportunities to obtain preferred activities, or pain relief (Iwata et al., 2002). The environmental and physiological factors that are associated with challenging behavior are evaluated using a process called functional assessment, functional behavioral assessment, or functional analysis. This evaluation assists in designing interventions. For example, if an individual engages in challenging behavior to gain attention, a target for intervention might be to teach the individual to recruit attention through a simple request and ignore the problem behavior when it occurs. If, however, the challenging behavior serves to avoid an activity, the intervention might involve either skipping the activity or teaching the individual to request a break.

The quickest approach to conducting a functional assessment is simply to administer checklists such as the Motivation Assessment Scale (Durand & Crimmins, 1988) or the Questions About Behavioral Function (Matson & Vollmer, 1995) to ask caregivers why they believe that an individual engages in challenging behavior. Interviews such as the Functional Assessment Interview (O'Neill et al., 1997) can provide more extensive information. Another option is to observe the individual directly in his or her everyday environment. Finally, experimental or analog functional analysis can be conducted. This approach involves systematically introducing and withdrawing the antecedents and consequences for problem behavior in a clinical, home, or school setting (Iwata et al., 1994), as illustrated in the study by Ahearn et al. (2007) described in the section on Research Methods.

The choice of prevention or intervention procedure depends on the function or functions the behavior serves for the individual. Common prevention strategies include practicing activities beforehand (priming or preteaching) or presenting visual schedules to help individuals with ASD anticipate upcoming events (Koegel, Koegel, & Frea, 2003; McClannahan & Krantz, 1998). Another approach is to use differential reinforcement, which involves reinforcing adaptive replacement behaviors for the challenging behavior. For example, in differential reinforcement for alternative behavior (DRA), an individual with ASD might be reinforced for saying, "I need help," but ignored for flopping down to the floor. In differential reinforcement of incompatible behavior, behavior that is topographically incompatible with the target behavior is reinforced. For example, to reduce the frequency with which an individual with ASD gets up and leaves a teaching situation, in-seat behavior would be reinforced. Based on a systematic review of single-case studies, Odom et al. (2003) identified differential reinforcement as an evidence-based strategy for young children with ASD.

Strategies for responding to a challenging behavior and reducing the likelihood that it will recur include extinction (withholding reinforcement for previously reinforced behavior), time-out (placing an individual in a situation in which reinforcement is unavailable), and response cost (taking away preferred objects or activities). Another reductive procedure, overcorrection, consists of restitution (restoring the environment to a better state than it was in before the challenging behavior occurred) and positive practice. For example, if an individual with ASD throws a plate of food on the floor, she may be required not only to pick up the food but also to clean the surrounding areas and to practice throwing out food in the garbage. Until the mid-1980s, contingent aversives such as low doses of electric shock were sometimes used for severe challenging behavior such as self-injury that was causing

significant tissue damage. Although research indicates that aversives often decrease challenging behavior rapidly (Matson & Taras, 1989), they are no longer implemented in the large majority of ABA programs because of ethical concerns, the potential for misuse, and the availability of non-aversive strategies (National Research Council, 2001). Behavior analysts currently recommend that if any reductive procedure is used, it should be based on a functional assessment and implemented as part of a multicomponent treatment plan that includes methods for preventing the occurrence of challenging behavior and increasing alternative, appropriate behaviors (Autism Special Interest Group, 2004). When implemented with these safeguards, single-case studies indicate that reductive procedures based on a functional assessment are often effective in decreasing challenging behavior, although additional studies are needed to examine the extent to which these improvements are maintained over time (Horner et al., 2002).

Applications of Applied Behavior Analysis to Teach Specific Skills to Individuals with Autism Spectrum Disorders

Social, Play, and Leisure Skills

Instruction on imitation is a standard feature of ABA and other intervention programs for toddlers and preschoolers with ASD (Dawson & Osterling, 1997; Rogers, 1998). The ability to imitate a verbal or physical action is an important prerequisite for learning more complex skills and is itself an important part of social interactions. ABA interventions to teach imitation usually involve one-to-one instruction in a DTT format. Instruction begins with a focus on imitation of simple gross motor actions (e.g., clapping hands) or actions with objects (e.g., putting a block in a bucket) and gradually progresses to more subtle actions (e.g., speech sounds) and chains of actions (e.g., sequences of motor movements). This approach can result in generalized imitation to new models (Young et al., 1994).

After an individual with ASD has acquired imitation skills, in vivo or video modeling can be used to teach a variety of social and play skills such as conversing with others, playing creatively, and taking turns during games (Bellini & Akullian, 2007). Peer-mediated social skills training also can boost such skills (Strain & Schwartz, 2001). Peers who are the same age as or slightly younger than the individual with ASD may be more effective than older peers (Lord & Hopkins, 1986).

Although these strategies produce immediate gains in social skills, generalizing these gains to new situations and maintaining them over time pose a challenge (Stahmer, Ingersoll, & Carter, 2003). Possible ways to improve generalization and maintenance include teaching individuals with ASD to self-monitor their interactions with others (Koegel et al., 1992), involving an entire class in implementing interventions

(Kamps et al., 1994), providing scripts or cues of social interactions that the individual can use across a variety of peers or situations (Krantz & McClannahan, 1993) or systematically expanding on social initiations that some individuals with ASD spontaneously direct toward peers (Kennedy & Shukla, 1995).

Most of these interventions were developed for preschool and school-age children with ASD. Given that social demands change across the lifespan, it is unclear how effective the interventions are for adolescents and adults with ASD. Also, because the focus has been on specific target behaviors, the extent to which they produce more global improvements in core features of ASD and lead to improved quality of life (e.g., meaningful friendships with peers) requires further investigation.

Another important subpopulation that has received relatively little scientific study is children with high-functioning autism or Asperger's Syndrome. Peer tutoring may be beneficial (Kamps et al., 1992; Thiemann & Goldstein, 2004). Preliminary evidence suggests that self-monitoring and contingency contracting also may be successful (Mruzek, Cohen, & Smith, 2007). Behavioral social skills training in a clinic is another potentially beneficial intervention (Barry et al., 2003), but results thus far have generally been disappointing (Bellini et al., 2007). A possible way to increase efficacy is to provide intervention within the context of a classroom throughout the school day (Lopata et al., 2006).

Communication

DTT is often used to establish communication skills in nonverbal individuals with ASD (Lovaas, 2003). Instruction usually begins with a focus on receptive language, particularly following simple requests such as "sit down" or "come here" and identifying familiar objects or people. Once an individual has established imitation skills, he or she may be taught to imitate saying individual words and then to use basic expressive communication such as saying a word to label an object.

For individuals with ASD who have limited or no expressive vocal language, ABA interventions may focus on augmentative and alternative communication systems. In the 1980s, most research focused on sign language and indicated that many individuals with ASD were successful in learning to sign despite making slow progress in acquiring vocal communication (Carr & Dores, 1981). In the 1990s, the focus shifted to systems in which individuals selected pictures to indicate what they wanted—notably, the Picture Exchange Communication System (Bondy & Frost, 2001). Research indicates that this too can be an effective strategy for establishing communication (Howlin et al., 2007; Yoder & Stone, 2006).

Enhancing an individual's communication skills concurrently may decrease problem behavior. Functional Communication Training is an approach in which instructors teach or reinforce a functionally equivalent communicative response that can replace problem behavior (Carr & Durand, 1985). For example, an individual with ASD may learn to make a verbal request for a preferred object or activity instead of

displaying aggression and may then begin to apply this new skill across settings (Durand & Carr, 1992).

Although ABA interventions have been developed to teach social communication skills such as conversing with others, repairing breakdowns in communication, and inferring implied meanings (e.g., Taylor & MacDonough, 2001), there is little research on the efficacy of such interventions. Also, as is true of interventions on social and play skills, the research that is available on interventions for social communication has focused mainly on preschool and school-age children with ASD and developmental delays. Consequently, research on adolescents and adults with ASD, as well as on individuals with high-functioning autism or Asperger's Syndrome, is a priority.

Repetitive Behaviors, Circumscribed Interests, and Other Problem Behavior

Functional assessments of stereotypic or repetitive behavior indicate that many individuals with ASD display such behavior at high rates regardless of environmental factors (Fisher et al., 1998). In some cases, however, the behavior may increase in response to specific events such as presentation of demands (Durand & Carr, 1987) or entry into an unfamiliar situation (Runco, Charlop, & Schreibman, 1986). Only a few studies have tested ABA interventions for reducing repetitive behavior. Simply increasing the availability of competing activities such as toys is one potentially effective strategy (Eason, White, & Newsom, 1982). Another approach is to interrupt the behavior and immediately redirect the individual to another activity (Ahearn et al., 2007). However, additional research is needed to confirm the utility of these interventions and test whether improvements are maintained over time. Unfortunately, even less information is available on ABA interventions for higher-order repetitive behavior such as an insistence on following routines or an intense preoccupation with a particular topic (Bodfish, 2004).

Daily Living, Community, and Vocational Skills

ABA interventions are often implemented to teach daily living skills such as toileting, dressing, brushing teeth, and food preparation (Matson et al., 1996). These interventions usually involve conducting a task analysis and then using chaining procedures to teach each step of an activity. The use of visual schedules, in which steps of an activity are displayed in separate pictures or photographs, appears especially useful (McClanahan & Krantz, 1998). ABA interventions also have been implemented to establish appropriate community behaviors such as crossing the street, but generalization of skills outside of the training context has been inconsistent (Haring et al., 1987). In addition, ABA curricula have been developed to teach academic and vocational skills. These curricula are based on a task analysis of the skills and involve developing the skills in a series of carefully planned, small steps (Engelmann et al., 1988). However, because evaluations of the efficacy of these curricula for individuals with ASD have been sparse, this is an area that merits further research.

Comprehensive Applied Behavior Analysis Programs: EIBI

In addition to conducting studies on focal interventions for specific target behaviors, behavior analysts also have developed comprehensive intervention packages. One comprehensive strategy is EIBI. EIBI is characterized by 20 to 40 hours per week of treatment for 2 years or longer, beginning prior to age 5 years. EIBI involves carefully structured, one-on-one, and small group intervention based on a broad curriculum that emphasizes communication, social skills, cognition, and pre-academics (e.g., colors, shapes, letters, and numbers; Leaf & McEachin, 1999).

There are also comprehensive ABA models for older children and adults with ASD throughout the lifespan (Handleman & Harris, 2006; Holmes, 1997). These programs take place in specialized classrooms, residential living programs, or occupational settings. They differ from EIBI in that they focus less on intensive, individualized, structured teaching and more on fostering participation in group activities and independent completion of tasks (without direct supervision).

Research shows that many individuals with ASD in comprehensive ABA programs successfully learn a variety of new skills (e.g., McClannahan, Macduff, & Krantz, 2002). At present, however, EIBI is the only type of comprehensive ABA program for individuals with ASD to have been tested in studies of long-term outcome. Research on EIBI suggests that ASD may be remarkably malleable in some cases during the first years of life (Rogers & Vismara, 2008).

The UCLA Young Autism Project

In the first study to draw widespread attention to EIBI, Lovaas (1987) and his colleagues at UCLA (McEachin, Smith, & Lovaas, 1993) evaluated an intervention that consisted of an average of 40 hours per week of individualized ABA instruction for 2 years or longer. Children with ASD began intervention when they were 2 or 3 years old. Intervention initially took place in children's homes and was conducted by teams of undergraduate students under close supervision by Lovaas, his graduate students, and other personnel who had 2 years of experience or more in Lovaas's intervention model.

During the first year of intervention, DTT was the primary intervention technique. An emphasis was placed on teaching skills considered necessary for subsequent progress, including compliance to elementary directions, imitation of others, and discrimination between instructional stimuli i.e., selecting a correct item from among a field of items, such as matching colors or pointing to objects or pictures called out by the examiner). At the same time, interventions were

implemented to reduce behaviors that interfered with learning (e.g., tantrums or aggression) through procedures such as extinction or time-out. More controversially, as a last resort, contingent aversives such as a slap on the thigh were occasionally used.

The second year focused on expressive and receptive language skills, including abstract language concepts (e.g., adjectives and other qualifiers, prepositions, pronouns), as well as generalization of new skills to preschool and other community settings. The third year emphasized pre-academics such as early reading and writing skills, observational learning (learning by watching other children learn), and peer interaction. Also, children spent increasing amounts of time in preschool or kindergarten. DTT was gradually reduced and replaced with more naturalistic instructional approaches.

Lovaas (1987) compared a group of 19 children with ASD who received this EIBI intervention to two control groups: a group of 19 children with ASD who received less intensive ABA based on the same intervention manual (Lovaas, 1981) and a group of 21 children with ASD who received services in the community. Assignment to groups was based on therapist availability. If sufficient therapists were available at intake to provide EIBI, a subject entered the EIBI group; otherwise, the subject entered the less intensive ABA group. Although the groups had similar IQs at intake, the EIBI group had a mean IQ of 83 at age 7 years, much higher than the mean IQ of 52 in the low-intensity intervention group and 57 in the community-intervention group that received community intervention. Nine children from the EIBI group (47%) achieved average intellectual functioning (IQ >85) and unsupported placements in general education classrooms. Lovaas (1987) concluded that these 9 children could be described as "normal functioning" and possibly even "recovered." A follow-up evaluation took place when children averaged age 13 years (McEachin et al., 1993). This evaluation indicated that the EIBI group maintained its gains and also outperformed the low-intensity group on measures of adaptive behavior and psychopathology. (The community-intervention group was unavailable for follow-up.)

Some investigators hailed these findings as a breakthrough and identified a number of strengths in the study, including groups that appeared well-matched on most intake variables, use of an intervention manual, and outcome evaluations conducted by blind examiners (Baer, 1993). However, others pointed out many possible flaws, notably nonrandom assignment to groups, use of different IQ measures at intake and follow-up, failure to measure some potentially important outcomes such as changes in behaviors associated with ASD, and impracticality of implementing aspects of the intervention in community settings (e.g., 40 hours of intervention per week and occasional use of contingent aversives) (Gresham & MacMillan, 1997; Schopler, Short, & Mesibov, 1989). Lovaas and colleagues disputed these critiques but concurred that replications with improved methodological design were required (Lovaas, Smith, & McEachin, 1989; Smith & Lovaas, 1997; Smith, Lovaas, & McEachin, 1993).

Subsequent Early Intensive Behavioral Intervention Studies

Following the initial report by Lovaas and colleagues, a number of other studies on EIBI began to appear. At this writing, the literature totals 21 studies of ABA intervention in which toddlers or preschoolers received 15 hours or more of instruction per week, and outcomes were assessed on standardized tests. Table 58-1 lists these studies. Two studies were RCTs and are summarized in the first two rows of the table. Next, the table lists 10 quasi-experimental studies. In these studies, procedures other than random assignment were used (e.g., basing assignment on therapist availability or family preference). However, the EIBI group was matched to control groups on subject characteristics such as age and IQ. Finally, the table includes one study with a multiple baseline design and eight studies in which pre- and post-intervention scores were compared but that had no experimental controls.

In eight studies, including both RCTs and three quasi-experiments, intervention was described as adhering to the manual developed for Lovaas's UCLA Young Autism Project (Lovaas, 1981, 2003). These studies are identified by an asterisk in the table. All of the studies on the UCLA model differed from Lovaas's (1987) investigation in that contingent aversives were not used. With two exceptions (Cohen, Amerine-Dickens, & Smith, 2005; Sallows & Graupner, 2005), the studies also differed in that children received fewer intervention hours per week. The most common outcome measures, presented in the three rows at the right of the table, were IQ (assessed with a variety of measures), adaptive behavior (usually tested with the Vineland Adaptive Behavior Scales; Sparrow, Balla, & Cicchetti, 1984), and unassisted placement in general education classes (ascertained from school records).

One RCT (Sallows & Graupner, 2005) compared EIBI directed by clinic personnel to EIBI directed by parents. (State funding was available for parents to hire and supervise therapists.) There were few differences between the clinic-directed and parent-directed groups, but both made gains from pre- to post-intervention that were comparable to those in the study by Lovaas (1987). For example, 11 of 23 subjects (48%) obtained average IQs and unassisted placement in general education at follow-up, similar to the rate of 47% reported by Lovaas (1987).

The other RCT (Smith et al., 2000a) compared EIBI to in-home parent training on ABA techniques. At follow-up, the EIBI group obtained an average IQ score that was 16 points higher than the average in the control group. The EIBI group also had a higher rate of unassisted placement in general education (4 of 15 children, compared to 0 of 13 in the control group). These differences were statistically significant but were only about half the size of the effects reported by Lovaas (1987). The EIBI group also obtained higher scores than the control group on measures of nonverbal skills and academic achievement, although the groups did not differ significantly on measures of adaptive behavior, language, or level of behavior problems. Thus, the EIBI group made substantial gains

Table 58–1.

relative to the control group on some measures, but the gains were more modest and circumscribed than in the Lovaas study (1987).

The three quasi-experiments on the UCLA Model (Cohen, Amerine-Dickens, & Smith, 2006; Eikeseth et al., 2002, 2007; Smith et al., 1997) yielded positive results on measures of IQ. Cohen et al. (2006) and Eikeseth et al. (2007) also reported gains in adaptive behavior, but this variable was not assessed in the study by Smith et al. (2007). In addition, Cohen et al. (2006) also found that children in the EIBI group were more likely than control children to have unassisted placements in general education, although Eikeseth et al. (2007) and Smith et al. (1997) did not obtain this result. These studies are noteworthy because they extended the UCLA Model in various respects: Cohen et al. (2006) provided intervention in a community agency rather than a university setting. Smith et al. (1997) focused on lower functioning children with ASD and severe developmental delay. Although children remained quite delayed following intervention, they made gains on two variables (IQ and acquisition of communicative speech). Eikeseth et al. (2007) studied children who were older than those in Lovaas's (1987) study (age 4–7 years at intake), implemented intervention at school instead of in the home, and included a comparison group that received the same number of intervention hours as the EIBI group. Results were comparable to those obtained with younger children. The three remaining studies on the UCLA Model also yielded positive results (Anderson et al., 2007; Birnbrauer & Leach, 1993; Smith, Buch, & Gamby, 2000a), although Smith et al. (2000a) found more evidence of progress during the first few months of treatment than at a follow-up 2 to 3 years later.

Considering all eight studies on the UCLA Model, some investigators have classified the model as an efficacious treatment (Rogers & Vismara, 2008). Meta-analyses by Reichow and Wolery (2009) and Eldevik et al. (2009) also support this conclusion. However, another meta-analysis (Boyd & Spreckley, 2009) found that the evidence remains insufficient to support clear conclusions, and writers such as Howlin, Magiati, and Charman (2009) have identified many methodological limitations. For example, both RCTs had small numbers of participants. The control group in the Sallows and Graupner (2005) study received nearly the same intervention as the EIBI group. Concerns also have been raised about the procedures for monitoring fidelity to the intervention protocols, and the focus on developmental tests such as IQ (e.g., Kasari, 2002). Potentially important outcomes such as reductions in behaviors associated with ASD and the impact of intervention on the family have received relatively little attention. For such reasons, some investigators have classified the UCLA Model as only possibly efficacious (Faja & Dawson, 2006).

Some other models have support from studies without a control group (e.g., Harris & Handleman, 2000; Perry et al., 2008) or studies with quasi-random assignment (Howard et al., 2005; Reed, Osborne, & Corness, 2007a, b; Remington et al., 2007) but not studies with random assignment. As such, they have been regarded as promising but not yet established

as efficacious or possibly efficacious (Rogers & Vismara, 2008). However, it should be noted that there are also studies that have failed to show benefits from EIBI (Bibby et al., 2002; Magiati, Charman, & Howlin, 2007). A possible reason is that these studies did not include procedures for assuring high-quality intervention (e.g., regular supervision of therapists), but in any event, they reveal that EIBI is not always effective.

Given that most EIBI studies have yielded positive outcomes, perhaps the next question is whether they have confirmed Lovaas's (1987) assertion that some children with autism achieve "normal functioning" after EIBI. None of the EIBI studies published before 2000 identified any such children. In contrast, more recent studies have indicated that a substantial minority of children (ranging from 27% to 48%) do perform in the average range in post-treatment assessments (Cohen et al., 2006; Howard et al., 2005; Sallows & Graupner, 2005; Smith et al., 2000b). However, Cohen et al. (2006) pointed out that they did not have enough data to describe the children in their study as normal-functioning. For example, they did not have information on whether children showed reductions in characteristics of autism.

Overall, despite some conflicting findings, EIBI—especially the UCLA Model—has substantial scientific support. Initial assertions that some children could be described as normal-functioning following intervention have not been replicated, but nearly all reports have described significant gains in IQ and other measures. These results provide reason for optimism. Nevertheless, it would be premature to conclude that its efficacy has been definitively proven. Additional research, especially large studies with random assignment to groups, remains a high priority (Lord et al., 2005).

