Using these original studies as a basis, researchers expanded upon these procedures to produce a more efficient intervention (Koegel & Koegel, 2006), resulting in what is now commonly referred to as "Contemporary ABA Approaches" or "Naturalistic Behavioral Interventions" (Landa, 2007; Koegel et al., 2008). Unlike more traditional models, contemporary or naturalistic behavioral approaches modify the principles of standard Discrete Trial Teaching so that instruction is centered on the child's interests and incorporated into meaningful daily routines. A variety of teaching methods fall under this category of contemporary/naturalistic ABA, including Incidental Teaching (McGee, Morrier, & Daly, 1999), Milieu Teaching (Warren & Bambara, 1989), and Pivotal Response Teaching (PRT; Koegel & Koegel, 2006). As a whole, the above-mentioned teaching methods are not only based on the scientific procedures of applied behavioral analysis but also incorporate elements of developmental and pragmatic approaches (Landa, 2007).

Researchers examining the limitations of the original Traditional Discrete Trial studies found that spontaneous and generalized improvements in first words and language were greater if intrinsic motivational components were incorporated into the intervention. That is, when motivational components were included in the intervention, children's rate of responsivity and correct responses improved, thereby creating a more efficient treatment approach. Furthermore, several individual components have been documented to be effective, such as providing child choice of stimulus materials or topics (Koegel, Dyer, & Bell, 1987), reinforcing communicative attempts (Koegel, O'Dell, & Dunlap, 1988), using task variation, incorporating maintenance tasks (Dunlap, 1984), and providing direct and natural rewards (Koegel, Egel, &

Williams, 1980; Koegel & Williams, 1980). When combined as a package, these variables were comparatively more effective in incurring change than the traditional Discrete Trial approach (Koegel, O'Dell, & Koegel, 1987). Initially the use of these intrinsic, motivational procedures were coined *The Natural Language Paradigm* (NLP) because they closely resembled the manner in which typical children were taught to use language in their natural environments. Incidental teaching approaches are similar to the NLP/PRT paradigm in that they rely on arranging the natural environment to attract children to desired activities and materials. The approach involves waiting for the child to initiate the teaching process, using this initiation to prompt communication, and then providing the item, activity, or topic contingent upon the child's response (McGee et al., 1983; McGee, Krantz, & McClannahan, 1985; McGee & Morrier, 2003). Such teaching strategies have changed the framework of traditional teaching models. Learning conditions using natural consequences have not only been documented to result in less avoidance and escape-motivated behavior (Koegel, Koegel, & Surratt, 1992) but have been shown to lead to increased improvements in the children's interest, happiness, and engagement (Dunlap, 1984) relative to approaches involving drilling children and then providing verbal praise or potentially unrelated small edibles.

The motivational strategies originally focused on language development, but since then they have been extended and shown to be effective across other areas, such as academics (Dunlap, Kern, & Worcester, 2001), speech intelligibility (Koegel et al., 1998), peer socialization (Harper, Simon, & Frea, 2008), joint attention (Bruinsma, Koegel, & Koegel, 2004; Vismara & Lyons, 2007), and socio-dramatic play (Thorp, Stahmer, & Schreibman, 2005). Additionally the procedures have been effective with improving communication in adults (LeBlanc et al., 2007). As a whole, rather than targeting individual behaviors one-by-one, procedures that focused on the core pivotal area of motivation resulted in widespread changes in a variety of other untargeted areas. Consequently, the core targeted areas were identified as "pivotal" in the learning process and thus the term *PRT* was coined (Koegel & Koegel, 2006).

In addition to improvements in the acquisition of first words and language, the benefits of PRT intervention included evidence that children demonstrated far lower levels of escape and avoidance-based disruptive behaviors when motivational procedures were incorporated (Koegel, Koegel, & Surratt, 1992). Simply put, when these motivational and naturalistic procedures were implemented, there were dramatic widespread positive improvements in the children's symptomology in a variety of areas including behavior, communication, and overall affect.

With an understanding of the historical trajectory of educating individuals with ASDs, the subsequent sections of this chapter will identify areas in communication requiring intervention and how those areas interact with an individual's ability to build relationships and independence.

Intervention

Initiations

The effectiveness of motivational procedures in teaching first words and language to children with autism has resulted in significantly more children learning to talk. In fact, although earlier procedures resulted in about only 50% of the children becoming verbal (Lord & Paul, 1997; Prizant, 1983), as many as 80% to 95% of the children become verbal when motivational procedures are incorporated at an early age (Koegel, 2000; Koegel & Koegel, 1995; McGee et al., 1999). However, in much of the literature, the use of highly desired items primarily has been used for teaching requests. Undeniably, requests are critical in communication, but many children with autism remain limited in the variation of their communicative functions (Wetherby et al., 1988). That is, language samples show that children with autism use their communication primarily, or exclusively, for requests and protests (Wetherby & Prutting, 1984). This lack of variety and restricted use of communication functions, coupled with the lack of spontaneity, and infrequent expressive communication in natural settings (Hauck et al., 1995), results in children getting very little practice with meaningful communication. Compounding these issues are findings that children with autism develop very few, if any, social initiations that have the function of information-seeking or curiosity. This varies considerably from typical language learners who demonstrate queries and initiations within their first lexicon (Owens, 2008). For example, prior to age 18 months, typical language learners generally use "that?" (first produced as an approximation, such as/da/?) as a prompt for parents to label items (Meyer & Shane, 1973). The intentions of these early verbalizations are both social and initiative, requesting a response from the communicative partner (Owens, 2008). Furthermore, these verbalizations are generally accompanied by nonverbal gestures such as eye contact, joint attention, and pointing (McLaughlin, 1998).

A number of researchers have undertaken the goal of teaching initiations to children on the spectrum to encourage the variety of language functions and to teach self-initiated strategies that the children can use to gain linguistic information and seek social interaction (Koegel et al., 2008). Early studies on initiations focused on teaching deictic questions to individuals with autism. In particular, teaching "wh-" questions has been of interest to researchers. Not only do many children on the spectrum fail to use questions at all, the small percentage of children who do often use them incorrectly and, specifically, not as requests for information (Hurtig, Ensrud, & Tomblin, 1982). In an early attempt to systematically teach question-asking, Hung (1977) taught children with autism to ask "What is ___ for?" and "What is/are _____ doing?" Assessments for generalization of the question outside of the clinic setting indicated that the questions could be programmed to occur if reinforcement was provided, but without reinforcement, the children did not demonstrate use of the questions for the purpose of "curiosity" or information

seeking. In another study, Taylor and Harris (1995) taught question-asking to elementary school children with autism using picture cards. To assess generalization, new unknown items were placed around the school and the children were taken on walks and stopped at the new items. The children generalized question-asking without verbal prompting; however, the act of stopping may have functioned as a nonverbal prompt. Another study (Koegel et al., 1998) focused on producing spontaneous use of question-asking by incorporating motivational items into the intervention. Specifically, the researchers began with highly desired items, placed them in an opaque bag, and prompted the children to ask "What's that?" Following the query, the children were provided with a highly desired item from the bag. Gradually and systematically, the items were faded and replaced with unfamiliar items the child did not label at baseline. Following the intervention, the children demonstrated generalization of question-asking across settings, people, and to novel items. Additional questions, such as "Where is it?" and "Whose is it?", were taught with a similar methodology using desired items and generalization of these questions was also observed (Koegel & Koegel, 2006). Finally, the use of verbs and verb conjugations was improved by teaching children with autism to ask "What's happening?" and "What happened?" during storybook activities (Koegel, Carter, & Koegel, 2003). In a longitudinal study, children who used, or were taught to use, these types of communicative initiations had better long-term outcomes and were perceived to appear more developmentally appropriate on normalcy scale ratings than adolescents and young adults with autism who did not use these self-initiated queries (Koegel et al., 1999).

Along with responding to peer initiations, initiations have also been taught in the context of play, such as approaching a peer or commenting on a joint activity. In one study, Pierce and Schreibman (1995) explored the use of peer-mediated strategies to increase social behaviors in children with autism. In particular, these authors taught typically developing peers how to use the motivational procedures of PRT with classmates diagnosed with autism. They found that not only were the typically developing peers able to successfully use the PRT procedures, but the students with autism exhibited generalized gains in both maintaining and initiating social interactions. Shabani et al. (2002) also attempted to increase verbal initiations in children with autism toward their typically developing peers during free-play episodes. They found that prior to intervention, although the children with autism responded to questions and initiations from adults, they seldom initiated communication with their peers. By using a tactile prompting device (i.e., vibrating pager), all the participating children increased their frequency of communicative initiations with their peers. Unfortunately, once the prompting device was faded, only one participant demonstrated maintained improvements in initiations. In a more recent study, Licciardello, Harchik, and Luiselli (2008) used preteaching, prompting, and rewards to encourage children with autism to initiate with their peers. Specifically, prior to play periods, the children were provided with instructions,

demonstrations, and behavioral rehearsal. Then, they were provided with child-choice to select both the activity and the play partner. The children briefly practiced the play initiation prior to each play session, and during the play periods, the children were verbally prompted if more than a minute elapsed without any play initiations. In addition, the children were praised and provided with rewards for appropriate play. The intervention resulted in the children demonstrating increases in both social initiations and within their natural free-play settings with their aides. However, no generalization or maintenance data were collected.

As a whole, these studies highlight the importance of child initiations. The positive long-term outcomes of children who initiate suggest that all children on the spectrum should have social verbal initiations as an integral part of their communication goals. Further, the improvements in socialization associated with interventions explicitly targeting initiations suggest that child initiations may function as another pivotal area for intervention based on evidence for widespread positive effects on other untreated areas.

Peer Interactions

School settings are ideal environments for social interventions because peers are abundant. However, research suggests that even with IEP social communication goals, children with autism rarely interact with their peers (Koegel et al., 2001). In fact, the most common communicative functions of children with autism in school settings appear to be requests, attention-seeking, and engaging in social routines; however, even these limited functions occur very infrequently, ranging from three to four times per hour (Stone & Caro-Martinez, 1990). Even more alarming are data collected in naturalistic settings, suggesting that teachers elicit expressive communication only an average of once per hour, despite recommendations that communication be elicited at a high rate (Chiang, 2008). Lack of communication opportunities has significant implications for children on the spectrum who will likely benefit from frequent and repeated practice (Hwang & Hughes, 2000).

Despite the fact that most children receive little intervention for socialization at school, a number of studies have described effective interventions with peers. For example, integrated play groups in which an adult monitors play initiations, provides scaffolding, structures the play, provides support when needed, and guides social communication can be helpful in promoting social interaction (Wolfberg & Schuler, 1999). Peer-buddy dyads in which children are taught to "stay with, play with, and talk to" a buddy have been shown to be effective in increasing appropriate social skills such as asking for objects, getting the attention of another child, turn-taking, and improving eye contact, even in the absence of an adult interventionist (Laushey & Heflin, 2000). Social skills training with peers can also be incorporated into academic learning tasks. For example, Kamps et al. (1999) conducted peer

tutoring sessions in which academic tasks were provided in the context of group learning, wherein the children learned to share ideas, correct each other's work, give praise, react calmly, provide encouragement, and help others. The procedures resulted in improved academic engagement and attention, as well as significantly higher levels of social engagement for the students with autism as well as their peers.

PRT (described above) also has been taught to typically developing peers in the context of full-inclusion classrooms (Harper et al., 2008). Specifically, triads consisting of two typically developing children successfully learned to implement the intervention during recess with a child with autism. Another study using PRT technique that included getting the child with autism's attention, varying the activities, narrating play, reinforcing attempts, and turn-taking were taught in school settings. These procedures, along with providing the typical peers with cue cards to take on the playground, resulted in improving both the amount of social play between the peers and the number of social initiations exhibited by the classmate with autism (Pierce & Schreibman, 1997).

Fortunately, minimal effort for staff training in these strategies can produce large changes in peer behavior and, subsequently, the child on the spectrum. As little as a few hours of training regarding friendships and specific procedures for working with the child with autism and Asperger's Syndrome has been shown to greatly increase the number of peer initiations and the child with autism's interactions with peers (Owen-DeSchryver et al., 2008).

Priming

Priming involves previewing or practicing activities before they are presented. Research in the area of academics has shown that if activities are presented to the child the evening before they are introduced in class, children with autism engage in significantly lower levels of disruptive behavior and much higher levels of academic engagement and performance (Koegel et al., 2003; Wilde, Koegel, & Koegel, 1992). Although priming was originally developed for improving academics, the effectiveness of this strategy has also been demonstrated in social areas. For example, Zanolli, Daggett, and Adams (1996) taught preschool children with autism to request toys, show items, and use requests to see another child's item. Three 5-minute priming sessions were implemented per week for 6 to 12 weeks with 10 to 14 trials provided during each session. The procedure was conducted first with dyads, then later with the whole class, and eventually faded. Priming resulted in increased play initiations by the child with autism toward typical peers, with as many as six different initiation topographies, including novel behaviors (e.g., saying the peer's name, smiling, and saying "I want that"). However, the authors indicated that generalization to new activities did not occur. Thus, more research assessing whether multiple exemplars or implementation of priming in more contexts would result in durable,

widespread gains is warranted. Yet this initial work underscored that priming is effective in increasing social initiations and can be conducted within the context of peer dyads as well as with an entire classroom.

Moreover, in another study, Sawyer et al. (2005) showed that priming, in the form of verbal instruction, was effective when used as a component of an intervention package. The package included prompting and rewards for targeted verbal comments and physical sharing in an integrated preschool classroom. The study demonstrated that with a package intervention that incorporated priming, preschoolers could learn to share and request to share toys with their peers.

In an adaptation of the original priming procedures, Schreibman, Whalen, and Stahmer (2000) used short, 1- to 4-minute video clips to prime children with autism who demonstrated disruptive behavior during transitions into community settings. The tapes did not show models engaging in the transition but simply successfully entering the community setting that was problematic for the child with autism. Results indicated that the procedure was effective with maintenance and some generalization observed across activities.

More recently, Gengoux (2007) used priming to increase the verbal initiations of children with autism during play episodes in natural settings with their typically developing peers. This study used short, low-demand practice sessions during which the child with autism practiced a preferred play activity before it was introduced at the child's full-inclusion setting. The study showed that although all of the participants exhibited low levels of initiations toward peers prior to the study, with priming, children on the spectrum significantly increased their rates to levels comparable to that of their typical peers.

Priming techniques are particularly promising as they do not require the interventions to be implemented in the setting where the problem behaviors are occurring. That is, if individuals engage in disruptive or asocial behavior, they may develop a negative history with peers or other community members that can reduce their likelihood of being welcomed into that environment. Furthermore, for older individuals and adults on the spectrum, this procedure has the advantage of decreasing stigmatization that may occur when an interventionist is present and intervening in natural settings. Overall, such antecedent interventions decrease the possibility of these potential adverse consequences by programming the positive behavior to occur *a priori*.

Incorporating Ritualistic Themes and Using Perseverative Interests

Many individuals with autism (particularly those with fewer support needs) and Asperger's Syndrome demonstrate circumscribed interests. In fact, it appears to be the norm rather than the exception, with 75% of younger children and 88% of older children on the spectrum engaging in circumscribed interests (Klin et al., 2007). The interests usually focus around

memorization of facts and can greatly interfere with everyday activities and socialization (Klin et al., 2007). One successful area of intervention research has focused on incorporating these highly motivational individual topics or themes into socially appropriate games. For example, Baker, Koegel, and Koegel (1998) selected children who showed little to no social interaction with their peers at lunch recess and exhibited areas of extreme restricted and repetitive interests. The children were taught a socially appropriate game using these perseverative interests by developing them into themes of an activity that could only be played with a group of children (e.g., one child who was highly interested in maps and knew all his states was taught to play a variation of tag on a large outline of a U.S. map that was painted on his playground). These activities increased the social interactions of the children with autism, and generalization across other activities following the implementation of intervention. Also the intervention capitalized on the child with autism's interests and areas of knowledge such that the child was eventually perceived as a highly valued member of the peer group.

In a related study, Baker (2000) showed that the procedure was also effective for increasing socialization between children with autism and their typically developing siblings. The intervention resulted in the generalization and maintenance of socialization between the siblings, joint attention, and improved affect. Interestingly, although the ritualistic behaviors were used as the basis of the social game, no increases in the frequency of the ritualistic behaviors were noted during other times of the day. Thus, these findings underscore that incorporating circumscribed interests into intervention may be especially promising given that there appears to be a collateral gain in the improvement of other untargeted pro-social behaviors. These additional gains are important given that even among young nonverbal children or children with limited language, joint attention increased in these circumstances (Vismara & Lyons, 2007). Since joint attention is a precursor to the onset of verbal communication (Mundy & Crowson, 1997; Toth et al., 2006), is social in nature, and is often limited or absent in children with autism interventions that have the collateral effect of improving untreated behaviors, such as joint attention, are especially worthy of study (Bruinsma, 2005; Vismara, 2006).

Clubs

A number of studies have recruited a group of typically developing students to support students with autism in their natural environments. In the 1980s, the Circle of Friends (CoF) program was developed for individuals who were moving from institutions into community settings but eventually was adapted for use in mainstream school settings (Haring & Breen, 1992). The procedure involves enlisting a group of classmates during a classwide meeting and then setting up a "circle" of friends who help provide support for a child with

special needs. The group also sets up, monitors, and reviews weekly targets in regular meetings that are facilitated by an adult (Frederickson, Warren, & Turner, 2005). One persistent issue that has arisen in these short-term programs and clubs is the lack of generalization and maintenance over time (Frederickson, Warren, & Turner, 2005). However, some have suggested that simultaneously targeting peers *and* the child on the spectrum may create more durable improvements in socialization (Kamps et al., 1992). In another study, Talebi (2008) formed lunch clubs at school based around the individualized interests of adolescents on the spectrum. These motivational activities resulted in improved social engagement, higher levels of social initiations, and generalization of these gains at later times and across other contexts. Thus, it appears that the most effective programs involving groups of children consist of targeting both typically developing peers and children on the spectrum, building on activities that will be mutually motivating to the child on the spectrum and the peers, and are conducted over a long period of time. The continued use of interventions involving groups of peers appears vital, given evidence that long-term generalization in the absence of clubs or "circles" has been elusive.

Video Modeling

Relatively recently, researchers have begun to incorporate video modeling technology in social interventions. Video modeling requires participants to watch videotaped demonstrations of a target behavior being performed (Charlop & Milstein, 1989) or videotaped segments of themselves (Falk, Dunlap, & Kern, 1996). The goal of these interventions is to teach individuals to either imitate the behaviors they observe or receive feedback on their own behavior. Video modeling may be especially effective among individuals with autism who have particular difficulty with picking up social cues in the complex, everyday environment. Specifically, video modeling may help the individual with autism identify who to imitate and what behaviors to model within specific contexts, as the clips can provide clear and appropriate frames of reference (McCoy & Hermansen, 2007). The success of video modeling interventions for children with ASDs may be attributed to their strengths in visual processing skills. Other benefits include the increased capability to gain a participant's attention while minimizing irrelevant features, thereby reducing the likelihood of problems associated with overselectivity (Bellini & Akullian, 2007).

In fact, video modeling interventions have been shown to be effective in teaching individuals on the spectrum a variety of social skills, including social initiations, play, perspective taking, compliment-giving, and conversational skills. For example, one study by Nikopoulos & Keenan (2004) examined the effects of video modeling on social initiations and play behaviors in three children with autism. Participants viewed a videotape of a typically developing peer and an

experimenter engaged in social interactive play. After watching these clips, the participants were observed during a play session. Results showed that both social interactions and reciprocal play skills improved, and the effects were maintained even after a 3-month follow-up period. Another study by LeBlanc et al. (2003) used video modeling and reinforcement to teach perspective-taking skills to three children with ASDs. The children viewed a video of an adult successfully completing two target tasks that included an explanation of why the model's behavior was correct. After viewing the video, each participant was asked perspective-taking questions until the participant provided three consecutive correct responses. At baseline, all children failed the tasks; however, video modeling with reinforcement was associated with all three children mastering the tasks and two of the three children generalizing these behaviors to other similarly related tasks.

An additional benefit of video modeling is that it may also be time- and cost-efficient, especially in comparison to in vivo modeling. A study by Charlop-Christy, Le, and Freeman (2000) compared the effectiveness of video modeling versus in vivo modeling for teaching social, communication, and daily living skills to five children (ages 7–11 years) with autism ASDs. The study used adult models performing various tasks at an exaggeratedly slow pace, either live or on video. Results demonstrated that video modeling led to faster acquisition of skills and greater generalization effects relative to in vivo intervention. Moreover, video modeling has been associated with maintenance and generalization of behavioral gains. For example, Charlop and Milstein (1989) demonstrated that video modeling not only served as an effective intervention strategy for increasing conversational speech in three children with ASDs but the skills maintained and generalized for all three participants at a 15-month follow-up.

Like most interventions, studies have suggested that video modeling is most successful when other interventions such as practice, self-management, or peer training are also simultaneously incorporated (Scattone, 2007). For example, Apple, Billingsley, and Schwartz (2005) focused on teaching compliment-giving responses and initiations to two boys with autism (age 5 years) through video modeling. Their study showed that there was limited generalization with the single strategy, but the employment of tangible reinforcement and self-management strategies served to improve treatment and maintenance effects.

The results of several studies have shown that both the nature of the model/learner relationship and the length of the model/learner relationship are particularly important factors in the degree of success of video modeling interventions (Jones & Schwartz, 2004). The literature indicates that when a video model is familiar to a participant, the intervention is more likely to be effective. Given this finding, some researchers believe that video self-modeling (VSM), which involves the observation of videotapes of oneself performing desirable target behaviors, may be an effective form of intervention.

A meta-analysis by Bellini and Akullian (2007) reviewed 23 single-subject design studies assessing the effectiveness of VSM for children and adolescents with ASDs. Intervention effectiveness was determined by examining the direct effect of intervention, maintenance, and generalization of behavior gains of both video modeling and VSM interventions. The overall results suggest that video modeling and VSM are effective intervention strategies for addressing social communication skills and behavioral functioning in children and adolescents with ASDs. Three of four studies that used video modeling and VSM to address social/conversation skills demonstrated that video modeling and VSM interventions both effectively foster conversation skills and promote the maintenance of skills over time and across different situations. The review included a study by Buggey (2005), which examined the effects of VSM with older elementary school children with autism. The participants watched a 3-minute video showing themselves engaging in positive and typical social interactions prior to the start of class. Following VSM, significant gains in the frequency of social interactions within the school setting were observed and maintenance of skills was shown to be 100%.

Moreover, Thiemann, and Goldstein (2001) incorporated video feedback with other intervention techniques to teach young children (ages 7–12 years) peer-directed social communication skills. Target behaviors included securing attention, initiating comment, initiating request, and contingent responses. Participants received 10 minutes of visual instruction using social stories, text cues, and pictures of social skills. The children engaged in 10 minutes of social interaction and subsequently participated in 10 minutes of video feedback. In these video feedback sessions, participants evaluated unedited videotapes of themselves from the previous social interaction. The participants demonstrated improved and consistent rates of social interactions compared to baseline. Following intervention, all raters reported improvements in reciprocal social behaviors between the participants and their peers. In particular, the participant's active involvement in the interaction, use of comments or questions, and responses to peers' utterances increased.

Although effective, the issue of long-term generalization of video modeling effects is always a concern, particularly when scripted utterances are taught. For example, Taylor, Levin, and Jasper (1999) used video modeling to increase play-related statements of two children with autism to their siblings. Although scripted comments improved significantly for each participant, unscripted comments did not increase using only the video modeling. Yet, as mentioned above, a combination of programs may enhance generalization. The use of multiple exemplars may also improve generalization. Maione and Mirenda (2006) assessed the effectiveness of video modeling and video feedback in instructing a child with autism (age 5 years) to use peer-directed social language during play. Results suggested that video modeling was effective in significantly increasing social language in two of the three play activities. Additional intervention consisting of the participant evaluating appropriate and inappropriate verbalizations, providing examples of appropriate verbalizations, and prompting

by the clinician resulted in a significant change in social language. Increases in the desired unscripted verbalizations and initiations were also noted. Thus, to increase and extend generalization effects, video modeling studies may benefit from the inclusion of individualized multiple exemplars.

Self-Management

Self-management is a procedure that teaches individuals to monitor their own behaviors (Quinn & Swaggart, 1994). Following appropriate engagement in targeted desired behaviors, individuals are taught to self-monitor the behavior. The individual is then rewarded by others or they are taught to deliver self-reinforcement. The value of self-management is that it is an instructional strategy, whereby the locus of control for the behavior is shifted from an external source, such as a teacher, therapist, or parent, to the individual (c.f., Jones, Nelson, & Kazdin, 1977).

Self-management and self-control, and the lack thereof in individuals, has long been discussed in the psychological literature, but systematic interventions using self-management only began to appear in the literature in the early 1970s. These early studies generally focused on typical adults addressing behaviors such as weight reduction (Horan & Gilmore, 1971), cigarette smoking (Chapman, Smith, & Layden, 1971), depression and other psychological difficulties (Mahoney, 1971), poor study habits, addictions, stress, and so on (*see* Yager, 1975). It wasn't until the late 1970s that research began to emerge suggesting that self-management may be a viable option for individuals with disabilities, such as mental retardation (Horner & Brigham, 1979; Wheeman, 1978) and learning disabilities (Edwards, 1976). In the mid-1980s, the procedures began to be implemented with individuals with more severe disabilities (Morrow & Presswood, 1984; Shapiro et al., 1984).