Areas for Future Research on Early Intensive Behavioral Intervention

EIBI studies have incorporated a relatively narrow range of outcome measures, focusing mainly on IQ and other measures of children's level of functioning. Only three studies in Table 58-1 included tests of whether characteristics of autism were alleviated in EIBI. Remington et al. (2007) found an increase in joint attention following EIBI. Weiss (1999) and Zachor et al. (2007) reported a reduction in autism characteristics, but Sheinkopf and Siegel (1998) did not. Smith, McEachin, and Lovaas (1993) argued that tests such as the Vineland Adaptive Behavior Scales (Sparrow et al., 1984) could serve as proxy measures of autism characteristics. However, it is now known that many children with ASD perform well on such tests yet still display autism characteristics that interfere with their functioning (Klin, Volkmar, & Sparrow, 2000). Thus, more detailed assessments of autism characteristics will be necessary (Lord et al., 2005).

Little is known about "active ingredients" in EIBI, such as the choice of intervention procedures, dose or intensity of treatment, and content of the curriculum (Kasari, 2002). For example, regarding intervention procedures, two studies indicated that EIBI was more effective than community treatment of

equal intensity (Eikeseth et al., 2002, 2007; Howard et al., 2005). These findings may indicate that the use of ABA procedures is an important component of intervention. However, in a third study, outcomes did not differ significantly between the EIBI group and the community treatment group (Magiati et al., 2007). Another issue pertaining to intervention method is that all EIBI studies in Table 58-1 emphasized DTT. No studies have been conducted comparing DTT-based EIBI to ABA approaches that rely more on incidental teaching (described in the next chapter) or to developmental models (Chapter 60).

Findings on intensity of intervention are similarly limited and inconsistent. The studies with the most number of intervention hours per week (Cohen et al., 2006; Sallows & Graupner, 2005) have yielded the most favorable outcomes, but a study in which children received nearly as many hours (Magiati et al., 2007) produced null findings. Apart from a small study by Reed et al. (2007a), direct comparisons of different levels of intervention intensity have not been conducted. Comparisons of interventions with different curriculum content also have not been performed.

Even in studies in which children with ASD showed large improvements following EIBI, there have been major individual differences in outcome. For example, the nine children who achieved the best outcomes in the Lovaas study (1987) made an average of 37 IQ points, but the remaining 10 children showed little change. However, it has been difficult to identify factors that predict differential response to interventions. For example, some studies suggest that intake IQ is positively correlated with outcome (e.g., Handleman & Harris, 2000; Sallows & Graupner, 2005), but other studies have not obtained evidence for such an association (Cohen et al., 2006; Smith et al., 2000b). Because EIBI requires considerable effort and resources, identifying factors that are associated with favorable outcomes has considerable practical importance.

Smith et al. (2007) recommended that following carefully designed RCTs to test efficacy and identify active ingredients, investigators should proceed to studies of effectiveness in community settings. This will be necessary for EIBI, which has already become widely available from community providers in many regions. For example, the Ontario Intensive Behavioral Intervention program was set up to provide services to children with ASD in the entire province of Ontario, Canada. A review of data on 322 children with ASD in this program indicated that children made gains on standardized tests and other measures from pretreatment to follow-up (Perry et al., 2008). Still, additional evaluations of such ambitious programs will be necessary to determine whether behavior analysts can "go to scale" and implement EIBI for much larger numbers of children than they have in the past.

Conclusion

ABA has become the most extensively studied psycho-educational intervention for individuals with ASD. On a practical level, ABA research has generated a number of potentially useful intervention techniques and comprehensive intervention packages—notably, EIBI—that may greatly enhance the functioning of individuals with ASD. On a theoretical level, ABA research has led to broad (although not universal) acceptance of single-case experiments as an appropriate strategy for evaluating interventions, increased understanding of the learning style of individuals with ASD, and suggested that ASD may be malleable if intervention begins early.

Challenges and Future Directions

- Extending ABA research to older and higher-functioning individuals with ASD: Almost all ABA intervention studies have focused on individuals with ASD who are young, developmentally delayed, or both. Obviously, these individuals are deserving of attention. However, older and higher-functioning individuals with ASD have been somewhat neglected, and increased efforts to develop and test ABA interventions for such individuals are warranted.
- Disseminating ABA teaching techniques: Some ABA intervention techniques have been refined over the course of many single-case studies but never presented in a format such as a published manual that would be accessible to non-specialists. Examples include peer-mediated social skills training and video modeling. These interventions also have not been tested in RCTs that would provide information on which individuals with ASD benefit most from them and what the long-term outcomes are. As a result, the interventions may be underutilized.
- Addressing core features of ASD: Along with the focus in individuals with ASD who have developmental delays, behavior analysts have emphasized accelerating overall rates of learning. In EIBI studies, the primary outcome measures have been cognitive tests such as IQ. Certainly, speeding up skill acquisition in individuals who have delays is a reasonable goal. However, alleviating difficulties that are core features of ASD (e.g., reciprocal interactions with others and social communication) is also crucial. A more systematic effort to create and test interventions for such difficulties is vital, and collaborations between behavior analysts and experts on the ASD phenotype could facilitate this effort.
- Conducting larger, more rigorous outcome studies: ABA research has involved either single-case experiments with small numbers of subjects or studies of EIBI at a single site. This state of affairs has allowed behavior analysts to work separately from one another and from other researchers. However, definitive tests of EIBI will require a concerted effort on the part of behavior analysts, probably in collaboration with investigators who have expertise in multisite RCTs and statisticians who can perform sophisticated analyses (e.g., to identify "active ingredients").

Naturalistic Approaches to Early Behavioral Intervention

⠿

Points of Interest

- Naturalistic behavioral interventions use specific behavioral teaching strategies such as prompting, shaping, chaining, and reinforcement, to teach skills during child-directed activities.
- Naturalistic behavioral interventions were developed specifically to increase the generalization and maintenance of skills.
- These interventions have been found to be effective for increasing a range of social communication skills in young children with ASDs, including expressive language, play, imitation, and joint attention.
- This intervention approach has been used successfully by a range of intervention providers, including teachers, parents, siblings, and peers.
- Several child and parent characteristics have been identified to predict those children who are likely to respond best to this intervention approach.

There is now a large corpus of data supporting the effectiveness of behavioral interventions for the treatment of children with autism spectrum disorders (ASDs). In fact, treatments based upon a behavioral (learning theory) model are the only treatments with a strong empirical basis supporting substantial improvement in many of these children (e.g., National Research Council, 2001; Schreibman, 1997; Schreibman, 2005). Developed via the methodology of applied behavior analysis and based primarily on operant discrimination learning, these interventions involve the systematic application of the principles of learning to human behavior. The data-driven nature of behavioral technology and treatment development has ensured our constant evaluation of effectiveness, allowing for the identification of both treatment strengths and weaknesses. The early behavioral interventions applied to children with autism involved a highly structured format

called *Discrete Trial Training* or DTT, which provided us with the first successful tools to teach individuals with ASDs (e.g., Baer, Peterson, & Sherman, 1967; Lovaas, 1987; Lovaas, Berberich et al., 1966; Lovaas, Koegel et al., 1973; Maurice, Green, & Luce, 1996; Metz, 1965; Schroeder & Baer, 1972).

DTT involves presentation of discrete trials that are small units of instruction composed of a discriminative stimulus provided by a therapist, the child's response, and an immediate consequence contingent upon the child's response. Each trial is followed by a short intertrial interval before presentation of the discriminative stimulus for the next trial. Trials are presented in blocks, with all trials focusing on the same target skill (e.g., discriminating red from blue). Complex behaviors are typically broken down into smaller component behaviors, and these components are taught one at a time until the complex behavior is learned. Over time and trials, more comprehensive behavioral repertoires are established. To summarize, programs using this procedure share these basic components: *(1)* the learning environment is highly structured; *(2)* target behaviors are broken down into a series of discrete subskills and taught successively; *(3)* teaching episodes, or trials, are initiated by the therapist and presented in a massed manner; *(4)* teaching materials are selected by the therapist and are often held constant within a task; *(5)* the child's production of the target response is explicitly prompted; *(6)* reinforcers, albeit functional, may be indirect in that they are not directly related to the target response; and *(7)* the child receives reinforcement only for correct responding or successive approximations (e.g., Lovaas, 2003; Maurice, Green, & Luce, 1996; Smith, 2001).

The contribution of this form of intervention cannot be overstated, as it represents the first form of treatment available that allowed children with autism to acquire a wide range of appropriate behaviors. A large body of literature attests to the substantial gains that these techniques may facilitate in children with autism (Cohen, Amerine-Dickens, & Smith, 2006; Goldstein, 2002; Green, 1996; Lovaas, 1987; McEachin,

Smith, & Lovaas, 1993; Miranda-Linne & Melin, 1992; Sallows & Graupner, 2005; Smith, Groen, & Wynn, 2000). Yet as effective as these early interventions proved to be, it was the case that continued study and evaluation of this original highly structured form of intervention exposed several significant limitations to their effectiveness (e.g., Schreibman, 2005).

The major identified limitations to these early DTT strategies related to the issue of generalization. Behaviors learned via this highly structured, repetitive-practice protocol often failed to generalize across people, situations, and settings (stimulus generalization); were not accompanied by changes in related behaviors (response generalization); and tended not to be durable (maintenance). Other problems noted included a lack of spontaneity, inflexible ("robotic") responding, and prompt dependency. In addition, the specific technique of DTT required treatment providers (clinicians, teachers, parents) to use a highly structured set of rules, which often made it difficult for parents to learn because these rules resulted in parent–child interactions that were quite different than the natural interactions one typically has with children. Further, these drill strategies were often not pleasant for the treatment provider and not usually fun for the child. Because the child might not be enjoying the teaching, often escape- and avoidance-motivated problem behaviors, such as tantrums, occurred (Koegel, O'Dell, & Dunlap, 1988). This could make the DTT approach less attractive for both adult and child (Koegel et al., 1988; Schreibman, Kaneko, & Koegel, 1991).

In response to the generalization and spontaneity issues that accompanied DTT training and also to address the fact that the implementation of this strategy was sometimes unpleasant for the child and treatment provider, more naturalistic forms of behavioral intervention were developed. Interestingly, a number of different laboratories across the country independently developed empirically based naturalistic behavioral strategies that are remarkably similar, as they involve some of the same features. These new naturalistic interventions were influenced by a seminal article by Stokes and Baer (1977), which described specific strategies for establishing generalization of learned behavior. The incorporation of these generalization strategies is evident in these interventions. They share the following components (note contrast with components of DTT described above): *(1)* the learning environment is loosely structured; *(2)* teaching occurs within ongoing interactions between the child and therapist; *(3)* the child initiates the teaching episode by indicating interest in an item or activity; *(4)* teaching materials are selected by the child and varied often; *(5)* the child's production of the target behavior is explicitly prompted; *(6)* a direct relationship exists between the child's response and the reinforcer; and *(7)* the child receives reinforcement for attempts to respond, not only correct responses or successive approximations (*see* Koegel et al., 1989). Thus, there is an emphasis on capitalizing on child motivation, fostering spontaneity, and bringing behavior under naturally occurring environmental contingencies. The goal is to promote generalization of treatment effects with

strategies that therapists will find more pleasant and thus be more likely to use. (*See* Delprato, 2001, for a direct comparison of discrete trial versus naturalistic behavioral strategies.)

The most commonly used of these naturalistic behavioral interventions go by the names of *incidental teaching* (Hart & Risley, 1968; McGee et al., 1983), *milieu teaching* (Alpert & Kaiser, 1992; Kaiser, Yoder, & Keetz, 1992), *the natural language paradigm* (Koegel et al., 1988), and *pivotal response training* (Koegel et al., 1989).

A more detailed description of PRT will serve to illustrate naturalistic behavioral interventions.

Pivotal Response Training

Pivotal Response Training (PRT) focuses on the training of "pivotal" behaviors that are assumed to lead to widespread changes in other behaviors (hence, the term *pivotal*). Motivation and responsivity to multiple environmental cues are each pivotal behaviors, and both are known to be problematic in the ASD population (e.g., Schreibman & Koegel, 2005). Enhancing motivation leads to increased responding and thus learning opportunities. Increased responsivity helps to "normalize" the child's attention to the environment and thus increase the likelihood of successful learning. (Sometimes additional pivotal behaviors are included, such as self-initiations [Koegel, Carter, & Koegel, 2003] and self-management [Schreibman & Koegel, 1996; Schreibman & Koegel, 2005] because each of these will likely be associated with widespread enhancement of learning and generalization.)

To enhance the pivotal behavior of *motivation*, several specific treatment components are utilized. These include the following (*see* Koegel et al., 1989, for a more detailed description of specific procedures):

1. *Child choice and shared control.* To maximize the child's interest in the learning situation, he/she is given a great deal of input in determining the specific stimuli and the nature of the learning interaction. A variety of materials (e.g., toys, games, snacks) is presented and the child is allowed to select an activity or object around which the learning interaction will occur. Throughout the session, the therapist is alert to the child's changing interests and allows the child to change to another preferred activity. During the teaching interaction, the therapist and child take turns with the materials and activity, thus sharing control. This allows the child to become accustomed to the back-and-forth nature of verbal and social interaction while also allowing opportunities for the therapist to model appropriate and/or more sophisticated responses.
2. *Intersperse maintenance tasks.* To enhance motivation by keeping the overall success and reinforcement level high, previously mastered tasks are interspersed frequently among new (acquisition) tasks, which are more difficult for the child.

3. *Direct/natural reinforcers.* Direct, rather than indirect, reinforcers are used. Direct reinforcers are consequences that are directly related to the response they follow. A direct reinforcer for the verbal response "car" might be access to a toy car as opposed to a food or token reinforcer. Access to a toy car is a direct and natural consequence of saying "car," whereas food is not.

4. *Reinforcement of attempts.* To maximize reinforcement and therefore enhance the child's motivation to respond, therapists reinforce all reasonable attempts made by the child to respond. Thus, reinforcers are contingent upon attempts that may not be completely correct and may not be quite as good as previous attempts but are within a broader range of correct responses. Again, this serves to keep the overall level of reinforcement high.

5. *Responsivity to multiple cues.* Research has indicated that for many children with autism who are overselective in their responding, training on a series of successive *conditional discriminations* teaches them to respond to simultaneous multiple cues. A conditional discrimination is one that *requires* response to multiple cues (e.g., Koegel & Schreibman, 1977; Schreibman, Charlop, & Koegel, 1982). For example, asking a child to go get her red sweater is a conditional discrimination task. This is because the child undoubtedly has more than one red item of clothing and more than one sweater. Correct responding depends on attention to *both* color and object. To enhance the child's responsivity to multiple cues, the therapist presents the child with tasks involving conditional discriminations. It is assumed that as the child learns to respond on the basis of multiple cues, his or her attention is more normalized, allowing for more environmental cues to become functional. Because stimulus control of behavior is no longer as restricted, enhanced generalization should result.

An important caveat regarding teaching response to simultaneous stimulus input is that typically developing children are not skilled at such responding until approximately 3 or 4 years of age (Lovaas, Koegel, & Schreibman, 1979; Schreibman, 1997); thus, if the child with autism is functioning at a mental age below this, teaching responding to multiple cues is not recommended.

Naturalistic Behavioral Interventions and Specific Target Behaviors

Naturalistic behavioral interventions such as PRT initially targeted language behaviors, and it is in this area where much of the literature is focused. The emphasis on vocal communication skills is certainly understandable, as it is a hallmark deficit area in this population. Subsequent foci have included other hallmark deficits including social behaviors, nonverbal communication, imitation, and play.

Language

As noted above, expressive language has been the primary target behavior in the majority of research reports involving naturalistic behavioral strategies such as PRT, and it is now well-supported that this form of intervention is very effective in increasing spoken communication in children with ASDs (e.g., Delprato, 2001; Koegel & Koegel, 2006; Laski, Charlop, & Schreibman, 1988; National Research Council, 2001). Multiple single-subject and long-term outcome studies have confirmed that naturalistic behavioral language interventions facilitate the functional use of language for many children with autism, including verbal imitation (Laski, Charlop, & Schreibman, 1988), labeling (Koegel et al. 1998), question asking (Koegel et al., 1998), spontaneous speech (Laski et al., 1988), speech intelligibility (Koegel et al., 1998), conversational communication (Koegel et al., 1998), and rapid acquisition of functional speech in previously nonverbal children (Sze et al., 2003). Further, as will be noted in some of the above cited studies, this class of interventions has been shown to be effective for children who enter treatment essentially nonverbal. Moreover, when compared to more highly structured behavioral strategies, such as DTT, the specific components of naturalistic behavioral interventions facilitate relatively greater increases in verbalizations and spontaneous language use (Delprato, 2001; Koegel & Williams, 1980; Koegel, O'Dell, & Dunlap, 1988; Williams, Koegel, & Egel, 1981). Also, when these components are combined into a single naturalistic intervention (e.g., PRT, incidental teaching), they lead to more generalized speech and language skills (e.g., Charlop-Christy & Carpenter, 2000; Delprato, 2001; Koegel et al., 1998, McGee, Krantz, & McClannahan, 1985, Miranda-Linne & Melin, 1992). The fact that interventions involving naturalistic strategies lead to increased generalization is not surprising, given that these strategies were specifically developed to address the generalization limitations noted with the more highly structured forms of behavioral intervention.

Over the past 15 years, naturalistic behavioral interventions have been adapted to teach nonverbal social communication skills, such as joint attention, imitation, and pretend play (Schreibman & Ingersoll, 2005; Whalen & Schreibman, 2003). Interest in teaching these skills has gained popularity for two main reasons. First, these behaviors have been identified as autism-specific deficits (APA, 2001); thus, they have been targeted in their own right as an attempt to lessen the symptoms of autism. Second, these behaviors have *developmental potential*. A number of studies have shown that joint attention (e.g., Bates et al., 1979), imitation (Bates et al., 1988), and pretend play (Fein, 1981) are associated with the development of language and other social communication skills in typical development. Thus, research has focused on teaching these skills to children with autism in an attempt to promote social communication development more broadly (Ingersoll & Schreibman, 2006; Kasari, Freeman, & Paparella, 2006; Stahmer, 1995; Whalen, Schreibman, & Ingersoll, 2006).

Joint Attention

One of the earliest forms of social communication involves joint attention. There have been several studies using a naturalistic behavioral intervention to teach children to respond to the joint attention (RJA) bids of others as well as to initiate joint attention (IJA). For example, Whalen and Schreibman (2003) used a multiple-baseline design across five young children with autism to examine the efficacy of a naturalistic behavior modification technique for teaching response to increasingly complex bids for joint attention (i.e., placing child's hand on object, tapping an object, showing an object, following a point to an object, following a gaze shift to an object) and initiation of joint attention (i.e., showing and pointing). In their study, all five children increased their ability to respond to the therapist's bid for joint attention, and four of the children maintained this skill at a 3-month follow-up. After RJA training, the children showed an improvement in their RJA ability on Loveland and Landry's (1986) joint attention assessment but did not increase their use of IJA, necessitating IJA training. In the second phase of their study, four of the five children increased their ability to initiate joint attention with the therapist. In addition, improvements were found in the children's use of coordinated joint attention with their caregivers, indicating some generalization of skills. However, maintenance of IJA behaviors was somewhat limited at 3 months post-treatment. Jones, Carr, and Feeley (2006) used a multiple-baseline design across behaviors to examine the effect of a related procedure on improving RJA and IJA when implemented by the children's preschool teachers (5 children) and mothers (2 children). In both cases, in response to intervention the children exhibited an increase in their ability to respond to, and initiate, joint attention. Similarly to Whalen and Schreibman (2003), the children did not begin to use IJA during RJA training; rather, they required specific instruction in initiating joint attention.

Two additional single-subject design studies have focused on teaching RJA alone to examine whether improvements in RJA lead to gains in IJA. Rocha and Schreibman (2007) replicated and extended Whalen and Schreibman's (2006) results using a parent-implemented approach with three young children with autism. They found that parents were able to implement the intervention effectively and the children increased their response to their parents' bids for joint attention. Interestingly, although not directly targeted, the children also showed an increase in their use of coordinated joint attention, indicating some generalization to IJA. Using a related procedure, Martins and Harris (2006) taught three preschoolers with autism to follow the gaze of the therapist. Again, all three children exhibited an increase in their ability to respond the therapist's bids. In contrast to Rocha and Schreibman (2007), they did not find collateral changes in IJA, suggesting that for some children, joint attention initiations must be targeted directly. However, Martins and Harris (2006) defined IJA as showing and pointing, which are more complex behaviors than coordinated joint attention. This difference might suggest that coordinated joint attention is more responsive to intervention than showing and pointing.

In a larger, randomized controlled trial, Kasari and colleagues (2006) examined the effectiveness of a naturalistic behavioral intervention to teach joint attention skills. This study compared the effect of a short-term naturalistic behavioral intervention that targeted joint attention skills to a naturalistic behavioral symbolic play intervention (*see* below) and a control. They found that the children who had received training in joint attention made greater gains in RJA and IJA skills as measured on the Early Social Communication Scales (ESCS; Mundy et al., 2003) than the children in the symbolic play intervention and control group. Further, children who had received training in joint attention made greater gains in language 1 year post-treatment than the children in the control group (Kasari et al., 2008), suggesting that teaching joint attention skills using a naturalistic behavioral approach can have long-term effects on language learning.

It should be noted that in all of the above mentioned studies, joint attention training was taught with a combined structured and naturalistic behavioral approach, with initial training typically conducted at the table in a structured fashion, followed by practice during child-led activities. However, in keeping with the naturalistic focus, all stimuli and reinforcement were natural (highly preferred toys) to the interaction. This use of structure during the initial training episodes differs somewhat from the naturalistic behavioral interventions that have been used to teach imitation and pretend play and may be indicative of the difficulty in teaching joint attention episodes or the fact that joint attention training is less easily incorporated into unstructured play. However, it is unclear whether the initial structure is necessary or whether joint attention can be taught in more natural contexts from the beginning. Further, RJA has been typically targeted before IJA, as it emerges earlier in development and is an easier skill for children to master (Whalen & Schreibman, 2003). However, it is unclear whether RJA is necessary to teach before IJA, whether they can be taught concurrently, or whether teaching IJA would lead to gains in RJA without direct training.

Imitation

There have been several studies that have taught imitation skills to young children with autism using a naturalistic behavioral approach. In a series of single-subject design studies, Ingersoll and colleagues have examined teaching spontaneous, generalized imitation skills to preschool-aged children with autism during play. The first study used a multiple-baseline design across five young children with autism to examine the effectiveness of this approach for teaching object imitation (Ingersoll & Schreibman, 2006). In response to treatment, all children showed substantial gains in their use of object imitation. Follow-up data obtained after 1 month indicated that all children maintained their gains of object imitation, which generalized to novel settings,

materials, and a therapist. Changes in object imitation were also evident on a structured imitation assessment and during a naturalistic, structured observation with the therapist and the caregiver. Perhaps more exciting was the finding that naïve observers blind to participants' treatment status rated the participants as exhibiting significantly more appropriate social communication skills and appearing more typically developing at post-treatment than pretreatment.

A second study targeted the imitation of meaningful gestures (Ingersoll, Lewis, & Kroman, 2007). This study used a multiple-baseline design across five young children with autism who had difficulty with the imitation and spontaneous use of descriptive gestures (e.g., spreading arms out for "big" or putting arms out at sides for "airplane"). All children showed an increase in their imitation of gestures, which generalized to novel environments and was maintained at a 1-month follow-up. In addition, three of the children exhibited substantial gains in their spontaneous use of gestures, whereas the other two exhibited small but consistent gains. Finally, naïve observers blind to treatment status rated the children as using more appropriate social communication during treatment than baseline.

In a third study, a multiple-baseline design was implemented, and three mothers were taught to implement the intervention techniques with their child (Ingersoll & Gergans, 2007). The mothers of the two nonverbal children were taught to use the intervention strategies to teach object imitation, and the mother of the verbal child was taught to target both object and gesture imitation. Results indicated that the parents learned to use the intervention strategies and their children improved their imitation skills. Importantly, the children's and parents' skills both generalized to the home and maintained over time.

Taken together, these studies indicate that imitation can be directly taught using a naturalistic behavioral intervention. Further, there is evidence that teaching imitation skills in this manner can lead to improvements in other social communication skills, including language, pretend play, and coordinated joint attention (Ingersoll & Schreibman, 2006), supporting the potential role that imitation plays in the developmental of more advanced social communication skills and its importance as a treatment target.

Pretend Play

Several studies have explicitly targeted pretend play skills in children with autism using a naturalistic behavioral approach. In the first of its kind, Stahmer (1995) used a multiple-baseline design across seven verbal children with autism to examine the effects of teaching symbolic play skills using a modified version of PRT. The results indicated that all children were able to engage in symbolic play skills with an adult at levels similar to those of language-age-matched typical peers. Generalization to new toys and new adults was also impressive, and these behavioral changes remained stable over time. Further, when rated by naive observers for creativity,

spontaneity, and "typical" play, children with autism improved significantly after PRT play training; however, their play remained qualitatively distinguishable from the play of the typical children (Stahmer, Schreibman, & Palardy, 1994). One area of difficulty for the children that continued after play training was play with another peer, which did not improve. In a related study, Thorp, Stahmer, and Schreibman (1995) taught three children with autism to engage in socio-dramatic play with an adult. Again, children made gains in their ability to carry out socio-dramatic play schemes, and these gains generalized to novel materials and settings and maintained over a period of 3 months. In both of these studies, the children had some initial appropriate play skills and had expressive language ages of at least 2.5 years.

Kasari and colleagues (2006) used a randomized design to examine the effect of a naturalistic behavioral symbolic play intervention with preschool-aged children with autism. In their study, children were randomly assigned to a symbolic play intervention, joint attention intervention, or control group. Their results indicated that the children who received training in symbolic play made greater gains in their overall level of play on a structured play assessment than children in the control group and had a higher number of symbolic play schemes and overall play level during an unstructured parent–child interaction than children in the control group and children who received training in joint attention, both immediately (Kasari et al., 2006) and 1-year post-treatment (Kasari et al., 2008). This finding provides strong evidence that naturalistic behavioral interventions are effective for teaching symbolic play. Further, in their study, the average expressive language age of the participants at pretreatment was 21 months, indicating that symbolic play skills can be taught to children with lower language ages than in previous studies.

Taken together, these findings suggest that naturalistic behavioral interventions are effective for increasing a range of play skills found to be deficient in children with autism. In some cases, these skills were found to be similar in rate to the play of typically developing children of the same language age (Stahmer, 1995). In addition, the generalization and maintenance of the play skills may be indicative of the reinforcing nature of play itself. These findings have led others to conclude that the naturalistic behavioral approach may indeed produce meaningful changes in play skills that are spontaneous and flexible and thus meet the true definition of play (Luckett, Bundy, & Roberts, 2007). Despite these positive outcomes, the evidence suggests that the children's play remained qualitatively distinguishable from the play of the typical children (Stahmer et al., 1994) and that generalization to typical peers was not evident, suggesting that social play may need to be explicitly taught (*see* section on peer-mediated intervention below).

Further, in all three studies, children also made improvements in nontargeted skills, including joint engagement (Kasari et al., 2006; Stahmer, 1995; Thorp et al., 1995), coordinated joint attention (Kasari et al., 2006; 2008), and language skills, both concurrently (Thorp et al., 1995) and 1 year later

(Kasari et al., 2008). These findings support the developmental potential hypothesis that teaching pretend play skills using a naturalistic behavioral intervention can lead to improvements in other social communication skills.

In sum, there is a growing body of evidence indicating that children with autism can be taught nonverbal social communication skills via naturalistic behavioral interventions. There is also some indication that training in these nonverbal behaviors can also lead to collateral changes in other, nontargeted social communication skills. These findings are particularly true for language skills, which have been shown to increase as a result of teaching joint attention (Kasari et al., 2006; Whalen & Schreibman, 2003), imitation (Ingersoll & Schreibman, 2006), and pretend play (Kasari et al., 2006; Thorp et al., 1995). Interestingly, although there is some evidence that joint attention training (Kasari et al., 2006) and language training (Gillett & LeBlanc, 2007) using naturalistic behavioral methods may lead to improvements in functional play, symbolic play skills have been found to be unaffected by joint attention (Kasari et al., 2006; 2008) or language teaching (Stahmer, 1995). There is also evidence that gains in general social engagement and coordinated joint attention result from teaching a variety of social communication skills using a naturalistic behavioral approach, including RJA (Rocha et al., 2007), imitation (Ingersoll & Schreibman, 2006), symbolic play (Kasari et al., 2006; 2008; Stahmer, 1995; Thorp et al., 1995), and even language (Bruinsma, 2004). However, changes in more advanced IJA skills, such as showing and pointing, require specific training (Jones et al., 2006; Kasari et al., 2006; Whalen & Schreibman, 2003). These findings suggest that you "get what you teach" (Kasari et al., 2006); however, there appears to also be some general treatment effects—particularly in the area of social responsiveness, functional play, and language. Further, these general treatment effects may become more pronounced over time (Kasari et al., 2008).

The possibility of general treatment effects is exciting, as it suggests that wide-ranging positive effects on development can occur in response to teaching a pivotal skill. One possible explanation for the general treatment effects seen across nonverbal social communication interventions is the use of naturalistic behavioral interventions that, through the use of following the child's lead and natural reinforcement (usually toys), may increase social engagement, functional play, and language skills. It is also possible that some nonverbal social communication skills require the same underlying ability (such as the ability to attend to another person), such that teaching one skill (e.g., imitation) improves a related skill (e.g., coordinated joint attention), whereas others do not (e.g., IJA and symbolic play). This possibility may explain why there is less "spill-over" with these treatment targets. It is also possible that increasing one skill directly affects another skill, as it appears to do with language (Kasari et al., 2008).

In conclusion, the naturalistic behavioral approach has been used to target a range of social communication skills found to be deficient in children with autism. These skills,

when targeted early in development appear to confer a wide range of benefits. However, it is still unclear which skills are most important to teach and at what point in development. Further research focused on the most efficient and effective way to teach social communication is needed.

Interventionists

Because naturalistic intervention strategies involve interactions that are more typical in terms of how individuals interact with children in the natural environment, it is not surprising that such techniques have been successfully implemented by a variety of treatment providers, including parents, teachers, and peers. Given that one of the main goals of naturalistic strategies is to enhance generalization of treatment effects, incorporating individuals with whom the child is likely to interact during his or her natural day makes perfect sense and has, in fact, proved to achieve these goals.

Parents

Naturalistic behavioral approaches, such as PRT, have been commonly utilized as a vocal language training program with an emphasis on parent training (Koegel et al., 1989). Indeed, parent involvement in the treatment of children with autism has been associated with increased maintenance and generalization of treatment (particularly language) gains both with highly structured (Crockett et al., 2007; Koegel et al., 1982) and naturalistic behavioral interventions (Hester et al., 1995; Schreibman & Koegel, 1996, 2005.). However, although both highly structured and naturalistic treatment strategies have been taught to parents who can subsequently use them effectively, it appears that naturalistic strategies are associated with other positive effects. For example, Schreibman, Kaneko, and Koegel (1991) had naïve observers view videotapes of parent–child dyads in which the parent was conducting a therapy session with the child. In one condition, parents were using a highly structured intervention (DTT), and in the other condition, parents were using a naturalistic intervention (PRT). The observers were asked to rate how happy, interested, and enthusiastic the therapist (parent) appeared when working with the child. Results indicated that parents were rated as having significantly more positive affect when using PRT. Further, Koegel, Bimbela, and Schreibman (1996) using a similar methodology asked naïve observers to rate the level of positive interactions during the family dinnertimes of families where the parents had been trained in DTT versus families where the parent had been trained in PRT. Pre- and post-parent training videotapes of the dinnertime family interactions were rated on four interactional scales (level of happiness, interest, stress, and general communication style). Both groups of families initially scored in the neutral range at pretreatment; this did

not change significantly at post-treatment for the DTT group. However, at post-training, the PRT group showed a level of positive interaction on all four scales, suggesting high degrees of happiness and interest, low stress during the interactions, and more positive communication. It is noteworthy that these studies support one of the main rationales for the development of more naturalistic teaching strategies: Such forms of intervention would be more pleasant for the treatment provider (in this case the parent) and as such would be more likely to be implemented.

Another benefit of naturalistic strategies is that they can—and indeed should—be implemented in naturally occurring situations. These strategies have the advantage of lending themselves quite well to integration into a family's daily routines. For example, parents are taught how to use everyday activities such as sorting laundry, shopping, playing in a park, and so forth, as teaching opportunities. This encourages the parents to use the effective treatment in a variety of settings and with a variety of target behaviors, both of which promote generalization. Further, parents find these strategies less disruptive than more highly structured teaching as they do not necessarily have to set up specific teaching times and set up special teaching environments. All of these benefits likely make naturalistic strategies more positive for parents and thus more likely to be implemented on an ongoing basis.

Teachers and Classrooms

Incidental teaching, a naturalistic behavioral strategy, was originally designed for use in preschool classrooms for disadvantaged but typically developing children (Hart & Risley, 1968). This approach has subsequently been used as the primary intervention approach in a number of research-based inclusive classroom programs for 2- to 4-year-old children with autism. These programs have demonstrated gains in language, play, and social interaction skills (e.g., McGee, Morrier, & Daly, 1999; Stahmer & Ingersoll, 2004). However, as with other research-based practices, the use of naturalistic interventions in classroom settings is a fairly recent phenomenon. Arick and colleagues (2003) developed a public school program that included PRT along with other research-supported behavioral practices. Reporting on outcome data for more than 100 children participating in the program, these investigators reported that the majority of children made significant progress in the areas of social interaction, expressive speech, and use of language concepts. The children in the program gained, on average, more than 1 month of language age for every month of instruction. Also, they displayed significant decreases in inappropriate and disruptive behaviors. McNerney (2003) used videotapes to show parents interacting with their children with autism to regular education preschool teachers. The parents were implementing techniques to promote expressive verbalizations via PRT. She found that, indeed, the teachers showed increases in their use of PRT procedures and also the number of opportunities they provided for their students to verbalize. Importantly, the children showed increases in the number of functional verbalizations made at school.

Although the use of PRT and similar approaches obviously hold promise in educational settings and those provided by teachers, it is still the case that such approaches are not yet used extensively in classrooms, and teachers who often report using such procedures (and believe they are) are simply not doing it well (Stahmer, Collings, and Palinkas, 2005). It is hoped that upcoming research will help bridge the gap between research and practice in this area.

Peers

To promote generalization of treatment effects, it is important that treatment be conducted in as many environments as possible and by others with whom the child with autism interacts on a regular basis. Peers are an obvious choice of interventionist because they are a naturally occurring part of the child's environment and because multiple trained peers mean multiple treatment providers are available. Indeed, peers have been taught to successfully use naturalistic behavioral interventions to increase language, play, and social skills in their peers with autism. McGee et al. (1992) used a multiple-baseline design to demonstrate the effectiveness of peer incidental teaching to increase the reciprocal interactions of three preschoolers with autism (age 3–5 years) and three typically developing children (age 4 years). After training as peer-tutors, the typically developing children used incidental teaching in the classroom setting to facilitate the use of verbal labels of preferred toys by their peers with autism. Maintenance of increased reciprocal interactions was demonstrated after adult supervision was withdrawn. One of the children with ASD generalized the increased interactions in free-play periods. Pierce and Schreibman (1995) used modeling, role, playing, and didactic instruction to teach typical peers of two 10-year-old boys with autism to implement PRT in a classroom setting. After peer implementation of PRT, the two children with autism maintained prolonged interactions with the peers, initiated play and conversation, and increased engagement in language and joint attention behaviors. These results were replicated and extended by subsequent investigations (Pierce & Schreibman, 1997a,b) showing that PRT training of peers led to collateral improvements in social behaviors, language complexity, and play complexity and that training of multiple peers led to increased generalization of treatment effects.

In a more indirect application of behavioral teaching in a naturalistic manner, the literature supports the effectiveness of "integrated" preschool and classroom environments for children with autism. Typically these are classrooms in which children with ASDs are placed with typically developing children (usually a ratio of two typically developing peers

per child with ASD) and where naturalistic behavioral strategies are embedded in activities with the peers (McGee, Daly, & Jacobs, 1994; McGee, Morrier, & Daly, 1999; Stahmer & Ingersoll, 2004; Strain & Cordisco, 1994; Strain, McGee, & Kohler, 2001). The rationale for such integrated classroom environments includes the obvious potential of typical peers as both intervention agents (either specifically trained or as part of normal interactions), behavior models, and as part of the type of environment within which we want these children to function (i.e., least restrictive environment). For example, Stahmer and Ingersoll (2004) report the outcomes for 20 toddlers with autism who participated in an inclusive program for children under age 3 years. (The program utilized both naturalistic and more highly structured interventions.) Outcomes on both standardized assessments and functional behaviors were compared for the children at program entry and at program exit (approximately 6 months later). The results of this program are impressive. Although only 11% of the toddlers with ASDs at intake scored in the typical range on standardized assessments, 37% of the children scored in this range at program exit. Further, although at intake, 50% of the ASD toddlers had a functional communication system, 90% of the children did at exit. The investigators also reported substantial increases in social and play behaviors.

Current Issues in Naturalistic Behavioral Strategy Implementation

Although the literature makes a convincing argument for the use of naturalistic behavioral strategies (such as PRT for children with autism), research continues with the goal of improving the overall effectiveness of such procedures and, importantly, determining which individuals will show the most positive treatment outcome. Naturalistic strategies have been found to be superior to more highly structured behavioral techniques (DTT) in terms of producing spontaneous and generalized social communication; however, it is unclear whether they are superior for teaching the wide range of skills children with autism need to learn, because comparative studies have examined only specific language skills (e.g., preposition use). It is possible that certain skills, such as spontaneous, social communication skills, are best taught using a naturalistic behavioral approach, whereas others are better taught using different teaching strategies. For example, it has been proposed that naturalistic behavioral approaches are more effective for teaching expressive language, whereas structured behavioral approaches are superior for teaching receptive language (Arick et al., 2003). Similarly, it has been suggested that naturalistic behavioral approaches are superior for teaching requesting skills, whereas developmental interventions may be more effective for improving commenting skills (Ingersoll, in press). Research that can examine which skills are best taught using a naturalistic behavioral approach is likely to be fruitful.

As is true of all interventions with this population, there is a wide heterogeneity of responding such that some children respond dramatically well, whereas others respond to a lesser degree, and a minority show no positive response. This renowned heterogeneity in response to treatment strongly suggests that other variables are interacting with treatment to affect response to intervention. Examples of such variables are child characteristics (including behaviors and neurobiological factors), parent/family variables (e.g., depression, stress), cultural variables (different cultures place emphasis on different behaviors and may find different forms of treatment differentially acceptable), and treatment/behavior interactions (i.e., some behaviors may be best targeted by different forms of behavioral intervention).

Sherer and Schreibman (2005) focused on child behaviors and identified a specific behavioral profile that predicted PRT treatment outcome of 4- to 6-year-old children with autism. These investigators first looked retrospectively at the treatment outcome of 28 children who had received PRT treatment. Identifying those children who showed the best response to treatment and those that showed the poorest response, the investigators identified a "responder profile" versus a "nonresponder profile" that characterized the different outcomes. During a structured observation with toys and an adult present, those children who were treatment "responders," when compared to "nonresponders," showed more interest in toys/activities, less social avoidance, more social approach behavior, more verbal stereotypy, and less nonverbal stereotypy. Next a prospective study was conducted wherein six children (age range 3–5.5 years) were identified where three matched the "responder" profile and three matched the "nonresponder" profile identified in the retrospective analysis. The children were matched on IQ, language age, and symptom severity to exclude these potential variables from accounting for outcome differences. Children were subsequently given intense PRT treatment for approximately 6 months. Within a multiple-baseline-across-subjects design, the investigators looked at communication, play, and social behaviors as dependent measures. As expected, the predicted "responders" evidenced substantial improvements in all behaviors, whereas the predicted "nonresponders" showed minimal or no gains.

Schreibman et al. (2008) conducted a subsequent study designed to determine whether all of the Sherer and Schreibman (2005) profile behaviors were required for treatment outcome prediction and if the predictive profile was specific to PRT as opposed to response to ANY treatment. In this study, investigators studied six children with autism (age 2–4 years) matching the original nonresponder profile on all but one of the profile behaviors (toy contact or avoidance) and then assessed their response to PRT. In addition, participants received a course of DTT to determine whether the profile predicted child response to this intervention. Results suggested that altering the original profile behavior of toy contact led to improved response to PRT, altering the profile behavior of high avoidance had little impact on treatment response, and the profile was not predictive of response to DTT.

Yoder and Stone (2006) compared a naturalistic behavioral language intervention, Responsive Education and Prelinguistic Milieu Teaching (RPMT), to a more structured augmentative communication intervention, the Picture Exchange Communication System (PECS; Bondy & Frost, 2001) in young, nonverbal children with autism. They found that that children who initiated joint attention at pretreatment made more gains in the RPMT, whereas the children with little joint attention made more gains in PECS.

There is also evidence to suggest that the effectiveness of naturalistic behavioral interventions vary based on the characteristics of the child's caregiver. For example, Yoder and Warren (2001) found that children whose mothers were initially more responsive and had more formal education made more progress in a naturalistic behavioral intervention (prelinguistic milieu teaching), whereas children whose mothers were less responsive and had less education made more gains in a developmental intervention (responsive interaction). Additional research that can identify for whom naturalistic behavioral interventions are likely to be most effective would likely improve child outcomes.

Although they are based on different underlying philosophies, naturalistic behavioral interventions share many similarities in their implementation with developmental and relationship-based interventions reviewed in this volume that make them highly compatible (*see* Ingersoll, 2010, for review). This compatibility has led some researchers to combine components from each approach in an effort to make more effective interventions. The resulting approaches, Enhanced Milieu Teaching (Kaiser & Hester, 1994), RPMT (Yoder & Warren, 2002), Project ImPACT (Ingersoll & Dvortcsak, 2006, 2010), and Roger and Dawson's Early Start Denver Model (Smith, Rogers, & Dawson, 2008) have been shown to be effective for teaching social communication skills to children with ASDs (Hancock & Kaiser, 2002; Kaiser, Hancock, & Nietfeld, 2000) and other developmental delays (Kaiser & Hester, 1994). However, it is unclear whether they are more effective than naturalistic behavioral interventions by themselves.