Finally in 1990, self-management procedures began being applied to individuals with autism. Koegel and Koegel (1990) showed that stereotypic behavior could be reduced by using self-management during academic tasks in a full-inclusion classroom and in community settings. This study was particularly important because in addition to demonstrating the effectiveness of the procedure among children with autism, it provided a framework for the programming of desired behavior in the absence of a treatment provider. Following this study, the procedures were replicated for improving play (Stahmer & Schreibman, 1992), and a 1-month maintenance of behavioral gains was observed even after removal of the interventionist and self-management device. In regard to communication, self-management procedures also have been adapted for use with social interactions in children with autism. Koegel et al. (1992) taught elementary-aged children, who initially were unresponsive to others, to monitor their social responsiveness to questions. All children improved their responsiveness and the behaviors generalized to home, school, and community settings in the absence of a treatment provider. Further, when the children were self-managing their behavior, concomitant decreases in untreated disruptive behaviors were evidenced.

Loftin, Odom, and Lance (2008) used a combination of self-management and peer training strategies to teach social initiations to three children with autism to target social conversation. Results demonstrated improvements in peer social interactions, collateral changes in the reduction of self-stimulatory behaviors, and generalization of these behaviors. In another study, Koegel and Frea (1993) showed that pragmatic behavior could be improved and that response classes appeared to be positively affected during intervention. Specifically, they targeted one or two pragmatic behaviors, such as eye gaze and nonverbal inappropriate mannerisms or topic perseveration, in children with autism who had mild support needs. The study showed that other, nontreated, pragmatic behaviors improved as a result of the self-management. This suggests that some pragmatic behaviors may function as a response class and that interventions targeting individual behaviors within a class may not be necessary.

Similarly, self-management has been successfully used in full-inclusion school settings, with demonstrated decreases in inappropriate and challenging behaviors and improvement in on-task behaviors (Harrower & Dunlap, 2001; Koegel, Harrower, & Koegel, 1999; Koegel et al., 1999). Appropriate question-asking using self-management also has been effective among teens and young adults with autism. Palmen, Didden, and Arts (2008) showed that question-asking improved after a relatively short intervention program of weekly 1-hour sessions for a duration of 6 weeks. These effects were maintained after a 1-month follow-up period.

Although self-management can indeed be a useful tool for individuals on the spectrum, fading of the self-management may be more challenging in individuals with greater support needs (Koegel et al., 1992). However, although there is a need for additional research, it appears that as individuals become more fluent with the targeted behavior, systematic fading may be possible (Boettcher, 2004).

Conclusion

The importance of communication and socialization for typically developing individuals is well-documented in the literature, and research over the past six decades has given us invaluable information about how these processes develop and interact (Landa, 2008; Paul, 2008). Evidence for the myriad of difficulties individuals with ASDs experience in social communication is also robust (Alpern & Zager, 2007; Paul et al., 2005). Addressing social communication issues to ensure that individuals on the spectrum have healthy and long-term friendships and relationships needs to be a priority in the area of ASDs. As previously discussed in this chapter, communication and socialization are inextricably intertwined, and recent research has confirmed that the linguistic outcomes of individuals with autism explicitly affect social

ability (Bono et al., 2004). This is important given research indicating that individuals with ASDs may be prone to poorer long-term outcomes. Individuals with disabilities have been found to be involved in the criminal justice system at much higher rates than persons without disabilities (Mayes, 2003; National Research Council, 2001). Overall, these findings highlight that social and communicative interventions may contribute to better outcomes.

It is apparent that several important themes emerge in the literature on language and social communication. First, a combination of inter-related programs that are simultaneously implemented may be more effective than single, isolated interventions.

Second, frequent exposure to social communication opportunities and prompting (with subsequent fading) of targeted linguistic structures appears to be important. Children on the spectrum who are learning language and social communication skills may need frequent engagement in these behaviors. Unfortunately, opportunities for expressive social communication are infrequently elicited by teachers of children with autism (Chiang, 2008). Training teachers to evoke language and communication on an ongoing basis may potentially improve the socialization of children on the spectrum with ongoing carryover to the home through parent education (Koegel et al., 2005). Further, models that rely solely on pull-out approaches for language and social intervention are not likely to result in generalization and maintenance. However, developing comprehensive models in which school speech/language pathologists, teachers, aides, and other interventionists implement sessions in the natural environment, while also training relevant peers and adults in those environments, should result in more effective generalized intervention results.

Along with providing frequent, regular, and systematic opportunities for social communication, intervention should focus on the positive occurrences and strengths of the child with autism (Cosden et al., 2006). Expanding on the child's strengths results in improved affect and increased generalization (Baker et al., 1998).

There is no doubt that inclusion with typical peers in natural and community settings is essential. Not only do children with autism have more frequent social interactions when they are included with typical peers rather than segregated settings (Brookman et al., 2003; Kamps et al., 2002; Kennedy & Shukla, 1995; Koegel et al., 1999), but issues of generalization do not arise when intervention takes place in inclusion and community settings (Albin & Horner, 1988; Koegel & Koegel, 1988; Licciardello et al., 2008). Further, ecologically valid social goals can be developed, increasing the likelihood that they will be used by the individuals and peers in those specific environments (Frederickson et al., 2005).

Moreover, within these natural settings, targeting both the child with autism *and* the typical peers has tended to be more effective than targeting either separately. Typical children can be of great support and role models for children on the spectrum (Harper et al., 2008; Pierce & Schreibman, 1997).

Teaching specific procedures to typical peers to enhance socio-communication goals has proven to be beneficial to both typically developing children and those on the spectrum.

Finally, spontaneity has emerged as an important pivotal area for children with Asperger's Syndrome and autism (Koegel & Koegel, 2006; Koegel & LaZebnik, 2009). Historically, intervention has been primarily adult-driven and adult-structured (Landa, 2007; Koegel et al., 1987). Teaching and creating opportunities for spontaneous self-generated communication (Koegel & LaZebnik, 2004) seems to result in more pragmatically appropriate interactions and improved long-term outcomes (Koegel et al., 1999).

In conclusion, most children with autism or Asperger's Syndrome receive little to no intervention for social communication throughout the day in school settings where peers are readily available. It has been clearly documented that multi-component interventions targeting both the child on the spectrum and the typically developing peers are effective in improving social communication and social interaction. Although longitudinal studies are still necessary, comprehensive interventions beginning in the preschool years and throughout the lifespan positively improve the social interactions of individuals on the spectrum. When individuals on the spectrum engage in improved social interactions, loneliness and isolation are likely to be reduced, sexual victimization and perpetration resulting from naïveté may become less frequent. That is, intervention may act as a potential barrier against the development of comorbid conditions, including depression and anxiety. There is evidence showing that interventions targeting the development of positive social interaction among children with ASDs and their peers can have an immediate effect on increasing positive affect (Baker et al., 1998; Koegel et al., 2005) and reports on self-esteem (Elder et al., 2006). Continued research on the long-term impact of social skills-based interventions—particularly using measurements of psychological well-being (i.e., symptoms of depression, anxiety, self-worth)—will undoubtedly be a growing area of clinical and theoretical exploration. In the meantime, the impact of social skills training in other populations may provide some insight into this matter. For example, in assessing the effects of a social problem-solving skills training program in adults with intellectual disabilities, Anderson and Kazantzis (2008) found that intervention was associated with an improvement in not only social-problem solving skills but also, for two of the three participants, symptoms of depression as well. The study is promising given that changes in symptoms of depression were observed after a relatively short duration of 15 sessions and suggests that a more long-term intervention in this domain may have widespread benefits on psychological well-being. In addition, there is some evidence supporting the notion that psychosocial interventions incorporating social skills training may prevent and improve symptoms of depression in typically developing children (Garber, 2006). Additionally, according to a review by Segrin (2000), most effective interventions for treating depression involve an emphasis on augmenting the social skills. Therefore, there appears to be a unique relationship

between social skills difficulties and psychological distress that may help guide the future direction of research and, particularly, the measurement of outcomes of intervention in the ASD population.

Challenges and Future Directions

Longitudinal studies indicate that many adolescents and adults on the spectrum experience poor psychological health and continued dependence on their parents or other care providers. In an effort to alter this problematic trajectory, future theoretical and intervention research should focus on pivotal areas to ensure that individuals on the spectrum achieve a life of independence with meaningful social relationships. Continued research to assure that interventions are systematically implemented and to define areas that have the greatest long-term impact is needed. Comprehensive intervention packages, and their longitudinal effect, are undoubtedly an important area of future research. Inclusion in school and community settings has proven to be superior in regards to academic and social progress. In addition, multicomponent intervention programs, targeting both the individual on the spectrum and the typical peers, has also resulted in greater outcomes. However, more research on specific target behaviors that, when targeted, yield the greatest generalize effects, specific teaching strategies that are most effective, preparation and success in the work setting, and understanding the development and creation of durable friendships and intimate relationships will need to be studied and understood in future research. Below is a list of challenges and ideas for future research directions.

- There is still a great need for the development and investigation of outcome measures to accompany intervention research to more comprehensively reflect changes in social and communication symptoms as well as collateral gains in other meaningful psychosocial variables, such as emotional functioning.
- As discussed above, many individuals with ASDs do not develop relationships, despite their desire to do so. Research focused on identification of additional social communication skills that may contribute to enhancing immediate and long-term social success continues to be an area of need.
- Related, research is needed to both appropriately assess and target social communicative skills according to the developmental demands present in different age groups, which will have the greatest impact on long-term development, so that adolescents and adults with autism can more easily adjust as socialization becomes more complex.
- Similarly, intervention components and procedures that contribute to the long-term maintenance of treatment gains over time, once intervention has been completed, is critically important. For example, given that the data from many interventions for social areas suggest that these effects may not entirely generalize and maintain

over time, in addition to the fact that developing "friendships" are often more difficult for individuals with ASDs, intervention components that may be more helpful with such long-term gains would be helpful.
- Understanding the motivational or behavioral characteristics of children who generalize social or communication skills compared to those who have more difficulty with generalizing treatment gains over time or across contexts would help inform the development of specialized interventions to address the different needs of children with ASDs. Doing so may also prove helpful in providing more robust findings of intervention effects across different children.
- Further examination of the interplay between the three core ASD symptoms, how such effects can contribute to social and communicative impairments, and the development interventions to address these contributing difficulties is important. For example, additional research on the impact of restricted interests on the overall functioning of ASDs and interventions to address these symptoms may an important factor in improving social difficulties.
- Expanding the application and conceptualization of existing interventions, such as those that are effective in improving for initiations and the use of priming for activities, to further develop and identify strategies to improve social and communicative functioning.
- Further development and understanding the role of motivational variables on early social and communicative functioning and how to use existing intervention strategies to tap into the development of successful social interactions may be helpful.
- Research that examines the longitudinal effect of targeted social communicative interventions on the development of romantic relationships in people with ASDs may help individuals with ASDs lead more fulfilling lives.

Occupational Therapy

Points of Interest

- Occupational therapy intervention for individuals with ASDs acknowledges the strengths and needs of the individual as embedded in and inseparable from the larger whole of meaningful daily life activities and social relationships.
- Individuals with ASDs and their larger social and cultural environments (e.g., families, school or work settings) are in constant interaction, each influencing and being influenced by the other. Therefore, those social and cultural contexts must be included in occupational therapy assessment and intervention processes.
- Similarly, the physical and temporal contexts of participation must be acknowledged and considered to ascertain how the individual with ASD "fits" into the particular situation and so that intervention strategies can be designed to address lack of fit.
- The meaning or value that an individual with ASD finds in various occupations and daily routines may differ significantly from that of persons without ASD, warranting careful attention to patterns in behavior that reveal motivation or purpose, and support intervention.
- Empirically supported strategies and approaches used by occupational therapists in addressing the needs of individuals with ASDs may be based on work from both occupational therapy and other fields, including education, psychology, and speech/language pathology. These strategies combine with a deep understanding of occupation and the wide array of factors that influence successful participation in daily life and result in individualized, comprehensive approaches to support participation for individuals with ASDs.
- Ongoing and future research endeavors for occupational therapists include work toward early identification, development of valid assessment tools, investigation of efficacious intervention approaches, as well as the further examination of the occupational experiences, values, and goals of people with ASDs and their families and significant others across the lifespan.

Introduction

Children, youth, and adults with autism spectrum disorders (ASDs) often find it difficult to participate successfully in one or more daily life activities or routines and to participate socially in family and community life. In addition, family members and other primary caregivers of individuals with ASDs often find their own participation in daily life difficult to orchestrate (Lee et al., 2008). Research indicates that both individuals with ASDs and their families often experience poorer quality of life, more social isolation, and/or a narrower range of life activities than do those who do not have ASDs (Donovan et al., 2005; Lee et al., 2008; Cederlund et al., 2008). Because occupational therapists are concerned with the ability of people, both individually and collectively, to participate meaningfully in these daily life activities and routines (occupations), as well as the social connections they imply, they are able to offer support and services to people with autism and their families in a variety of ways. Settings for occupational therapy service delivery may vary across the lifespan but often include early intervention settings, schools, family home, group homes, supported employment, outpatient clinics, mental health settings, and community-based programs.

The scope of occupational therapy practice includes a primary focus on enhancing participation in personal activities of daily living (e.g., basic self-care tasks), instrumental activities of daily living (e.g., meal preparation, financial management, care of pets), formal and informal education, work (including volunteering), play (e.g., constructive, social, symbolic, and outdoor play), and leisure (e.g., hobbies, restorative activities),

and social participation at the levels of community, family, and friendships. Patterns, routines, and habits in these areas of occupation are addressed, as are the social, communication, sensory processing, cognitive, emotional, and motor aspects of occupational performance. In working specifically with people with ASDs, occupational therapists consider both core and associated features of the disorder in terms of their influence on patterns of and participation in occupation and identify strengths as well as areas of need in an effort to optimize engagement and participation in these occupations.

The DSM-IV-TR (APA, 2000) identifies core characteristics of autism as qualitative impairments in social interactions, qualitative impairments in communication, and restricted, repetitive, and stereotyped patterns of behavior, interests, and activities. Differences in sensory processing have also been documented as an associated feature in many individuals with ASDs (Kientz & Dunn, 1997; Baranek et al., 2006; Tomchek & Dunn, 2007) and appear correlated to core features (Ben-Sasson et al., 2009; Boyd et al., 2010; Gabriels et al., 2008; Hilton, Graver, & LaVesser, 2007). The influences of these core features and commonly associated characteristics on occupational participation can be significant. For example, tooth brushing may be a very difficult and unsatisfactory routine for both parent and child because of sensory processing difficulties and communication deficits that exacerbate the problem by limiting the ways the child has to let the parent know about the specific problem (i.e., is it the bristles of the brush, the texture, smell or taste of the toothpaste, or the echo of the parent's voice in the small tiled bathroom that are aversive?). Similarly, the inclusion of a 10-year-old with autism in outdoor play with his class may be quite limited by the child's insistence on repetitive play sequences, an overfocus on one particular aspect of the play, and/or difficulty managing the spontaneous nature of social interactions during the play.

The role of occupational therapists working with people with ASDs may include the following:

- Assessing the participation of those with ASDs in the occupations that are meaningful to them and/or to others involved with them, levels of satisfaction with that participation, and the contributions of that participation to quality of life. Both strengths and needs should be identified in the assessment process.
- Planning, implementation, and review (evaluation) of intervention (individual-, group-, or population oriented) that facilitates successful participation in daily life occupations
- Using educational and consultative models of service delivery to support families, teachers, other service providers, friends, and others in the community (coaches, religious leaders, scout leaders, etc.) who live, work, or play with individuals with ASDs
- Developing, contributing to, and/or disseminating results of programs of research that focus on early identification, development of relevant, functional assessment

tools, trajectories of life participation and assessment of needs across the lifespan, and both early and lifespan interventions.

The remainder of this chapter will focus primarily on the occupational therapy processes of assessment and planning, implementing, and reviewing intervention for people with ASDs, as well as the use of education and consultation to support family members and others. The role of occupational therapists in research will be addressed briefly at the end of the chapter and under "Future Directions." We begin with the presentation of a conceptual framework that informs the delivery of occupational therapy services, and the ways in which this framework may be applied in practice to individuals with ASDs and their families and caregivers. A number of empirically supported strategies are included in the discussion of intervention and in case examples, but an extensive examination of the wide variety of specific intervention approaches and strategies that may be used by occupational therapy practitioners is beyond the scope of this chapter. (For more information on specific intervention approaches, please *see* Miller-Kuhanek, 2004; Baranek, Wakeford, & David, 2008; and Case-Smith & Arbesman, 2008.) Also, much of the discussion that follows addresses occupational therapy intervention for an individual with ASD, but because that individual is part of an important social context (e.g., family) the word "client system" in this chapter will be used to denote the individual and those key others as a single entity.

Participation in Occupational Situations

We use the term *occupational situation* to denote not only the daily life activity or routine (occupation) in which the individual needs or wants to participate but also the conditions surrounding that occupation, such as the physical, social, and cultural environments, as well as the temporal context (e.g., time of day, sequence of steps within the activity). Figure 63-1 shows the components of the occupational situation in relationship to one another, with participation in the occupation at the center, embedded in the contextual components. Because the occupational situation is a transactional (or dynamic) system, the two larger sets of arrows are used to represent the ongoing transactions that occur among contexts and participation (i.e., one's participation in an activity is influenced by context, and context is ultimately influenced by the fact that one is participating in something within it). There is a similar transaction that occurs that links all the individuals in the social context with one another and with all other contexts, as well as with the occupation itself, and these are represented by the smaller arrows to and from the person symbols. When considering the participation of a particular individual (the lighter person symbol in Figure 63-1), that individual is still embedded in the social context rather than

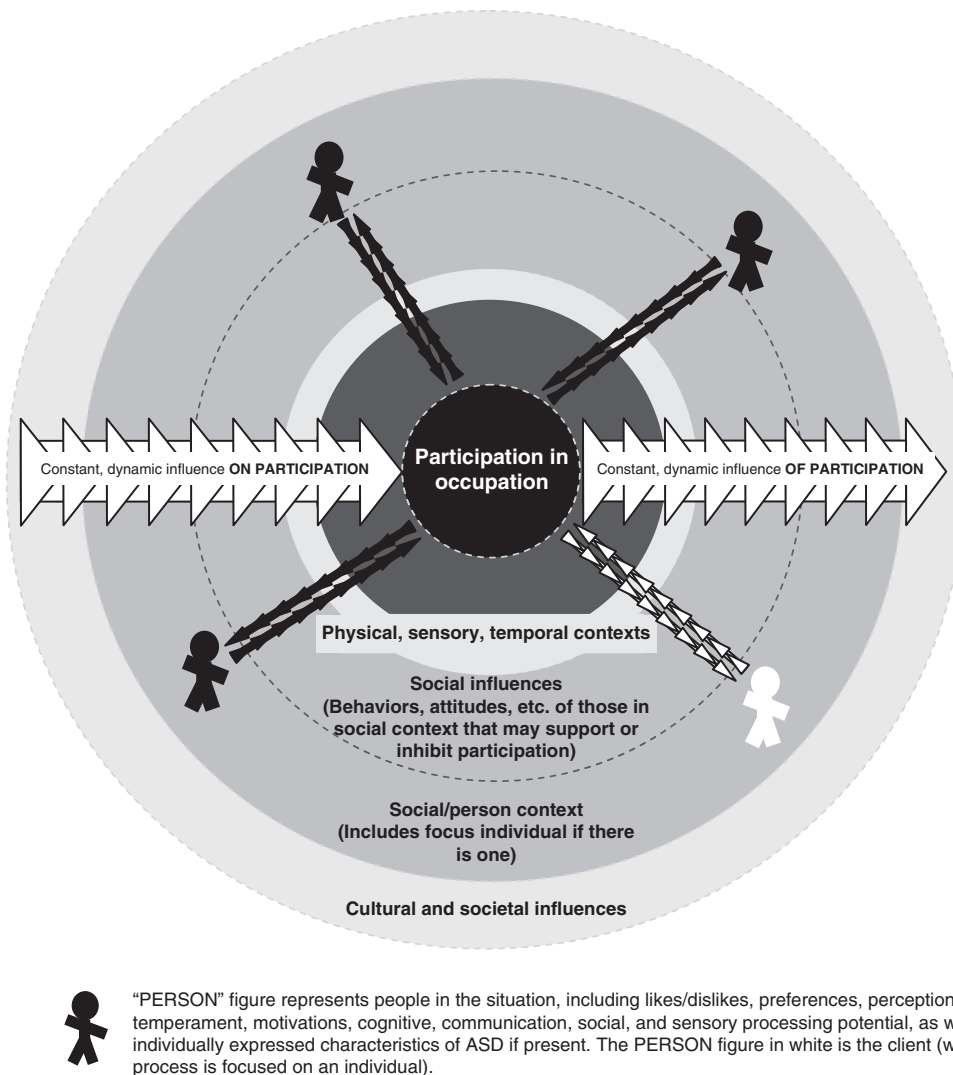
"PERSON" figure represents people in the situation, including likes/dislikes, preferences, perceptions, temperament, motivations, cognitive, communication, social, and sensory processing potential, as well as any individually expressed characteristics of ASD if present. The PERSON figure in white is the client (when the process is focused on an individual).


Figure 63–1. Participation in Occupational Situations (POS). "Person" figure represents people in the situation, including likes/dislikes, preferences, perceptions, temperament, motivations, cognitive, communication, social, and sensory processing potential, as well as any individually expressed characteristics of ASDs if present. The person figure in white is the client (when the process is focused on an individual).

separated from it. Although the Participation in Occupational Situations (POS) framework represents a conceptualization of occupational participation in general (i.e., it is not a "disability model"), its use to guide intervention for individuals with ASDs enables a perspective that views strengths or successes as easily as it does weaknesses or needs and allows for the use of a broader range of empirically supported interventions and translational research initiatives than does the use of approaches that target specific factors within the individual. More specific approaches (e.g., sensory processing, behavioral models, etc.) might be helpful as a part of overall intervention planning but are limited in their ability to provide a foundation for reasoning about *all* the contexts and factors that contribute to the ability of the person to participate in meaningful daily life activities.

From Conceptualization to Practice

The bridge between the conceptual foundations of occupational therapy and the practice itself is the practitioner's use of the most reliable, valid, and relevant evidence available, in concert with his/her own clinical reasoning and experience. Evidence-based practice in occupational therapy for people with ASDs includes the use of research, other relevant literature, information directly obtained from the client, and the expertise of the practitioner in areas that include the diagnosis itself and related or comorbid factors, tools, and methods for assessment; intervention strategies; methods of service delivery; family or caregiver concerns; specific occupations/activities; and/or the influence of contextual issues on occupational

performance. The assessment process is informed by information about the development and psychometric properties of evaluation tools to determine their appropriateness for use with an individual with ASD. Many tools used for evaluation of people with other diagnoses or functional difficulties were not developed or standardized in a manner that makes them relevant or useful for those with ASDs, making the selection of evaluation tools a key first step in the occupational therapy process for this population. Similarly, intervention planning is incomplete without the examination of the evidence that supports action plans and specific intervention strategies, and this examination extends to information shared and recommendations made when the therapist is engaged in consultative modes of service delivery as well (Tickle-Degnen, 2002). The evidence may come from a variety of sources, and although research literature is typically considered the strongest evidence, all evidence should be examined for its integrity and its applicability to the specific client situation in question. In a recent study supported by the American Occupational Therapy Association's Evidence-Based Literature Review project, Case-Smith and Arbesman (2008) present a synthesis and review of interventions that may be used in occupational therapy practice with people with ASDs, categorized into six areas (sensory integration and sensory-based interventions; relationship-based, interactive interventions; developmental skill-based interventions; social-cognitive skills training, parent-directed or parent-mediated approaches; and intensive behavioral intervention). When tools, approaches, or strategies for which there is little or no solid evidence are included in an assessment of intervention plan, that plan should also include the systematic, well-documented collection of data to determine the efficacy of those strategies for the particular client. In addition, reliable, relevant evidence should be used not only in the planning of assessment and intervention but also as part of the ongoing process of re-evaluating and revising those plans (Tickle-Degnen, 2000).