These research directions are necessary to determine for which skills, children, and families naturalistic behavioral interventions may be best-suited. Such work will also likely lead to information about how such treatment strategies may be refined and altered so as to lead to positive treatment outcome for more children overall.

Conclusions

Naturalistic behavioral interventions now enjoy a substantial empirical foundation for affecting a wide range of skills in children with autism. Although initially developed primarily in response to identified limitations to the highly structured discrete trial teaching format, naturalistic strategies such as PRT have been expanded to focus directly on behaviors such as communication, social involvement, imitation, and pretend play. Further, these strategies have been shown to be effectively implemented by a variety of treatment providers including parents, teachers, and peers. Although the potential for naturalistic behavioral strategies to target a comprehensive set of skills exists, the fact remains that children's response to treatment can be highly idiosyncratic and heterogenous. Thus current and future research must address for which children and for which behaviors such intervention strategies are most suited.

Challenges and Future Directions

- Compare effectiveness of this approach to other evidence-based interventions for children with ASDs for teaching a wide range of skills.
- Better characterize and identify treatment responders and nonresponders to this intervention approach.
- Further identify characteristics of effective intervention providers using this approach.
- Examine whether adding techniques from the developmental and relationship-based literatures can increase the effectiveness of this approach.

Relationship-Based Early Intervention Approach to Autistic Spectrum Disorders: The Developmental, Individual Difference, Relationship-Based Model (The DIR Model)

Key Points

- The DIR Model *(1)* focuses on functional emotional capacities—joint attention, engagement, two-way communication, problem solving, and symbolic thought—which provide the foundation for development and *(2)* treats impeding sensory motor and regulatory challenges—auditory, visual-spatial, motor—through interactive learning relationships with parents, teachers, and therapists. These interactive experiences are believed to improve the connectivity of cortical neurons that process sensory motor information. This improvement, as a mechanism of improvement, is consistent with the current view of autism as a disorder of connectivity between different parts of the brain.
- Central to the DIR Model is the role of the child's natural emotions and interests. Studies have shown that they are essential for engagement and interaction between children and caregivers. These interactions improve the neural connectivity and thus enable successively higher levels of social, emotional, and intellectual capacities.
- Deficits associated with autism stem from compromises in an infant's ability to connect emotions (or intent) to motor planning and sequencing, to sensations, and later, to early forms of symbolic expression.
- With caregivers' creating states of heightened pleasurable and other affects tailored to the child's unique motor and sensory-processing profile, the child can develop and strengthen the connection between sensation, affect, and motor action, which leads to more purposeful affective behavior. This, in turn, leads to reciprocal signaling, a sense of self, symbolic functioning, and higher-level thinking skills.
- Clinical outcome reports have long described the benefits of DIR intervention, and new research is confirming the importance of developmental models of assessment

and very early intervention, which can change the course of the disorder.

Relationship-based approaches are part of a broader category of developmental approaches that help children with autistic spectrum disorders (ASDs) and related special needs conditions. Based on a modern understanding of human development, these approaches recognize the importance of relationships; interactions with primary caregivers, therapists, and peers; and individual differences in infants' and children's ability to process sensations and plan actions. Developmental approaches call for early identification and early and intensive intervention.

A feature common to most developmental-relationship-based approaches is the focus on human interactions as a primary learning path. The Developmental, Individual-Difference, Relationship-Based Floortime Model (DIR Model) presented in this chapter systematizes an understanding of the child and his family and culture, including diagnostic profiles. This comprehensive framework enables clinicians, parents, and educators to construct a program tailored to the child's unique challenges and strengths.

Central to the DIR Model is the role of the child's natural emotions and interests. Studies have shown that they are essential for engagement and interaction between children and caregivers. These interactions improve the neural connectivity and thus enable successively higher levels of social, emotional, and intellectual capacities.

Floortime, derived from the DIR Model, is a specific intervention technique in which parents and other members of the intervention team follow the child's natural emotional interests while challenging the child to master richer social, emotional, and intellectual capacities. Floortime emphasizes the child's initiation, reciprocity, continuous flow of interactions, reasoning, and empathy. With young children, these playful interactions often occur on the "floor," but they expand to include conversations and interactions in other places.

The DIR Model guides a team that often includes speech therapists, occupational therapists, educators, mental health (developmental-psychological) professionals, and, where appropriate, biomedical personnel. Parents and other family members and caregivers are vital in developmental, relationship-based approaches because of the importance of their emotional relationships with the child. This chapter will describe the DIR Model in greater detail.

The Developmental, Individual-Difference, Relationship-Based Model

The "D" of DIR: Functional Emotional Developmental Capacities

Table 60-1 lists the six Functional Emotional Developmental levels, which explain how children integrate all their capacities (motor, cognitive, language, visual-spatial, sensory) to carry out emotionally meaningful goals. The support for these levels is reviewed elsewhere (Greenspan, 1979, 1989, 1992, 1997b).

The "I" of DIR: Individual Differences in Sensory Modulation, Sensory Processing, Sensory Affective Processing, and Motor Planning and Sequencing

These biologically based individual differences are the result of genetic, prenatal, perinatal, and maturational variations and/or deficits. They can be characterized in at least four ways:

1. Sensory modulation, including hypo- and hyper-reactivity in each sensory modality (touch, sound, smell, vision, and movement in space).
2. Sensory processing in each sensory modality, including auditory processing and language and visual-spatial processing. Processing includes the capacity to register, decode, and comprehend sequences and abstract patterns.
3. Sensory-affective processing in each modality (e.g., the ability to process and react to affect, including the capacity to connect "intent" or affect to motor planning and sequencing, language, and symbols). This processing capacity may be especially relevant for ASD (Greenspan & Wieder, 1997, 1998).
4. Motor planning and sequencing, including the capacity to sequence actions, behaviors, and symbols, such as symbols in the form of thoughts, words, visual images, and spatial concepts.

The "R" of DIR: Relationships and Interactions

Affective interaction patterns include developmentally appropriate, or inappropriate, relationships with the caregiver, parent, and family. These interaction patterns bring the child's

biology into the larger developmental progression and can contribute to the child's functional developmental capacities. Developmentally appropriate interactions with a child mobilize his intentions and affects and enable him both to broaden his range of experience at each level of development and to move from one functional developmental level to the next. In contrast, interactions that do not deal with the child's functional developmental level or individual differences can undermine progress. For example, a reserved caregiver may not be able to easily engage an infant who is under-reactive and self-absorbed. A child who does not have the interactive support of a parent to explore negative emotions symbolically can have anxiety, rigidities, obsessions, and constricted affect.

The Importance of Affect

Explorations of the types of thinking that are part of skillful social interactions (i.e., emotional intelligence) and concepts of multiple intelligences have supported and increased interest in the role of emotions (Gardner, 1983; Goleman, 1995; Committee on Integrating the Science of Early Childhood Development, 2000; Kasari et al., 2006). A clinical outcome report study on DIR suggests that with an emphasis on emotional interactions, a subgroup of children diagnosed with ASDs can learn to engage with others; think creatively, logically, and reflectively; enjoy peers; and do well academically in regular classes (Greenspan & Wieder, 1998; Greenspan, 1999; Interdisciplinary Council on Developmental and Learning Disorders Clinical Practice Guidelines Workgroup, 2000).

Despite this support for and greater interest in the role of emotions in human development, there has not been sufficient understanding of how emotions and emotional interactions impact intelligence and related cognitive and language abilities as well as many complex social and self-regulation skills. There has also not been an understanding of the psychological or neurological mechanisms of action by which emotions shape these different aspects of the mind. Because of this lack of understanding, emotions have taken a back seat to cognition, language, and memory. Therefore, the question remains: What role does emotion play in the developmental steps and pathways through which such distinctly human capacities as symbol formation, language, and reflective thinking emerge in the life of each new infant and child?

The Core Psychological Deficit in Autism and the Developmental Pathways to Joint Attention, Pattern Recognition, Theory of Mind, Language, and Thinking

Suggested autism-specific developmental deficits include those in the following abilities: *(1)* empathy and seeing the world from another person's perspective (Baron-Cohen,

Table 60–1.
The six functional emotional developmental levels

Level	Description
1. Shared attention and regulation	Attends to multisensory affective experience and, at the same time, organizes a calm, regulated state (e.g., looks at, listens to, follows the movement and voice of a caregiver, and moves purposefully).
2. Engagement and relating	Engages with caregivers and expresses affective preference and pleasure (e.g., shows joyful smiles and warm affection with a familiar caregiver). Engagement evolves to include tolerating wider ranges of emotions, such as anger, frustration, disappointment, and fairness, within the relationship.
3. Purposeful emotional interactions	Initiates and responds to two-way presymbolic gestural communication (opens and closes circles of communication, e.g., back-and-forth smiles, sounds, and gestures that build around a common theme, such as reaching for and grasping a rattle in the caregiver's hand and then returning it when the caregiver reaches out).
4. Shared, social problem-solving (joint attention)	Organizes chains of two-way communication to solve social problems (opens and closes many circles of communication in a row); maintains communication across space; integrates affective polarities; and synthesizes an emerging prerepresentational organization of self and other (e.g., taking Dad by the hand to get a toy on the shelf). Here, aware of what he can and cannot do (self) to get the toy he wants, the child seeks the help of someone else (other). Prior to representing intent or ideas in words, the child does so through gestures and actions.
5. Creating ideas	Creates and functionally uses ideas as a basis for creative or imaginative thinking, giving meaning to symbols (e.g., engaging in pretend play, using words to meet needs, "Juice!").
6. Building bridges between ideas (logical thinking)	Build bridges between ideas as a basis for logic, reality testing, thinking, and judgment (e.g., answer "Wh" questions, including "Why"; engage in debates opinion-oriented conversations; elaborate pretend dramas).

1994); (2) higher-level abstract thinking, including making inferences (Minshew, Goldstein, & Siegel, 1997); (3) shared attention, including social referencing and problem-solving (Mundy, Sigman, & Kasari, 1990); (4) emotional reciprocity (Dawson & Galpert, 1990; Baranek, 1999); and (5) functional (pragmatic) language (Wetherby & Prizant, 1993). Neuropsychological models that have been proposed to account for the clinical features of autism further elaborate these autism-specific developmental deficits (Baron-Cohen, Leslie, & Frith, 1985; Sperry, 1985; Baron-Cohen, 1989; Frith, 1989; Bowler, 1992; Klin, Volkmar, & Sparrow, 1992; Dahlgren & Trillingsgaard, 1996; Pennington & Ozonoff, 1996; Ozonoff, 1997; Dawson et al., 1998; Greenspan, 2001). However, do deficits in these abilities actually occur downstream from other primary deficits?

Clinical work and current research (Greenspan, 2001; Greenspan & Shanker, 2004; Greenspan & Shanker, 2007; Wieder & Greenspan, 2003) suggest that the deficits described above stem from an earlier capacity that is compromised in children with ASDs. This earlier capacity is an infant's ability to interconnect emotions or intent, motor planning and sequencing, and sensations. It evolves into early forms of symbolic expression of their intent or emotions, such as pretending to have a tea party or act mad, which later lead to more elaborate use of symbols to create ideas (Greenspan, 1979, 1989; Greenspan, 1997b). It is hypothesized that the biological differences associated with ASDs may express themselves through the derailing of this connection, leading to both the primary and secondary features of ASDs.

The Sensory-Affect-Motor Connections

In healthy development, an infant connects the sensory system to the motor system through affect (e.g., turning to look at a caregiver's smiling face and wooing voice rather than scowling face and harsh voice). With caregivers' creating states of heightened pleasurable and other affects tailored to the child's unique motor and sensory-processing profile, the child can develop and strengthen the connection between sensation, affect, and motor action (e.g., simultaneously looking, listening, and moving while engaging in meaningful problem-solving interactions). This leads to more purposeful affective behavior, which, in turn, leads to reciprocal signaling, a sense of self, symbolic functioning, and higher-level thinking skills.

As the infant negotiates the first four Functional Emotional Developmental levels (see Table 60-1; shared attention and regulation, engagement, two-way communication, and shared social problem solving), she engages in progressively more complex patterns of affective signaling with caregivers (Greenspan & Shanker, 2004). These long chains of coregulated affective gesturing enable the child to recognize various patterns involved in satisfying her emotional needs. She learns, for example, how to solicit a caregiver's assistance to obtain some out-of-reach desired object. This solicitation becomes finely tuned, back-and-forth interactions requiring joint attention (through vocalizations and facial expressions) in a coregulated solution. She learns what different gestures or facial expressions signify—the connection between certain kinds of facial expressions, tones of voice, or behavior and an

individual's mood or intentions. Recognizing when her dad is grumpy, she waits to ask for what she wants. This ability to read the patterns of others and, through recognition of one's own patterns, form a sense of self, is the basis for what is called *intention reading* or *theory of mind*.

This ability to read patterns is also essential if a child is to have and act on expectations—to know when to expect different kinds of responses from his caregiver or to know what love, anger, respect, and shame feel like. It is equally essential if the toddler is to know how to grasp the intentions of others. Pattern recognition, intention reading, and joint attention emerge from and require mastery of the first three Functional Emotional Developmental levels, as shown in Table 60-1 (Greenspan & Shanker, 2007).

Understanding the complexity of this process has led to the early identification of challenges and to the formulation of interventions that are tailored to the child's biological profile and vulnerabilities. This early intervention increases the likelihood that the child will achieve some relative mastery of these critical early affective transformations and of the subsequent abilities for joint attention, theory of mind, and higher levels of language and symbolic thinking. When affect is brought into the treatment of sensory motor processing challenges in language comprehension and visual-spatial knowledge, affective transformations convert labels into meanings. Thus begins the process of comprehending symbolic imagery as well as communicating thoughts and feelings, promoting more complex and abstract reasoning, shades of gray and multicausal thinking, as well as reflective capacities of self and others (Greenspan & Wieder, 1998).

Theory into Practice: DIR Assessment and Intervention Model

The theory outlined above was assessed on a representative population of more than 1,500 children whose parents were administered the Greenspan Social-Emotional Growth Chart (Greenspan, 2004). The results of this assessment suggests that mastery of the early stages of functional emotional development is necessary for children's social referencing and joint-attention capacities (such as reciprocal, shared social problem solving) and for progression to the subsequent stages of symbol formation, pragmatic language, and higher-level thinking (including theory-of-mind capacities such as empathy) (Bayley, 2005). This data set, supportive of the DIR Model, opens the door to further research on the central nervous system and compromises in these early emotional interactions.

Many of the core elements in the DIR Model have a long tradition in early interventions, having been used in speech and language therapy, occupational therapy, visual-spatial cognitive therapy, special and early childhood education, and playful interactions with parents (which is consistent with the developmentally appropriate practice guidelines of the National Association for the Education of Young Children [NAEYC]; Bredekamp & Copple, 1997). The DIR Model contributes to these traditional practices by further defining the child's developmental level, individual processing differences, and the need for certain types of affective interactions in terms of a comprehensive program where all the elements can work together toward common goals.

In this model, the therapeutic program should begin as early as possible so that the children can re-engage in emotional interactions that use their emerging, but not fully developing, capacities for communication (often initially with gestures rather than words). Recent improvement in early identification now makes it possible to screen and identify challenges for a child at risk for ASDs who is less than 1 year old. However, the DIR Model can be applied to any age, as it is a developmental framework useful across the lifespan.

The Functional Developmental Profile

Implementation of an appropriate assessment of all the relevant functional areas requires a number of sessions with the child and family. These sessions must begin with discussions with the caregivers and observations. The assessment process, which is described in detail elsewhere (Greenspan, 1992; Greenspan & Wieder, 1998), includes: *(1)* two or more 45-minute clinical observations of child–caregiver and/or clinician–child interactions; *(2)* developmental history and review of current functioning; *(3)* review of family and caregiver functioning; *(4)* review of standard diagnostic assessments, current programs, and patterns of interaction; *(5)* consultation with speech pathologists, occupational and physical therapists, educators, and mental health colleagues, including the use of structured tests on an as-needed, rather than routine, basis; and *(6)* biomedical evaluation (*see* Figure 60-1).

The assessment then leads to an individualized functional profile that captures each child's unique developmental features outlined above in the description of DIR and creates individually tailored intervention programs (i.e., tailoring the program to the child rather than fitting the child to a general program). The profile describes each of the child's functional developmental capacities and contributing biological processing differences and environmental interactive patterns, including the different interaction patterns available to the child at home, at school, with peers, and in other settings.

The DIR Intervention Program

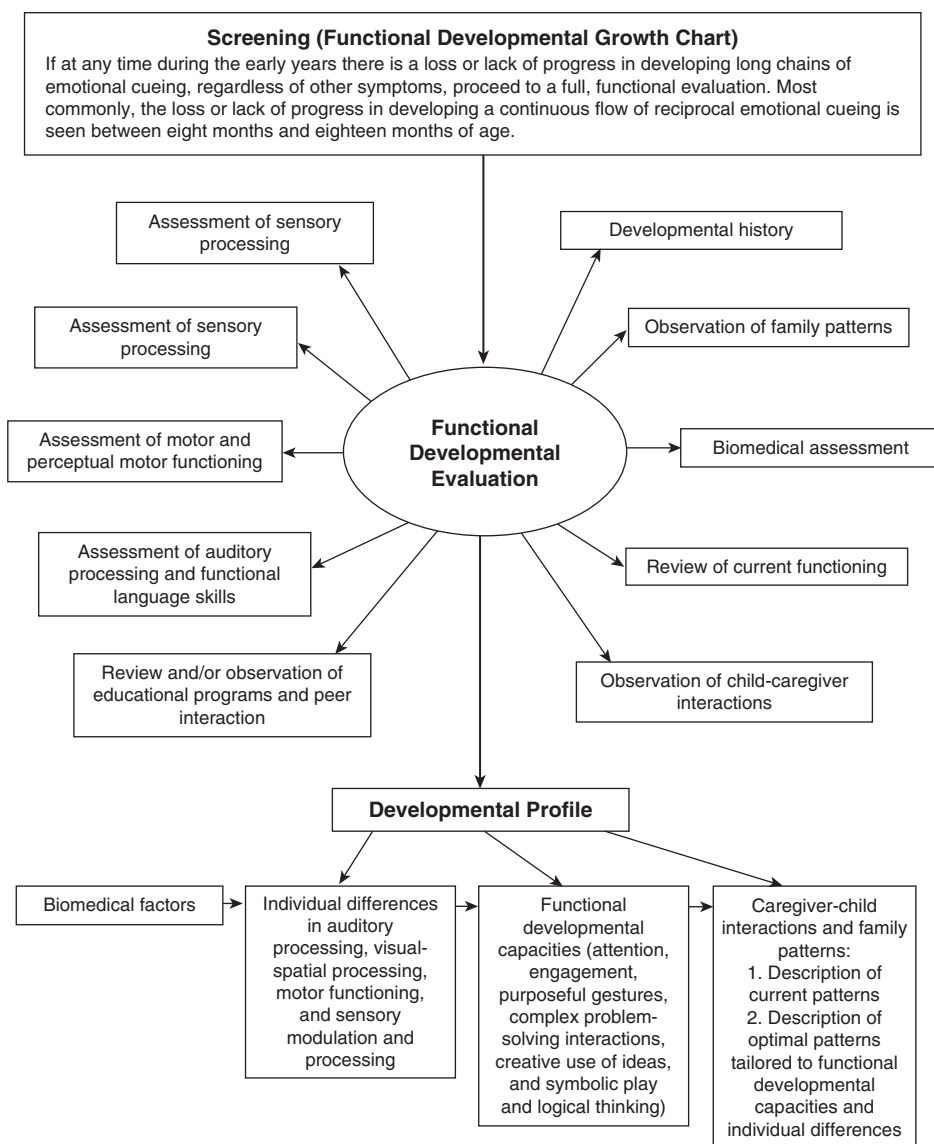
The DIR Model enables the formation of a comprehensive intervention program for infants, toddlers, and preschoolers with ASDs and other developmental challenges. The program helps them to re-establish the developmental sequence that went awry (with a special focus on helping them become affectively connected and intentional). The program is built on *(1)* determining which of the functional emotional levels described earlier have been mastered fully, partially, or not at all; *(2)* understanding children's individual differences in sensory modulation, processing, and motor planning; and


Figure 60–1. Outline of the DIR approach to assessment and evaluation.

(3) establishing a relationship that creates interactive, affective opportunities to negotiate the partially mastered or unmastered functional emotional developmental process. Rather than focus only on isolated behaviors or skills, the DIR-based approach focuses on the more essential functional emotional developmental processes and differences that underlie particular symptoms or behaviors. The goal is to pinpoint what is compromised and construct the developmental foundations for healthy emotional, social, intellectual functioning.

The DIR-based intervention is fundamentally different from behavioral, skill-building, play therapy, or psychotherapy. The primary goal of this intervention is to enable children to form a sense of themselves as intentional, interactive individuals; to develop cognitive, language, and social capacities from this

basic sense of intentionality; and to progress through the six Functional Emotional Developmental capacities.

The DIR-based Intervention Model can be conceptualized as a pyramid, with each of the components of the pyramid building on one another (*see* Figure 60-2).

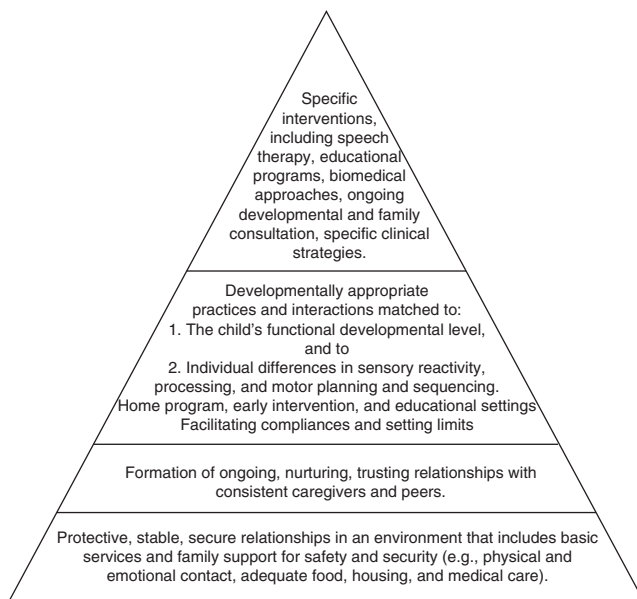
As shown in Figure 60-2, elements of a comprehensive program include home-based and educational elements, clinic-based therapies for both child and caregivers, as well as nutritional and biomedical components. Most children require most, if not all, of the following components for a comprehensive program as each addresses a major area requiring further development, and each component provides the countless opportunities for successful spontaneous and semi-structured interactions that have been derailed.


Figure 60–2. DIR-based intervention pyramid for children with ASD.

1. Home-based, developmentally appropriate interactions and practices:
   - Spontaneous interactions (Floortime) that follow the child's lead to focus on joint attention and engagement. The interactions eventually become a continuous flow and then advance to problem solving. The subsequent progression into creative pretend play supports mastering the full range of emotional and cognitive abilities and prepares the child for higher levels of abstract thinking. As the child gets older, Floortime becomes more reality-based conversations and reflective talk-time (20- to 30-minute sessions, eight or more times a day; as children improve, they can usually engage in longer sessions).
   - Semi-structured, affect-based problem solving, such as dealing with real-life situations where the child encounters problems throughout relevant daily experiences where he or she must interact with the parent to solve (e.g., finding his favorite crackers that are in a plastic bag, finding the tub empty when asked if ready for a bath, searching for daddy who is calling from somewhere in the house, negotiating with a sibling for a toy, or working on tasks together to support reasoning, planning and sequencing, etc.). These incidental learning opportunities require back-and-forth, problem-solving discussions or nonverbal interactions that promote logical reasoning when relevant to the child's experience or desire. If it is a problem for the child, it is affect-based. When relevant and meaningful to the child, these opportunities lead to interactions that support interconnectivity between different areas of the brain and the sequences necessary for execution.

   - Visual-spatial, motor, and sensory activities prescribed by OT, PT and visual-spatial cognitive therapists (VCTs) for 15 to 30 minutes or more, four times a day. These semi-structured activities or games may include running and changing direction, jumping, spinning, swinging, deep tactile pressure, perceptual motor challenges, including looking-and-doing games, visual-spatial movement, discrimination, visual thinking and logic games, including treasure hunts and obstacle courses. For some children, the above activities can become integrated with the pretend play of Floortime.
   - Play dates with older or younger peers who are natural play partners and will pursue and interact with the child or respond to the adult's coaching and mediation. The number of play dates a week should match the age of the child (i.e., a 3-year-old should have three play dates a week). Later, these can expand to small groups and semi-structured activities with other children in clubs and music, art, drama, and sports activities.

2. Clinic-Based Therapies
   - Speech therapy—developmentally based models or semi-structured models when indicated (e.g., the Developmental Social-Pragmatic Model [DSPM] [Gerber, 2003], the Affect-Based Language Curriculum [ABLC] [Greenspan & Lewis, 2002] and the Social Communication, Emotional Regulation and Transactional Support [SCERTS] [Prizant et al., 2003]).
   - Sensory integration and sensory motor-based occupational therapy and/or physical therapy.
   - Family consultation and counseling to help parents design and implement their comprehensive programs, support family functioning, and provide advocacy where needed.

3. Educational program, daily, with parent collaboration
   - For children who can interact and imitate gestures and/or words and engage in preverbal problem solving, the program can be either an integrated inclusion program or a regular preschool program with an aide.
   - For children not yet able to engage in preverbal problem solving or imitation, a special education program where the major focus is on engagement, preverbal purposeful gestural interaction, preverbal problem solving (a continuous flow of back-and-forth communication), and movement is needed.
   - As children prepare for academic learning, some may require individualized instruction or tutoring in reading, mathematics, visual thinking, as well specific learning techniques—for example, the Lindamood-Bell Learning Process (www.lindamoodbell.com) and visual-spatial exercises from *Thinking Goes to School: Piaget's Theory in Practice* (Furth & Wachs, 1975). The other considerations involve smaller class size and

facilitative environments that do not overwhelm the child.

4. Consideration of nutrition and diet, biomedical interventions, and, when indicated, medications that address regulation and anxiety, possible seizures, and enhance motor planning and sequencing, concentration, and learning.

5. Augmentative technologies geared to improve communication, auditory and visual-spatial processing, sensory modulation, and motor planning.

DIR-based intervention is a dynamic program, and the frequency or changes in the program depend on their progress, although Floortime, and later reflective Talktime, remain constant. In some cases, therapies and other program components can be modified if a strong home program guided by the therapists is implemented. In addition, specific techniques or tools may be indicated, such as augmentative communication, assistive technology, and activities to support imitative and ritualized learning such a social games, drama, sports, etc. As the child progresses, various activities will become part of a child's social activities, such as clubs, sports, music, and drama. During the early years, a comprehensive program of intensive intervention is very important but then can transition into more typical activities as the child progresses.

Floortime

Floortime is the most important element of this comprehensive program. Floortime refers to unstructured "play" sessions, where the child is in the lead and initiates the ideas and the adult both follows and gently challenges the child to support spontaneous, purposeful, and flowing reciprocal interactions at both pre-symbolic and symbolic levels. In addition to Floortime "play," the Floortime principles of follow the lead, engage, challenge, and expand inform all the child's therapies so that children are maximally interested and engaged in learning interactions.

In Floortime, the caregiver first enters into the child's world by showing interest in the child's activity and then engages with the child. Once the child and caregiver have established a rhythm—a back-and-forth communication (gesturally and verbally with deference to the child's sensory profile)—the caregiver next, gently and carefully, expands on the child's activity. The expansion occurs when the caregiver creates a challenge within the context of the child's interest.

Floortime Example

A nonverbal and unengaged child was fixated with four crayons—touching, rolling, and lining them up. To become a partner in this activity, Mom sat next to her daughter and, following her lead, touched and rolled the crayons too, carefully and non-intrusively. After being accepted as a partner in the activity, Mom moved to the next phase—challenge and expand. Staying with the crayons because this was the child's interest,

she gently rolled the crayons into a small bag, which she then set on her head. Intrigued, the child reached up and grabbed the bag off Mom's head. A beginning—the child related Mom to the crayons—shared attention. Mom put the bag on her head again, and the child pulled it off a second time. Some back and forth. The third and fourth times, the child smirked a little as she got the bag off Mom's head. Now for a more complex challenge. Mom had to think about how to change the game slightly to expand the interaction without taking over and dampening the child's engagement. Mom hid the bag in her hand and showed the child the backs of both fists. Sure enough, the child opened Mom's hands to discover which one held the crayons. Upon finding them, she beamed with delight.

The principle is to increase the complexity of the child's motor behavior, such as searching in Mom's hand, while maintaining the shared attention. The same holds for increasing the complexity of the sensory input. Mom can add sound—wow's, eee's, woooo's, whatever—as her child searches for the crayons in slightly more difficult places. Then the child combines emotion, shared attention, motor planning and sequencing, visual-spatial thinking, and auditory processing, all which started with the child's fixation with four crayons and a Mom who followed the child's lead, engaged, challenged, and expanded.

Challenges and Principles in the DIR-Based Intervention Model

The critical principle in each aspect of a comprehensive intervention program is to engage the child at his or her level and to help the child master that level and subsequent levels. Often, teams are working at multiple levels at one time. A child, for example, who has partial mastery of using ideas but is not fully engaged or interactive, still needs work at the earlier levels.

As focus and engagement are fostered, attention must be paid to the children's profile of individual processing differences (regulatory profile), as described earlier. For example, if they are over-reactive to sound, talking to them in a loud voice may lead them to become more aimless and withdrawn. If they are over-reactive to sights, bright lights and even very animated facial expressions may be overwhelming for them. On the other hand, if they are under-reactive to sensations of sound and visual-spatial input, talking in a strong voice and using animated facial expressions in a well-lit room may help them attend. Similarly, in terms of their receptive language skills, if they are already at the point where they can decode a complex rhythm, making interesting sounds in complex patterns may be helpful. On the other hand, if they can only decode very simple, two-sequence rhythms, simpler rhythms will be better. One may find that children remain relatively better focused in motion, such as when they are being swung. Certain movement rhythms may be more effective than others.

It is especially difficult to foster a sense of intimacy. As children are encouraged to attend and engage, it is critically important to take advantage of their own natural interests. It is most helpful to follow their lead and look for opportunities

for that visceral sense of pleasure and intimacy that leads them to want to relate to the human world. Intimacy is further supported as children are helped to form simple, and then more complex, gestural communications.

Illustration

A father was continually struggling to get his very withdrawn son to interact with him. When the father tried to draw him out by asking questions, the child ignored him. In a therapy session, the therapist suggested trying simple gestural interactions first.

While his son was exploring a toy car, the father put his finger on it very gently and pointed to a particular part, as though to say, "What's that?" In touching it, the father actually moved the car so the son felt the car moving in his hands and noticed, without upset, his father's involvement. The son pulled the car closer to him and looked at where the father had put his finger.

This more physical, gestural communication sparked at least a faint circle of communication: opening—the father's building on the son's interest in the car by touching a spot; closing—the son's looking at that particular spot and pulling the car towards him.

This circle created a foundation for more complex communication. After this minimal interaction, the son began to move his car back and forth. The father got another one and started first moving it back and forth next to his son's and then toward his son's car but not crashing into it. The son initially pulled his car away but then engaged by moving it faster toward his father's. A few circles were closed in a row, and real interaction was beginning.

As their gestural interaction became complex—the father hiding his son's car and his son pointing, vocalizing, and searching for it—it fostered expanding from gestures to symbols. During this gesturing, the father started to describe his own action by saying, "fast" and "slow." After he repeated these words several times, the boy zoomed his car past his father's and uttered a close approximation to "fast." The father beamed, amazed that his son could learn a new word and use it appropriately so quickly.

A major challenge is children's tendency to perseverate. One child would only repeatedly open and close a door. Another would only bang blocks together. The key is to transform the perseveration into an interaction. Caregivers can use children's intense motivation to their advantage to get gestural circles of communication opened and closed. For example, they can get stuck in a door or have their hands caught between some blocks. They can be gentle and playful as the child tries to get them out of the way (like a cat-and-mouse game). As gestural interactions occur, behavior becomes purposeful and affective. When doing "playful obstructions," "fencing in," or "playing dumb," they can modulate child's feelings of annoyance and can help soothe and comfort as well use affect cues and joint problem solving to "help," although often children find "playful obstruction" amusing.

As children become more purposeful and guided by their own initiation and intent, they can imitate gestures and sounds more readily and start simple but emotionally meaningful symbolic actions such as feeding a doll or kissing a bear. With continuing challenges to be intentional, they copy complex patterns and imitate sounds and words, often gradually beginning to use words and "pretend" on their own.

As one moves toward more representational or symbolic elaboration, it can be challenging to help children differentiate their experiences. They need to learn cause-and-effect communication at the level of ideas and to make connections between various representations or ideas. Caregivers become the representation for reality and the ability of clinicians or parents to enter the symbolic world of children and become "players" becomes the critical vehicle for fostering emotional differentiation and higher levels of abstract and logical thinking.

Relating to children when they are feeling strong affects is critical. They are connecting words to underlying affects that give them purpose and meaning. When children are motivated—for example, in trying to negotiate to get a certain kind of food or to go outside—there is often an opportunity to open and close many symbolic circles. The child who tries to open the door to go outside and is angry that he cannot may, in the midst of feeling annoyed, open and close 20 circles of communication if the adult soothingly tries to find out what he wants to do outside.

Children with ASDs find it especially difficult to shift from concrete to abstract modes of thinking because they do not easily generalize from a specific experience to other similar experiences. There is a temptation to teach them answers and repeat the same question by scripting the dialogue or providing scaffolding so they might guess and fill in the blank. However, they can only learn to abstract and generalize through active, emotionally meaningful experiences that help them connect affects or desires to reasoning and actions. Long conversations with debates are most helpful as it helps the child express his or her own opinions and the reasons for them (e.g., "I like juice because it tastes good") rather than memorized elaborations of rote facts (e.g., "The juice is orange") (Greenspan & Wieder, 1997).

As children develop, becoming symbolic and abstract is most often derailed by anxiety, which occurs secondary to poor language and visual-spatial processing. The child who may already have words to express what he wants and even why may not adequately understand what someone else is saying and may become anxious about feelings and ideas outside his comfort zone. Sometimes the child tries to respond, but his comments become tangential, associative, or off topic and the conversation becomes fragmented. Poor visual-spatial knowledge also derails the child's making sense of what he sees and knowing where he is in space. Without these abilities, he cannot respond purposefully to situations at hand. When both language and visual-spatial weaknesses interact, the child may appear distracted, inattentive, and/or illogical. Children who get stuck at concrete levels of language and thought derive security from what they see. Dependent on visual anchors

and rituals, they have difficulty developing flexibility and logical abstracting abilities.

Summary

In summary, as the child progresses through the Functional Emotional Developmental levels of regulation and joint attention, engagement, two-way communication, shared social problem solving, creating ideas, and logical thinking (*see* Table 60-1), the therapeutic program works on mobilizing all levels at the same time in each and every interaction. The therapeutic program often evolves to a point where the child and family are involved in three types of activities: *(1)* spontaneous, creative interactions (Floortime); *(2)* semi-structured, problem-solving interactions to learn new skills, concepts, and master academic work (e.g., creating problems to solve, like negotiating for cookies or mastering spatial concepts, such as "behind" and "next to," by discovering where the favorite toy is located); and *(3)* motor, sensory, language, and visual-spatial play to strengthen fundamental processing skills. It is important to note that the DIR Model and intervention program apply as children get older when the different dimensions of development continue to be uneven and/or when the focus needs to shift to emotional development, learning challenges, and anxiety and mood regulation. The DIR Model can guide the intervention of each child and family and his or her unique profile as development unfolds across the lifespan.

Selected Research and Outcome Studies on the DIR-Floortime Model

In the following section, we briefly review selected studies relevant to the DIR approach. Built on years of research in developmental psychology (Greenspan & Wieder, 1998; Greenspan & Shanker, 2004) that underscores the importance of early relationships and family functioning (Greenspan, 1992), the DIR Model also integrates research contributions from various disciplines, such as speech and language pathology (Tannock, Girolametto, & Siegal, 1992; Wetherby & Prizant, 1995; Gerber & Prizant, 2000), occupational therapy (Ayres, 1979; Williamson & Anzalone, 1997; Case-Smith & Miller, 1999), and social work (Shahmoon-Shanok, 2000). Neuroscience research lends further support to developmental interventions (Mundy, Sigman, & Kasari, 1990; Minshew & Goldstein, 2000).

Centers for Disease Control and Prevention

A survey conducted by the National Center for Health Statistics of the Centers for Disease Control and Prevention of over 15,000 families nationwide included emotional variables from the DIR Functional Emotional Developmental Levels. This survey identified 30% more infants and children at risk (most of whom were not receiving services) than prior health surveys (Simpson, Colpe, & Greenspan, 2003).

National Research Council

Importantly, the National Research Council of the National Academy of Sciences, in their 2001 landmark report, *Educating Children with Autism* (Committee on Educational Interventions for Children with Autism, 2001), called for tailoring the treatment approach to unique features of the individual child and recommended to give priority to interventions that promote functional, spontaneous communication.

200 Case Chart Reviews

The first study to show initial evidence for the DIR Model was published in 1997 (Greenspan & Wieder, 1997). Greenspan and Wieder reviewed charts of 200 children who were diagnosed with ASDs and who were part of a cohort of children seen by the authors over a period of 8 years. All children met the criteria of autism or pervasive developmental disorder not otherwise specified (PDD-NOS) as described in DSM-III-R and DSM-IV, and scored in the autism range on the Childhood Autism Rating Scale (Western Psychology Services, 1988). All 200 cases received a comprehensive relationship and developmentally based intervention program for at least 2 years, under the supervision of Dr. Stanley Greenspan and/or Dr. Serena Wieder. The children ranged in age from 22 months to 4 years, with the majority between 2.5 and 3.5 at the initial evaluation. The goal of the review was to reveal patterns in presenting symptoms, underlying processing difficulties, early development, and response to intervention to generate hypotheses for future studies.

The study identified sensory processing and modulation difficulties in all the children, and the authors hypothesized that different underlying processing patterns seemed to include a difficulty in connecting affect and sequencing capacities and could be a possible common denominator, suggesting that difficulties with relating and intimacy are often secondary to underlying processing disturbances. (*See* Table 60-2.) They also suggested that the difficulty in engaging in complex purposeful gestural communication could be an early marker and that contrary to traditional beliefs, a significant number of children may have relatively better functioning in the first year with a regression in the second and third years when these more complex skills are required for social interaction.

According to the authors, the chart review suggested that a number of children with ASDs are, with an appropriate intervention program, capable of empathy, affective reciprocity, creative thinking, and healthy peer relationships. The authors also concluded that focusing on individual differences,

Table 60–2.
Presenting conditions of 200 cases of children with autistic spectrum disorders

Functional Developmental Component	Patients with Mild-to-Severe Impairment	Description of Functional Developmental Component
Presenting functional, emotional, developmental level	24%	Partially engaged and purposeful with limited use of symbols (ideas)
	40%	Partially engaged with limited complex problem-solving interactive sequences (half of this group evidenced only simple purposeful behavior)
	31%	Partially engaged with only fleeting purposeful behavior
	5%	No affective engagement
Sensory modulation	19%	Over-reactive to sensation
	39%	Under-reactive to sensation (with 11% craving sensation)
	36%	Mixed reactivity to sensation
	6%	Not classified
Motor planning dysfunction	52%	Mild-to-moderate motor planning dysfunction
	48%	Severe motor planning dysfunction
Low muscle tone	17%	Motor planning dysfunction with significant degree of low muscle tone
Visual-spatial processing dysfunction	22%	Relative strength (e.g., can find toys, good sense of direction)
	36%	Moderate impairment
	42%	Moderate-to-severe impairment
Auditory processing and language	45%	Mild-to-moderate impairment with intermittent abilities to imitate sounds and words or use selected words
	55%	Moderate-to-severe impairment with no ability to imitate or use words

developmental level, and affective interaction could be especially promising.

Greenspan and Wieder described that after 2 years of intervention, 58% of treated children no longer met the criteria for ASDs. They became warm and interactive, relating joyfully with appropriate, reciprocal preverbal gestures; could engage in lengthy, well-organized, and purposeful social problem-solving and share attention on various social, cognitive, or motor-based tasks; used symbols and words creatively and logically, based on their intent and desires, rather than using rote sequences; and progressed to higher levels of thinking, including making inferences and experiencing empathy. Some children in this group developed precocious academic abilities two or three grade levels above their ages. They all mastered basic capacities such as reality testing, impulse control, organization of thoughts and emotions, differentiated sense of self, and ability to experience a range of emotions, thoughts, and concerns. Finally, they no longer showed symptoms such as self-absorption, avoidance, self-stimulation, or perseveration. On the Childhood Autism Rating Scale (CARS), they shifted into the non-autistic range, although some still evidenced auditory or visual-spatial difficulties (which were improving), and most had some degree of fine or gross motor planning challenges.

Furthermore, children who made progress tended to improve in a certain sequence. First, within several months,

they began showing more emotion and pleasure in relating to others. Contrary to the stereotypes of autism, they seemed eager for emotional contact. The problem was that they had trouble figuring out how to achieve it. They seemed grateful when their parents helped them express their desire for interaction. After parents learned to draw them out by various Floortime approaches, even children who had been very avoidant and self-absorbed began seeking out their parents for relatedness.

In 2005, Greenspan and Wieder published a 10- to 15-year follow-up study (since the start of treatment) of 16 children diagnosed with ASDs that were part of the first 200 case series and were part of the 58% of children who showed great improvements (Greenspan & Wieder, 2005). The children were all boys and ranged in age between 12 and 17 years, with a mean of 13.9 years. All these children had received a comprehensive relationship and developmentally based intervention program, including Floortime at home and DIR consultation, for at least 2 years (maximum 5), between ages 2 and 8.5 years. The authors described that after 10 to 15 years since receiving the intervention, these children became empathetic, creative, and reflective adolescents, with healthy peer relationships and solid academic skills. Based on these findings, the authors suggested that some children with ASDs can master the core deficits and reach levels of development formerly thought unattainable.