Assessment

Although the occupational therapy assessment process may begin with a referral based on a specific need, the practitioner typically is interested in gathering as holistic a perspective on the client, typical environments, and desired or necessary occupations as possible. This is accomplished through a combination of interview methods (directly with the client and/or caregivers), structured and unstructured observations, and, at times, the administration of standardized assessment tools. Adherence to recommended practices that include client- and family-centered approaches dictates that the concerns, priorities, and desired outcomes of the individual and family/caregivers be considered central to the occupational therapy process (AOTA, 2008), so identifying those priorities and goals during the assessment is critical. Occupations that may be identified as challenging for young children with ASDs include many self-care activities, such as brushing teeth,

washing hands, toileting and feeding, as well as constructive (building), symbolic, social and outdoor play, and, as children get older, pre-academic and academic tasks such as coloring, drawing, and writing may be added to the list of occupational challenges. Outings and errands in community settings such as a restaurant, the grocery store, or public library may be difficult, as may participation in religious events and family activities such as birthday parties or going to watch a sibling play basketball. Adolescents and adults with ASDs may have difficulty with many of these same types of occupations that comprise family, school, and community life (Cederlund et al., 2008) and may be in need of support to participate in leisure activities (Hilton, Crouch, & Israel, 2008) and to find and maintain paid or volunteer types of work. Social participation and the development of friendships are challenges faced by individuals with ASDs, regardless of age. Challenges for parents and other family members often include trying to integrate ways to meet their own needs for participation in various aspects of life with the need to provide structure, support (social, emotional, and financial), and treatment opportunities for their family member (DeGrace, 2004).

As the priority occupations are identified, the therapist can also begin to ascertain what current occupations are successful (as it is important to understand what is creating that success), determine the role of the environment in supporting or inhibiting the performance of occupations, and assess the extent to which individual likes, dislikes, temperament, abilities, and characteristics of autism (as expressed in that individual) support or inhibit occupational performance. Elements of occupational engagement and participation that are successful or satisfying and the interests, strengths, and resources of the client can be used both to provide motivation and to support intervention for areas of need.

Examination of the occupational situation (contexts or environments in which key occupations take place) should include consideration of the physical environment (e.g., arrangement and availability of objects, materials, built structures, elements of nature), the sensory characteristics (e.g., the frequency, duration, intensity, novelty, and complexity of different types of sensory input that may occur), the social environment (e.g., who is present, what they are doing and what role they have, how they relate to the client), the temporal context (e.g., time of day, sequences of activity, habitual or routine aspects of what happens in that environment), and cultural context, including broader cultural influences such as behaviors expected from workers in customer service jobs in the United States, as well as group or setting-specific manifestations of culture, such as a preschool teacher's use of the word "friend" for all children in the class, whether or not real friendships are evident among them all.

The individual also brings to the situation his or her own personality, temperament, preferences, perceptions, abilities (including cognitive, motor, sensory processing and communication), learning history, and needs, in addition to the specific characteristics of autism that are individually expressed. To the extent that they influence the performance of various activities

or occupations, these characteristics of the individual should be included in the assessment process. Because the dynamics of participation in occupation are so embedded in the social context, the extent to which the individual is aware of, attends to, and interacts with others should be examined carefully during assessment. Observation and interview methods may yield sufficient information about the individual, but the therapist may administer standardized measures, such as those related to sensory processing and also may use the results of assessments conducted by other members of the team (e.g., speech-language pathologists and psychologists). In addition, the specific likes, dislikes, obsessions, habits, and routines of the individual should be determined, as they not only influence the performance of specific occupations but also provide insight into how occupations may hold meaning. This information is particularly salient for the design of intervention strategies that align with the motivation and strengths of the individual. Table 63-1 lists

resources that may be helpful in conducting an occupational therapy assessment for individuals with autism, although not all of them have been specifically validated for this population.

Of particular importance to the assessment process is an analysis of occupational performance (AOTA, 2008), and this should be included in the assessment process whenever possible. As noted by Polatajko, Mandich, and Martini (2000), consideration of the individual's motivation for, understanding of, and actual ability to perform all or part of an activity must occur during direct observation of the individual performing the occupation in question in a natural context. In addition, the efficiency of performance, the amount and types of assistance needed, and the spoken and unspoken expectations regarding that performance must be understood by the therapist. This direct observation can offer valuable insights into difficulties and successes experienced by the individual and those participating with him/her that are not readily available with other methods of assessment. First, the occupation may hold different meaning for the individual with autism than it would for an individual without autism. Second, the way in which the individual understands or goes about the occupation to be performed may be affected by factors such as overfocus on particular parts of the activity and lack of attention to the activity as a whole, a need for sameness that makes it difficult to try something new, or difficulty expressing verbally what is or isn't understood about the task. Third, the interaction of the individual and the environment may be influenced by subtle or overt factors to which the individual has heightened, diminished, or unusual responses. This applies particularly to the sensory qualities of that environment and may include the frequency, intensity, duration, rhythm, novelty, and/or complexity of sounds, visual stimuli, movement and touch sensations, aromas, and tastes. Performance analysis allows the occupational therapist to observe facial expressions, eye gaze, gestures and other body movements as well as hear verbal communications from the client, all of which yield a much greater understanding of the client's actual experience of the occupation than is available when only interviews or standardized measures are used for assessment. This understanding by the therapist leads, in turn, to the harpist generating intervention strategies that are individualized and contextually relevant, using strengths, and targeting the observed, rather than "imagined," difficulties in performance.

Case Example:

Harold, a charming and relatively easy-going 3-year-old boy with autism, was usually cooperative in basic self-care occupations and particularly loved bath time. He had little expressive language, although receptively he was more competent, and he was able to follow simple routine one-step directions fairly consistently. He demonstrated aversion to high-pitched or sudden loud sounds and was a "picky eater" but otherwise tended to be hypo-responsive to sensory experiences, often needing significant movement, visual, and auditory (such as singing or "silly noises") input to get his attention. One of the

difficulties noted by his mother, Maria, was getting his hair cut. She reported that although she took him to a salon that specifically catered to children, as soon as they pulled into the parking lot, Harold began to get upset and was often hard to get into the salon. Once inside, he could be distracted by the engaging toy play areas in which children and parents could wait or by looking at the selection of DVDs from which children could choose something to watch while getting their hair cut. However, when it was actually his turn and he was encouraged to climb into one of the four barber chairs (which were shaped like animals or vehicles), he began to cry and tantrum, and this often persisted throughout the haircut. Maria questioned whether or not this was a sensory processing issue, although she noted that he didn't mind having his hair combed or washed. Despite what seemed like a rather thorough conversation about this situation between the therapist and Maria, and the generation of several possible intervention strategies, the therapist still felt that until she had actually observed the situation, efficient intervention would be difficult to implement. Therefore, the therapist scheduled one of her next appointments with Harold and his mom for a morning on which Harold was scheduled to get a haircut.

Harold's behavior on arriving at and entering the salon was much as Maria had reported. Although there were other children there playing in the waiting area and getting their hair cut, Harold did not seem to attend to them, even when those in the play area were pointed out to him. As the therapist observed Harold at the DVD rack, she noted that he became over-focused on the Little Einstein™ videos (which he particularly liked), looking at and touching them one by one on the rack, repeatedly. When it came time for him to choose one, however, he had difficulty shifting his attention away from this activity and choosing only one. Maria eventually selected one for him, choosing the one that was his favorite and that he also had at home. Once he was seated in the "truck" seat and the DVD was playing on the small screen in front of him, Harold calmed down. The hair stylist then began cutting his hair with scissors, starting at the back. As she moved to the side, however, Harold began to get upset and swipe at the scissors with his hand. As she backed off, he again calmed down. Observing his facial expressions and eye movements as the hair stylist again tried to cut the hair near Harold's ears, the therapist noted that Harold seemed to catch the stylist in his peripheral vision, disrupting his attention to the video and creating a subtle startle reaction. It seemed that when all his visual attention was on the video, he essentially could "ignore" the stylist. When the therapist noted this out loud, the stylist picked up on the cue, and stayed behind Harold to finish cutting his hair. Harold had no further difficulty until it was time to leave, as he had to stop watching the DVD and give back the case, which he had been holding.

As a result of this performance analysis, the therapist recommended the following beginning intervention strategies:

1. Allow Harold to choose a DVD from among two of his favorites at home, take it with him to the salon, watch it there, and then bring it home again.

2. Have the stylist stay behind Harold to cut his hair (out of his peripheral view).

Four weeks later, at his next hair cut, these strategies were used, and Harold participated in the process without having a tantrum or getting upset. As time went on, the stylist was able to also use an electric razor on the hair on Harold's neck and over his ears, which hadn't been tried before because of concerns about his potential responses to this. Using only Maria's description of the haircut scenario, enhanced by the therapist's questioning, any number of intervention strategies may have been generated, many of which may not have led to a more successful trip to the hair salon. However, given the opportunity to observe and really see how Harold was participating in and reacting to this whole situation allowed the therapist to suggest strategies that targeted the specific problems noted, resulting in an efficient resolution of the problem.

In this example in which "getting a haircut" is the occupational routine, larger socio-cultural influences about grooming and appearance intersected with the values and preferences within Harold's family, creating a situation in which Harold was expected to get his hair cut fairly short every 4 weeks or so. This "haircut" situation also included the social, physical, and sensory characteristics of the environment in the hair salon, some aspects of which were actually supportive of Harold's participation. Harold was good at focusing on the movies he really liked, was careful with the DVD case, and, because of his typical low levels of arousal, was perfectly happy to sit still in the barber chair and watch TV. However, his past experience in this environment was not particularly positive, he didn't attend to the other children (and so wasn't able to use them as models), he had difficulty with the transitions that involved the DVD, and his heightened awareness of things in his peripheral visual field created difficulty for Harold. In addition, neither his mother nor the hair stylist, despite good intentions, had been able to change the situation, including their own behavior, to create a more successful performance. Harold's participation in getting a haircut was being created by all of these factors interacting with one another, and the therapist had to recognize and consider all aspects of this transaction in both assessment and intervention. The POS framework emphasizes that the potential for success in occupational participation is not housed in the characteristics of the individual alone but rather is the result of a working transaction within the situation as a whole. Therefore, all of these factors must be considered and examined in the assessment process, and that examination should include performance analysis whenever possible.

Intervention

Occupational therapy intervention occurs in three parts: planning, implementation, and review (AOTA, 2008). Although these may occur in a single discrete sequence at times, particularly in the initial process with a client system, they frequently

"cycle" with some variability, depending on factors such as the methods and length of service delivery, desired outcomes of intervention, and documentation requirements. Intervention planning, implementation, and review should occur as a collaborative process that includes, at the least, the individual, family/caregivers, and the occupational therapist. Depending on the specific practice setting, a larger team may be involved (teachers, speech-language pathologist, psychologist, employer, coach, etc.), affording more collaboration for the benefit of the client.

Planning

Optimal intervention planning evolves naturally from the assessment process described above and takes into consideration not only the strengths and needs of the individual but also the concerns, expectations, strengths, resources and limitations of those living or working with that individual on a regular basis, as well as the situations in which the occupations typically occur. As the POS framework implies, the transactional nature of all participation in occupation means that a change or strategy inserted in one aspect of the action will have an effect on all other aspects, so intervention is planned with this understanding in mind. In addition, intervention plans must take into account the core and associated features of autism, particularly as they are expressed in the individual.

Plans for intervention begin with the establishment of goals that reflect the outcomes desired by the client, stated in measurable terms and targeting change in occupational performance, social participation, quality of life, and/or client satisfaction with one of more of these. Based on these stated goals, more specific plans for action can be designed and optimal methods of service delivery chosen. Action plans may include any or all of the following types of occupational therapy intervention: therapeutic use of self, use of occupation and purposeful activity, consultation, and education (AOTA, 2008), as they are appropriate to the client and situation. (Further discussion of these types of intervention and their specific application to people with ASDs follows below.) Although methods of service delivery in general occupational therapy practice may range from segregated (one-on-one or "pull-out") to integrated (within the natural contexts, activities and routines of the client), use of the POS framework and of performance analysis as a key assessment method, and the difficulties many people with ASDs demonstrate with generalization, should lead to the use of the most integrated models of service delivery possible in any given situation. Specifically planned, intentional uses of more segregated models may be appropriate at times, but plans should include transitions to more natural situations as quickly as possible.

Although it may seem premature to some, occupational therapy intervention planning should encompass discharge planning as well. Because occupational therapy is indicated for situations in which there is not a good "fit" among the individual/client, important occupations, and the contexts in which those occupations occur, the need for occupational therapy services may come and go for any particular client. As a part of intervention planning, the therapist discusses with the entire client system how often progress and goals will be reviewed, what will happen when goals are met, and what resources may be available in the community or elsewhere during times when occupational therapy services are not needed. This type of planning also takes into account the need for and process of transitions that may occur when occupational therapy services will be provided in a different manner or setting. The integration of intervention planning and discharge planning does not necessarily limit the course or scope of occupational therapy services provided in the present, nor does it preclude the re-institution of services when the need arises, but it allows all involved to be prepared for what follows the current course of intervention.

Implementation

Implementation of occupational therapy intervention is the enactment of the plan designed by the therapist, client, and others in collaboration with one another. As noted above, intervention strategies may fall into one or more of the following categories of intervention type: therapeutic use of self, use of occupation, and purposeful activity, consultation, and education.

Therapeutic use of self refers to the intentional use, by the therapist, of his or her interactive style, personality, perceptions, or insights as supports to the therapeutic process. The most common uses of this type of intervention are to develop rapport with the individual or entire client system and/or to enhance motivation. The therapist's role is to support the relationship between him- or herself and client (individual or entire system), help establish and maintain trust, and ideally create a relationship in which the client feels safe and willing to take on challenges. The importance of the therapist–child relationship in working with individuals with ASDs cannot be overstated. The willingness and ability of the therapist to attend to and be present with the individual allows significant opportunities to read subtle cues as intentional communication, to try to discern and understand motivations that are not obvious, and to respond with respect and reasonable expectation. Given the difficulties that most with children with ASDs have communicating with others and establishing social connectedness, the effort of the therapist to establish a relationship is an exceptionally important aspect of intervention.

Another role of the therapist is to elicit specific behaviors in the individual. The body of literature on relationship-based interventions for individuals with ASDs is particularly relevant to this type of occupational therapy intervention (Case-Smith & Arbesman, 2008). For example, research on the use of responsive interaction strategies with children with autism indicates that when parents, through their own behaviors,

encourage and support their children in engaging in reciprocal social interactions, the children are able to develop pivotal behaviors such as joint attention, turn-taking, and imitation, all of which are key to learning and further participation in a variety of occupations (Greenspan & Weider, 1997; Baranek, Reinhartsen, & Wannamaker, 2001; Mahoney & Perales, 2003, 2005). In addition, Nadel et al. (2008) found that children with autism were more likely to approach adults who were imitative and playful than adults that were not. Although there is no significant research specifically targeting the use of these types of responsiveness by therapists, the use of interpersonal strategies that include sensitive attention to an individual's cues, and responses to those cues in ways that are contingent, reciprocal, and affectively appropriate, are well in line with the occupational therapist's role. Most responsive strategies can be embedded incidentally in a variety of occupational situations, as noted in the example below. These behaviors may include the positioning of the therapist relative to the individual, following the individual's lead in the activity, reinforcing all efforts at intentional communication, imitation of the individual's actions or vocalizations, and scaffolding behaviors (Mahoney & MacDonald, 2007). Returning to the POS framework, the therapist's goal is to create change in occupational participation through intentional change in the social context. Later in the chapter, further discussion of other types of intervention will examine how changes in the behaviors of others in the social context also can be used to support participation.

Case Example

Sarah is a 6-year-old girl with autism and minimal verbal skills who likes painting with a brush on large sheets of paper while vocalizing to herself in a low sing-song voice. She often uses repetitive actions to dip her brush and to make single slow strokes on the paper. If the teacher sits behind her in an effort to help her, Sarah actually waits for the teacher to give her a physical prompt to dip her brush in the paint again. Sarah doesn't attend to children or adults around her and doesn't look at the teacher even if the teacher is giving her physical prompts. The occupational therapist, Thomas, understands that Sarah may find it easier to interact with an adult initially, although his ultimate goal is to support Sarah's participation in the occupation of painting with classmates. Therefore, Thomas chooses several behaviors he can enact to elicit more social interaction and sense of shared engagement from Sarah and help her build more variety in her approach to painting. The first is to position himself in front of her, so that face to face interaction is possible, and he can read her facial expressions and follow her eye gaze. The second is to imitate her actions and vocalizations, using his own brush and paint, painting at the top of her paper. Attending carefully to small changes in her facial expression and posture, he sees that she's noticed what he's doing, although she hasn't looked up at him yet. He continues to imitate her, and she looks up at him briefly before returning to her own painting. He continues to

imitate her actions and vocalizations but speeds them up a bit, becoming slightly more animated in his behavior. Sarah looks up at him with heightened interest, so he repeats his action. He sees that Sarah is very alert to his presence and actions, which is a nice change, but she isn't yet changing her own activity-related behaviors, so he alternates imitating her exact actions with animating his actions and vocalizations. Eventually Sarah takes turns with Thomas, imitating him interspersed with his imitation of her. Thomas is now able to introduce "new ways" of painting, such as using different colors and making different strokes with her brush. Her participation in this occupation has now changed to include "doing with," and her understanding and performance of painting has changed. Although her goal of painting with her classmates, as a shared experience, has not yet been met, she is closer to it than she was, and her occupational therapist can now work to connect her with the other children who are also painting.

Use of purposeful activity and occupation is a core foundation of occupational therapy intervention, and although certainly the choice of specific occupations and activities is a key element of this, the context, structure, and process of the occupation are of equal importance. It should be noted that the intervention strategies that are discussed in the following section may have been specifically validated for people with autism, but others may have been designed more generally to support the participation of people with many different abilities and disabilities. A combination of these two approaches may be considered. In a commentary published in the *Journal of Autism and Developmental Disorders*, Wolery (2000) made an astute statement that perhaps still holds true today: "To date, we have no strategies that are effective for all children with autism and are contraindicated for all other children with disabilities. Thus, the research on teaching other students with disabilities…may have relevance for students with autism." A similar stance seems appropriate for occupational therapists working with people with autism of all ages—using empirically supported strategies developed for other populations or by other professions broadens the possibilities for finding a combination of strategies that work well for any individual or client system in a particular occupational situation. The use of reasonable but relatively "uninvestigated" strategies may be undertaken with regular collection of data and re-assessment to assure efficacy of the intervention and satisfaction of the client system.

Because participation in occupation is intended, at most times, to be both the means *and* the end of occupational therapy intervention, the continuity between goals and intervention strategies should be evident. Thus the selection of the occupation or activity during which intervention will be embedded is based on specific goals and the routines and daily life activities of the entire client system. At times, opportunities for new occupations or for participating in familiar occupations in different settings will be included in intervention, again based on the needs of the individual and of the client system as a whole.

Another element to be considered in the selection of activities/occupations is meaning: the meaning of the activity/occupation for the individual and the meaning for the family or other significant social system. The meaning perceived by the individual may differ slightly or significantly from that perceived by family or others, and clarity about the purpose of participation and the expectations of all involved are important considerations. Spitzer (2004) expands on this idea and emphasizes the need to attend to the perception or subjective experience of the individuals in the occupational situation. In the example of Harold and the haircut situation, the meaning to Harold of getting a haircut is difficult to know with certainty but likely was significantly different from that of his mother, Maria, for whom the meaning involved the appearance of her child and her role as a mother who cared appropriately for her children.

The context, structure, and process of occupation used in a therapeutic setting offer significant opportunity for variation and for creating a situation that "fits" the client well.

Using the POS framework as a guide, the occupational therapist may consider intervention that targets or uses the various contexts (cultural, social, physical, sensory, and/or temporal) that create the occupational situation and may also make adaptations to the structure or process of the occupation itself. It should be noted that although these elements are addressed separately below, they are essentially inseparable, and strategies are typically used in combination to provide an individualized intervention designed to support participation in the specific occupational situation, as a whole.

In each occupational situation, cultural context may be a broad construct that reflects values and beliefs thought to be representative of a large group of people (e.g., U.S. citizens, Latino immigrants, Catholics) or may be more localized or specific, representing the values and beliefs of a much smaller group of people, such as a school, workplace, classroom, or family. Because "culture," regardless of its expanse, is often enacted through routines and rituals and often relies on interpersonal interaction for its perpetuation (Bonder, 2004; Iwama, 2005), it is an important context to consider when working with individuals with ASDs. The extent to which the individual's rituals and routines are consistent or in conflict with the rituals and routines of the identified culture will affect group membership of the individual and participation in occupation (Spitzer, 2004; Iwama, 2005). Similarly, the ability of the individual to engage in the types of social exchanges in which cultural norms are shared will effect participation. Occupational therapy intervention then must address the "fit" between the individual (including both strengths and challenges) and cultural context, either using the norms of the culture to support occupational participation or seeking change to create a better fit when necessary. This also includes work within family culture, as the previous rituals, routines, and meaningful daily life activities of the family may be restricted or abandoned to meet the needs of the individual with autism (DeGrace, 2004).

Adaptations to or constructions of the social context are particularly difficult to describe as separate from the occupation itself because they are inherently embedded in one another. The social context provides the "venue" for the learning, doing, changing, and terminating of occupation, and occupation, or activity, simultaneously does the same for social participation. This creates the opportunity for various roles in the social context, such as partner, learner, and teacher. For example, Humphry and Wakeford (2006) relate the interchange between Matthew, a preschooler with autism, and the social context of his classroom as he develops interest and participation in building with blocks. His interest evolves from encouragement from his mother and teacher to see what other children are doing with blocks, and then his own spontaneous peripheral participation (i.e., watching) as classmates build with blocks. As his interest builds his willingness to participate actively, he's drawn in to the "block building situation." As he is supported to participate on a more active level, his actions affect those of his peers and vice versa, and his participation expands to use of other types of materials for building, which then leads to another type of social opportunity—that is, shared construction of a structure. As evidenced in part by this example, occupational therapists may work to support the social participation of the individual to facilitate participation in a "group occupation," further develop or refine performance of a particular occupation, and/or support the development of friendships.

Peer-mediated interventions are well-researched and have significant empirical support as successful strategies for enhancing social interactions for individuals with ASDs. DiSalvo and Oswald (2002) present a review of a variety of tested methods to support peer interactions for children with autism, and these methods range from group (e.g., integrated peer groups) to one-on-one (e.g., peer tutors) contexts and represent a continuum from direct teaching of peers to direct teaching of the target child. Peer-mediated approaches have been documented not only to support the development of social skills but also to support participation in particular occupational situations, such as outdoor play (Kern, 2006; Harper, Symon, & Frea, 2007), other play settings (Bass & Mulick, 2007; Lee, Odom, & Loftin, 2007), and a variety of self-care and classroom routine behaviors (Kohler et al., 1997). Friendship clubs (Kampa et al., 2003), peers as on-camera subjects in video-modeling strategies, and the use of peer "buddies" are among the ways in which peers may be used to support occupational participation.

A number of strategies mentioned previously may be used in addition to or combination with peer-mediated strategies. Social Stories may be used to support engagement in occupation and peer interactions simultaneously. For example, Sandt (2008) outlines how social stories may help children with ASDs participate in both the activities and social interactions that occur in physical education classes, and Barry and Burlew (2004) describe a study in which social stories were successful in changing both object and peer play skills of two children with severe autism. In a description of a low-tech adaptation to support outdoor play for a preschooler with ASD, Wakeford (2008) discusses the use of visual supports in a book format

with pictures of both activities and playmates from which the child could make choices. She also describes the use of the book strategy as a setting for collaboration between children in both the creation and the later reading of the book. The use of music in combination with peer-mediated approaches is examined by Kern (2006) and found helpful in establishing increased peer interaction and participation in an outdoor play activity. Danko and Buysse (2002) recommend the identification of special skills and potential common interests as a way to facilitate opportunities for social interaction between children with ASDs and their peers, as well as assuring that the environment contains materials for activities that encourage mutual engagement. Occupational therapists may guide or implement such intervention based on relevant information obtained during the occupational therapy assessment about both the individual and the environment. In addition, occupational engagement may be used to develop or enhance social connections, as in Reynold's (2006) case report regarding the participation of an older child with ASD on a lacrosse team and the ways in which her engagement in the game led to increased social interaction and group membership with her teammates.

Adaptations to or modifications of the physical and sensory environment may be designed to support desired behaviors, to inhibit undesired behaviors, or both. For example, Yuill et al. (2007) found that the expanse of space and arrangement of structures in a playground setting had significant effects on the play and social behaviors of eight boys with ASDs. Similarly, Duker and Rasing (1989) demonstrated that changes made in the arrangement of a classroom environment resulted in more on-task behaviors and fewer self-stimulatory behaviors for three young men with autism. The identification of a "home-base" is described as a modification to the physical environment that allows children with autism a place to "regroup" when the environment becomes too challenging (Dunn, Saiter, & Rinner, 2002). Considerations for the safety of the individual may also lead to adaptations to the physical environment, including placement of gates or barriers or installation of alarm systems to alert caregivers if the individual tries to leave a particular area independently. As noted in a chapter by Baranek, Wakeford, & David (2008), research on environmental modifications to address sensory processing issues is scarce, but those environments may be adapted to provide more opportunities for movement or other types of sensation or to decrease the amount or type of sensation present, depending on the needs of the individual. For example, the carpet, pillows, and bookshelves for a preschool reading corner were moved to a corner of the room near a large window. This allowed 4-year-old Katie to take advantage of the comfort and opportunities available in the reading corner without having to cope with her aversion to the visual and vibratory sensations created by the fluorescent light over the area in which the reading corner once resided.

In addition to these kinds of larger changes in the layout and use of physical space, the addition and location of objects and materials in the environment may also be used to support

participation in various ways. Introducing new items or materials by placing them in view but not as focal objects may have a "priming" affect, allowing the individual to accommodate to the new item before interacting with it directly (Dunn et al., 2002). Locating all the scissors at the end of the table where the child with autism is sitting sets up a situation in which others interact with him or her to obtain a pair of scissors during art class. Adding visual supports to the environment (Ball, 1999; Odom et al., 2003), such as step-by-step pictures for toothbrushing at the sink (Pilebro & Bäckman, 2005), may increase on-task behaviors and independence in self-care routines.

Temporal context includes not only the time of day but also the duration and frequency of the occupation, what activities or routines have come before and what will come after the occupation in question, and transitions. The significantly temporal nature of habits and routines makes them important as well, and this is particularly true when parents, teachers, employers, friends, and others have routines and expectations about the use of time that are different from those of the individual. In addition, temporal considerations intersect with cycles of hunger, thirst, and fatigue, and all of these in turn affect the ability of the individual to process sensory information, communicate optimally, and pay attention to that which is salient to the current activity. Intervention strategies that target the temporal context may include addressing how long the activity lasts, how often it occurs (e.g., frequency of opportunities), the duration and frequency of transitions, the sequence of activities, the extent to which the creation of a routine or habit is encouraged, and/or ways to assure that the individual's needs for food, drink, and rest are met within the sequence of activity. Common strategies include the use of timers, teaching first-then concepts, musical or visual "warnings" about or signifiers of transition times, alternation of active and sedentary activities, giving the individual a "job" to have a socially acceptable reason for moving about, and establishing consistent, predictable routines for basic self-care tasks. Strategies with empirical support include the use of visual supports to communicate about time use (e.g., picture schedules, written list of the order of activities) (Ball, 1999; Dettmer et al., 2000) and the use of musical elements to support the timing and sequencing of self-care (Kern, Wakeford, & Aldridge, 2007) and classroom activities (Register & Humpal, 2007). Transitions are often particularly difficult for people with ASDs, and a combination of strategies (i.e., to increase salience of cues about and predictability of transitions) is often necessary for there to be a successful move from participation in one occupation or activity to participation in the next (Sterling-Turner & Jordan, 2007). These strategies, however, typically affect one or more other people, as illustrated in the case example below, and collaboration to assure satisfactory outcomes for the client system as a whole is important.

Case Example

Josh, a 17-year-old youth with ASD, has been working at a diner-style restaurant every weekday morning before school

for 2 months. His parents alternate dropping him off at the restaurant based on their own work schedules, so that his mom drops him off 3 days, and his dad drops him off on 2 days. After he's completed all his work tasks, he catches the school bus in front of the diner. Josh has a list for each day on which he marks off each task as it gets done. For the first month of the job, an occupational therapist provided on-site support for Josh, starting on a daily basis and by the end of the month dropping to once a week or as needed. Since he's had the job, the first task on the list has been to help the manager bring all the large garbage cans from outside into the back part of the kitchen. Other tasks include taking all the chairs down off the tables and making sure that each table has full containers of salt, pepper, sugar packets, and ketchup. Josh is a good worker and the manager is very pleased to have him. However, over the last several weeks Josh has been arriving a little earlier at work the days his dad drops him off because of changes in his dad's work schedule. This has become a problem because the manager has things he needs to do before he's ready to help Josh get the trash cans into the kitchen. This means Josh has to wait for the manager, and this makes him anxious. Josh paces, touching things in the kitchen rhythmically as he walks, and he sings, getting louder and louder over time. The manager gets distracted, trying to reassure Josh, and then takes longer to complete his own tasks, prolonging even further Josh's waiting time, and escalating the situation. Although there are a number of possible interventions that would address the temporal dissonances here, the solution that caused the least disruption and was possible for all involved was to move the trash can task to last on Josh's list and have him begin taking chairs off tables first, as that was a task he could do on his own, whether the manager was available or not. Because he works five mornings a week, Josh had frequent opportunities to learn the new sequence of tasks, supported by the visual reminder of the list and minimal coaching by the therapist, and within a little over a week was initiating his "new" first task on his own.

As noted previously, the structure and process of occupation may also be adapted in a variety of ways to support participation. A number of empirically supported strategies for adapting the structure or process of occupation are discussed in some detail in publications by Baranek, Wakeford, and David (2008), Case-Smith and Arbesman (2008), and Dunn, Saiter, and Rinner (2002). The use of visual supports in the form of activity schedules, choice boards, step-by-step task sequences (Bryan & Gast, 2000), work systems (Hume & Odom, 2007), Social Stories™ (Gray & Garand, 1993; Kuoch & Mirenda, 2003), and variations on social stories (Brownell, 2002; Marr et al., 2007) are among the most successful means of adapting the structure or process of occupational participation. The addition of musical elements, mentioned previously, and the use of priming (Dunn, Saiter, & Rinner, 2002; Koegel et al., 2003), are supported in the research literature as effective augmentations that support participation of those with ASDs, and video modeling has been used by both occupational therapists

(Kashman, Mora, & Glaser, 2000) and other professionals (McCoy & Hermansen, 2007) to teach both social and functional skills. Adaptations to the sensory qualities of a routine, activity, or occupation may support those who need more or less intensity, predictability, novelty or complexity of sensation to participate optimally (Dunn, Saiter, & Rinner, 2002; Baranek & Wakeford, 2000). For example, for some children who need enhanced sensory input to maintain an appropriate arousal level, sitting on an inflatable cushion or therapy ball during tabletop work may be helpful, as may standing up to work. Using textured surfaces for drawing activities, singing rather than saying task directions, adding sand to paints in art class, or using brightly colored tape to mark work areas may also be useful for other children. For some children who tend to be over-responsive to one or more types of sensory input, clearly delineated spaces in which to sit or stand may be helpful (thus diminishing the chances of unexpected touch by others), as may being first or last in a line. Allowing the individual to explore new materials or processes by watching others (a form of priming) and visual supports or songs that create predictability about the task may also be helpful. Some individuals who demonstrate sensory-seeking behaviors may benefit from some of the strategies listed above related to enhancing sensation, as well as to having objects or "fidget" toys, and opportunities to engage in "heavy work" activities, such as carrying a laundry basket, raking, vacuuming, or pushing a cart loaded with work supplies. The field of special education offers other naturalistic intervention measures that may support occupational participation for people with autism, including the use of positive reinforcement, prompting, time delay, and incidental teaching (Cowan & Allen, 2007; Vuran, 2007; Liber, Frea, & Symon, 2008; Kurt & Tekin-Iftar, 2008). The use of alternative and augmentative communication and other types of technology have been documented as a way to support functional communication and overall participation as well (More, 2008).

Consultation and education are methods of service delivery that can be used to support parents, siblings, other family members, and a wide variety of possible others who are involved with the individual with autism. These methods of service delivery may occur simultaneously with, in addition to, or even in the absence of the occupational therapist's work directly with an individual and may also be used to address the needs of a client that is not an individual but rather is a group, organization, or population. Consultation typically involves the occupational therapist in a collaborative relationship centered on making recommendations or generating solutions to identified problems but not as the party responsible for implementing the actual plan or for the results of the plan. For example, an occupational therapist may help the mother of child with autism generate ideas for a playroom environment that maximizes the child's opportunities for functional toy and social play; the mother then implements all or some of the ideas. Education typically involves the therapist in providing information or instruction to others, but without immediate or specific changes in the occupational participation

or performance of a client. For example, an occupational therapist may provide a workshop on sensory processing in autism and its potential effect on worker behaviors for staff of a job training program.

Both consultation and education draw on the ability of the therapist to use themselves and their knowledge therapeutically, to develop rapport, to maintain good relationships, and to create an environment that facilitates willingness to learn, to accept challenges and potentially to make changes. This is particularly important given the increasing use of natural environments and integrated models of service delivery in early intervention and school settings and the rise in parent-mediated intervention approaches that are being investigated and used for children with autism. Team and collaborative approaches are recognized as optimal to develop the strengths and meet the needs of people with autism in a variety of settings, and the ways in which the occupational therapist provides consultation and education to others can affect the overall efficacy of intervention.

Parents and siblings of an individual with autism may require particular attention in terms of consultation and education services for a number of reasons. Despite both anecdotal and scientific reports that include positive parent perspectives on living with and loving a child with autism, the difficulties of this situation also are well-documented. Parents of newly diagnosed or young children may need help with a variety of issues, including finding community, educational, and therapy resources; beginning to understand their child's ASD; and learning the basic, ongoing types of intervention strategies that are likely to support their child's participation in a variety of environments and activities. Parents of young, adolescent, and adult children with autism report significant concerns about issues such as sleeping and eating patterns, pre-academic and academic success, social skills and development of friendships, sexuality, financial stability, independent living skills, and, ultimately, what will happen to their child when one or both parents die. Parenting stress in this population is variable, depending on a number of factors, but depression is not uncommon, especially among mothers. Also, given the research examining the genetic factors linked to autism, there is the possibility that siblings of the individual are also on the autism spectrum and/or that one or both parents have subthreshold characteristics of autism (broader autism phenotype). Although this may not be true in the majority of cases, it speaks to the need for occupational therapists to consider carefully the perspective, learning and interaction style, and coping mechanisms (internal and external resources) of the parents and family members to whom they may be providing consultation or education.

Review and Outcome Measurement

During and after the implementation of intervention, the occupational therapist reviews and evaluates, with the client, the effectiveness of chosen strategies and the outcomes of the intervention process. As noted previously, assessment and intervention should be planned and implemented based on a combination of client input, the most reliable evidence available, and the experience and reasoning of the occupational therapist. Intervention review is conducted as a part of evidence-based practice and in regard for ethical obligations to make the best and most appropriate use of the client's resources. Methods of review may include re-evaluation using assessment tools that were used on initial evaluation, the accomplishment of outcomes stated in short- or long-term goals, and/or the use of quantifiable measures of progress such as goal attainment scaling. Outcomes may include changes in the actual performance of targeted occupations, level of participation in occupational situations as a whole, satisfaction of the client, and/or quality of life. Intervention review and measurement of outcomes allows the client and the therapist to determine which interventions are working and how quickly progress is being made and to determine whether there is a need for changes in the intervention plan or initiation of a discharge plan.

Research

The contributions of occupational therapists to research evolve from unique perspectives on occupation and on the wide array of factors that influence the many behaviors that comprise daily life and participation in occupation. For example, an emphasis on the "lived experience" of the client as a central theme in occupation has led to research examining the meaning of occupation for children with autism (Spitzer, 2003) and the orchestration of daily life for families of children with autism (DeGrace, 2004). Occupational experiences were also the focus of a study conducted by Hilton, Crouch, and Israel (2008), who investigated the extent to which children with high-functioning autism participate in leisure or social events outside of school. In addition, an understanding of the mechanisms that underlie the ability of the individual to process and use sensory information, and the relationship among sensory processing, self-regulation, and participation occupational situations, has led to research focused on early identification of autism (Baranek, 1999; Reznick et al., 2007), a better understanding of the difference in sensory processing in people with autism relative to those with other disabilities or typically developing persons (Baranek et al., in revision, Watson et al., 2007; Watling, Dietz, & White, 2001), the development of assessment tools that help discriminate between those with ASDs and those with other disabilities or typical development (Kientz & Dunn, 1997; Baranek et al., 2006), and the influence of sensori-motor differences on the performance of self-care tasks in preschoolers with autism (Jasmin et al., 2009). To date, much of the intervention research related to occupational therapy approaches for children with autism focuses on sensory integration or sensory-based methods and has been criticized for lack of scientific rigor, small sample sizes, lack of focus on functional

or occupational outcomes, and lack of transparency or replicability (Baranek, 2002; Mulligan, 2003; Schaff & Miller, 2005). Therefore, in addition to the continuation of programs of research already being conducted by occupational therapists working with and for people with autism, there is a particular need for scientifically rigorous research that addresses occupational experiences and outcomes for people with ASDs and their families across the lifespan, is developed in collaboration with stakeholders and an interdisciplinary team, is replicable, and includes dissemination to consumers, service-providers, and other researchers. This is consistent with calls for a different approach to research from within the profession of occupational therapy (Kielhofner et al., 2004) and for translational research initiatives coming from the National Institutes for Health (2008) and the nteragency Autism Coordinating Committee (2009).

Challenges and Future Directions

Occupational therapists are spearheading a wide range of studies that will lead to continuation and further development of translational ASD research programs related to early identification, tool development, and intervention approaches, as well as the further examination of the occupational experiences, values, and goals of those with ASDs and their families and significant others across the lifespan. However, challenges that must be faced and important future directions include the following:

- Addressing a need for more collaborative involvement from consumer populations (people with ASDs and their family members) in processes of assessment, intervention, and research, by
  - developing a variety of ways in which people with ASDs and their families can effectively and comfortably provide information, opinions, and ideas in research, educational, and intervention processes, and
  - continuing to work with client/consumer populations to develop a greater understanding of the spectrum of autism, and the life experiences of those on that spectrum and their families.
- Addressing a need for effective and appropriate identification and assessment tools, by
  - continuing contributions to research on early identifiers of ASDs, and
  - developing and validating occupational therapy assessment tools that are relevant for those with ASDs.
- Addressing a need for intervention methods that are evidence-based and easily replicable, by

  - continuing to develop methods for effective intervention with very young children and their families,
  - creating new approaches to consultation that support client systems as a whole,
  - becoming more innovative in the use of technology,

  - further examining and using strength-based models of intervention,
  - developing and testing of intervention "packages" (approaches that combine a variety of strategies and/or in which occupational therapy is one of several components in a comprehensive program), and
  - developing model approaches or programs that specifically support those with ASDs in the development of friendships.

Augmentative and Alternative Communication Systems

Points of Interest

- It is important to consider presentation format and stimulus duration when using AAC systems with persons with autism.
- A visual-constant system (i.e., one in which the stimuli are visual and always present) may best complement the strengths of this population.
- Research suggests that a variety of AAC systems can be effective in teaching communication to persons with autism.
- However, the most effective AAC system for a specific child needs to be individually chosen.
- When choosing an AAC system for an individual, practitioners should consult the literature as well as consider both individual and environmental characteristics.

Introduction

Much attention has been placed on the development of communication in persons with autism. By definition, autism is a social communicative disorder, including qualitative impairments in both verbal and nonverbal communication (APA, 2000; Schreibman, 2005). Approximately one-third of persons diagnosed with an autism spectrum disorder (ASD) will not develop functional natural speech by adulthood (National Research Council, 2001). If speech does occur, onset is usually delayed and it is often characterized by abnormalities such as echolalia, idiosyncratic words or phrases, monotonous intonation, and an inability to sustain reciprocal conversation (Howlin, 2006; Kanner, 1943). Although communication interventions for children with autism have a long history of targeting verbal speech (Baer et al., 1968; Risley & Wolf, 1967), progress is often extremely slow and limited

(Lovaas, 1977; Howlin, 1989). Poor outcomes have led interventionists to turn to other means, including augmentative and alternative communication (AAC) (Howlin, 2006).

Augmentative and Alternative Communication Systems

The American Speech-Language-Hearing Association defines *augmentative and alternative communication (AAC) systems* as "an integrated group of components, including the symbols, aids, strategies and techniques used by individuals to enhance communication. The system serves to supplement any gestural, spoken, and/or written communication abilities." (ASHA, 1991, pp. 9–10.) *Augmentative* refers to the process of supplementing existing speech to increase communication, and *alternative* refers to the use of technology other than natural verbal speech to communicate (e.g., sign language, picture cards). Application of AAC has extended to people with sensory and motor deficits (e.g., individuals with visual and hearing impairments and cerebral palsy), intellectual and developmental disabilities (e.g., Down syndrome, Fragile X Syndrome, fetal alcohol syndrome, and autism), and physical disabilities (e.g., Amyotrophic Lateral Sclerosis) (Beukelman & Mirenda, 2005).

Autism and Augmentative and Alternative Communication Systems

AAC systems have been used to address the communicative deficits of persons with autism since the 1970s (Ogletree & Harn, 2001). Early applications focused on manual signs, tangible symbols, lexograms, and orthographic symbols. In the 1980s, the use of visual-spatial symbols gained popularity.

More recently, advances in technology have led to an increase in the use of computer software programs and voice-output communication aids for persons with autism (Mirenda & Erickson, 2000).

In this chapter we will review the different AAC systems that have been used with persons with autism, along with the relevant research for each system. Although several different categorizations can be used when presenting AAC systems (e.g., aided versus unaided, input versus output), we have chosen to categorize AAC systems along two dimensions that are relevant for this population: presentation format and stimulus duration. This format, adapted from Charlop-Christy and Jones (2006), will guide our discussion of the potential benefits and limitations for using each type of AAC system with persons with autism.

Presentation Format

Since Kanner (1943) first described children with autism, it has been well-documented that although these children's verbal skills are significantly impaired, their visual-spatial skills may be normal or even advanced (Hermellin, 1976). For example, many of these children perform quite well on embedded figures and block design tests (*see Mitchell & Ropar, 2004 for a review of visual-spatial abilities in persons with autism*).

This discrepancy between visual and verbal skills has been empirically validated by several studies. Lincoln, Courchesne, Kilman, Elmasian, and Allen (1988) assessed the intellectual functioning of 33 individuals with autism ranging in age from 8 to 29 years with the Wechsler Intelligence Scale for Children–Revised (WISC-R) (Wechsler, 1974) or the Wechsler Adult Intelligence Scale–Revised (WAIS-R) (Wechsler, 1981). Participants received the lowest scores on the Comprehension and Vocabulary subtests, which require the most verbal reasoning, and the highest scores on the Block Design and Object Assembly subtests, which require the most visual skills.

Other studies have found that when compared to typically developing controls, persons with autism show deficits in their verbal skills but not in their visual skills. Rumsey and Hamburger (1988) compared the performance of 10 men with infantile autism and average verbal and nonverbal intelligence, ages 18 to 39 years, with normal controls on a range of neuropsychological tests that measured language and visual-spatial abilities. Results indicated that although the men with autism did not perform differently from the controls on the visual-perceptual measures, they performed much worse than the controls on simple and complex verbal problem-solving tasks. A similar pattern of results was found in Ozonoff, Pennington, and Rogers' (1991) comparison of 23 people with ASD, ranging in age from 8 to 20 years, with 23 controls matched for IQ, age, sex, and socioeconomic status.

These results have also been replicated in studies that focus on children with autism. In Williams, Goldstein, and Minshew (2006), 56 high-functioning children with autism were compared to 56 control children matched for age and IQ.

The children with autism performed worse than the controls on the complex language tasks but not on the visual-spatial tasks.

Although the previous studies were conducted with high-functioning persons with autism, this cognitive profile is also found in low-functioning children with autism (Quill, 1997). In addition to demonstrating higher abilities on nonverbal problem-solving tasks than on verbal reasoning problems, low-functioning persons with autism also have severe receptive and expressive language impairments (Bristol et al., 1996). In fact, as the overall degree of mental retardation increases, so does the gap between verbal and nonverbal abilities (Quill, 1997).

If persons with autism have advanced visual skills, then visually based interventions should have high rates of success with this population. Quill and Grant (1996) found that language comprehension increased for four nonverbal children with autism when both oral and graphic instructions were presented simultaneously. For example, although the children did not initially respond to purely oral questions, such as "Which one is [*attribute*]," they were able to correctly respond when the verbal question was paired with a picture that depicted the attribute. Other successful visual interventions include video modeling (e.g. Chalrop-Christy et al., 2000; Sherer et al., 2001), cue cards (e.g., Charlop-Christy & Kelso, 2003), and photographic activity schedules (e.g., MacDuff et al., 1993). This research implies that visual AAC systems might be effective systems for persons with autism.

Stimulus Duration

The issue, however, is more complex than presentation format. Research indicates that stimulus duration is also an important consideration. In the studies previously mentioned (Lincoln et al., 1988; Ozonoff et al., 1991; Rumsey & Hamburger, 1988; Williams et al., 2006) the participants with autism performed best on the tasks in which the stimuli were visible for the entire duration of the task (e.g., form discrimination, matching, block design, object assembly, and pattern analysis). These results suggest that constant visual stimuli may be preferable to transient visual stimuli.

Research on attention and memory processes further support this conclusion. Children with autism demonstrate impairments in rapidly shifting attention (Courchesne et al., 1994) This suggests that children would have difficulty attending to, and therefore encoding, a series of rapidly spoken words or rapidly presented visual stimuli, such as gestures or pictures. Visually constant stimuli, on the other hand, would be easier to attend to, and children could attend to the stimuli until they were successfully encoded (Quill, 1997). Research on memory in persons with autism also supports the use of visually constant stimuli. Persons with autism perform better on cued-recall memory tasks than on free-recall memory tasks (Quill, 1997). Therefore, constant visual stimuli may enhance memory because they can serve as visible retrieval cues.

Presentation Format and Stimulus Duration Applied to Communication

When applied to communication, the two dimensions of presentation format and stimulus duration yield three different modalities of communication training. Communication training may be *auditory-transient*, *visual-transient*, or *visual-constant* (Charlop-Christy & Jones, 2006). In auditory-transient AAC systems, the stimuli are presented auditorily and do not persist in time. Once a word is spoken, the stimulus is gone. Clearly, there would not be an auditory-constant system. Visual-transient AAC systems present information visually for brief periods of time. For example, in sign language, the stimuli consist of body movements, which, once they are performed, are no longer available. In contrast, in visual-constant AAC systems, the stimuli are also visual, but they are always available. For example, a picture is a visual stimulus that, unless removed, is always available to the AAC user.

Table 64-1 depicts these modalities, along with providing AAC examples for each category. In the following sections, we will review each modality and the relevant AAC systems, referring back to their potential advantages or disadvantages for persons with autism given our previous discussion on presentation format and stimulus duration.

Auditory-Transient

In the auditory-transient modality, stimuli are presented in the auditory modality and only last for brief periods of time. For example, in speech, the sounds of words do not persist over time. Therefore, a child with autism needs to "hear" speech, attend to it, remember it, and then figure out its meaning (Charlop-Christy & Jones, 2006). These steps may be difficult given the population's difficulties with encoding

Table 64–1.

Augmentative and alternative communication systems categorized by stimulus duration and presentation format

Stimulus Duration	Presentation Format	
	Auditory	*Visual*
Transient	*Auditory-transient*: Speech; Computer-generated vocalization.	*Visual-transient*: Sign-language; Gestures.
Constant	*Auditory-constant*: N/A.	*Visual-constant*: Picture Exchange Communication System (PECS); Voice-output communication aids (VOCAs).

verbal information and may partially explain why communication interventions that focus on verbal imitation have limited success (Charlop-Christy et al., 2008; Lovaas, 1977). Computer-generated vocalizations, unless paired with a visual stimulus, have the same limitations as speech.

Visual-Transient

In visual-transient communication, information is presented visually but it also does not persist through time (Charlop-Christy & Jones, 2006). Sign language is an example of a visual-transient AAC system. The body movements that are used in sign language are presented visually, but they do not last. Studies that report on the use of signs with persons with autism first appeared in the 1970s (e.g., Bonvillian & Nelson, 1976; Fulwiler & Fouts, 1976; Konstantareas et al., 1978). After we review this area of research we will return to the potential problems with using a visual-transient system with persons with autism.

Sign Language

Although initial sign-language programs were based on formal systems, such as American Sign Language (ASL), today abridged versions are often used with persons with autism. These versions may incorporate simpler hand movements or a modified vocabulary (Howlin, 2006). Initial studies with persons with autism compared the effects of presenting speech and sign language together on receptive vocabulary (Brady & Smouse, 1978; Carr & Dores, 1981; Carr et al., 1984), expressive vocabulary (Barrera et al., 1980; Barrera & Sulzer-Araroff, 1983; Layton, 1988; Yoder & Layton, 1988), or both expressive and receptive vocabulary (Layton, 1988). The results of these studies demonstrate that, for many participants, total communication training generates faster and more complete learning of vocabulary in comparison with speech alone conditions. These findings were especially robust for participants who demonstrated low verbal-imitation skills (Carr & Dores, 1981; Carr et al., 1984; Yoder & Layton, 1988). Although these findings seem to support the use of sign language for children with autism, almost all of these studies taught receptive or expressive labels in response to questions such as, "What is this?" or, "Show me the sign for [object label]." That is, the participants were not using sign language to communicate functionally in the natural environment. It is unclear if the participants in these studies would use sign language to request preferred items. Unfortunately, little research has examined the use of total communication to teach communication that is functional (i.e., can be used to spontaneously request a variety of items; Mirenda, 2003).

One study, conducted by Richman, Wacker, and Winborn (2001), compared the use of signing with a picture communication system in a functional communication training (FCT) program. A highly aggressive 3-year-old boy

with pervasive developmental disorder (PDD) learned both to sign "please" and to exchange a generic picture for "please" when requesting preferred items. The child acquired both systems, and aggression decreased when reinforcers were presented for either exchanging a card or signing "please." When reinforcement was provided concurrently for both systems, the child showed a preference for signing. From these results, researchers concluded that signing may have been more efficient (i.e., required less effort) for this particular child. Keep in mind, however, that this study had one participant and that heterogeneity and individual differences are common for this population. Also, the child in this study learned only one sign. Other studies, which target multiple signs, suggest that even after extensive training, students with autism are likely to acquire only a few functional signs (Layton & Watson, 1995). Clearly, more research based on the principles of best evidence is needed to empirically investigate the use of sign language as a means of teaching communication to persons with autism.