Social-Emotional Growth Chart

The DIR Model also served as the theoretical framework to develop the Greenspan Social-Emotional Growth Chart (SEGC) (Greenspan, 2004). This norm-referenced surveillance and screening of key social-emotional milestones in infants and children from birth to age 42 months is now part of the new Bayley Scales Kit of Infant and Early Childhood Development. Published by PsychCorp, the SEGC was field-tested on a representative sample of 1,500 infants and young children, and it is now offered as a surveillance and screening instrument for ASDs, with a sensitivity of 87% and specificity of 90%.

The P.L.A.Y. Project

In 2007, Dr. Richard Solomon and colleagues published an evaluation of The PLAY Project Home Consultation (PPHC), a widely disseminated program that trains parents of children with ASDs in the DIR Model (Solomon et al., 2007). Sixty-eight children from age 2 to 6 years (average 3.7 years) completed an 8- to 12-month program where parents were encouraged to deliver 15 hours per week of 1:1 interaction. Pre/post ratings of videotapes by blind raters using the Functional Emotional Assessment Scale (FEAS) showed significant increases ($p \le 0.0001$) in child subscale scores. That is, 45.5% of children made good to very good functional developmental progress. Overall parents' satisfaction with PPHC was 90%. Average cost of intervention was $2,500/year. Despite some limitations, the pilot study of The PLAY Project Home suggests that the model has potential to both enhance developmental progress of young children with autism and to be a cost-effective intervention. The PLAY model has evolved from a small, university-based, clinical program into a low-cost train-the-trainer model that has the capacity to be disseminated nationally. [1]Dr. Solomon is now conducting an NIMH-funded randomized, controlled, community-based clinical trial of the PLAY Project (Phase II SBIR grant), including 3-to 5-year-old children with ASD.

Related Research

A recent article published by Zwaigenbaum and colleagues highlights the challenges related to early detection, diagnosis, and treatment of ASDs in very young children (Zwaigenbaum, et al., 2009). The authors outline the principles of effective intervention for infants and toddlers with suspected or confirmed diagnosis of ASDs, including responsive and sensitive caretaking, enriched language environments using responsive rather than directive interaction styles, environments that provide opportunities for toddlers to take initiative in their learning, and interventions that are individualized and targeted to specific skills. Furthermore, the authors underscore that existing programs for older children "cannot simply be extrapolated" to younger children.

In addition, other developmental relationship-based approaches have shown to have positive effects, including the work of Gerald Mahoney, Ph.D., and Frida Perales, M.Ed.

(Mahoney & Perales, 2005), and Sally Rogers (The University of Colorado model) (Rogers & DiLalla, 1991; Rogers et al., 2000).

In 2010, Dawson, Rogers, and colleagues reported the results of a randomized controlled trial of a comprehensive developmental behavioral intervention for improving outcomes of toddlers (18–30 months) with ASDs using the Early Start Denver Model in a 2-year program (Dawson et al., 2010). They found significant improvement in IQ, adaptive behavior, and change in the autism diagnosis. Their cohort maintained growth in adaptive behavior compared with a normative sample reflecting the benefits of early intervention. Adaptive behaviors are most reflective of the benefits of the developmentally based interventions.

Conclusion

This chapter presents a brief overview of the DIR Model and discusses its implications for assessment, intervention, and understanding the developmental pathways leading to ASDs. It also presents studies that support the DIR Model and other related research findings. A developmental, relationship-based approach can change not only the way we think about developmental disabilities, including ASDs, but what is included in the research base to improve assessment and interventions. At this time the field is expanding, beginning to go beyond reporting outcomes according to IQ scores and educational placement. But it still needs research standards for studying developmental models that are defined by the relevant areas of developmental functioning as described here and the primary goals for each child and family.

Future Directions

- Research that captures the complexity of developmental disorders and differentiates the interventions and outcomes of children with different profiles.
- Integrated educational models that utilize affect-based developmental curricula to make learning experiences meaningful and build the foundations for higher level emotional and cognitive functioning, including ongoing training of those working in school settings.
- Long-term outcome studies that focus on the critical junctures of development for different subtypes along the autism spectrum and identify the opportunities and ongoing processing interventions that will support continued development.
- Long-term studies of parent and sibling experiences and their relationships with children on the autism spectrum.
- Expansion of social and community relationship models in various childhood settings, which extend into adulthood and identify the variables and interventions which provide continuity.

NOTES

1 The state of Michigan Autism Workgroup, convened by the Dept of Health, includes the PLAY Project among the accepted therapies. The PLAY Project, available in a dozen regions of the state, serves hundreds of children in Michigan and is supported by such well-respected agencies as Easter Seals and Mott Children's Health Center in Flint. Furthermore, Easter Seals Crossroads has contracted with P.L.A.Y. Project and is beginning to implement this intervention into all of its charter locations.

Intervention for Infants and Toddlers with Autism Spectrum Disorders

Points of Interest

- Current knowledge about infant–toddler treatments and their efficacy, both in ASDs and in other clinical groups.
- Characteristics of children in this age group that might respond most favorably to such treatment.
- Characteristics of treatments for this age group that have the greatest empirical support.

One of the most exciting areas of current autism science involves the search for infant behavioral markers of incipient autism. Prospective studies of high-risk infants have now identified several behavioral risk markers for autism spectrum disorders (ASDs) risk as early as age 12 months (Nadig et al., 2007; Ozonoff et al., 2008a; Zwaigenbaum et al., 2005). The most recently funded studies are homing in on the 6- to 9-month period, with optimism that predictive markers of risk will be identified before developmental delays and aberrant behavior patterns of social and communicative development take hold.

However, the primary purpose of early detection of ASDs is to prevent or mitigate the full onset of autism and its associated severe disabilities in multiple domains. Early detection science requires that early treatment science develop in parallel, so that tested treatments are ready for infants identified by early detection. As our ability to identify infants and toddlers with suspected or confirmed ASDs improves, the need for research on the efficacy of very early intervention or prevention approaches for autism becomes critical (Rogers, 2009). Although a variety of evidence-based interventions exist for preschoolers with autism (see Rogers & Vismara, 2008 for a recent review), it is not at all clear that such interventions would be equally beneficial, or even appropriate, for children under age 2 years. There is currently very little empirical research on efficacious treatments for children with autism who are 24 months and younger, although a number of intervention approaches for children in the 12- to 24-month range are currently being investigated.

Current Interventions in Autism Spectrum Disorders

Efficacious interventions have been identified for children with autism in the 2- to 5-year age range. In fact, well-structured, long-term interventions delivered in early childhood appear to be the most effective interventions that currently exist for decreasing the level of disability associated with ASDs (Lovaas, 1987; McEachin et al., 1993; see review in Rogers & Vismara, 2008). Current delivery of early intervention for ASDs tends to follow one of three main approaches. One involves the application of principles of applied behavior analysis (ABA) delivered 1:1 to increase target skills and decrease problem behaviors. ABA-based interventions may be delivered in a mass trial, didactic style of teaching, most often based on Discrete Trial Teaching (Lovaas, 2002), or they may be delivered in a more interactive, child-centered style focused especially on communication and behavior interventions, as typified by the work on Pivotal Response Training (PRT) (Koegel et al., 1999) and incidental teaching (McGee et al., 1999; Sundberg & Michael, 2001).

The second main approach—the developmental approach—applies the principles of developmental science and follows the sequences of typical child development. Developmentally based approaches focus great attention on communicative, cognitive, and social development and deliver interventions in a child-centered, interactive style that emphasizes the quality of the adult–child relationship and adult sensitivity and responsivity to children's cues. Developmental approaches have been tested and found to be beneficial in short-term controlled designs (Aldred et al., 2004; Drew et al., 2002; Mahoney & Perales, 2003, 2005). The most widely

known interventions associated with a developmental approach include Social Communication, Emotional Regulation and Transactional Support (SCERTS; Prizant et al., 2006); Floortime (Greenspan et al., 1997); Relationship Development Intervention (RDI) (Gutstein, 2005); Early Start Denver Model (Rogers & Dawson, 2009); and Hanen (McConachie et al., 2005), although the empirical support for these approaches is limited at this time. Some approaches combine a developmental approach with teaching strategies that are based on ABA. These include Milieu Therapy (Warren et al., 2006; Yoder & Stone, 2006) and the Early Start Denver Model (Smith et al., 2006); both combine a developmental curriculum with play-based interactive teaching approaches that integrate teaching methods from ABA.

The third widely used approach is Treatment and Education of Autistic and Related Communication-handicapped Children (TEACCH; Schopler et al., 1995), and its principles of structured teaching are widely used in specialized preschool classrooms for children with ASDs, in the United States and in many other countries as well. The TEACCH approach follows a developmental curriculum that particularly emphasizes cognitive and adaptive development. What sets TEACCH apart is its emphasis on delivery in a very structured group environment, with visual and other environmental accommodations based on a neuropsychological model of autism that emphasizes difficulties with auditory processing and communication development, working memory, top-down control of attention, and altered sensory perception. The TEAACH approach differs from the above approaches with its emphasis on adapting the environment by providing external support to promote focused attention to learning tasks, development of independent work habits, and use of a variety of visual systems to organize one's activities and one's time.

Although there is some empirical evidence supporting all three of these approaches, the most well studied approach (*see* Rogers & Vismara, 2008, for a review of the evidence and the standards) is the Discrete Trial Teaching method described by Lovaas (1987). Several controlled trials by different investigators have demonstrated that groups of preschool-aged children receiving at least 20 hours a week of Lovaas's intervention, delivered 1:1 by highly trained and carefully supervised staff for a year or longer, make significantly greater gains in IQ—and sometimes in other areas as well—than do comparison groups of children. The evidence from that approach, however, involves children who are mostly ages 2 years to 4 years. There is no published evidence of this approach when used with children below age 2 years, other than one case study (Green et al., 2002).

To summarize, current practices in early intervention for preschoolers with ASDs include *(1)* traditional intensive behavioral intervention based on Discrete Trial Teaching; *(2)* developmental approaches that can also incorporate ABA teaching strategies but emphasize developmental science and the adult–child relationship; and *(3)* the TEACCH model involving structured teaching to maximize independent learning within a group context. Research has not yet addressed whether optimal outcomes are tied to a specific intervention type or to a specific number of hours of intervention. However, there is evidence that pretreatment child characteristics are the best predictors of outcome—particularly the child's level of language, IQ, social engagement, and degree of stereotypies (Sallows & Graupner, 2005; Sherer & Schreibman, 2005). The common elements across the various approaches with the best evidence suggest that the critical elements of treatments related to better outcomes include: the earliest possible start of intervention; delivery of interventions for 25 hours or more per week using 1:1 ratios; use of teaching strategies based on ABA; emphasis on language development, social development, play, imitation, and joint attention; and family involvement (National Research Council, 2001). To date, there have been no comparative effectiveness studies of early intervention in autism—a great need in the autism early intervention field.

Differences Between Preschool and Infant Learning

To what extent can the existing approaches for preschoolers with autism be directly applied to infants and toddlers under age 2 years? Although there is a strong temptation to take existing treatments and simply apply them to younger and younger children, there are compelling reasons for resisting. Research on child development has taught us that infants are qualitatively different learners than preschoolers in a number of ways (Kagan, 2008). Socially, the preschool period is a time to learn to interact with peers, to develop parallel and interactive play skills, to use language as a tool for social interaction, and to learn to participate in small groups of children. Preschoolers relate to parents as both play partners and as authority figures, and they are learning to respond to directions and interactions from unfamiliar adults. Preschoolers can play together without adult interaction for significant periods of time.

In contrast, infancy and toddlerhood is a period in which infants are developing secure attachments to consistent caregivers through dyadic exchanges (Belsky & Fearon, 2002; Bowlby, 1969; Sroufe et al., 1999). Communication between the partners is carried out largely via affective cues and nonverbal gestures (Bruner, 1977), and much of the baby's early communication is nonintentional and depends on adults' sensitive interpretation and responses for success. Infants ages 9 to 12 months and older are typically wary and avoidant of unfamiliar adults and interact freely only with familiar, responsive caregivers. Infants are in dyadic interaction with a caregiving adult through most of their waking hours, and a great deal of this interaction involves caretaking experiences —holding, feeding, changing, bathing, carrying, playing. Furthermore, this type of interaction occurs during a period of rapid brain development, and this kind of social engagement plays a key role in facilitating cortical specialization and

the development of perception and representational systems for social and language development (Dawson, 2008). Significant deprivation of this type of interaction during the infant period has severe long-term effects on child development, as seen in a long line of studies on the effects of institutional care on infants, the latest of which involves infants from Romanian orphanages (Rutter, 1999).

Preschoolers have developed the capacity to understand that objects and actions can be used to represent other objects. They readily grasp that photos represent known people and things, that actions in play can represent other events, and that words represent things, people, feelings, thoughts, actions, and events. They have a sophisticated ability to learn by watching others via observational learning skills, even without opportunities to practice. They are acquiring the conventional symbol systems of their culture, and they use these symbols to establish shared reference to topics of conversation, play, and learning. Thus, although object manipulation is important for preschoolers' learning, objects are tied to symbols, and preschoolers move fluidly between objects and representations, as seen in their pretend play, interactions with books, conversations, and efforts to draw representationally.

Infants' relations with objects are quite different than preschoolers'. Infants learn through visual and motor experiences involving direct, hands-on experiences with objects. They do not easily grasp the relationship between actual objects and their visual representations through photos, drawing, and so forth (Zack et al., 2009). Although there is evidence of some mental representation in infancy, as seen in deferred imitation and memory (Meltzoff, 1988), infants do not use representational systems in their play or communication until later in the second year of life. They are instead constructing prototypes of actual objects, people, and events from their day-to-day experiences. Although infants appear capable of a few imitative acts early on (Meltzoff & Moore, 1977), they do not appear to learn new behaviors readily through observation of others until the second year of life, and even then, imitative learning occurs most easily for meaningful actions on objects, gestures, and words that are embedded in ongoing social activities and intentionally modeled by a social partner.

Interestingly, even repetitive behaviors occur differently in these two age periods. Repetitive motor behaviors are commonly seen in infants, and they are considered to have important roles in motor development and cognitive development (Piaget, 1966; Thelen, 1979, 1996). Among other things, repetitive motor behaviors provide the infant with experiences involving the effects of their acts on the environment, and they appear to involve a practice period for movement aspects of emerging motor skills. "These movements appear to be manifestations of inherent motor patterning characteristics of neuromuscular pathways at certain stages of maturation" (Thelen, 1981, p. 9), not functionally related but motorically related. These motor stereotypies tend to drop off toward the end of the first year of life as the infants gain intentional control of their bodies and action patterns.

A different type of repetitive behavior emerges in the preschool period: rituals and habits, seen as "just right" behaviors when distressed (Evans et al., 1999). These ritualized behaviors appear to help children cope with anxiety, and this relationship strengthens over the childhood period (Pietrefesa & Evans, 2007).

Zwaigenbaum and colleagues summarize these points well:

> "The social and learning characteristics of infants and toddlers contrast sharply with those of preschool-aged children, whose experience involves higher levels of autonomy, increased influence of peers, less contextualized learning and memory, and greater facility with symbolic thought and communication. Interventions that address the learning characteristics of infants and toddlers need to focus on natural learning environments and contexts, child initiative and sensory-motor exploration, and the development of nonverbal intentional communicative acts and reciprocal play with social partners." (Zwaigenbaum et al., in press)

Existing Studies of Infant–Toddler Autism Spectrum Disorder Interventions

Until recently, published intervention research for children with autism ages 24 months and younger was limited to descriptive studies (Green et al., 2002; McGee et al., 1999). There are now several published treatment studies of ASD for 2-year-olds using group designs with some type of comparison group. In contrast to the Lovaas model, none of these interventions have used the discrete trial teaching method. Instead, they use a more responsive and child-centered approach, and they focus on work with parents to follow children's leads, embed interventions into daily routines, and stimulate joint attention, imitation, and play (Aldred et al., 2004; Carter et al., in press; Drew et al., 2002; Green et al., 2010; Kasari et al., 2010; Landa et al., 2010; Mahoney & Perales, 2003, 2005; Oosterling et al., 2010). This change in approach fits well with current research findings emerging from the autism literature that demonstrate the impact of caregiver sensitivity and following children's leads in language development. Both longitudinal studies (Siller & Sigman, 2002) and treatment studies (Mahoney & Perales, 2003, 2005) have documented the specific contribution of this type of interaction on child gains, both short and long term. Let us turn to the published studies for infants and toddlers with ASDs.

The first set of studies published, mostly between 2002 and 2009, documented positive outcomes related to treatments. One of the first studies from this period was provided by Drew et al. (2002), who tested the effects of a home-based, parent-delivered developmental intervention in a pilot randomized controlled study involving 24 toddlers with autism (mean age: 23 months) who met full criteria for autistic disorder.

Children were assigned to an experimental parent training group or to a community services control group. The parents were trained during 3-hour home visits by a speech pathologist every 6 weeks in two main areas: the pragmatics of social communication and behavior management. The behavior management intervention involved using operant reinforcement approaches, interruption of unwanted behavior, and reinforcing alternative behaviors for promoting compliance during joint action interactions. The pragmatics interventions involved development of joint action routines involving books, mirrors, and toys and other objects within which the parents carried out explicit teaching of joint attention, play, imitation, turn taking, use of visual supports for communication, and stimulation of nonverbal gestural communication in their interactions with their children. Parents were to use the techniques daily in their home routines and also in joint play sessions with their children for 30 to 60 minutes daily in set-aside activities. After 12 months of treatment, significantly more children in the treated group developed speech (8 of 12) than in the comparison group (3 of 12), and the only children who acquired phrase speech during the year were in the treated group. There was also a trend toward significance for the treated group to understand more words. Unfortunately, however, the treated group had a significantly higher nonverbal IQ than controls at the start of the study (88 vs. 66), which may have contributed to their greater language gain. The treated group lost 11 IQ points on the nonverbal measure over the course of the treatment, whereas the IQ scores of controls remained stable. Thus, the evidence presented in this study provides some support for the efficacy of this intervention in fostering language development over a 12-month period. Furthermore, the study was replicated in another RCT by Aldred et al. (2004).

Mahoney and Perales (2003, 2005) published two outcome studies involving a group of children with ASDs, most of whom were 2 years or younger at the time of enrollment, in a relationship-based intervention called "Responsive teaching." The focus of the intervention is to increase parental responsivity to children's "pivotal developmental behaviors," which in this model include attention, persistence, interest, initiation, cooperation, joint attention, and affect. Parent–child dyads were provided with an hour per week of intervention for a year, although on the average, 32 hours were provided over the treatment year. The intervention focused on play-based interactions and natural routines. Parents were found to significantly increase responsiveness and positive affect after the intervention, with parents of children with ASDs showing more changes than a comparison group of parents of children with developmental delays without ASDs. Children with ASDs made greater progress in communication and cognitive abilities in the temperamental-behavioral domain than did a comparison group of children. Furthermore, child change was, in part, related to parental changes in responsiveness, supporting the conceptual model.

Wetherby and Woods (2006) reported on an intervention for 17 toddlers with a mean age of 18 months at the start of a parent-delivered intervention consisting of two home visits per week from a professional staff member and one parent–toddler play group per week. Individualized social-communication goals were established for each child, and parents were taught to incorporate interventions using naturalistic techniques into daily play and caretaking activities. Outcomes involved two analyses: pre–post comparisons without control for expected developmental changes, which yielded significant changes in virtually all social-communicative domains, and a comparison to a community group matched for age and diagnosis at outcome. Significant differences were found in number of words, gestures, and consonants in the treated group compared to the comparison group, but the methodological problems in the research design prevented assessment of any intervention-specific effects on children's development.

Finally, Dawson, Rogers, and colleagues conducted a randomized controlled trial of the Early Start Denver Model (ESDM; Rogers & Dawson, 2009) on 48 infants ages 18 to 30 months (Dawson et al., 2010). Children were randomly assigned to one of two groups: *(1)* the intervention group who received, on average, 25 hours of the ESDM weekly for 2 years, with an average of 15 hours per week delivered in the home by trained therapists and another 10 to 15 hours delivered by parents; *(2)* the community treatment group who received ongoing assessment and monitoring and standard community-based treatments. The ESDM is a developmental, relationship-based intervention approach that uses teaching techniques consistent with applied behavior analysis (ABA) to foster social-communicative, cognitive, and language gains in young children with autism and to reduce atypical behaviors associated with ASDs. The content of intervention for each child comes from assessment using the ESDM Curriculum Checklist (Rogers & Dawson, 2009). Adults delivering ESDM focus on behaviors involved in capturing and holding children's attention; fostering their motivation for social interaction through highly enjoyable routines; use of joint play activities as the medium for treatment; developing nonverbal and verbal communication, imitation, and joint attention; and the use of reciprocal, turn-taking exchanges inside joint activity routines to foster social learning. At 2 years after the baseline assessment, the ESDM group showed significantly improved developmental and adaptive behavior scores compared to the community treatment group, with language measures showing particularly large group differences. A significantly higher proportion of children in the ESDM group also showed changes in diagnostic classification involving milder autism symptoms compared to the community treatment group. The size of the group differences was favorably comparable to those coming from studies using the Lovaas model. However, as this is the initial study of this approach, independent replication is needed before one can assess the efficacy of this model—a statement that applies to all the studies above other than Mahoney and Perales' work.