In the meantime, interventionists considering the use of sign language with persons with autism should evaluate certain characteristics of this AAC system. First, remember that sign language is a visual-transient modality (Charlop-Christy & Jones, 2006). Processing sign language requires both attention to the visual stimulus and an ability to hold the visual stimulus in one's memory after the sign is no longer being displayed. The transient form of sign-based communication requires faster processing speed of visual stimuli than of visual stimuli that are constant (e.g., a picture) (Charlop-Christy & Jones, 2006). Furthermore, when generating communication, sign formation requires a two-stage recall memory process: *(1)* a search of one's memory for potential signs, and *(2)* a discrimination process to decide which of the potential signs is correct (Light & Lindsay, 1991). In contrast, visually constant systems, which rely on recognition memory, do not require users to search their memory for the correct stimuli; the visuals are always present, thus lowering the processing demands placed on the system user (Mirenda, 2003).

In addition to the limitations of a visual-transient system, sign language has other features that may make it difficult for persons with autism. First, one of the prerequisites of symbolic communication, such as sign language, is the use of more basic communication forms, such as gestures (Miranda & Erickson, 2000). Persons with autism characteristically lack the use of complex gesturing to communicate (Schreibman, 2005). Many children with ASDs do not demonstrate gestures beyond taking a person by the arm to the item they want. Extensive training with basic gesturing (including proximal and distal pointing) would be required to develop an ability to understand the use of gestures prior to sign-language training (Miranda & Erickson, 2000).

Second, not everyone is familiar with sign language. Unless primary communicative partners, such as family members, are willing to learn sign language, the ability of nonverbal persons with ASDs to communicate is limited (Weitz et al., 1997; Wilkinson & Hennig, 2007). Furthermore, even if primary

communicative partners do learn to sign, communication is still not completely functional because the user may be unable to communicate with unfamiliar persons (Mirenda & Erickson, 2000). The need for a translator for community outings thus makes independent living less likely.

Lastly, sign language requires that participants possess manual dexterity (Sundberg & Sundberg, 1990; Wraikat et al., 1991). Unfortunately, persons with ASDs often demonstrate difficulties with fine-motor actions, coordination, and gross-motor imitation, making the process of learning signs difficult (Seal & Bonvillian, 1997; National Research Council, 2001). As a result, persons with ASDs often develop idiosyncratic signs. Communication partners must not only know sign language, but they must also know how the specific person's signs differ from standard signs (Wilkinson & Hennig, 2007).

The benefits of sign language should not be discounted before future research further explores the applications of this AAC system to persons with autism. Better methodology, larger sample sizes, and replications of present research are needed. Thus, much more exploration into the use of sign language is suggested before a conclusion about this AAC with children with ASDs can be reached.

Visual-Constant

Information in the visual-constant modality is presented visually and persists over time (Charlop-Christy & Jones, 2006). The majority of AAC systems fall under this category, including orthography, picture schedules, Aided Language Simulation (ALS), System for Augmenting Language (SAL), voice-output communication aids (VOCAs), and the Picture Exchange Communication System (PECS). As we review each AAC system, remember the benefits that the visual-constant modality may have for persons with autism. Because these visual stimuli persist over time, they accommodate the potential need for longer periods of processing time (Ogletree & Oren, 2006). Furthermore, visual-constant stimuli are easier to attend to, enhance encoding, and may serve as a memory aid during retrieval processes (Charlop-Christy & Jones, 2006).

Orthography

Orthography refers to written stimuli. Research on orthography has focused on using the written word as an AAC *input.* That is, children are shown a word, and then taught to respond appropriately. In an early study, three nonverbal adolescents with autism were taught three words both expressively and receptively (La Vigna, 1977). In the expressive task, the participants were shown an object and taught to choose the corresponding word card. In the receptive task, the participants were shown the word card and taught to choose the corresponding object. It took the participants an average of 1,471 trials to master three words both expressively and receptively.

Given the slow rate of acquisition, orthography may be more appropriate for higher-functioning persons (Howlin, 2006). In fact, research findings indicate that written scripts can be used to teach complex social behaviors to children with autism in elementary and middle school. For example, Charlop-Christy and Kelso (2003) taught conversational skills to three children with autism, ages 8 to 10 years, who were verbal and literate. In this study, children successfully responded to a conversational question and asked a contextually appropriate question after just two to four presentations with the cue cards. After training, this skill was generalized across setting and conversation topic, in the absence of cue cards. Similarly, Krantz and McLannahan (1993) used written scripts to facilitate social initiations. During an art project, four children with autism were given a card with 10 single-line social initiations (e.g., "John, did you like to swing outside today?"). Initially, the children were physically prompted to read each script and then cross it off when finished. The scripts were then faded one word at a time. After training, the children's initiations had increased to the same range as three of their typically developing peers.

These studies provide support for the use of orthography as an effective AAC input system for literate persons with autism. High-functioning persons with autism seem to be able to attend to the visually constant stimuli, encode them, and then respond appropriately. This AAC system would be especially useful for children who are hyperlexic, a specific condition which is found frequently among persons with autism (Ogletree & Oren, 2007). The main characteristic of *hyperlexia* is an above-average reading level paired with a below-average comprehension level for spoken language. Hyperlexic children are often able to learn to speak through extensive repetition and memorization. The condition is closely associated with autism, but there is some debate as to whether it is an autism spectrum disorder or a completely distinct disorder.

Research, however, has not been conducted on the use of orthography as an AAC output system, or as an alternative to verbal speech. That is, empirically controlled research is needed on the use of written material provided by the person with autism to communicate. Such AAC systems might consist of small laptops on which persons with autism can type messages, text messaging apparatuses such as cell phones, and writing.

Picture Schedules

Like orthography, picture schedules are also a visual-constant AAC input system. Picture schedules can be divided into within-task schedules and between-task schedules. In within-task schedules, children learn to follow pictures to complete an activity. For example, Bryan and Gast (2000) taught four children with autism, ages 7 to 8 years, to follow four pictures that sequenced an academic activity (e.g., file-folder games, worksheets). The participants learned to complete the activity using the picture schedule, and after

training, the children were able to generalize the skill to a novel activity. Picture schedules can also be used for self-help skills. In Pierce and Schreibman (1994), three low-functioning children with autism, ages 6 to 9 years, were taught a variety of skills such as dressing, setting the table, and doing laundry. Each participant learned three sequences with a picture schedule, completed the sequences even when the therapist was not present, and generalized the skill across setting and task.

Picture schedules can also be used for between-task schedules. These programs help participants learn to transition from one activity to another. For example, MacDuff and colleagues (1993) taught four children, ages 9 to 14 years, to follow a picture activity schedule that included six different after-school activities (e.g., LEGOs, puzzle, TV, handwriting worksheet) and lasted for approximately 60 minutes. The participants were taught to follow their schedules through graduated guidance, which was faded until the teachers were no longer in close proximity to the participants. After training, which ranged from 13 to 27 sessions, the participants maintained the behavior, and generalized the skill to new sequences with the same photographs and to new sequences with different photographs. In a similar study with younger children, the parents of three children with autism, ages 6 to 8 years, learned to help their children follow picture schedules that depicted a variety of home-living tasks. In addition to acquiring the sequences, the children also displayed increases in social initiations and decreases in disruptive behavior, which were maintained for up to 10 months (Krantz, MacDuff, & McClannahan, 1993). These studies seem to indicate that picture schedules are extremely effective visual-constant AAC input systems. However, similar to orthography, picture schedules have not been used as AAC output systems for persons with autism. Although picture schedules may allow other people to communicate with persons with autism, they do not allow persons with autism to communicate with other people. This is an important distinction, because complete communication is bidirectional.

Aided Language Simulation

Aided Language Simulation (ALS) is a visual-constant AAC system that is used for both input and output. Goossens (1989) introduced ALS to teach individuals to both understand and use visual symbols as a means of communication. Through this system, as the communication partner talks to the ALS user, he or she also points to symbols on the user's communication display. For example, the partner might point to the symbol for "ball" while saying, "I see ball." Pairing the visual symbol with the spoken word may increase message saliency and assist in receptive and expressive understanding of vocabulary. In addition to AAC input, AAC output through ALS occurs when the user points to symbols on the communication display. In more advanced stages, the communicative partner responds contingently to the user by scaffolding more advanced communication and language (Goossens et al., 1992). For example, a child may point to a picture of a ball,

and in response, the communicative partner would point to picture symbols for "big," "red," and "ball," while saying, "Look, the big, red ball." Although Harris and Reichle (2004) found that three children with moderate cognitive disabilities increased their symbol comprehension and production following ALS implementation, no studies have been published on the effectiveness of ALS with persons with autism.

System for Augmenting Language

The System for Augmenting Language (SAL) is very similar to ALS in that it also emphasizes augmenting both the input of the communication partner and the output of the AAC user. The main difference is that voice-output communication aids (VOCAs) are considered critical to SAL (Romski & Sevcik, 1992). In SAL, each learner's VOCA has a display of visual-graphic symbols. Communication partners are instructed to use the symbols and VOCA to augment their speech input during naturally occurring communication opportunities. For example, at break time, the teacher would push the picture symbols for "Let's play outside" and the VOCA would produce a digitized speech output. Learners are also encouraged to use the device throughout the day (Mirenda, 2001).

Research on the effectiveness of SAL with persons with autism is limited. However, Romski and Sevcik (1996) conducted a 2-year longitudinal study that examined the effectiveness of SAL with 13 students, ages 6 to 20 years, two of which had autism. All of the students were given a VOCA, and communication partners were taught to use the VOCAs, incorporating the components of SAL. At the end of 2 years, all of the participants learned to use SAL, with a total of 20 to 70 symbols mastered. Seven of the participants, including the two with autism, produced messages that consisted of combining two or more symbols. Five years later, all of the participants were still using their VOCAs with an average of 70 symbols (Romski et al., 1999). Although more research with persons with autism is needed, these studies suggest that SAL may be effective for both receptive and expressive communication skills.

Voice-Output Communication Aids (VOCAs)

As described earlier, voice-output communication aids (VOCAs) are electronic devices that produce digitized or synthetic verbal messages when the VOCA user presses a picture, line drawing, or other visual graphic symbol that is on the device board (Mirenda, 2001). In their recent review of VOCAs, Lancioni and colleagues (2007) found that between 1992 and 2006, 16 studies have been published on the use of VOCAs with persons with a range of developmental disabilities, including autism. Out of the 39 students in these studies, all but three succeeded to use VOCAs to varying degrees of success. For example, although some students only learned to use a single message for a single item, other students learned to use a variety of messages to request a range of preferred items

(see Datillo & Camarata, 1991; Dyches, 1998; Schepis & Reid, 1995).

Only a few studies have specifically studied the effectiveness of VOCAs with persons with autism. Schepis, Reid, Behrman, and Sutton (1998) used naturalistic teaching strategies to teach four children with autism, ages 3 to 5 years, to use VOCAs during snack and play routines. Over a 1- to 3-month period, all four children demonstrated increases in their communicative interactions. In addition to using their VOCAs to request preferred items, the children also used the AAC system to respond "yes" and "no," to make statements, and to make social comments (e.g., "thank you").

More recently, Sigafoos, Didden, and O'Reilly (2003) taught children with autism or autistic-like characteristics, ages 3 to 13 years, to request objects using a VOCA. All three children were able to request, "I want more" to obtain access to a variety of preferred food, drink, and activity items. The children's requesting behaviors were not affected by the presence or absence of digitized speech output, which was manipulated by the researchers. Furthermore, the digitized speech output did not cause any decreases in the children's verbal speech. In fact, one child began to speak single words toward the end of the study.

Proponents of VOCAs argue that one of their strengths is that the verbal messages can be easily perceived by other people, including those who are unfamiliar with that particular AAC system (Lancioni et al., 2007). Durand (1999) tested this assumption in a study that taught five persons with severe disabilities, ages 3 to 15 years, to use VOCAs through functional communication training. All of the children engaged in severe problem behaviors, such as hand biting, screaming, crying, head banging, and aggressions toward others. With their VOCAs, they were taught to produce alternative communicative behaviors (e.g., "I need help," "I want more") that served the same function as their problem behaviors. After instruction at school, all of the participants were able to independently use their VOCAs in community settings with community members who had never been trained in VOCA use. In another study, however, Dyches, Davis, Lucido, and Young (2002) found contradicting results. Researchers taught an adolescent girl to make requests with a VOCA and with a simple pictographic display and assessed community members' responses to requests made by these two AAC systems. Although the participant was able to generalize both systems to the community settings, community members took slightly longer to acknowledge requests produced by a VOCA as compared to requests made by nonelectronic picture displays. It is unclear if this difference resulted in a qualitatively different communication experience for the user or for the receiver of the communicative act, highlighting the need for more research on the effectiveness of VOCAs when used with untrained community members. Future research should investigate parents' perceived barriers of the effectiveness of VOCAs, including factors such as difficulty with programming, inconsistent reliability, and difficulty using the device in a conversational manner (Bailey et al., 2006).

The Picture Exchange Communication System (PECS)

The Picture Exchange Communication System (PECS) is a visual-constant AAC system that targets communication through the exchange of graphic iconic symbols (Frost & Bondy, 1994). For example, instead of saying, "I want juice," a child who uses PECS may bring a picture of juice to his mom. PECS was developed specifically for children with autism with limited or no functional verbal communication; however, its use has since expanded to include both children and adults with a range of developmental disabilities (Mirenda, 2001). PECS training is divided into six steps that mirror the development of communication and language in typical children (Bondy & Frost, 2001). The training protocol is discussed in detail in the PECS training manuals (Frost & Bondy, 1994, 2002) and is briefly outlined below.

- *Phase I: How to Communicate.* The child learns how to exchange one picture for a desired item with the communication partner.
- *Phase II: Distance and Persistence.* The child learns to travel to the communication book and to the communication partner.
- *Phase III: Discrimination Between Symbols.* The child learns to discriminate between different picture symbols to find the picture symbol of the current preferred item.
- *Phase IV: Using Phrases.* The child learns to combine picture cards to make phrases. For example, the child who wants juice will combine the "I want" picture card with the picture of juice on the sentence strip and exchange the sentence strip with the communication partner.
- *Phase V: Answering a Direct Question.* The child learns to answer questions, such as, "What do you want?"
- *Phase VI: Commenting.* The child learns to comment by combining the "I see" and "I hear" picture cards with other picture symbols. The child also learns to answer other questions, such as "What do you see?"

In addition to relying on a visual-constant modality, PECS training incorporates three other aspects that contribute to its success as a communication intervention for persons with autism. First, PECS is unique in its application of behavioral principles to an AAC intervention that emphasizes functional communication. The developers of PECS view functional communication as "behavior (defined in form by the community) directed to another person who in turn provides related direct or social rewards." (Bondy, 2001, p. 127.) Therefore, there is a link between the communicative act (exchanging a picture of juice) and the child's desire (thirst for juice). By teaching mands (requests) before tacts (comments), the child learns that communication is meaningful because it results in the acquisition of a desired item (Charlop-Christy & Jones, 2006). An emphasis on functional communication that is both meaningful and motivating increases the likelihood that the communicative behavior will occur again (Skinner, 1975).

Second, in addition to emphasizing functional communication, PECS training increases the likelihood that communication will be spontaneous. Unlike other communication interventions that begin training with a verbal prompt (e.g., "Point to what you want"), no verbal prompts are used in PECS training. Instead, a second trainer physically prompts the child from behind. The physical prompter does not socially interact with the child, and only prompts the child to exchange the picture card once he or she indicates a desire for the item (Bondy & Frost, 2001). The physical prompt can be quickly faded through a time delay procedure (e.g. Charlop & Trasowech, 1991). This procedure decreases the likelihood of prompt dependence and ensures that the communicative behavior is child-initiated (Charlop-Christy & Jones, 2006).

Third, PECS recognizes that communication is a social behavior. In typically developing children, communication involves much more than verbal language (Koegel, 2000). In fact, before they learn to speak, typically developing children learn to communicate with their caregivers through other behaviors such as looking, approaching, or pointing (Bondy & Frost, 2001). It is important to recognize the social nature of communication, because social deficits are one of the core features of children with autism (Kanner, 1943). Research indicates that children with autism are either delayed in or lack the social skills (e.g., imitations skills, simple gesturing, social responsiveness, and joint attention) that have been established as critical prerequisites for verbal speech development (Happe, 1994; Koegel, 2000; Schreibmen, 2005). PECS addresses these deficits by ensuring that children with autism learn the basic social elements of communication (e.g., approaching a communication partner and gaining his or her attention) before they learn to discriminate between different pictures (Frost & Bondy, 1994), increasing their likelihood of becoming successful communicators in a social world.

PECS Research

PECS is one of the most widely researched AAC interventions for persons with autism. We will present this literature by dividing it into four main topic areas: *(1)* PECS acquisition, *(2)* PECS generalization and maintenance, *(3)* ancillary benefits of PECS training, and *(4)* comparison studies. The majority of PECS research focuses on PECS acquisition in the training environment. In their review of PECS and VOCA usage with persons with developmental disabilities, Lancioni and colleagues (2007) found that between 1992 and 2006 17 studies have been published on PECS. In these studies, out of a total of 173 participants, only three participants failed to acquire PECS and a fourth participant ended training because of illness. These findings seem promising; however, the authors note that one must be cautious when interpreting PECS success. Although some of the studies only required participants to exchange one picture for a preferred item (e.g., Sigafoos et al., 1996), other studies required participants to learn PECS through Phase V (e.g., Charlop-Christy et al., 2002). A person

who has learned to exchange one picture for one preferred item would not seem to have acquired functional communication as defined by Bondy (2001).

A smaller number of studies have taught PECS to persons with autism according to the guidelines in the PECS manual (Frost & Bondy, 1994, 2002). These studies also indicate that, when taught correctly, persons with autism will successfully acquire PECS through Phase III or higher (*see the following for studies that present acquisition data: Charlop-Christy et al., 2002; Ganz & Simpson, 2004; Kravits et al., 2002; Magiati & Howlin, 2003; Tincani et al., 2006*). As characteristic of most skills, duration of PECS training varies for each child. For example, although the three children in Charlop-Christy and colleagues (2002) reached criterion in Phase V after an average of 246 trials, the three children in Ganz and Simpson (2004) reached criterion in Phase IV after an average of 346 trials. In a third study, after 6 months of PECS training in the classroom, the average PECS level for 34 children with autism was between Phases IV and V (Magiati & Howlin, 2003). In conclusion, the research demonstrates that children with autism can easily acquire PECS in the training environment through Phase III or higher.

Fewer PECS studies have included generalization and maintenance measurements. Some of the most rigorous generalization data comes from a study that taught PECS to adults with developmental disabilities (Stoner et al., 2006). In this study, the three adults who learned to use PECS through Phase IV at home also generalized PECS use to fast food restaurants in the community. Studies limited to persons with autism also indicated that participants can generalize PECS use across people (Tincani et al., 2006), across stimuli (Marckel et al., 2006), and across activities (Schwartz et al., 1998). However, more rigorous assessments are needed before we can conclude that persons with autism generalize PECS use outside of the training environment to all naturally occurring settings and situations and with a variety of people. Current research in our lab is assessing children's generalization of PECS use across environments, situations, and people. Initial results indicate that four children with autism who were taught PECS in a workroom generalized spontaneous PECS use to a playroom with a therapist, to their homes with a parent, and to the community with a stranger. One child required minimal training in one of the generalization settings, and the other children did not require any additional training for generalization to occur in all three settings (Greenberg et al., 2010). Furthermore, only one study has included follow-up data on participants' PECS use (Howlin et al., 2007). In this study, classrooms of children with autism were randomly assigned to an immediate treatment group, delayed treatment group, or control group. Treatment consisted of a 2-day PECS workshop for teachers, six half-day school-based training sessions, and 5 months of consultation with a PECS expert. Although both treatment groups showed increases in PECS use immediately after treatment, the children in the immediate treatment group did not maintain these gains 10 months after the consultation had ended. Clearly, more data is needed on PECS maintenance, especially when treatment occurs in 1:1 sessions.

The third area of PECS research presents findings on the ancillary benefits of PECS training. These studies have found that increases in communication with PECS are related to other positive outcomes (Charlop-Christy et al., 2002; Frea et al., 2001; Anderson et al., 2007). After PECS training, the three children in Charlop-Christy and colleagues (2002) showed increases in social behaviors such as eye contact, joint attention, play, requesting, and initiations and decreases in problem behaviors including tantrums, grabbing, out-of-seat behaviors, and disruptions. In another study, a 6-year-old child who learned PECS spent more time playing and less time watching TV (Anderson et al., 2007). Lastly, Frea et al. (2001) demonstrated that once a child learned to communicate effectively with PECS, aggressions toward others decreased. This research demonstrates the importance of functional communication. Once children learn how to use PECS, this form of communication may replace other more maladaptive forms of communication, such as tantrums or aggressions. Furthermore, PECS training reinforces social behaviors such as approaching other people and exchanging pictures with them. These interactions seem to teach PECS users that social interactions can be reinforcing, setting them on the path of becoming social initiators—an important achievement for persons with autism.

The most widely studied ancillary benefit of PECS training concerns concomitant changes in the participants' verbal speech (Anderson et al., 2007; Chalrop-Christy et al., 2002; Carr & Felce, 2007; Ganz & Simpson, 2004; Howlin et al., 2007; Kravits et al., 2002; Liddle, 2001; Magiati & Howlin, 2003; Schwartz et al., 1998; Tincani et al., 2006). Many of these studies report positive results. The three children in Charlop-Christy and colleagues (2002) showed increases in both their imitative and spontaneous speech during free-play and academic sessions. Furthermore, two of the three participants increased their mean-length utterances during and after PECS training. In another single-subject study, PECS training was related to an increase in the number of intelligible words spoken by three children with autism during their PECS training sessions (Ganz & Simpson, 2004). Lastly, although not experimental, Schwartz and colleagues (1998) found that when PECS had been implemented in the classroom for 1 year, 44% of the students showed marked increases in their spoken language.

Although most of the studies indicate that PECS leads to increases in children's verbal speech, some studies have not found such results. In Howlin and colleagues' (2007) randomized group design, PECS training was not related to increases in the frequency of speech or improvements on language test scores for the children in the two treatment groups. Likewise, although Carr and Felce (2007) report that PECS training led to an increase in communicative initiations during classroom observations, this increase was almost entirely accounted for by an increase in the participants' PECS use, not verbal speech. Mixed results indicate the need for more research on the effects of PECS training on learners' verbal speech. Particular attention should be paid to initial differences in the speech profiles between those persons who acquire

verbal speech and those who do not. Furthermore, researchers must explicitly describe the sessions in which speech was measured—differences in speech may emerge between PECS training sessions and free-play observations and between sessions in which the PECS book is available or not.

The final area of PECS research compares PECS with other AAC systems such as sign language and VOCAs. Although researchers are now attempting to determine which is the best AAC system for persons with autism, contradictory results indicate that the answer may not be a simple one. Studies comparing PECS and sign language report outcomes such as rate of acquisition, generalization, and the participants' preferred system. Several studies support the use of PECS. For example, Chambers and Rehfeldt (2003) taught four mands to four adults with mental retardation, ages 19 to 40 years, with both sign language and PECS using an alternating-treatments design. Three of the four participants required fewer training sessions to acquire the four mands using PECS than using sign language. The fourth participant did not reach criterion in either modality. Three participants generalized PECS use across settings, and two of the participants generalized sign use across settings. When the items were out of view, all four participants were more likely to request them using PECS than using sign language. Adkins and Axelrod (2002) taught a 7-year-old boy with PDD to request a variety of items with PECS and American Sign Language (ASL). They report that the PECS acquisition rate was faster than the ASL acquisition rate (an average of 7.1 trials for PECS versus an average of 15.7 trials for ASL). These results were consistent even when the same word was taught under both systems. Furthermore, the child was more likely to generalize PECS use outside of training sessions than to generalize ASL.

Results from Tincani (2004) are not so clear-cut. In this study, two children with autism spectrum disorders, ages 5 and 6 years, learned to request items with PECS and sign language in an alternating-treatments design. One participant demonstrated a high percentage of independent mands with sign language after the training was modified to remove modeling prompts. The other participant demonstrated a higher percentage of independent mands with PECS. Both participants were more likely to emit word vocalizations during the sign language sessions. However, once the PECS protocol was modified to include a 4-second delay, the second participant's word vocalization increased to an average of 90% of sessions.

Clearly, these studies do not indicate a clear preference for one AAC system over the other. Some researchers conclude that a student's motor imitation skills should be considered prior to training (Tincani, 2004). This relates to response effort (Richman et al., 2001). If a child has severe fine motor delays, sign language might be less efficient than PECS. It would also be useful to compare the participants' memory skills prior to training. Whereas sign language requires recall memory, the visual symbols in PECS provide constant reminders, and allow the participants to use recognition memory (Miranda, 2003). Although visual-constant systems might be better adapted to the memory deficits in persons with autism (Charlop-Christy & Jones, 2006), this might not be an issue for persons with

high recall memory. Typical of children with autism, there are individual differences that need to be taken into account before determining which AAC system should be used. The treatment of autism has never been "one-size-fits-all."

Other studies have compared the use of PECS and VOCAs. Again, the results are mixed. Although PECS and VOCAs are both visual-constant systems, VOCAs differ in the addition of digitized or synthesized voice output (Lancioni et al., 2007). In their review of PECS and VOCAs, Lancioni and colleagues (2007) describe four studies that compare the use of these two AAC systems (*see Bock et al., 2005; Dyches et al., 2002; Son et al., 2006; Soto et al., 1993*). Two of these studies compared picture boards (instead of PECS) and VOCAs with adults with mental retardation. Whereas the participant in Soto and colleagues (1993) preferred the VOCA, the participant in Dyches and colleagues (2002) preferred the picture board.

Bock and colleagues (2005) taught six nonverbal boys diagnosed with developmental delay, all age 4 years, to request items using PECS and VOCAs in a pull-out room at their schools. Three of the children acquired requesting skills faster with PECS than with their VOCAs. The other three children did not demonstrate differences in acquisition rate between AAC systems. After training, generalization of both systems was assessed in each child's main classroom. During these sessions, both systems were available to the children. Generalization results were mixed; three of the children demonstrated a clear preference for PECS, two of the children demonstrated a clear preference for VOCA, and one child did not show a clear preference for either system.

Only one published study has compared these two AAC systems with children with autism (Son et al., 2006). Three children, ages 3 to 5 years, were taught to request two snack items with both PECS and VOCAs. Acquisition rates did not differ for either system. After training, both systems were available to the children for the preference assessment sessions. One child showed a clear preference for her VOCA, and she chose it in 94% of opportunities. The other two children showed a clear preference for PECS, choosing it in 72% and 98% of opportunities.

As Lancioni and colleagues (2007) note, these studies do not indicate that one AAC system is better than another. Persons with autism are able to acquire both PECS and VOCA when making requests (Son et al., 2006).

Conclusion

Although research on children with autism and AAC systems has made substantial progress since AAC systems were first introduced with this population, the literature has areas of contradiction. It is not yet clear which AAC system is best for the majority of children with autism. However, this does not mean that science cannot inform our decisions. Interventionists should consult the literature to decide which AAC system would be best for each child on an individual basis. This process should involve a thorough consideration of many different

factors including the child's strengths and limitations, certain family variables, and other environmental constraints. When evaluating the specific child, important considerations would include the child's communication needs, the child's visual and auditory skill levels, the child's motor abilities, and the child's social skills mastery level. For example, if the child has strong visual discrimination skills and poor fine motor skills, PECS might be a better choice than sign language. If the child can make more complex statements via pictorial representations, then VOCAs might be the best choice.

Interventionists must also recognize that children do not develop in isolation. Children develop in complex environments, which will affect their communication in significant ways. Therefore, environmental variables must also be considered when choosing an AAC system for a specific child (Mirenda, 2003). Several of the most influential environmental variables might stem from the child's parents or primary caregivers. Children's parents are often their primary communicative partners. If an AAC system is going to be successful for the child, then its implementation must also be both supported by and feasible for the parents. In fact, AAC systems are most effective when AAC decisions are family-centered (Bailey et al., 2006). In addition to the child's parents, broader contextual variables should also be considered. Interviews with adult AAC users and their family members identified environmental factors as having the potential to both contribute to and impede AAC effectiveness (Lund & Light, 2007). A significant consideration would be community members' familiarity with different AAC systems. For example, if community members do not know sign language, then PECS or VOCAs might be more effective. Funding might also be of importance. If service providers will not fund more expensive AAC systems, families might not be able to afford VOCAs. Lastly, the educational system's preferences should be factored into the picture. If teachers in a particular school encourage their students to communicate through sign language, they might not support the use of PECS for one child.

In conclusion, AAC decisions for children with autism must be made on an individual basis. Ideally, AAC use will result in functional, spontaneous communication across a variety of settings and with a variety of people (Mirenda, 2003). This goal will only be met if child, family, and environmental characteristics are all taken into consideration. Additionally, researchers should continue to explore the use of AAC systems with children with autism to better inform AAC decisions.

Challenges and Future Directions

The predominant theme throughout this chapter, and in other areas of autism work, is the need for more research. Since AAC systems were first introduced with persons with autism, we have learned a lot about their applications and potential benefits. However, there is still much more to know as most of the literature has been done with non-ASD populations. We end by highlighting three central questions to be addressed by future research.

1. *Which AAC system is best for persons with autism?*

As previously discussed, there is much work to be done in determining the best AAC system for persons with autism. Comparison studies will make important contributions to this field. However, it is essential that these studies follow evidence-based research practices. Most importantly, studies must demonstrate experimental control (Cooper et al., 2007). In comparison studies, experimental control is established when the researchers demonstrate that changes in the participants' communicative behaviors are attributed to the AAC interventions, and not to any other confounding variable. When studying persons with autism, the best experimental method is often single-subject design (Cooper et al., 2007; Simpson, 2003). Single-subject design accounts for the heterogeneity of the population, highlighting variability within the data and between participants (Simpson, 2003). In addition to adhering to empirically validated research practices, researchers must also ensure that they are targeting socially significant behaviors (Cooper et al., 2007). This is especially important when studying AAC systems. Studies that target one request have not demonstrated that the AAC system leads to effective communication. Lastly, more comparison studies should include generalization and maintenance measurements (Schlosser & Lee, 2000). Studies that only compare acquisition rates between two AAC systems will not be able to conclude that one AAC system is more effective than the second AAC system. Truly functional communicative behaviors will be used across environments and maintained over time. Therefore, the most useful comparison studies will also highlight which AAC systems that lead to superior generalization and maintenance over other AAC systems.

2. *What is the relationship between AAC use and the development of verbal speech?*

Although AAC systems should provide persons with autism with a means of communication that is just as effective as verbal speech, many people still view verbal speech as an important milestone for persons with autism. Verbal speech is used by interventionists and researchers to distinguish high-functioning from low-functioning persons with autism (Charlop-Christy, 1987; Schreibman, 2005). Furthermore, many parents are often hesitant to implement AAC systems, fearing that their use will decrease the chances of their children ever speaking (Millar et al., 2006). In their review of the impact of AAC systems on speech production in individuals with autism, Schlosser and Wendt (2008) conclude that AAC systems frequently lead to modest gains in speech production, but that more empirical research is needed to investigate this area. Although more empirical research is needed to confirm that AAC use leads to increases in verbal speech, parents and interventionists should no longer be concerned that AAC use will lead to a decrease in children's verbal speech or prohibit children from ever acquiring verbal speech.

3. *Do AAC systems lead to functional communication?*

Functional communication is achieved when children spontaneously use the skill in naturally occurring settings and situations (Horner & Budd, 1985). Functional communication should be our goal with AAC systems, as it is the only mark of successful communication. If AAC systems are functional, then children will use them to communicate effectively in their everyday lives (Mirenda, 2003). Unfortunately, research to date does not demonstrate that this goal has been met.

Embedded in this definition are two components: *(1)* communication must be spontaneous, and *(2)* communication must generalize. These two aspects are often difficult for persons with autism (Koegel, 2000; Lovaas et al., 1973; Lovaas et al., 1974; Schreibman, 2005). Koegel (2000) notes that although children can easily acquire AAC systems, they may have difficulties with generalization and require prompts in untrained situations. Although several studies have empirically investigated the generalization of AAC systems with persons with autism (e.g., Adkins & Axelrod, 2002; Marckel et al., 2006; Schwartz et al., 1998; Tincani et al., 2006), they have only measured AAC use in a limited number of settings and with a restricted number of people and items; these studies do not give us the complete picture of children's AAC use outside of training and research situations.

Two different lines of research could address these limitations. First, AAC studies should include generalization measurements that attempt to reflect a variety of naturally occurring settings and situations. This implies that generalization probes should be conducted across settings, people, items, and situations. Second, other studies must look beyond these generalization measurements. Although important, generalization probes will not be able to capture all of the situations in which you would expect communication. Furthermore, behavior during research sessions does not always reflect behavior in real-world contexts (Charlop-Christy et al., 2008). Situations are often contrived and the presence of the researcher may influence both the child's and the communication partner's behavior. A generalization probe might indicate that a child frequently uses PECS at home with a parent during 10-minute sessions observed by the researcher, whereas the child might not use PECS as frequently in these real-world contexts during other times when the researcher is not present.

Autism researchers could benefit from looking at research trends outside of our field. Recently, AAC as a discipline has begun to stress the importance of including other outcome measurements. Lund and Light (2006) argue that determining the effectiveness of AAC involves more than looking at how frequently it is being used. If AAC is functional, it will impact the individual's overall communication and functioning. These researchers stress the importance of looking at long-term outcomes across a range of domains, including receptive language, reading comprehension, communicative interaction, functional communication, educational and vocational achievement, self-determination, and quality of life. One way of approaching this issue involves interviewing parents of children who use AAC (Marshall & Goldbart, 2008). One of the major roadblocks to effective AAC use may be difficulty with implementation. AAC use can be expensive for families (especially when buying electronic devices, such as VOCAs), time consuming, and stressful (Lund & Light, 2007). If AAC is not feasible for the parents to implement, then it is unlikely to become functional for the child.

Research on the functionality of AAC systems reminds us of our goal. AAC systems should provide persons with autism with a means of communication—communication that is not prompt-dependent and context dependent, but rather communication that is spontaneous and effective in all situations and settings. This is a lofty goal. However, if achieved, it has the potential of dramatically improving the lives of many persons with autism. It is our hope that these benefits will continue to motivate researchers to study the applications of AAC systems with persons with autism.

65 ⊞ Edward G. Carr†

Positive Behavior Support and Problem Behavior

Since the writing of this chapter, Professor Edward (Ted) Carr passed away following an automobile accident. Dr. Carr was greatly admired by his colleagues and students for his innovation in developing novel and compassionate strategies for improving the quality of life for people with autism. His methods are now practiced worldwide and have been incorporated into the recommendations of the Individuals with Disabilities Education Act, federal legislation that seeks to insure quality education for individuals with disabilities. We are honored to have his work represented in this volume.

Points of Interest

- Problem behavior is the major reason that people with autism spectrum disorders fail to make a good adjustment to society.
- Positive behavior support is effective for reducing problem behaviors and thereby increasing quality of life and adaptation in individuals with autism spectrum disorders.
- Positive behavior support is a transdisciplinary approach that uses educational methods to build life skills and systems and context change methods to redesign an individual's living environment.
- Even the most severe problem behaviors including aggression, self-injury, tantrums, and property destruction can be successfully treated.
- The reconceptualization of autism as a whole-body disorder highlights the necessity for examining the impact of illness and abnormal metabolism on problem behavior. These biological setting events represent new treatment targets that can broaden the scope of intervention.

Problem behavior is the major reason why people with autism spectrum disorders (ASDs) fail to make a good adjustment to society. In this chapter, I will begin by defining problem behavior. Then, I will address the issues of prevalence and clinical significance as well as the nature and relevance of the positive behavior support (PBS) perspective. The five-term contingency, a conceptual scheme for understanding problem behavior, will be presented and related methods for assessing the functions and contexts associated with problem behavior will be discussed. Next, I will highlight the critical linkage between assessment and the systematic, rational development of effective intervention strategies. A tripartite model for conceptualizing interventions—namely, avoid/mitigate/cope—will be described, and the multiple strategies that follow from

this conceptualization will be presented. I then discuss the issue of outcome success. Finally, a roadmap for identifying future directions in research and practice will be outlined with respect to knowledge gaps that need to be addressed.

What is Problem Behavior?

Problem behavior includes aggression, property destruction, self-injury, and tantrums as well as noncompliance, pica, stereotypy/self-stimulatory behavior, and a variety of other disruptive behaviors. Although dangerous behaviors such as aggression and self-injury clearly merit close attention from scientists and clinicians, parents report that behavior that is "merely" difficult is often a source of family distress. Thus, elopement, feces smearing, and bizarre vocalizations can—like more dangerous behaviors—generate fear, emotional and physical exhaustion, and public embarrassment on the part of family members (Turnbull & Ruef, 1996). In sum, problem behavior must be defined not only in terms of its topographical characteristics but also in terms of its impact on others.

How Prevalent is Problem Behavior?

Problem behavior can be two or three times more likely to occur in people with developmental disabilities than in the general population (Einfeld & Tonge, 1996). In the absence of intervention, problem behavior generally persists over time and may even become worse (Emerson et al., 2001a).

Epidemiological studies of populations of individuals with an array of developmental disabilities have yielded prevalence rates of problem behavior as low as 2% to as high as 70% (Sigafoos, Arthur, & O'Reilly, 2003). One particularly well-designed total population study reported prevalence rates of

10% to 15% (Emerson et al., 2001b). Variability in prevalence rates across studies reflects differences in sample size, the mix of diagnoses represented in the sample, structural properties of the survey methodology employed, and settings selected for evaluation.

Why is Problem Behavior Important?

Problem behavior is among the leading causes of institutionalization (Bruininks, Hill, & Moreau, 1988). It disrupts family life (Lucyshyn, Dunlap, & Albin, 2002), promotes segregated rather than inclusive education (Janney & Meyer, 1990), and limits employment opportunities (Nisbet & Vincent, 1986). Because problem behavior destroys quality of life, understanding and effectively addressing such behavior requires an approach that is sensitive to broad social, emotional, educational, and ecological contexts. PBS was developed to address these broader concerns.

What is Positive Behavior Support?

PBS is a transdisciplinary approach to understanding and treating problem behavior and other challenges to personal and community adjustment. It uses educational methods to build life skills and systems and context change methods to redesign an individual's living environment (Carr, 2007; Carr & Pratt, 2007). The purpose of all these strategies is to minimize or eliminate problem behavior in ways that promote improved quality of life. Nine elements define the overall approach (Carr et al., 2002).

First, there is a focus on comprehensive lifestyle change and improved quality of life as the ultimate goal of intervention. Lifestyle change results from a broad approach that addresses the multiple dimensions defining quality of life (Hughes et al., 1995): social relationships, personal satisfaction, employment, self-determination, recreation and leisure, community adjustment, and community integration. It is deficiencies in these areas that create the conditions that promote and exacerbate problem behavior (Emerson, McGill, & Mansell, 1994; Koegel & Koegel, 2006; Koegel, Koegel, & Dunlap, 1996). Second, there is a recognition that meaningful support must be provided over protracted time periods. In other words, one must embrace a lifespan perspective to intervention. Third, interventions must have ecological validity—that is, they must be effective in the natural settings of home, school, and community, and they must be implemented by typical support people such as parents, teachers, and job coaches. Fourth, key stakeholders (e.g., parents, teachers, friends) must be involved as collaborators in helping to develop interventions. Fifth, there is an emphasis on social validity of both procedures and outcomes. In other words, typical support people must agree that the intervention strategies selected are practical, desirable, and

effective and represent a good fit with their values and needs. Sixth, there is a recognition that the best conceived intervention plans will fail if they are embedded in systems that are disorganized, dysfunctional, or unsympathetic to the broad goals of PBS. Therefore, a signature characteristic of PBS involves systems change and multicomponent intervention. Seventh, there is an emphasis on prevention. This perspective stresses the idea that proactive interventions that build functional skills and redesign environments decrease the likelihood of future episodes of problem behavior. Eighth, there is flexibility with respect to methodological practices. PBS research does not rely exclusively on experimental methodology but, when appropriate, employs correlational analyses, naturalistic observations, and case studies.

The ninth and final feature of PBS is the most distinctive. Specifically, PBS draws information from multiple scientific disciplines and theoretical perspectives (Carr, 2007). A crucial aspect of PBS is its reliance on applied behavior analysis (ABA) and its accompanying operant conceptual framework emphasizing the role of learning principles in building skills and reducing problem behavior. However, no single approach, including ABA, will be able to address all relevant issues. Therefore, PBS has evolved from its ABA roots to embrace other disciplines, including organizational management, community/ecological psychology, cultural psychology, positive psychology, and biomedical science. Thus, altering systems so that they are responsive to human needs requires knowledge of organizational management (Ambrose, 1987). The themes of prevention, social support, and empowerment (all central to PBS practice) are associated with an extensive research literature in community/ecological psychology (Rappaport & Seidman, 2000). Cultural psychology provides essential information about values and customs, family structure, and child-rearing practices relevant to intervention with diverse ethnic groups (Chen, Downing, & Peckham-Hardin, 2002). The emerging field of positive psychology directly addresses quality-of-life issues as well as environmental redesign and, as such, is germane to enhancing PBS efforts (Seligman et al., 2005; Snyder & Lopez, 2005). Finally, biomedical science is a rich source of information about physiological and illness factors that can exacerbate problem behavior and diminish quality of life (Bauman, 2006; Carr & Herbert, 2008; Herbert, 2006).

Not every PBS intervention encompasses all nine of the features just discussed, but PBS, as an integrated field, does. The PBS process is facilitated by having a conceptual framework for understanding problem behavior in a way that leads logically to intervention.

A Five-Term Contingency for Understanding Problem Behavior

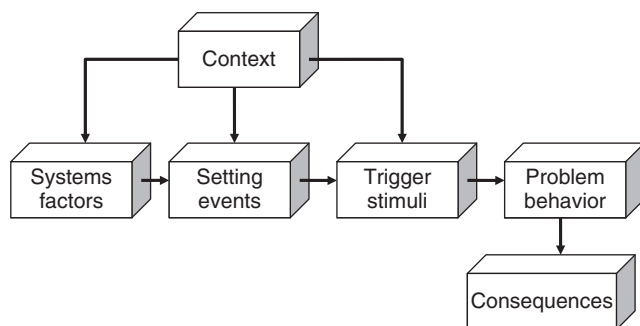
Figure 65-1 shows a conceptual framework that can be used to tie together many of the themes relevant to PBS. The framework has five variables. Three of them (systems, setting events,


Figure 65–1. A five-term contingency for understanding problem behavior.

trigger stimuli) define the context for problem behavior and are comprised of all variables that precede (are antecedent to) such behavior. One factor, consequences, is comprised of all variables that follow the behavior. The remaining variable is the problem behavior itself, controlled by both antecedents (context) and consequences.

It will be helpful to begin by defining each variable. First, consider context. A trigger (or discriminative) stimulus is a discrete antecedent event that is strongly correlated with reinforcement of behavior. Because it reliably predicts that a specific response (behavior) will be followed by a reinforcer, the presence of the discriminative stimulus is likely to trigger a specific behavior.

A setting event is a variable that influences ongoing discriminative stimulus–response relations. Depending on the nature of the setting event, it can either facilitate or inhibit the likelihood that a given discriminative stimulus will trigger a specific behavior. An important mechanism through which setting events affect behavior is referred to as an "establishing operation" (Michael, 1982). This mechanism works by altering how reinforcing or aversive the consequences of behavior are. That is, the discriminative stimulus is either more or less likely to trigger a given response, depending on whether response consequences have become more reinforcing or more aversive.

Systems refer to broad organizational, ecological, and cultural variables that produce clinically significant settings events (Carr et al., 1998).

Consequences refer to those events that reliably follow a behavior. One major and very important consequence class is referred to as a reinforcer, but it is also variously described as the payoff, motivation, function, purpose, or intent of the behavior.

Finally, there is the behavior itself that, for present purposes, refers to any of the multiple types of problem behavior described and defined earlier, although in intervention, it can also refer to prosocial behavior.

A concrete illustration of the five-term contingency will help clarify its role in understanding problem behavior. Consider a systems variable relevant to organizational management in a school. Specifically, the school has a policy wherein all children who display major problem behavior are put in a special resource classroom. In doing so, an environment is inadvertently created that is noisy, elicits much negative

feedback to students from the overstressed teacher, generates high rates of peer teasing and arguments, and promotes student anxiety because of ever-present danger from poorly behaved peers. All of these factors are setting events produced by an ill-conceived policy at the systems level. These setting events, in turn, cause discriminative stimuli related to simple academic assignments (e.g., a teacher request to read a passage from a book and answer questions) to become highly aversive. That is, reading becomes onerous in the context of high noise levels, frequent reprimands, being teased and threatened, and experiencing anxiety. The student responds not by reading but by tearing the book to pieces and screaming at the teacher. In other words, the request to read has become a trigger for aggressive behavior. The teacher responds by allowing the student to escape from having to complete the reading task. Thus, the consequence of aggression is a desired outcome—namely, cessation of the aversive reading task. The student has now learned that aggression in response to an aversive trigger stimulus terminates that stimulus. This series of events, repeated across a variety of academic tasks, compromises learning and will produce a student who displays aggressive behavior throughout the school day.

Types of Consequences (Functions)

Ultimately, people with autism display problem behavior because it serves a function. The research literature suggests two classes of functions: obtaining positive reinforcement and obtaining negative reinforcement. Reinforcement, whether positive or negative, increases the future likelihood of any problem behavior it follows.

Positive reinforcers are consequences that are added (presented) following the display of problem behavior. Attention (e.g., an expression of concern following an act of self-injury) is a common type of positive reinforcer that ensures that the behavior will be repeated in the future (Durand et al., 1989). Another type of positive reinforcer involves the presentation of tangibles (e.g., preferred foods) or access to preferred activities following outbursts of problem behavior, in a vain attempt to mollify the individual (Durand & Crimmins, 1988). Sensory reinforcement (e.g., stroboscopic effects produced by hand-flapping in front of a light source) is a third type of positive reinforcement (Rincover et al., 1979).

Negative reinforcers are consequences that are removed (withdrawn) following the display of problem behavior. These consequences are aversive in nature. Therefore, any problem behavior that is followed by successful avoidance or escape from such consequences is likely to be repeated whenever the individual encounters them in the future. Unfortunately, academic, home, and work tasks are frequently aversive to people with autism, and therefore, their termination following an outburst of problem behavior functions as a negative reinforcer (Carr, Newsom, & Binkoff, 1980). Equally unfortunately, given the nature of autism, social interaction can be very aversive and evoke problem behavior that functions to escape such interaction (Taylor & Carr, 1992).

It is often the case that many different behaviors can serve the same function, and the same behavior can serve multiple functions. Therefore, the most useful analysis of behavior involves an understanding of function and not topography. The "why" of problem behavior (function) is ultimately more important than the "what" of problem behavior (topography).

Types of Antecedents (Contexts)

Function does not exist in a vacuum. It is embedded in and created by specific contexts. Although, as noted, trigger stimuli and setting events can be distinguished on technical grounds, a specific stimulus can function as either, depending on circumstances. For example, a sudden noise can immediately evoke tantrums in a child with auditory hypersensitivity, in which case the noise is functioning as a trigger stimulus. Alternatively, the presence of noise may make an academic task aversive to a child, thereby evoking escape-motivated tantrums, but only when the task is given. In this case, the noise is functioning as a setting event rather than a trigger stimulus (i.e., here, the task, rather than the noise, is the trigger stimulus). Investigators have often focused their attention initially on identifying classes of contextual variables (consisting of both trigger stimuli and setting events) that appear to be closely associated with problem behavior.

Trigger Stimulus/Setting Event Contexts

One plausible way of parsing the research literature on contextual variables is to organize them into one of three categories: social contexts, activity/routine contexts, or biological contexts. Members of each context category have been identified, empirically, as factors that can evoke and/or exacerbate problem behavior. The research literature, although not always uniquely focused on persons with ASDs, nonetheless has great clinical relevance to them. Several examples from each generic category identified in research (e.g., McAtee, Carr, & Schulte, 2004) are briefly noted next and described more fully later.

Social contexts involve factors pertaining to relationships and interpersonal interactions. Thus, problem behavior worsens in the context of poor rapport between people, low levels of attention from others, being denied access to preferred items, and frustration resulting from difficulty in communicating with others.

Multiple aspects of common home and school routines and activities constitute a second category of contexts. Thus, activities that are too difficult, too long, too noisy, or too crowded can set off problem behavior. Activities that involve waiting, unpredictability resulting from changes in routine, and being required to make transitions between settings and activities are also factors related to an increased likelihood of problem behavior.

Biological contexts involving factors related to medication side effects, illness and pain, fatigue, anxiety, and negative mood have all been demonstrated to contribute to problem behavior.

Systemic Contexts

The third aspect of context, systems, represents a topic area that has not, until recently, been the focus of substantive research. Yet, an emerging research base relevant to home (Lucyshyn et al., 2002) and school (Crone & Horner, 2003) highlights the importance of systemic factors in understanding problem behavior.

The core idea behind systemic assessment is that it is necessary to go beyond the person who is displaying problem behavior to fully understand the range of factors influencing such behavior. One set of factors concerns the organizational structure and content of service systems. Another set of factors concerns the structure and characteristics of family systems.

The study of service systems has identified a number of factors reliably associated with problem behavior (Emerson et al., 1994). These include (1) restricting an individual's choices with respect to housing, employment, recreation, and social partners, thereby creating nonpreferred, even aversive, environments; (2) a failure to provide meaningful activities that fully engage the individual; (3) a lack of social support and community networking that isolate the individual, creating barren, unstimulating environments; (4) a lack of resources that results in little opportunity to fully integrate into the broader community (e.g., unavailability of transportation that makes trips to restaurants, movies, sporting events impossible); (5) an insufficient number of competent personnel who know how to create opportunities for enhanced quality of life; and (6) the presence of staff who have conflicting visions of critical service goals; for example, some staff emphasize containment and placidity, whereas others emphasize community integration and personal development.