Two additional randomized controlled studies just published deserve mention here. Kasari et al. (2010) conducted an RCT involving 38 families, half of whom carried out a specific

joint attention intervention during 24 weeks of weekly treatment, and were followed up one year later. Those receiving the intervention demonstrated moderate to large differences compared to the wait-list condition on both measures of joint engagement and joint attention, and also on diversity of play skills, both at the end of treatment and at a one year follow-up point. Landa and colleagues (2010) carried out a randomized controlled trial with 50 toddlers examining the effects of an enhanced imitation, joint attention, and affect sharing intervention carried out within a group program over a six month period of time. The intervention resulted in significantly improved imitation skills in the experimental group which were maintained over a six month period.

However, in contrast to these positive findings, some important negative findings have also recently been published. All three involve parent implemented interventions and used very high quality designs, including randomized assignments and blind assessors, to examine intervention effects. The British PACT study by Green et al. (2010) examined the treatment previously tested in small trials by Drew (2002) and Aldred (2004). This large, multi-site RCT found no effect of the intervention on expressive or receptive language, or on ADOS scores, tested in the lab, nor in teacher ratings involving social communicative skills in the classroom. The only significant effect occurred in improved ratings in the treatment group involving ratings of parent synchrony and of child shared attention to parent (similar to the findings in the Kasari et al. [2010] study). Two other groups also failed to find effects on standardized testing of parent-implemented interventions compared to community treatment groups. Carter and colleagues (in press) found no overall group effect of the Hanen More than Words treatment, and they found an interaction of language ability with treatment outcomes, in which those children with more language skills at the start of Hanen intervention did less well than community controls, while those with minimal language at the start did better than community controls. Oosterling et al. (2010) conducted a Dutch study of parent-implemented intervention with sessions carried out across a year's time. This group found no differences in child skill level or parent skill level compared to community controls at the end of the study.

How do we reconcile these differences? Future research will help us, and a number of additional, large, well-controlled studies of parent implemented interventions for toddlers will be published soon. At this point, perhaps the most important take-home message is that the effect of early intervention for ASD is not a slam-dunk. Not all interventions make as much of a difference as they seem. Most children progress over time, including those with ASD, and progress seen during an intervention cannot be confidently attributed to the intervention unless there is a comparison group to model the effects of time and other experiences on skills. Children with autism progress, and some interventions lead to much more progress than expected. We will have to wait for the next round of studies to start to interpret what crucial ingredients of toddler interventions stimulate large effects on language, social

development, and cognition. Soon, the field should have enough efficacy data for the extraction of key variables for effective intervention for toddlers with autism.

Prospective studies of infants who will develop autism have been invaluable in defining the earliest symptoms that appear in infants (*see* Rogers, 2009, for a recent review) and are now consistently documenting differences in children by age 12 months who will later develop autism (Landa & Garrett-Mayer, 2006; Ozonoff et al., 2008a; Ozonoff et al., 2008b ; Zwaigenbaum et al., 2005). The newest autism screening tools are also targeting the 12- to 14-month period (Resnick et al., 2007; Swinkels et al., 2006; Wetherby et al., 2008). Although many infants who will later develop autism do not show symptoms at 6 months (Zwaigenbaum et al., 2005), case studies have shown that some do, as described in a series of case studies by Bryson et al. (2007). The characteristics that appear in the 6- to 11-month period, described by Bryson and colleagues (2007), include unusual visual examination and fixations, unusual repetitive patterns of object exploration, delays in motor development, temperamental fussiness and difficulty with transitions, and, for infants closer to 12 months, decreases in eye contact, social initiative, joint attention, and emotion sharing, as well as a failure to respond to name.

Studies with long-term data indicate that only a subset, perhaps half, of infants who will develop ASDs are symptomatic in the first year. However, for the group that has symptoms by 12 months, the course of onset appears more rapid, and the degree of delay and atypicality more severe, than those infants whose onset is more prolonged and occurs later than 12 months, excluding those with frank regression (*see* review by Rogers, 2009). However, there is only one paper describing an intervention approach for infants at risk for ASDs in the 6- to 11-month range, and this is a single case study (Vismara & Rogers, 2008).

A long line of studies of the early phenotype of ASDs has clearly identified the key characteristics that differentiate autism in toddlerhood: imitation, joint attention, emotion sharing, language development, nonverbal gestural communication, and repetitive behaviors with objects (Lord, 1995; Rogers, 1998; Stone et al., 1997a; Stone et al., 1997b; Wetherby et al., 1998). These characteristics at age 12 months also predict autism in infant sibling studies (Landa & Garrett-Mayer, 2006; Zwaigenbaum et al., 2005), and this well-documented profile provides for intervention targets in the toddler period. However, before age 12 to 15 months, these skills are not part of a typical developmental repertoire, and interventions for the 6- to 11-month-old period will need to draw from both the symptom presentation of these infants and existing infant intervention literature from other disorders.

We recently conducted a thorough review of the infant intervention literature in other developmental disorders to extract main intervention principles (Wallace & Rogers, 2010). Because some of the symptoms that define autism at these early ages are also seen in infants and toddlers with other developmental and medical disorders (e.g., language delays, regulatory problems, repetitive behaviors), design of efficacious

interventions for such symptoms in ASDs may be helped by reports of efficacious interventions for these symptoms in other groups in the 6- to 11-month period. It is to this literature that we now turn.

Effective Aspects of Infant Interventions in Other Groups

A variety of studies have examined effects of various interventions and caretaking strategies for both infants with developmental risk and those with typical development. We will review the most powerful variables isolated in these literatures.

Interventions for Infants with Developmental Risk or Disability

Thirty-four Level 1 or Level 2 studies (those involving the use of comparison groups or randomized control trials) (Nathan & Gorman (1998)) were identified that focused on infants and toddlers in the 0- to 3-year chronological age range and found positive effects of their interventions. The interventions involved infants with prematurity, Down syndrome (DS), or those at risk for intellectual disability (ID) resulting from ID in the mother and low socioeconomic status. Seven characteristics of the interventions appeared linked to better outcomes either through manipulations in the research design or through commonalities across those approaches that yielded improved outcomes in the experimental groups.

First, the majority of effective interventions involved **parent coaching**, including parental use of the interventions daily at home, therapist modeling of the intervention to the parent, and/or the provision of activities through the parent that matched the individual child's developmental profile. Parental use of specific developmental activities was a major component of the majority of these studies. In many (Ross, 1984, with very premature infants; Sanz et al., 1996, 2002, 2003, with Down Syndrome; and Sloper et al., 1986, with Down Syndrome), parents and infants had regular sessions with a therapist and then carried out specific activities at home daily between sessions. Even the two center-based studies involving infants at high risk for ID (Ramey & Campbell, 1984; Ramey & Smith, 1977) strongly involved parents via the use of frequent home visits. Furthermore, Sanz and colleagues (1996, 2003) experimentally demonstrated the superiority of therapist modeling and coaching of parents versus use of written materials for parents in supporting progress of infants with Down Syndrome on measures of motor, verbal, social adaptation, and social relationships.

A second feature affecting outcomes involves the **frequency and length of the intervention.** The majority of the effective studies involved weekly sessions in the clinic or at home across a substantial portion of the 0- to 3-year age range (Aronson & Fallstrom, 1977; Infant Health and Development Program [IHDP], 1990; Resnick et al., 1987; Sanz, 1996; Sanz Aparicio & Balana, 2002, 2003). In contrast, many ineffective interventions

or those which had only short-lasting positive effects in the literature were short-term interventions that consisted of few or widely spaced contacts (e.g., Palmer et al., 1988; Piper & Pless, 1980).

Third, most of the effective interventions involved **individualized activities designed to meet the developmental needs of each child.** Many were based on a manualized curriculum and approach (*see* IHDP, 1990) that allowed for individualization of the parent activities and adjustments based on child progress (i.e., Response to Treatment [RTI]; Resnick et al., 1988; Sanz et al., 2002).

The fourth characteristic of the effective studies involves **beginning the interventions as early as possible** after diagnosis. Outcomes from these early delivered interventions were strong and long-lasting. Brooks-Gunn et al. (1992), for example, found long-term differences in several areas of development, including both verbal and nonverbal skills, in a very large network intervention study for premature infants. Sanz and colleagues (2002) experimentally demonstrated the benefit of earlier intervention for infants with DS involving greater gains in motor, verbal, social adaptation, and social relationships.

Fifth, several studies demonstrated the positive effects of interventions focused on **increasing parental sensitivity and responsivity to infant cues**, including following children's leads for decreasing infant fussiness and negative temperamental qualities (Seifer et al., 1992) and improving infant social competence (Barrera et al., 1990). Promoting First Relationships (Kelly & Barnard, 1999) is a well-articulated example of a relationship-focused parent education approach that focuses on dyadic relations and parental responsivity and sensitivity.

Sixth, many of the effective early interventions were **broad-based**, in that they focused on improving many areas of the child's functioning, such as language, motor skills, and self-help skills (Aronson & Fallstrom, 1977; Field et al., 1980; IHDP, 1990; Kelly & Barnard, 1999; Ramey, Mulvihill, & Ramey, 1997; Ramey & Smith, 1977; Resnick et al., 1987; Ross, 1984). Rather than narrowing in on one or two areas, these interventions took a broader approach to helping the child.

Finally, many effective interventions **offered parents support** above and beyond that provided via the intervention itself. For example, in many studies of effective interventions, parents were offered support in the form of group therapy, psychosocial therapy, or material assistance and case management. A great majority of these provided a forum wherein parents could freely express grief and frustration, as well as assisting with more practical, tangible concerns (Bidder, Bryant, & Gray, 1975; Connolly et al., 1980; Gianni et al., 2006; Greenberg, Calderon, & Kusche, 1984; IHDP, 1990; Olafsen et al., 2006; Resnick, Armstrong, & Carter, 1988; Resnick et al., 1987).

Data from Typical Infant Development Research

Further guidance comes from studies involving effects of caregiver variables on typical infant development, including research on parental affect, following children's leads, parental sensitivity, elaboration, scaffolding, and motherese.

Situation-appropriate and contingent parental affect is considered vital to infants' development of emotion regulation. Infants are unable to regulate their emotions independently and depend on parental interventions to help with regulation and to learn self-regulation. Nichols, Gergely, and Fonagy (2001) have described the process wherein infants come to elicit appropriate affective responses from caregivers. Human infants show an initial species-specific sensitivity and propensity to engage in affective interactions with their caregivers. As parents provide contingent appropriate facial and vocal affective reactions to infants' positive and negative emotional displays, infants come to develop an increased awareness of their own emotions. An important component of this affective reflection, according to the authors, is that parents reflect back to infants their own behavior at a pace and activity level that is in tune with their behavior.

Adults' following of the child's lead in play and language has been shown to contribute positively to many aspects of development, including language development. McCathren, Yoder, and Warren (1995) concluded that providing follow-in directives to children (i.e., following their lead in play and language) contributes positively to language development, while providing directives against the child's lead (i.e., redirectives) contributes negatively to some aspects of children's language development. The authors propose that follow-in directives contribute positively to children's language development because they maintain established joint attention episodes. They also report studies demonstrating that following a child's lead contributes positively to the development of joint attention, vocabulary, and verbal responses. Similarly, Rocissano, Slade, and Lynch (1987) discovered that toddler compliance and maintenance of joint attention episodes were more optimal during moments when parents followed their child's lead, rather than broke the engagement by providing asynchronous directives, for example. Thus, among both typically developing youngsters and children with developmental delays, following a child's lead in play activities can prove vital for the learning opportunities presented within an episode.

Similarly, caregiver sensitivity has been shown to be important to infant mood and affect, as well as maternal–infant attachment quality (Lohaus et al., 2004). Aspects of sensitivity include perception of infant cues, correct interpretation of such cues, prompting, and appropriate reaction. Additional related components include warmth and behavioral contingency. These factors are closely related to following a child's lead as they involve mothers adjusting their responses and behaviors to the needs of their children. Appropriateness of maternal sensitivity is a frequent intervention target for special needs populations, especially for mothers and infants born prematurely (e.g., Barrera, Doucet, & Kitching, 1990; Barrera, Rosenbaum, & Cunningham 1986; Rauh et al., 1988).

Being sensitive to children's cues and following their leads does not preclude parents from elaborating on their children's play and vocalizations. Appropriate elaboration techniques, including modeling and praising of novel vocalizations during play, is an important component of parental teaching of infants. Hursh and Sherman (1973) have found that appropriate modeling in the form of vocal elaboration and positive reinforcement increases children's vocalizations already in their repertoire, as well as increases usage of novel vocalizations. These techniques provide children with opportunities to acquire novel skills within child-directed, elaborated activities.

Deeply imbedded in successful parent–infant learning opportunities are episodes of scaffolding. According to Stevens et al. (1998), scaffolding consists of the adult controlling elements of a task that are initially beyond an infant's capacity. To scaffold successfully for their children, parents simplify the task, maintain attention and motivation, demonstrate, and mark critical features. As the infant's skills mature, the parent diminishes support. Research suggests that parental scaffolding positively affects infant development in a multitude of realms, including game learning (Hodapp, Goldfield, & Boyatzis, 1984), attention, and problem-solving (Findji, 1994).

A final caregiver variable that appears to have a positive effect on the language development of typical infants is the use of motherese. A way of speaking to infants with increased prosody, increased pitch, slowed production, exaggerated pitch contours, simplified vocabulary, and repetition, motherese is typically utilized with exaggerated positive affect by parents (Sokol et al., 2005; Weppelman et al., 2003). Infants appear to prefer listening to motherese, rather than to typical, adult-directed speech (Weppelman et al., 2003). The use of motherese thus serves to increase infants' attention to communication by making speech more interesting. In addition, the use of motherese appears to facilitate many language-learning tasks. Because in motherese focused words tend to be placed on pitch peaks and in salient positions, such as at sentence end, this type of speech may assist infants in learning salient words (Weppelman et al., 2003). Kemler Nelsen et al. (1989) have found that infants are sensitive to segment-marking cues in motherese but not in adult-directed speech. Motherese may also facilitate associative learning for nonlinguistic information and aid listeners in separating speech from background noise (Weppelman et al., 2003).

Guidelines for Infant–Toddler Treatment

To summarize, the literature from the few studies of infant–toddler ASD intervention and from both the clinical and the typical infant–toddler literature suggest that autism-specific interventions for infants and toddlers should focus on the importance of particular characteristics of the child's ongoing social environment and experiences. Sensitive caretaking, enriched language environments using responsive rather than directive interaction styles, environments that provide opportunities for infants to have an active role in their own learning, and interventions that are individualized and targeted to specific skills in infants and parents (rather than a more general support or service coordination model) appear to characterize efficacious infant/toddler interventions. Because infants at risk of autism are, first and foremost, developing infants, variables that positively affect infant outcomes in other groups of infants

should also characterize interventions for infants at risk of autism until future empirical evidence indicates otherwise. The literature suggests that although interventions designed for older children with autism can certainly inform research and practice focused on infants and toddlers, existing efficacious models for preschoolers with autism should not be applied to infants and toddlers without significant adaptation.

Interventions are culturally determined and typically reflect the value system, philosophy, and practices of the originators. The intervention models described above have at their core a particular cultural style of interacting with infants and young children. However, cultures vary markedly in the ways that adults talk to and interact with children (Goldin-Meadow & Saltzman, 2000; Rabain-Jamin & Sabeau-Jouannet, 1997). Cross-cultural psychology stresses the importance of goodness of fit between culturally based interaction styles and value systems of those providing help and those seeking help.

Delivery of a specific treatment approach without considering the cultural appropriateness of the parent–child interactive style, expectations, and values of the approach and those of the family seeking help may limit or prevent its acquisition and use by parents and other family members (Dyches et al., 2004). Cultural fittedness includes both the language being used and the values and priorities being discussed with the family. Is the intervention being delivered in the dominant language of the family (Harry et al., 1995)? If this is not occurring, then one is virtually assured that the intervention is not culturally fitted to the family. However, the concepts of race and of socioeconomic status are often confused with the concept of culture. To understand families' cultural value systems and culturally defined behavioral and interaction patterns, both researchers and clinicians must be careful to discuss families' views and preferences directly rather than relying on assumptions based on physical features or demographic information (Brown & Rogers, 2003). Suggestions for this type of dialogue can be found in Mandell and Novak (2005). Expectations such as being videotaped, learning interventions within a parent group, coming to a clinic, or sharing family information with persons outside of the family's cultural group violate cultural norms for some groups and may be barriers for participation (Birkin et al., 2008). Even the core promise of early intervention—of treating a disability and possibly facilitating a different outcome than would have occurred without the intervention—is at odds with some families' needs to accept the child as he or she is (King et al., 2006) and other families' needs to be private about the child's differences (Dyches et al., 2004). It may also be at odds with cultural ideas involving the degree of control individuals have over life outcomes (Mandell & Novak, 2005). Clinician values concerning child outcomes involving autonomy in decision making, personal independence, and self-assertion may not be values shared by the family, and in the case of children with more severe disabilities, cultural clashes between parents and professionals may be particularly evident (Brown & Rogers, 2003). Assuring that intervention goals reflect family priorities, rather than clinician priorities,

allows for important points of dialogue between families and interventionists.

Because infant–toddler intervention (and indeed, intervention for children of every age) is mediated via family interactions, it is necessary that interventionists work with families to actively assess and evaluate the aspects of a specific intervention approach that "fit" the family and those that do not. Doing so requires that the interventionists are aware of the cultural biases—habits, values, practices—in the intervention approach and that they are aware of their own cultural values and behaviors. Once the fit is evaluated and potential difficulties identified, the interventionist has the responsibility of either tailoring the chosen intervention approach to improve the fit or considering other approaches that might be a better fit. The assumption is that intervention approaches for infants and toddlers must be congruent with family lifestyle, interaction styles, values, and priorities to provide maximum benefit.

Adjusting particular aspects of interventions to accommodate cultural differences, however, presents its own set of problems, because changing the intervention means that the tested and manualized intervention is not what is being delivered, and in making the needed changes, one may, in fact, alter the variables that have led to its efficacy in clinical trials. There is no simple solution to this dilemma. At the individual level, ongoing tracking of children's progress and learning rate and of parental fidelity of delivery of the intervention will indicate when changes to the intervention plan and/or procedures need to be made to enhance child learning. On a larger scale, as intervention groups seek to adopt established interventions and apply them in cultures other than the one in which they were developed and tested, there arises a need for efficacy research to determine whether outcomes in the new culture mirror outcomes in the culture of origin. Finally, interventionists who are culturally fitting interventions to specific cultural needs of families or groups should write up the adaptations and provide them to others, so that practices develop that can then be tested.

Discussions of interventions for 6- to 11-month-olds need to be carried out within the context of public support for such interventions. Public laws pertaining to infant and toddler interventions differ from those pertaining to children ages 3 years and older. The legislation involving infant–toddler interventions appears to have been influenced by the research literature in a number of ways. Let us briefly review the specifications of public law as it pertains to infant interventions.

The Individual with Disabilities Education Act, Part C: Early Intervention for Infants and Toddlers with Disabilities

Infants' and toddlers' access to publically funded interventions was legislated most recently in the IDEA: Individuals with Disabilities Education Act, Part C: Early Intervention Program for Infants and Toddlers with Disabilities, Federal Register,

May 8, 2007 (Dept of Education, Office of Special Education and Rehabilitative Services [OSERS] 34CFR Part 303). The purpose of this act was to provide financial assistance to states that offer early intervention services to children under age 3 years who are at risk of developmental delays because of biological and environmental factors. Such funds were to be used only for services that a child needs but that are not paid for by other public or private sources (payor of last resort).

Several Requirements Were Placed on Service Providers, Summarized Below

1. Such services were to be multidisciplinary (two or more) and comprehensive and were to meet the developmental needs of the infant in cognition, communication, motor, social or emotional, and adaptive domains. Services were also to meet the needs of the family as they request for them to assist their infant's development.

2. The service delivery process must begin with an evaluation of child and family needs from two or more disciplines, either from the service team or from previous assessment. The evaluation is followed by the development of a written Individualized Family Service Plan (IFSP) in a meeting with the family, to be reviewed at least every 6 months. The IFSP must contain clear and measurable goals and outcomes for the intervention. It also defines the services to be delivered, which may include assistive technology, audiology, family training including counseling and home visits, health and medical services, occupational therapy, physical therapy, psychological services involving assessment, interpretation, and planning, service coordination, social work services, special instruction, speech and language pathology, transportation, and vision services. Other needed services can also be included if identified in the IFSP.

3. Families must consent to the plan before services are delivered, and once consent is obtained, all services consented to must be delivered. Progress is to be reviewed and plans modified as needed to achieve the stated goals during these meetings.

4. Child interventions are to be carried out in environments that would be natural for infants without a disability and include the home to the maximum extent possible.