The study of family systems has likewise identified several factors whose presence severely undermines the ability of parents to effectively manage their child's problem behavior (Singer et al., 2002). Thus, marital discord, parental social isolation, parental depression, parental stress, and poverty or lack of personal resources are all associated with difficulty in behavior management.

A focus on assessing systemic factors at either the service delivery or family level is a hallmark of the PBS approach (Carr et al., 1998) and provides useful information concerning what factors one might focus on in developing broad intervention strategies. Having described the types of contexts and functional consequences that influence problem behavior within a five-term contingency, we can now proceed to answer the question of what assessment strategies are available to identify these factors in real-world settings.

Methods for Assessing Function (Consequences) and Contexts

Three classes of assessment are in common use: indirect observation, direct observation, and experimental (functional

analysis). Collectively, these methods are referred to as functional assessment because behavior is a function of both consequences and contexts.

Indirect Observation

Indirect observation is often referred to as informant assessment because it involves gathering information from teachers, parents, and, if possible, the person with ASD (i.e., informants). It can take the form of structured interviews, rating scales, record reviews, and person-centered planning.

The functional assessment interview (FAI) uses a structured format in which informants are asked to respond to questions concerning the nature of the behavior itself, categories of setting events and discriminative stimuli, and putative functions (purposes) of the behavior (O'Neill et al., 1997). The Motivation Assessment Scale (Durand & Crimmins, 1992) and the Contextual Assessment Inventory (McAtee et al., 2004) are rating scales, the former used to identify behavior functions, and the latter, multiple contexts. Record reviews might involve accessing archival information, regarding behavior and its controlling variables, from behavior logs completed by staff (Carr, Ladd, & Schulte, 2008).

Finally, reflecting the PBS emphasis on analyzing broader service and family systems, person-centered planning (Kincaid, 1996) is an interview assessment tool used to identify barriers to and opportunities for choice, engagement, community integration, resources, and family issues, any of which could provide a context for either problem behavior or positive, individual development. Relatedly, structured interviews and rating scales are also available to assess the integrity of living, employment, and recreational environments, all of which impact quality of life and problem behavior (Schalock & Felce, 2004). Family systems factors, which are also critical to quality of life, can be assessed using a variety of instruments (e.g., Abidin, 1997). Thus, assessing marital discord, parental stress, and depression can help identify relationships between the broader family ecology and problem behavior.

Direct Observation

Direct observation does not involve the use of intermediaries. Rather, behavior is observed directly as it is occurring in natural settings. Direct observation most commonly takes the form of A-B-C (antecedent-behavior-consequence) charts, scatter plots, and structured recording of environment–behavior sequences as they unfold in real time.

ABC charts (e.g., Carr et al., 1994) use a format that allows the observer to write down simple narrative descriptions of behaviors (B) as they occur and then to describe the antecedent trigger (discriminative) stimuli (A) as well as the consequences (C) that follow the behavior. A scatter plot (Touchette, MacDonald, & Langer, 1985) involves the use of a grid divided into time-intervals that cover each day of observation (e.g., the entire day may be broken down into half-hour blocks of time). High, low, and zero levels of problem behavior are operationalized and represented by symbols that are entered into the grid, providing a visual pattern of the times of day in which problem behaviors cluster. These times of day are then examined for the presence and type of correlated trigger stimuli and setting events.

Structured recording methods, also referred to as descriptive analysis, provide precise time-based information on A-B-C sequences as they are occurring (e.g., Emerson et al., 1996). Most commonly, the information is presented as frequency counts (e.g., the number of aggressive acts per unit of time) or time samples (e.g., the percentage of 10-second blocks of time, in 1 hour, that contain an aggressive act). Although structured recording is, arguably, the most precise and reliable method of direct observation, it is costly in terms of time and personnel requirements. Also, it is purely correlational in nature, and therefore, one cannot say with certainty that problem behavior is actually controlled by specific antecedents and consequences—only that it is temporally associated with them.

Direct observation at the level of service systems, in contrast to trigger stimuli and/or setting events, is substantially more complex and much less well-developed methodologically. Nonetheless, quality-of-life issues pertaining to systemic factors are an ongoing focus of research. In particular, direct observation methods pertinent to choice, engagement, social activity, and community involvement exist (Felce & Emerson, 2000; Schaloch, 1996). Methods also exist for studying family systems variables related to marital discord, social isolation, depression, and stress. Assessing these factors could yield important insight into the mechanisms responsible for deterioration in problem behavior. For example, research on marital discord demonstrates that it produces inconsistency in child-rearing practices (Downey & Coyne, 1990), a mechanism that could result in poor implementation of intervention strategies that might otherwise decrease the likelihood of problem behavior.

Experimental (Functional Analysis)

Functional analysis involves the experimental manipulation of the antecedents (context) and consequences of problem behavior to identify those variables that have a causal relationship to the behavior. For example, one might manipulate a specific discriminative stimulus (e.g., a task demand) by systematically presenting and withdrawing it. Further, whenever an aggressive behavior (e.g., hitting) occurred, one might allow the child displaying it to escape from the task. If no hitting occurred, then the child would not be allowed to escape. If the child subsequently showed increasing levels of hitting in the presence of the task and little hitting in its absence, then one would have learned two things. First, the function (purpose) of the hitting is to escape from a (likely) aversive task. Second, the task itself is a reliable trigger for hitting. Using variations of this method, it is possible to identify the multiple functions (e.g., attention, escape, tangibles, sensory) and multiple discriminative stimuli that control the behavior (Iwata et al., 1982).

Unlike direct observation, functional analysis can identify causal relationships between environment and behavior. However, it is time-consuming, requires a level of expertise beyond that of many practitioners, raises ethical issues because it involves purposely introducing variables that evoke problem behavior, and is extremely difficult to carry out in complex, natural environments, thereby diminishing its ecological validity (Desrochers, Hile, & Williams-Mosely, 1997).

Best Practices in Assessment

Because each assessment method has limitations as well as strengths, a multi-method approach is the best way to increase the probability of accurately identifying important variables. The three approaches described are commonly used together to ensure that clinically significant information is not missed (Carr et al., 1994). Further, because the variables controlling problem behavior often change over time, best practice dictates ongoing and repeated assessment rather than an initial assessment with no follow-up.

Linking Assessment to Intervention

Several large meta-analyses have found that intervention is about twice as likely to succeed when it is based on a careful functional assessment as when it is not (Carr, Horner et al., 1999; Didden, Duker, & Korzelius, 1997; Scotti et al., 1991). Functional assessment leads directly to an intervention model that focuses on both context and consequences as a general strategy for ameliorating problem behavior.

A Tripartite Model for Conceptualizing Intervention: Avoid/Mitigate/Cope

The key principle of PBS intervention is derived from a knowledge of functional assessment within a five-term contingency. The key principle is that problem contexts produce problem behaviors; therefore, by modifying problem contexts and the behavioral consequences that help create these contexts, we should be able to reduce or eliminate problem behaviors.

There are three generic ways in which problem contexts can be effectively addressed. First, one can avoid the context. Second, one can mitigate the context so that it no longer evokes problem behavior. Third, one can teach skills that allow an individual to cope with the context.

An example will help illustrate the logic of the avoid/mitigate/cope model of intervention. Consider one problematic context noted earlier—namely, having to wait. For example, a child must wait in line at the checkout stand in a grocery store. The child responds to this context with violent tantrums. A parent could address this problematic context by shopping only during "slow" times when lines are very short. This strategy avoids the context by eliminating waiting. When the context cannot be avoided (i.e., the family must shop at a busy

time), the parent can introduce highly preferred toys into the routine. This strategy, an example of mitigation, changes the nature of the context by adding new stimuli (toys) that evoke appropriate behavior (playing), thereby replacing inappropriate behavior (tantrums). Finally, when neither avoidance nor mitigation are possible (e.g., busy store and parent did not bring toys), the child can be taught to self-regulate, a coping skill. For example, the child may be instructed to place a checkmark on a piece of paper for every 30 seconds of good behavior and receive a reward (e.g., a special treat) proportional to the number of checkmarks accumulated at the end of the waiting-in-line routine. In this case, a long wait becomes desirable as it presents opportunities for many checkmarks and substantial rewards. Furthermore, self-regulatory behavior replaces tantrums. A discussion of some of the many variations of avoid/mitigate/cope is presented next to illustrate the breadth of the model and its relationship to functional assessment and PBS. Each of these strategies can contribute, incrementally, to various aspects of individual functioning relevant to improving quality of life.

Avoid

An avoid strategy involves eliminating the trigger stimuli and setting events that evoke problem behavior. For example, if noise is a known problem context for a child (O'Reilly, Lacey, & Lancioni, 2000), then a parent may want to avoid unnecessary exposure to this context (e.g., no exposure to loud music, crowded shopping malls, motorcycles). However, complete avoidance is almost never possible in the real world of home, school, and community. Unfortunately, many parents try to approximate complete avoidance by limiting community excursions, by dropping otherwise meaningful home routines, and by shielding their child from certain types of social situations. This tactic impedes the major goal of PBS—namely, developing a good quality of life. In sum, although the judicious and limited use of an avoid strategy may be appropriate in certain circumstances, for the most part, problem contexts will need to be addressed via mitigation or coping.

Mitigate

Mitigation is a generic strategy for reducing problem behavior in which the stimulus properties of the problem context are altered. Specifically, someone other than the individual with ASD introduces new stimuli that evoke nonproblem (appropriate) behavior and/or minimize aspects of the stimulus context that are currently evoking problem behavior. Environmental redesign is a core feature of all mitigation strategies within a PBS model. Several major strategies are discussed next.

Rapport Building

Negative social relationships (poor rapport) can function as a setting event to make common tasks and demands highly

aversive, thereby triggering escape-motivated problem behavior (Magito, McLaughlin, & Carr, 2005). In illustration, a female staff member who has a history of negative interactions with a young man with autism asks him to clean his room. The young man responds by trashing his room and the demand is withdrawn. However, when the same demand is presented by a staff member who has excellent rapport with the young man, the result is cheerful compliance. The staff member who has poor rapport with the man is then taught to pair herself with a wide variety of reinforcers (e.g., giving the man his favorite foods, playing his favorite music), to respond positively to his communicative attempts, and to share enjoyable activities with him in a reciprocal, not dominating, manner. The quality of the relationship (a PBS imperative) improves, and problem behavior is virtually eliminated (Magito, McLaughlin, & Carr, 2005). Redesigning the social environment to include many new stimuli that evoke appropriate behavior and that reduce the aversiveness of the interaction brings about the desired change.

Providing and Honoring Choices

Providing choices mitigates the aversiveness of a task situation or activity by allowing the individual to select tasks and activities that are currently more reinforcing or less aversive to him or her. In this manner, the need for escape-motivated problem behavior is undermined and positive engagement with preferred tasks and activities is strengthened. The introduction of choice reconfigures the environment, minimizing stimuli that trigger problem behavior and maximizing stimuli that trigger appropriate behavior (Dunlap et al., 1994).

Social Stories

A social story is a sequence of sentences, sometimes accompanied by pictures, that help an individual to know how to behave in difficult situations (Gray & Garand, 1993). For example, a child finds waiting in line for recess very frustrating and responds by throwing a tantrum to escape from the line and gain access to the playground. In response to this problem, a social story is constructed in which the difficult situation is carefully described (e.g., "At my school, before we go to recess, we wait in line with lots of other children."); specific instructions are given that direct the child on how to behave (e.g., "I have to wait my turn before leaving the building, keep my hands to myself, and not push my classmates out of the way; if I'm having trouble waiting, I can always think of the fun things I'll soon be doing out on the playground."); and the perspectives of other children are clearly stated together with desirable consequences (e.g., "The other children will like that I didn't push them and will want to play with me more once we're outside."). From a functional standpoint, social stories are a series of discriminative stimuli that prompt and trigger appropriate behavior and specify the rules governing when such behavior will be reinforced. Further, social stories greatly enhance the predictability of events,

an important consideration given that individuals with autism experience unpredictability as aversive. When a social story is repeatedly rehearsed with a child, evidence suggests that problem behavior may be replaced with socially appropriate behavior (Scattone et al., 2002).

Behavioral Momentum

In this procedure, stimuli that are discriminative for problem behavior (e.g., difficult task demands) are interspersed or embedded among stimuli that are discriminative for socially appropriate behavior (e.g., easy task demands; conversations about pleasant events). Once an individual with autism has been responding appropriately to a series of nonproblematic discriminative stimuli (i.e., a positive behavioral "momentum" has been established), the problematic stimulus is presented (Mace et al., 1988). The result is a reduction in problem behavior. This procedure is likely effective because the presence of many nonproblematic discriminative stimuli evoke appropriate behavior that is positively reinforced by others, and the increase in reinforcement level, in turn, likely mitigates the aversiveness of the problem context (e.g., difficult demands), thereby undermining the motivation for escape-motivated problem behavior.

Curricular Modification

The essence of this strategy is to identify the aversive features of task stimuli (e.g., the academic curriculum) that evoke escape-motivated problem behavior and then to alter those features. For example, one might alter features related to task length and task content. Mitigating the problematic context in this manner can produce a decrease in problem behavior (Dunlap, Kern-Dunlap, & Robbins, 1991).

Noncontingent Reinforcement

If problem behavior functions to access certain reinforcers, then it may be possible to redesign the environment in such a way that the reinforcers are provided noncontingently (i.e., for "free"). In principle, sensory reinforcers, attention, and tangibles could all be provided, as appropriate, after fixed periods of time throughout the day. Thus, if self-injurious behavior is maintained by attention, one could provide attention, intermittently, irrespective of the individual's behavior at any given moment. This "free" attention, in fact, has been shown to reduce self-injurious behavior (Vollmer et al., 1993). Similarly, noncontingent reinforcement (NCR) applied to tangibly motivated problem behavior can reduce that behavior as well (Lalli, Casey, & Kates, 1997). NCR makes problem behavior nonfunctional and unnecessary. Further, the free reinforcers being provided likely also function as discriminative stimuli for appropriate behavior (e.g., when a sought-after tangible object such as a preferred toy is provided, the child will play with the toy; this play behavior replaces the problem behavior).

Altering Setting Events

As noted earlier, affective states involving negative mood, agitation, and irritability can all serve as powerful setting events that increase the likelihood of discriminative stimuli (e.g., academic task demands, home chores) acquiring aversive properties, thereby evoking escape-motivated problem behavior. It would be logical, therefore, to redesign the environment to include countermanding setting events that are associated with positive affect and that have a calming influence. This context-based intervention should decrease the aversiveness of the discriminative stimuli, making escape unnecessary. In fact, research demonstrates that the insertion of countermanding setting events, variously referred to as neutralizing routines (Horner, Day, & Day, 1997) or positive mood induction (Carr et al., 2003) and consisting of preferred activities (e.g., pleasant conversation, joking, planning special events), sharply reduces problem behavior and improves affect, a quality-of-life goal consistent with PBS.

Systemic Mitigation

Although there are many narrative accounts concerning the utility of mitigation at the systemic level, there is a dearth of programmatic research demonstrating remediation of problem behavior with this approach. A notable exception to this deficiency is a study of service systems in the United Kingdom (McGill, Emerson, & Mansell, 1994). The investigators implemented broad-based interventions that focused on intensive community integration, structured involvement that included meaningful engagement in housework, occupational and recreational activities, as well as staff development pertaining to effective skills. Environmental redesign produced marked increases in constructive activity and marked decreases in minor and major problem behavior. This investigation can serve as a model for the field as to what can be accomplished from mitigation efforts at the systemic level.

Coping

Coping is a generic strategy for reducing problem behavior in which the individual with ASD acquires a skill that he/she can use to change the stimulus properties of the environment in ways that make problem behavior unnecessary. In mitigation, it is others who initiate constructive stimulus change, whereas in coping, it is the individual with ASD who initiates the change. Coping strategies are often related to the functions of the problem behaviors they are designed to replace. Further, these strategies are consonant with the PBS emphasis on prevention and the paradoxical notion that the best time to deal with problem behavior is when it is not occurring.

Functional Communication Training

This intervention involves teaching an individual specific communicative responses that serve the same function (functional equivalence) as the problem behavior they are intended to replace (Carr & Durand, 1985). In illustration, if functional assessment shows that a child engages in self-injury to attract the attention of an adult, then that child can be taught a communicative phrase (e.g., "Look what I drew, Mom!") that also attracts adult attention. Typically, any attention for self-injury would be withdrawn as well, a process referred to as extinction. Once the communicative phrase is well-established, the child has no need for self-injury anymore and the problem behavior decreases (Carr & Durand, 1985; Wacker et al., 1990). Communication alters the behavior of others, thereby producing a new stimulus environment that supports prosocial behavior.

Self-Management

This strategy involves teaching people three distinct but integrated skills: self-monitoring (i.e., to discriminate their own target behavior—e.g., aggression—and record its presence or absence), self-evaluation (i.e., to make a judgment as to whether their ongoing behavior is prosocial or problematic), and self-reinforcement (e.g., providing themselves with special treats contingent on the presence of prosocial behavior and/or absence of aggression after a period of time has elapsed). This skill can alter the stimulus properties of the environment—that is, because many reinforcers are newly available, these may reduce the aversiveness of the situation in the case of escape-motivated behavior. Further, the prosocial skills themselves may evoke positive reactions from others and this additional attention may, therefore, undermine the need for attention-seeking problem behavior. Several studies have demonstrated that self-management can produce rapid decreases in many problem behaviors, including stereotypy, that are normally quite refractory to intervention (Koegel & Koegel, 1990; Koegel et al., 1992).

Relaxation

As noted previously, anxiety can be a biological setting event. Therefore, it may promote escape-motivated problem behavior in contexts that elicit such anxiety. Progressive muscle relaxation is a skill that can be taught to a range of people with developmental disabilities (Cautela & Groden, 1978). This skill helps the individual to cope with and reduce anxiety and is thus responsive to the functional properties of the problem behavior. Relaxation has been used effectively to reduce even severe problem behavior such as self-injury (Schroeder et al., 1977).

Social Problem-Solving

People with ASDs have deficits in social behavior and problem solving in situations that require sensitivity to the social and emotional cues provided by others. The incomprehensibility of most social situations leads to frustration, failure, and eventual "meltdowns." Therefore, it is useful to teach people with

ASDs how to identify and understand the social and emotional perspectives of others and how to develop and organize strategies for dealing with common social situations. A wealth of pragmatic suggestions and strategies based on clinician experience has been described in detail (Myles & Southwick, 1999).

Multicomponent Intervention: A Best Practice

As we have seen, problem behavior in the natural environment is evoked by many contexts and serves many functions. For this reason, multicomponent intervention and related PBS perspectives have become a best practice in dealing with problem behavior. As noted, each mitigate and cope strategy is proactive, reflecting the PBS emphasis on prevention. However, these strategies are commonly combined when they are used to address problem behavior in the home (Lucyshyn, Albin, & Nixon, 1997), school (Crone & Horner, 2003), workplace (Kemp & Carr, 1995), and community (Vaughn et al., 1997). Further, strategy implementation by natural intervention agents (parents, teachers, job coaches) operating in natural contexts (home, school) highlights the PBS focus on ecological validity. The involvement of key stakeholders (Turnbull & Turnbull, 1996) and a concern with social validity (Carr, Horner et al, 1999)—namely, with the feasibility and acceptability of intervention (both key features of PBS)—are woven into the fabric of multicomponent approaches. Because the variables influencing problem behavior may change over time, the PBS emphasis on lifespan perspective is an important aspect of longitudinal research exploring improvements over a period of years, rather than weeks or even months (e.g., Carr, Levin et al., 1999). The PBS embrace of scientific fields and disciplines beyond applied behavior analysis can be seen in research that focuses on quality-of-life issues related to positive psychology (Dunlap et al., 2003), cultural factors (Wang, McCart, & Turnbull, 2007), organizational management (Sailor et al., 2006), and biomedical influences (Carr & Blakeley-Smith, 2006). In sum, multicomponent intervention is the nexus for the critical features that define PBS and facilitate its effectiveness in addressing problem behavior in complex real-world contexts.

Outcomes: How Well Have We Succeeded?

Several meta-analyses have been conducted examining data across hundreds of studies of problem behavior (Carr, Horner et al., 1999; Didden et al., 1997; Horner et al., 2002; Scotti et al., 1991). Extracting information from the studies most relevant to PBS yields the following conclusions:

1. Even the most severe problem behaviors including aggression, self-injury, tantrums, and property destruction can be successfully treated.
2. There is an 80% or greater reduction from baseline in the level of problem behavior for about two-thirds of the cases, 90% or greater reduction for about one-half of the

cases, and a 100% reduction for about one-quarter of the cases (Carr, Horner et al., 1999). It is likely that these figures are underestimates because they only summarize data to 1999 and there have been a large number of successful studies reported since. However, no full-scale meta-analysis exists that captures these more recent data.
3. There are relatively few studies examining and reporting maintenance of intervention effects beyond 1 year. Although durable change has been demonstrated, small sample size mandates cautious interpretation.
4. Improvements in specific aspects of quality of life are well-documented. However, there are relatively few studies examining and reporting multidimensional changes in quality of life related to problem behavior reduction. Although positive change has been noted, small sample size, again, is an issue.

Conclusion

Problem behavior needs to be addressed from a broad perspective that integrates skill building, environmental redesign, systemic influences, and biomedical factors. A conceptual framework that adopts this perspective is most likely to lead to the development of interventions that alter quality of life while at the same time reducing problem behavior. Ultimately, it is an improved quality of life for people with autism and for those who love them.

Challenges and Future Directions

Gaps in the extant literature highlight areas where additional research is needed to further enhance our understanding of problem behavior and increase the number of intervention options available.

- Overwhelmingly, research has focused on externalizing problem behavior. Yet, it is known that internalizing disorders (anxiety, depression) can function as setting events to exacerbate externalizing behavior. Therefore, exploring this linkage through appropriate assessment could help elucidate the potential contribution of cognitive-behavior therapy (Reaven & Hepburn, 2003).
- There is a need to develop algorithms for translating, in a rational and prescriptive manner, complex assessment information from the five-term contingency into intervention development related to the wide array of options stemming from the tripartite model of intervention.
- Long-term maintenance of behavior gains across the lifespan is a function of systems and not procedures (Carr, 2007). An intervention package is effective over time

only if it is applied with integrity over time. Therefore, the factors responsible for sustained intervention efforts must be identified and strengthened.

- The systemic component of the five-term contingency is grossly under-researched. More studies of organizational management and community psychology at the level of service systems (Emerson et al., 1994; Knoster, Villa, Thousand, 2000; Sugai et al., 2000) need to be undertaken to identify the systemic factors responsible for problem behavior and the environmental modifications needed to promote prosocial behavior.

- A sole focus on the individual with ASD does not capture family systems variables that impact problem behavior and intervention sustainability. Relationship discord, personal strengths, parent affective distress, social isolation, and cultural factors must be examined in relation to problem behavior, goal setting, intervention selection, and satisfaction with outcomes. Many of these issues relate to the emerging field of positive psychology (Seligman et al., 2005) that can serve as an additional source of useful concepts and methods.

- The reconceptualization of ASDs as whole-body disorders (Herbert, 2005) highlights the necessity for examining the impact of illness and abnormal metabolism on problem behavior. Problem behaviours may reflect underlying pain and discomfort and may be misinterpreted unless the health of the individual with ASD is considered. These biological setting events represent new treatment targets that can broaden the scope of intervention (Bauman, 2006; Carr & Herbert, 2008).

- The relationship between problem behavior and multiple dimensions of quality of life is likely bidirectional. Research on this relationship, although nascent at present, has the potential for broadening our understanding of the factors that control problem behavior while addressing the central goal of PBS—namely, improving quality of life.

- Research is needed on identifying the factors that lead to the emergence of serious problem behavior. This prevention agenda may be pursued by exploring early developmental processes (Guess & Carr, 1991) and proactive redesign of the environment to eliminate those factors whose cumulative impact over time leads to behavioral deterioration.

Social Skills Interventions for Children With Autism Spectrum Disorders

Points of Interest

- Children with ASDs often experience a variety of social challenges that may hinder their ability to establish meaningful relationships with other children; therefore, increasing social contact and peer interactions for children with autism is an important goal.
- Important active ingredients in successful social skills interventions for children with ASDs include: the context of intervention, methodological approach, facilitation agent, content (target goals), and dose.
- Children with ASDs are responsive to a wide variety of interventions aimed at increasing their social engagement and social skills repertoires. However, there remains a concern regarding the lack of maintenance and generalization of the intervention effect that suggests that acquiring skills may require a longer period of time and additional and continuous social support may be needed.
- Randomized controlled treatment trials need to be conducted on a larger scale in children's natural settings to determine whether a specific intervention type is more efficacious than mere clinical attention or is relevant for the general population of children and adolescents with ASDs.