Missing from IDEA is any description or requirement regarding the intensity or frequency of services to be delivered, which instead is left to the discretion of the agencies and/or IFSP team. As such, the delivery of services to infants and toddlers with autism can vary tremendously from one state to the next. Currently, in Sacramento, CA, a 24-month-old with ASD may receive as many as 35 hours per week of 1:1 intervention in his or her home and may also receive a session or two of individual speech/language therapy and occupational therapy per week. In other regions within the same state, services may consist of a 1-hour visit weekly by a professional,

and a 1.5-hour play group with several toddlers and parents biweekly. Thus, publicly provided services vary tremendously for families, both within and across states. Many families pay out of pocket to fund services of appropriate intensity and content for their children. Out-of-pocket expenses can involve as many as $40,000 to $50,000 or more per year. Families sell their homes, use college savings funds, and incur great debt to purchase services for their children. Furthermore, service delivery typically requires the parent's presence and often parental transportation. One parent may need to end employment, thereby reducing family income, to support intervention for the child.

Thus, the current public service delivery systems addressing Part C requirements have as strengths a family-based model, an orientation that focuses on child development, child health needs, and family supports and involvement, interventions occurring in natural environments, and multidisciplinary teams. However, decisions about the nature and intensity of services for infants and toddlers at risk for ASD are entirely at the discretion of the public service agency and IFSP team delivering care. Without definition of appropriate services for infants and toddlers with ASD either through the public service system or in the empirical literature currently available, families and practitioners are left to make decisions in the absence of information. Given the increase in infants and toddlers being identified with autism risk, and the strong statements by the American Academy of Pediatrics and the American Academy of Neurology about the need for autism screening during the first two years of life, empirical information about treatment efficacy is badly needed (American Association of Pediatrics, 2003; Filipek et al., 2000).

Conclusion

Whereas research programs in infant screening and diagnosis of autism are moving rapidly forward, research programs in infant treatment of autism have only just begun. Although beginning trials assessing the efficacy of infant–toddler intervention have been conducted, the science is still at an early stage and we currently have no identified infant–toddler interventions that meet the criteria necessary to consider them empirically supported interventions. The current published literature is limited to case studies, uncontrolled studies, and a few controlled but as yet unreplicated findings. However, this is presently an active area of research, with a number of controlled studies in progress. Data is beginning to appear from these studies for 12- to 24-month olds. Interventions for even younger infants have only just begun.

Although we lack data from autism infant–toddler intervention studies to define the key ingredients of efficacious interventions, the intervention research from other infant and toddler groups provides some well-replicated findings, the consistency of which suggests that they should be incorporated into the design of intervention approaches for infants and

toddlers with ASDs. These include: *(1)* focus on parent–infant interactions as a main delivery system for the intervention; *(2)* use of the infant's direct, active experience rather than computerized, pictorial, or video content as the basis for intervention; and *(3)* a style of interaction characterized by adult following of child's focus of attention and interests rather than directing infant attention as the vehicle for communication interventions. However, individual differences in terms of both infant and family characteristics, as well as a cultural perspective, need to be taken into consideration when developing or delivering manualized interventions, both for parents and for children.

In addition to the need for models, there is the need for measures to assess both autism risk and progress during infancy. The research on screening and assessment instruments for infants as young as age 12 months is currently in progress, and the search for valid autism risk markers below age 12 months is underway. We need both teaching curricula and measures of core constructs like joint attention, repetitive behavior, imitation, functional play, emotion sharing, and gesture use—the behavioral variables that define the autism phenotype in this period—that are psychometrically sound and simple and fast to administer and score, for clinical use. We currently rely on autism diagnostic instruments as measures of treatment-related change as well as diagnostic status; more sensitive instruments are needed if we are to measure intervention associated changes in infant and toddlers over the short term—necessary for evaluating treatment efficacy and making needed adjustments for individual children.

Finally, we need studies of well-articulated, manualized intervention approaches for 6- to 15-month-olds at risk of ASDs that detail the content of the intervention as well as the teaching procedures used to impart the intervention to parents and to children. Content needs to be clearly defined, assessment tools described or provided, and decision-making approaches detailed. Teaching procedures need to be described in detail, and measures for examining adherence to the model—treatment fidelity instruments—need to be provided. Fidelity measures need to address each set of interactions that deliver the intervention. How is the interventionist to impart the intervention to the parent? To the child? How is the parent to impart the intervention to the child? Each of these interactions delivers the intervention, and the intervention model should define these and then report the degree of adherence that occurred. Finally, these methods need to be scalable and exportable if they are going to address the needs of the many children who are now diagnosed with ASDs.

The promise of early intervention for enhancing the skills and lives of children with ASDs first appeared in 1987, and now, 24 years later, we have the opportunity to intervene as symptoms first appear. Based on what is known about infant learning and infant brain development, delivering interventions in infancy has maximal likelihood of optimized outcomes, of perhaps stopping autism in its tracks. Our capacity to deliver on this promise depends on the speed and quality of early identification science to highlight autism risk and early intervention science to guide treatment.

Challenges and Future Directions

To support infant intervention for ASD, future research agenda must focus on the following:

- Development of programs of research on infant intervention for ASD risk
- Development of treatment models that allow for individual differences among families
- Development of models that allow for cultural fittedness
- Development of psychometrically sound measures that assess autism risk
- Development of psychometrically sound measures to assess changes in core symptoms
- Development of efficacious manualized interventions for 6- to 15-month-olds with ASD symptoms.

Relationships, Independence, and Communication in Autism and Asperger's Disorder

Points of Interest

- Motivation
- Social Interaction
- Psychological Health
- Initiations
- Communication
- Pivotal Response Treatment
- Behavioral Intervention
- Outcomes
- Generalization

Linguistic aptitude and communicative competence are critical to healthy relationships, gainful employment, and independence in adulthood. For individuals with autism spectrum disorders (ASDs), these are core deficits; therefore effective treatment in these areas is essential for positive long-term outcomes (Alpern & Zager, 2007; Howlin, Mawhood, & Rutter, 2000; Koegel et al., 1999; Koegel & LaZebnik, 2009). A lack of communicative competency can lead to significant problems, including a decreased number of social relationships (Howlin, 2000; Jobe & White, 2007; Orsmund, Krauss, & Seltzer, 2004), increased feelings of loneliness (Howlin, 2000; Jobe & White, 2007; Jennes-Coussens, Magill-Evans, & Koning, 2006; Jones & Meldal, 2001), social isolation and withdrawal, and poorer quality of friendships, (Strain & Schwartz, 2001; Bauminger & Kasari, 2000; Stewart et al., 2006). In fact, although individuals with ASDs may experience a range of comorbid conditions (Gadow DeVincent, Pomeroy, Azizian, 2004; Green et al., 2000; Klin et al., 2005; Meyer et al., 2006; Tantam, 2000), depression and anxiety disorders appear to be the most prevalent (Matson & Nebel-Schwalm, 2007; Ghaziuddin, Ghaziuddin, & Greden, 2002; Gillott & Standen, 2007; Shtayermman, 2007; Sterling et al., 2008; Tsakanikos et al., 2007). Therefore, it seems that social factors may play an important role, as individuals who lack adequate social

communication have been found to be five times more likely to develop a comorbid diagnosis of depression in adulthood (Stewart et al., 2006). This interplay between ASD-related deficits and comorbid features has been linked to disruptions in underlying brain development (Amaral, Schumann, & Nordahl, 2008; Geschwind & Levitt, 2007), adding to the complexity of ensuring successful outcomes in this population. Therefore, given evidence that deficits in social and communicative competence can contribute to poorer psychological health, these factors appear to a play a pivotal role for later outcome and intervention.

Although a failure to develop age-appropriate peer relationships is a primary diagnostic criterion of autism and Asperger's Syndrome (American Psychological Association, 2000), research suggests that contrary to beliefs that people with ASDs prefer to be alone, most have a desire for meaningful friendships and romantic relationships (Jobe & White, 2007; Jones & Meldal, 2001; Jennes-Coussens et al., 2006; Howlin, 2000). When examining the broader autism phenotype, regardless of the desire for social relationships, the degree of ASD symptoms has been significantly correlated with a fewer number of and shorter duration of friendships (Jobe & White, 2007). This has significant implications given that depression is frequently related to loneliness and impacted by lack of successful social communication skills (cf., Howlin, 2000).

Despite evidence indicating that individuals with autism and Asperger's Syndrome desire both casual and intimate social relationships, and the association between dissatisfactory social relationships and comorbid conditions, there is an unfortunate paucity of research addressing this area. Outcome studies are particularly lacking. A review of the literature suggests that only a minority of individuals on the spectrum, even with a diagnosis of autism and few support needs or Asperger's Syndrome, achieve any remote semblance of integration into what most people would consider to be a desired lifestyle in adulthood (Alpern & Zager, 2007; Cederlund et al., 2008;

Howlin et al., 2004; Larson, Doljanac, & Lakin, 2005; Muller et al., 2003; Seltzer et al., 2004).

Specifically, in a summary of the literature, Howlin (2000) reported that only 16% to 50% of individuals with ASDs were living semi-independently, whereas 5% to 55% held paid work positions. Perhaps most tragically, despite their desire for meaningful romantic relationships, only up to 14.3% of adults on the spectrum were married. In contrast, almost 95% of typical adults are employed (U. S. Department of Labor, 2008), and 70% of adults are married (U. S. Census Bureau, 2006). More recently, Seltzer et al. (2003) corroborated these trends based on a study in which data were collected on ASD symptom patterns exhibited by 405 adolescents and adults. Similarly, Orsmund et al. (2004) assessed the peer relationships and social activities of 235 adolescents and adults with autism. They documented that only a small percentage of participants had relationships that met the ADI-R criteria for friendship, which was defined as a "same-aged friend with whom varied, mutually responsive and reciprocal activities were engaged in outside of organized settings" (p. 250).

It is important to emphasize that although individuals with ASDs continue to face long-term needs and challenges (Alpern & Zager, 2007; Howlin, 2000), the above findings should motivate, and serve as a base for, research in these areas. If anything has been learned from research conducted with this population over the past four decades, it is that very little is permanently unchangeable. The purpose of this chapter is to discuss research findings, best practices, and future directions that are necessary to move toward these goals. Because comprehensive socio-communication interventions need to begin early, this chapter will discuss interventions for early childhood that may be of particular importance to achieving long-term positive outcomes.

Defining and Measuring Communication

It is important to begin by discussing a few issues that complicate research in the area of communication. One area relates to the accurate nomenclature of communication and communicative acts. In particular, numerous definitions have been employed to describe a hallmark of social communication—namely, spontaneous (as compared to prompted) communication. Although researchers have emphasized the importance of spontaneous communication, particularly among children on the spectrum, definitions of "spontaneous" greatly differ, resulting in confusion and lack of consistency in terminology across the language literature (Chiang & Carter, 2008). Clear and uniform definitions are necessary for the identification and conceptual understanding of spontaneous language, given evidence that spontaneous communication is significantly related to independence and reduced need for support (Carter & Grunsell, 2001; Sigafoos & Reichle, 1993). Additionally, given that individuals on the spectrum may be highly prompt-dependent, defining exactly what constitutes spontaneity is challenging.

Furthermore, Carter and Hotchkis (2002) point out there exists in the literature two conceptually opposing views of spontaneous language—binary and continuum. A binary conceptualization of spontaneous communication refers to an "all-or-none" phenomenon (i.e., either the behavior is spontaneous or not; Chiang & Carter, 2008, p. 695), with numerous studies in the literature employing this model (Charlop & Trasowech, 1991; Koegel, O'Dell, & Koegel, 1987; Krantz & McClannahan, 1993).

However, while some studies view spontaneity as binary (Carter & Hotchkis, 2002; Chiang & Carter, 2007), most would agree that the degree of spontaneity an individual exhibits is multifaceted and may be associated with both the conversational partner and environmental cues. These findings have led to support for a tiered or continuum model of defining spontaneity. Halle (1987) argues that communication is always cued by environmental antecedents; therefore, a conceptualization that takes into account the potential influence of these controlling stimuli may be necessary to understand and describe spontaneous communication. Further complications for describing spontaneous language arise when taking into account the possible impact of state events (e.g., hunger, thirst, etc.) on spontaneous language. In addition, delayed echolalia can arguably be viewed as evidence for spontaneous language, even though it may be inappropriate and associated with previous antecedent cues. It seems, therefore, that a variety of important considerations are necessary when reporting results of spontaneous language across communication intervention programs. Factors such as the degree to which the natural cues in the environment trigger communication, the presence and level of influence of natural cues drawing the speaker's attention (Carter & Hotchkis, 2002), the type of speech acts the individual initiates (Koegel, Carter, & Koegel, 2003), and the association between spontaneous utterances within the existing social setting are extremely important variables. Moreover, these considerations should be clearly defined in research articles.

Vocal imitation within a communicative context is a common strategy for typical language learners but occurs at a significantly lower rate in children with autism (cf. Knott, Lewis, & Williams, 2007). In contrast, echolalic utterances, which may or may not have communicative intent, are common among individuals with ASDs. Given that some individuals exhibit high levels of echolalia, it may be important to assess whether it is being used in appropriate contexts and whether it is functional in any way. This is important given evidence that different types of echolalia exist (e.g., delayed and immediate) and may serve a variety of communicative functions (Wetherby & Prizant, 1987). Carefully defining echolalic or imitative utterances as a communication tool, assessing the appropriate or inappropriate spontaneous use of these utterances and considering the possibility of echolalia as a language learning strategy among individuals with ASD should be carefully analyzed for consistency across the literature.

Finally, although communication is relatively easy to measure in clinical and controlled settings, it is more challenging

in natural settings—particularly in the context of intimate relationships, such as friendships and dating. Research exploring these issues and interventions to target socialization is warranted given that untreated, these deficits can lead to a large array of problems, including lack of intimate relationships and successful employment (Howlin, 2000). As children with ASDs mature and as more individuals are fully included in educational and community settings, social validation of interventions and feedback regarding intimate relationships require the continued development of effective monitoring and measurement systems in the context of natural settings.

In general, the above issues have led to a shift from interventions provided in isolated contexts to teaching functional communication and pragmatics in relevant social contexts (Stone & Caro-Martinez, 1990), but the bulk of the studies have focused on younger children. Future research on defining and measuring social communication in natural contexts, as well as intervention procedures to help individuals develop long-term social relationships, attain meaningful employment, and address mental health issues, is urgently needed across various developmental stages. The remainder of this chapter discusses empirically validated procedures for improving language and social communication. Although not exhaustively, we will discuss various interventions for individuals with high to low support needs and their applicability for different age ranges.

Communication and Typical Development

Researchers have long discussed the necessity of using typical development as benchmarks for ASD intervention. This principle makes especially good sense when it comes to communication. The typical development of communication is one of the most vastly researched areas in human development, providing the perfect context by which communicative needs of ASDs can be evaluated (Tager-Flusberg, Paul, & Lord, 2005).

Given the seemingly quick pace of communicative development in typically developing individuals, it is not a surprise that many parents find themselves in awe of their child's ability to acquire such important skills (Paul, 2008). From the very beginning, typically developing children are communicators. Stark (1979) identified five stages of infant vocalizations. The first 2 months of life are comprised of reflexive cries and vegetative sounds, whereas the second through fifth months consist of cooing and laughing vocalizations. Paul (2008) discusses the emergence of cooing and laughing as important for the development of communication because these behaviors primarily occur in response to social interactions, setting the stage for the inextricably social nature of communication.

Between 4 and 8 months of age, infants appear to engage in purposeful vocal play and this stage is marked by the beginning of babbling (Stark, 1979). Simple babbling then quickly

develops into reduplicated babbling (e.g., bababa) between age 6 and 9 months (Stark, 1979). The ways in which babies use their babbling to both initiate and respond to back-and-forth interactions with adults has been described by some as "proto-conversations" (Bateson, 1975). In fact, researchers who have examined these proto-conversations have found that they are marked by turn-taking and reciprocity, components of advanced conversations seen in later development (Locke, 1995; McTear, 1985; Paul, 2008). The period between 9 and 18 months is marked by jargon babbling, and it is during this time that joint attention emerges (Bakeman & Adamson, 1984) and first words become consistent (Bates, 1979; Linder, 1993; Stark, 1979). Despite a relatively small vocabulary during this period, toddlers are by no means passive communicators. On the contrary, they are active social communicators (Paul, 2008), as evidenced by their use of pointing, holding out objects, and/or gesturing to initiate social communicative interactions (McLaughlin, 1998).

By around age 15 months, typical children have a receptive vocabulary of an average of 50 words. This period is followed by an ever-increasing expressive vocabulary, with the average 18-month-old toddler using approximately 50 to 100 words. Communication then seems to "explode" with children developing expressive and receptive use of hundreds of words by their second birthday (Fenson et al., 1993; Paul, 2008). As if this "explosion" in vocabulary were not impressive enough, this period is also marked by growth in the quality of communication. That is, young children's communicative acts, both initiations and responses, begin to serve a variety of functions including requesting, protesting, commenting, calling attention to oneself, greetings, and question-asking (Bates, 1979; Linder, 1993; Wetherby et al., 1988). The development of question-asking is especially noteworthy because it marks the first time that children use communication to direct their own learning (Fredeen & Koegel, 2006; Halliday, 1975; Meyer & Shane, 1973).

Children's communication skills continue to develop dramatically during the preschool years as they begin to expand the length and complexity of their utterances to develop conversational skills. For example, children ages 2 to 3 years can initiate a subject of conversation and take a few turns in exchanging information and details (McTear, 1985). Although lacking in sophistication, children between ages 5 and 6 years have developed discourse skills that resemble those of adults (Cook-Gumprez & Kyratzis, 2001; Fredeen & Koegel, 2006). In fact, by the time children reach adolescence, their conversations are fast-paced and remarkably complex (e.g., contain abstract topics, idioms, metaphors; Brinton, Robinson, & Fujiki, 2004). Although there are obvious differences between the communication skills of toddlers, preschoolers, adolescents, and adults, there is also an undeniable commonality of an inherent social function (Landa, 2008). Furthermore, social ability impacts communicative outcomes (Bono, Daley, & Sigman, 2004); thus, these early benchmarks provide guidance in working with the ASD population.

⠿

Communication, Socialization, and Diagnostic Criteria for Autism Spectrum Disorders

As Landa (2007) notes, "communication is a broad concept, encompassing linguistic, paralinguistic, and pragmatic aspects of functioning" (p. 16). Each of these domains consists of a variety of components. For example, the domain of linguistics comprises elements such as phonology, morphology, syntax, and semantics, whereas the paralinguistic domain includes components such as proxemics, intonation, and gestures. Finally, the pragmatic domain consists of a variety of elements related to discourse management. Interestingly, Landa further discusses how diagnostic criteria for autism related to socialization is inherently intertwined with symptoms manifested in the communication domain. That is, despite separate symptom categories, "some of the criteria specified for social impairment are intimately involved in the pragmatic aspects of communication" (p. 17), including the nonverbal lack of sharing interest and spontaneous enjoyment or the lack of social or emotional reciprocity (American Psychiatric Association, 2000; Landa, 2007). It is not surprising that without intervention in pragmatic areas, even adolescents and adults with fewer support needs continue to have difficulty with overall social communication (Alpern & Zager, 2007). For example, Brinton and colleagues (2004) discuss how conversations of typically developing adolescents include many social elements that require individuals to be able to take the perspectives of others. In the past, such skills seem to have been achieved by relatively few individuals with ASDs, often resulting in unintentional miscommunications and misunderstandings (Alpern & Zager, 2007; Hurbutt & Chalmers, 2004). These findings underscore that future interventions need to be designed to incorporate the natural social factor of communication.

In sum, Paul (2008) captures the essence of communicative development when she states that it is a dynamic process between the person and their social environment. This notion seems especially true for designing and assessing interventions for individuals with ASDs. As such, the remainder of this chapter will focus on discussing interventions designed to improve not just communicative functions but also the overall social communicative well-being of individuals with ASDs.

⠿

History of Intervention and Pivotal Response Teaching

The first scientifically documented effective interventions for instating first words and improving language use in children with autism were conducted in the 1960s (Ferster & DeMyer, 1961; Hewitt, 1965; Lovaas et al., 1966). These interventions were based on the principles of operant conditioning (Newsom & Rincover, 1998) and were implemented in highly structured settings that focused on teaching the child with autism to imitate first sounds or syllables, then several sounds or syllable reduplication, which subsequently focused on the semantic meaning of words (Landa, 2007; cf. Lovaas, 1987). These early studies resulted in a teaching method commonly known as Traditional Discrete Trial Training and/or Early Intensive Behavioral Intervention (Landa, 2007; Smith, 2001). In the original Applied Behavior Analysis (ABA) studies, as with the more current standard Discrete Trial models, communication was taught serially using drills in mass trials that were implemented in the context of stimulus-response-consequence chains, using arbitrary rewards (e.g., edibles and social praise), and often these rewards were not related to the child's specific behavioral response. Generally, intervention was implemented in a clinical room, free from distracting stimuli with the adult maintaining tight control over interactions, selecting stimuli/materials, and initiating instruction (Landa, 2007). Although effective for initial acquisition of speech for a large portion of children (Lovaas, 1987), generalization and spontaneity were considerable problems. Thus, a great deal of subsequent research focused on strategies promoting generalization, spontaneity, and maintenance of newly learned behaviors (Koegel & Koegel, 2006).