Given the pressure teachers are under to make academic benchmarks, the social and emotional well-being of children can be overlooked. However, for many children, these social goals are critical to their overall school adjustment. Feeling connected to others can lead to a sense of belongingness that in turn can foster both social-emotional adjustment and academic competence at school (Ladd, Kochenderfer, & Coleman, 1996).

Although all children need to have their social and emotional needs met at school, the needs of some children may be even more challenging. Children with an autism spectrum disorder (ASD) have significant challenges in relating to others, maintaining peer relationships, and making friends. Yet, more and more, parents are requesting full inclusion into general education classrooms for their children with ASDs, in part to promote normalized social interactions, and the possibility of friendships with typically developing children (Kasari et al., 1999). Schools are now beginning to recognize the need to accommodate all children in their classrooms; however, meeting the needs of children with ASDs will take concerted efforts on the part of all involved, including teachers, parents, and peers.

In this chapter we consider what we currently know about the social lives of children with ASDs, including their social interactions with peers and the development of friendships. We identify a number of challenges that children with ASDs face—particularly in school settings with the general population of children—and then examine the effectiveness of current interventions for children with ASDs, with a focus on active ingredients of intervention. Finally, we suggest some avenues for future research in this area.

Characterizing Social Skills and Children With ASD

The term *social skills* is generically used to encompass several domains of social functioning. Matson, Matson, and Rivet (2007) define social skills as interpersonal responses that allow children to adapt to the environment through verbal and nonverbal communication. Children naturally learn and expand their social skills through multiple interactions with others. For children with social deficits, such as children with autism, these natural opportunities are restricted because of a range of impairments in social recognition, communication, and comprehension (American Psychiatric Association, 2000). Broadly, children with ASDs may experience challenges in social

reciprocity, initiation of interactions, emotional behavior, eye contact, joint engagement, empathy, and perspective taking. These social deficits affect children's ability to connect with peers and to develop quality relationships with others.

All of these challenges affect how well children with ASDs relate to their peers and others. More than two decades ago, Wing (1988) described three categories of children with ASDs, including those who could be described as "aloof and indifferent," "passive," and "interactive but odd." Children who are aloof and indifferent are the children who tend to ignore others and avoid social contact altogether. An example is the child who becomes engrossed in the slats of the fence surrounding the playground and is oblivious to other children who may try to engage him or her in a game or conversation or the child who may actually leave an area of play when other children enter. The child who is passive tends to accept social contact when it is initiated by others. Such children are sometimes subjected to various roles (e.g., puppy, baby, monster, etc.) in games whether he or she wanted those roles or not. Finally, children classified as "interactive but odd" are motivated to interact with others but typically lack the skill needed to build positive social relationships. They may seek out interactions and then not understand why others avoid them when they do something annoying or unusual.

Given these classifications of children with autism, one might expect that they would be isolated in their classrooms, with limited peer interactions and few friends. At least with young children with autism, this does not seem to be the case. Most higher-functioning children with autism in the primary grades are not isolated in their classroom peer social networks as reported by peer nominations (Chamberlain, Kasari, & Rotheram-Fuller, 2007). Chamberlain et al. (2007) reported that although none of the children with autism in second and third grade classrooms was isolated, these mostly male children were often on the periphery of their classroom social structure. Their connections to others in the class tended to be with a small group of other children, typically female peers. These findings suggest that children with autism are able to establish some social connections with other children in their classroom but may need to be taught specific social skills such as how to hold a conversation, take the perspective of others, and engage in pretend play to be more centrally connected in their class social networks (Scattone, 2007). In addition, many children with autism must learn the subtleties of social interactions, such as developing an awareness of personal space, showing empathy, and reading body language, which may help form stronger connections and higher quality relationships with peers (Scattone, 2007).

Increasing social contact and peer interactions for children with autism is an important goal. However, peer interactions are not the same as developing a selective relationship or friendship with another child. By definition, friendships are "affectionate attachments between two individuals" that are built upon recurring experiences and social interactions (Bukowski, Newcomb, & Hartup, 1996). Friendship has been shown to provide children with a breadth of positive outcomes, including the sense of belongingness and self-worth (Bagwell, Newcomb, & Bukowski, 1998), emotional support, protection from loneliness, isolation, and rejection (Bollmer et al., 2005; Parker & Asher, 1993), and positive school adjustment (Ladd et al., 1996). Thus, it is important to not only promote peer interactions but to also consider friendship development.

Friendships

Friendships are defined by qualities such as companionship, support, closeness, and conflict. Therefore, it is not just whether children have friendships that make a difference in their development and well-being but rather the quality of these friendships that is important (Bukowski, Newcomb, & Hartup, 1996). Friendship quality has been proposed as creating various psychological benefits and costs for children that, in turn, affect their development and adjustment (Ladd et al., 1996).

Multiple reports indicate that more than half of children, adolescents, and adults with autism do not have friends or even acquaintances (Howlin et al., 2004; Orsmond, Krauss, & Seltzer, 2004). These data are derived primarily from parent report, and parents may or may not be privy to their child's innermost feelings about their friends. When researchers have asked children and adolescents themselves, they almost all report having a friend (Bauminger & Kasari, 2000; Chamberlain, Kasari, & Rotheram-Fuller, 2007). When reciprocal nominations are analyzed, however, more than 80% of friends nominated by children with autism are not reciprocated. Thus, a complicated picture emerges in which children may feel they have a friend despite the fact that it is not reciprocated. This may explain why the quality of the friendship is often rated lower than that of typical children (Bauminger & Kasari, 2000; Chamberlain et al., 2007). Thus, non-reciprocated friendships along with poorer reported quality of friendship by children with autism may place children with autism at risk for feelings of isolation and loneliness despite their identification of a friend.

Although truly reciprocal friendships can be difficult to achieve for some children with ASDs, other children are able to succeed. Bauminger and colleagues (2008) are beginning to describe children with reciprocal friendships; for example, in a 2008 study of preadolescent children with high-functioning autism and their reciprocal friends, they found that both groups of children perceived friendship qualities similarly. These data suggest that preadolescents with high-functioning autism have capacities for interpersonal awareness and are similar to typically developing children in their understanding of friendship relationships. Better understanding of how these children came to develop reciprocal friendships will be important in designing interventions for children with ASDs who struggle with establishing friendships.

The foregoing studies typically have examined younger children with ASDs. As children become older, the nature of

their peer relationships undergoes significant change as adolescents spend increasingly more time in the company of their same-age friends (Larson & Richards, 1991). During adolescence, friendship gradually deepens in terms of quality features such as closeness, commitment, companionship, intimacy, security, and acceptance of differences among friends (Berndt & Savin-Williams, 1993; Buhrmester, 1990; Marsh et al., 2006; Shulman et al., 1997). As a result, adolescence and young adulthood may be a particularly challenging time for many individuals with autism because of the increasing importance of intimate relationships. Stoddart (1999) has reported that adolescents with Asperger Syndrome experience low self-esteem and have increasing self-awareness of their differences. They also experienced frequent teasing and rejection by their peers, concerns about peers' perceptions, and a lack of ability to make friends (Stoddart, 1999). As a result, adolescence may be an important period for intervention to buffer negative feelings and/or poor psychological outcomes.

An underlying theme that is implicit in several studies regarding friendship quality is the argument that friendship exerts a positive force on development. Nevertheless, there are reasons to expect that the effects of friendship may not always be positive. Certain types of friendships, such as those that are imbalanced, unreciprocated, or marked by conflict, may not provide the sorts of experiences that promote development and well-being (Bukowski, Newcomb, & Hartup, 1996). Conflict and disagreement are common in children's close friendships and may be even more common in friendships where one child has autism. Consequently, several interventions have been developed to enhance social skills and reduce conflict to promote quality friendships in children with autism.

Interventions for Social Skills: Active Ingredients

Unlike most interventions for children with ASDs that are comprehensive and cover all areas of development, social skills interventions tend to be targeted and time limited. With preschool-aged children, particular times during the school day may be targeted for peer interactions, and with older children, a social skills group may be constructed that meets once or twice per week. Whether child-oriented or group-oriented, most interventions search for the active ingredients that will improve children's social skills and ultimately their social connections to others. Aspects of interventions that may be important active ingredients include:

a) the *context* of interventions (e.g., at home or at school during class time or during playground time);
b) *method*—a wide range exists from general applied behavior analysis approaches to more developmental approaches and to specific methods such as video modeling, scripts, social stories, and self-management;

c) the *agent* of intervention, such as sibling-, peer-, or adult-mediated intervention;
d) *content* of interventions, whether focused on, for example, social etiquette, or peer engagement or social knowledge and understanding;
e) *dose*—both intensity and density, such as how often the intervention is delivered and for how long.

It is fair to say that most studies have focused on *method and content*, with content often referring to only a single or limited number of social behaviors that are tested using a single subject design. Agent—who mediates the intervention—becomes important in both the method and context of the intervention. Studies have yet to vary these factors so that it is not possible to determine their importance to social skill development. A number of potential comparisons could be investigated, such as comparing group versus dyad-focused social skills intervention, home- or clinic- versus school-based intervention, and peer-mediated versus adult directed interventions.

Below we discuss the ways in which interventions have addressed these potential active ingredients. We acknowledge however, that we are only at the beginning stages of this work. At this point, we have far too few intervention trials that have varied these different ingredients, so the importance of each ingredient is not well-established. Moreover, many studies examine the combination of a variety of active ingredients, so it is not so easy to separate the importance of each factor.

Context of Intervention

Children's social interactions with others can vary widely by context. For example, children may interact with family members frequently but rarely talk or engage peers at school. Thus, they may appear more socially engaged at home than at school. Agent of intervention (e.g., a family member) may be confounded with context (in this case, home). Overall, very few interventions have been carried out only at home as a way of increasing children's social interactions. An exception is interventions designed to improve the interactions between children with ASDs and their siblings. Far more studies have been carried out in school or community settings. However, even within school settings, the context of intervention can vary from naturalistic interventions on the playground to individualized pull-out sessions with the target child.

Home

Results of the few studies in the home setting have demonstrated that siblings can be effective as trainers and change agents in improving the social interactions of children with autism (Strain & Danko, 1995; Strain et al., 1994). Typically developing siblings have been taught to promote play and play-related speech, to praise play behaviors, and to prompt their siblings with autism to respond to initiations, with skills being generalized and maintained after withdrawing intervention (Bass & Mulick, 2007; Celiberti & Harris, 1993).

In one study, Coe et al. (1991) demonstrated that older elementary children could effectively implement procedures to increase social interactions of younger siblings with autism. Two children with autism received an at-home intervention to increase social behaviors, whereas their typically developing siblings were taught to increase rates of prompts and praise to children with autism for several behaviors. This latter intervention produced increases in targeted behavior for children with autism, as well as increases in the social interactions of children with autism and their older siblings (Coe et al., 1991; McConnell, 2002; Rogers, 2000). Thus, siblings may be valuable intervention agents to foster social skills in children with autism.

Home interventions with siblings may translate to greater social skill with peers in other contexts such as school. However, for the most part, these generalization effects have not been tested. However, one intervention examined an intervention with parents at home and tested the effects of the intervention on their children at school. In this study (Delano & Snell, 2008), the social engagement goals at school for three boys with ASDs were identified and written into individualized social stories that each parent read to their child before and after school. Two of the three boys improved in their prosocial behaviors as a result of the intervention according to observations of children at their school.

School

Efforts to increase social development have led to higher rates of inclusion of children with autism into regular education settings. Despite more exposure to neurotypical peers and more opportunities for social engagement in inclusive settings, research has shown that physical proximity alone does not lead to improved social interactions in children with autism (Myles et al., 1993). Inclusive settings may be a challenging environment for children with autism, particularly during free play or recess times, when children are on the playground and activities may be unstructured and/or unmonitored. Because of the complexity of the playground, some children with autism may feel socially overwhelmed and/or disoriented. As a result, they may spend their free time inside the school buildings (Wainscot et al., 2008) or in the far corners of the playground (e.g., along the edge of the grass, near the fence, etc.) in an attempt to avoid areas of the school that are busy and require good communication skills. Also, the activities that often occur outside the school buildings during break and lunch times typically involve games with multilayered rules such as football, handball, and soccer (Wainscot et al., 2008). These games could pose particular difficulties for children with autism because they are heavily dependent on nonverbal communication and gestures and involve complicated motor coordination. Thus, children with autism can experience difficulties maintaining joint engagement with peers on the playground leading to poor or absent peer relationships. Indeed, more than 90% of children with autism can be discriminated on the playground from children with other disabilities by four behaviors including poor social engagement with peers, lack of respect for personal space, isolation, and inappropriate behavior (Ingram et al., 2007).

Despite the need for interventions on the playground, studies have not directly examined practices that might improve these interactions for children with autism. Most interventions take place inside classrooms. Moreover, in inclusive programs, teachers often are not on the playground; rather, classroom aides or specially hired playground assistants are present to ensure child safety. Aides typically do not directly teach peer play or intervene in children's play, often believing that recess is a "break" from classroom work. Thus, we need further study of children with autism on the playground, both in observational work highlighting individual differences and in effective interventions.

Method (Approach) of Intervention

Because children with autism have varied repertoires of social skills, many different social skills training programs have been designed and implemented. The most commonly applied treatment approach involves applied behavior analysis (ABA) methods. These intervention methods are designed to create multiple learning opportunities and enable high rates of success. The treatment progresses gradually and systematically from relatively simple tasks, such as responding to basic requests made by the instructor to more complex skills that include conversing and interacting with peers. The methods are used by therapists in clinic and home settings as well as by teachers or trained aides in classroom and playground settings.

Although a number of interventions have used very structured and often discrete trials to teach children a particular social skill, such as making eye contact, the trained skill does not always transfer to more naturalistic and unpredictable situations. One issue is that the child's mastery of the skill is tied to the particular teaching context so that the skills do not generalize or transfer to other settings and people. For example, the child may learn to greet his peers in a specialized social group and consistently demonstrate this skill in the confines of the group. However, at school, when faced with a greater diversity of children on the playground and in class, he or she may be unable to generalize greetings. Thus the "mastered skill" fails to be performed.

One response to the lack of generalization from highly structured ABA approaches has been the development of approaches that integrate more traditional methods of ABA into developmental and naturalistic ABA interventions. Pivotal Response Training, Milieu Therapy and Incidental Teaching (Goldstein, 2002) are all examples of approaches that integrate more developmental methods into their ABA teaching strategies. For example, pivotal response training (PRT) focuses on teaching pivotal areas such as motivation, self-management, and self-initiations through multiple cues (Pierce & Schreibman, 1994) and achieves collateral behavior changes not specifically targeted (Koegel & Frea, 1993). Reinforcement is also delivered using natural reinforcers, such as giving the child the ball when he says "ball" rather than a

piece of candy. These naturalistic intervention strategies are more likely to facilitate generalization than are strategies that teach skills out of context.

Another common approach for teaching a wide array of skills is video modeling (VM), an instructional process that consists of videotaping behaviors (treatment targets) so children can develop the ability to memorize, imitate, and generalize specific behaviors (Charlop-Christy & Daneshvar, 2003). Using the child in situations in which he or she is successful (video self-modeling [VSM]) as an instructional approach shows particular promise (Bellini & Akullian, 2007). Several studies have shown that VM and VSM may enhance communication skills, academic performance, perspective taking, and social and self-help skills in children with autism (Bellini & Akullian, 2007; Charlop & Milstein, 1989; Charlop-Christy & Daneshvar, 2003; Taylor, Levin, & Jasper, 1999). Many single-subject designs have been conducted on various components of social behavior using ABA, integrative ABA methods, and VM, suggesting that these approaches are effective for teaching social skills. However, generalization continues to be problematic with any approach, highlighting the difficulty in teaching skills that are so subtle and ever-changing depending on context and partner.

Despite the differences among approaches in teaching and delivering social skills interventions, there are also similarities. Almost all studies have focused on the teaching of individual and targeted social skills, such as greeting a peer, entering a group game, and navigating disagreements. The way in which these skills are taught typically involve a number of different strategies, including repetition through discrete trials, role play, and reversal, positive and corrective feedback to improve children's performance, and "homework" assignments to practice learned skills in naturally occurring environments (Matson et al., 2007). Most studies also focus on delivery of the intervention to an individual child with autism that is mediated through others, such as adults (parents, teachers, therapists) or children (peers or siblings).

Thus, in addition to the techniques used to teach social skills, the agent delivering the intervention becomes important to the method and may affect how well the method is delivered. A treatment could be delivered to the child by an expert therapist, a teaching assistant or shadow teacher, a trained peer, or the parent. Although the best approach is to bring everyone into the treatment plan for an individual child, this happens all too rarely.

Agent of Intervention: Adult- vs. Peer-Mediated Social Skills Intervention Approaches

Adult-mediated methodologies have met some success in enhancing interaction with peers (Goldstein & Cisar, 1992), promoting independent play skills (Taylor, Levin, & Jasper, 1999), increasing social initiations (Goldstein & Cisar, 1992),

improving perspective taking (Charlop-Christy & Daneshvar, 2003), teaching daily living skills (Pierce & Schreibman, 1994), and promoting generalization across settings (Strain et al., 1994; Koegel et al., 1992; McConnell, 2002; Scattone, 2007). In general, an adult therapist works individually with the target child with autism to increase social skills. The therapist may also train another adult (i.e., teacher, aide, parent) to teach the child social skills.

The most common adult-mediated intervention is to assign a one-on-one aide or shadow teacher to a particular child (Giangreco & Broer, 2006). These aides are only minimally trained but may be systematically supervised by an expert. A cause for concern is that often the least trained person is responsible for a child's intervention in a school setting. In many cases, the teacher may not engage with the child nor see him or herself as responsible for the child's education when an aide is assigned to the child. Aides are often concerned with the amount of responsibility they are given to provide academic and social interventions to the child they are assigned, and the role of expert in which they are often placed (Marks, Schrader, & Levine, 1999).

There is great variability in how aides work; some are assigned to an individual child only, whereas others work with the entire class. Few outcome data exist for this type of intervention some of which suggests that the 1:1 aide may not be effective for facilitating better social interactions for children with ASDs (Giangreco & Broer, 2006; Humphrey & Lewis, 2008). In one study, nearly half of the paraprofessionals believed the child they were assigned to saw them as their primary friend. Children themselves questioned whether the adult who was there to support them marked them in the eyes of their classmates, ultimately interfering with friendship development (Humphrey & Lewis, 2008). Future research studies should more closely examine the efficacy of aide-mediated approaches for promoting social skills and children's close relationships with peers.

A second intervention approach focuses on teaching typically developing peers to engage the child with autism by initiating, prompting, and reinforcing social interactions. Peer-mediated approaches represent the largest and most empirically supported type of social intervention for children with autism (Bass & Mulick, 2007; McConnell, 2002). The use of typically developing peers in social skills interventions as peer tutors or buddies has led to higher rates of eye contact, turn-taking interactions, higher tolerance for waiting (Laushey & Heflin, 2000) and social interaction in young children with autism (Strain & Danko, 1995; Strain et al., 1994). Typically developing peers have assumed a number of roles in peer-mediated intervention studies and have been taught to initiate social interactions and organize play activities (Odom & Strain, 1986), respond to the child with autism (Kamps et al., 2002; Kamps et al., 1992), monitor behavior requests (Morrison et al., 2001), and serve as tutors for schoolwork and recreational activities (Orsmond, Krauss, & Seltzer, 2004). In many paradigms, peers role-play with adults until they have learned the strategies successfully. Subsequently, the peers are cued by

the adults to begin to interact with the target children around typical play materials and activities, often on the playground in children's schools, during playdates, or in the community (Bauminger et al., 2008; Harper, Symon, & Frea, 2008; Koegel et al., 2005; Licciardello et al., 2008; Rogers, 2000).

Both the adult-mediated and peer-mediated approaches have demonstrated some success in enhancing or improving children's social skills repertoires; however, many studies employ single-subject designs and have not been subjected to direct comparative research designs in the child's natural environment (Williams White et al., 2007; Bellini et al., 2007). Moreover, we have less evidence of maintenance of learned skills over time, and generalization to new groups of children, or new contexts, thus raising issues of how well the interventions match the needs of children, how teachers motivate children to maintain engagement, and how the environment supports children's social relationships.

Despite the lack of empirical evidence indicating which approach is more effective, one consistent finding is that children with autism are responsive to a wide variety of interventions aimed at increasing their social engagement and social skills repertoires. There remains a question, however, as to whether various approaches lead to maintenance and generalization of the intervention effects. It is likely that children need additional and continuous social support systems (e.g., both child-specific and mediated by others) built into their everyday lives (e.g., in the community, at school, at home, etc.). The answer may lie in targeted school-wide systems change and greater professional development and accountability for teachers if we are to help children with ASDs to acquire, maintain, generalize, and expand their learned social skills.

Group Social Skills Approach

Group social skills programs combine both adult- and peer-mediated approaches. They are commonly implemented outside school settings, such as in clinics with children who often do not attend the same schools or programs. In some intervention programs, these groups are comprised of both typically developing children and children with autism, whereas other studies have utilized groups that consist of only children with autism (Chung et al., 2007; Kroeger, Schultz, & Newsom, 2007; Mackay, Knott, & Dunlop, 2007). Studies of group social skills programs have noted progress in social communication in both reduction of inappropriate talking and increase in appropriate talking (Chung et al., 2007), prosocial behaviors (Kroeger et al., 2007), and social skills and competence (Mackay et al., 2007). Within these settings, curricula are employed that focus on a limited set of social skills, such as entering social groups, starting a conversation, dealing with bullying or rejection, and so forth. Although these groups provide opportunities for peer interaction and practice of these skills, these situations may not generalize to peers outside of the particular environment.

Thus far, there are few large-scale randomized group-based treatment studies and limited application of manualized intervention programs (Lopata et al., 2008; Williams White et al., 2007). Few investigations have utilized group designs to control for confounding factors such as the effects of maturation and time over the course of treatment. In one study, Solomon et al. (2004) utilized a randomized comparative group design to examine the effectiveness of a social enhancement program for 18 children with high-functioning autism. Children participated in small groups for a 20-week intervention with a curriculum that included emotion recognition and understanding, perspective taking, and executive functioning skills. The intervention was effective in increasing emotion recognition and problem solving, and both groups (i.e., intervention and waitlist control) improved in their perspective-taking skills. Although the authors have noted limitations, they have suggested that group social treatments have potentially positive effects for children on the autism spectrum (Lopata et al., 2008; Solomon, Goodlin-Jones, & Anders, 2004). However, until randomized controlled treatment trials are conducted on a larger scale in children's natural settings, it will be difficult to determine whether a specific intervention is more efficacious than mere clinical attention or is relevant for the general population of children and adolescents with autism (Rao et al., 2008).

A major limitation of current studies is the lack of evidence for generalization across contexts, people, and time (Bellini et al., 2007; McConnell, 2002; Rogers, 2000; Williams White et al., 2007). One explanation for the poor generalization and maintenance effects for the various social skills interventions is that a single manualized social skills treatment may not be effective for all children with autism. Because autism is a spectrum disorder, children affected by autism exhibit a variety of symptoms. As a result, one intervention may be particularly effective for one child and ineffective for another child with autism. One issue that has not been dealt with adequately is the content of interventions and the connection of that content for particular children with autism.

Content of Interventions

Most interventions are manualized and cover a number of different skills aimed at initiating and maintaining interactions. Often, a separate topic may be presented at each session, such as greeting peers, initiating conversation, reading emotions, and managing conflicts. These topics may be specific to enhancing peer interactions (Barry et al., 2003), developing friendships (Laugeson et al., 2009), or managing anxiety (Sofronoff, Attwood, & Hinton, 2005; Wood et al., 2009). Given the variability in child repertoires, manualized treatments need to be flexible to meet individual needs to be maximally effective.

Two important factors related to content of social skills interventions are: *(1)* the developmental appropriateness of skills that are taught, and *(2)* flexibility in delivering a manualized, evidence-based intervention. In terms of developmental appropriateness, one concern is the lack of

assessment of children in natural settings with peers prior to intervention. Thus, children may attend social skills groups that utilize a manualized intervention, but the topics may not be individually relevant to their particular strengths and weaknesses. Bellini (2006) noted that few treatments connect the focus of the treatment to the individual developmental needs of the child. As an example, a young child may be taught to initiate play with a peer by asking, "Can I play?" but if the child lacks play skills he will not be able to sustain engagement with the peer. In this case, a more appropriate goal may be to teach the child play skills. Indeed, a number of parent and therapist mediated interventions have been developed to teach children joint engagement and play skills with adults (Kasari et al., 2006; Schertz & Odom, 2007), but these types of interventions have rarely been transferred to children and their peers. Play times in classrooms are provided as a break from work times. Play may not be specifically taught, and yet children with autism may be at a loss for how to engage both materials and peers in jointly engaged play routines (Wong, 2007). One question for future research is whether teaching play routines to children with and without autism leads to more peer engagement without teaching discrete skills of social interactions (e.g., asking questions, giving materials, etc).

Although many programs ultimately aim to help children develop friendships, this area of social skills may be particularly important for older children with ASDs and likely needs to be directly targeted. Recent evidence suggests that using a parent-mediated approach is effective in helping adolescents with ASDs to develop friendships (Laugeson et al., 2009). In this approach, groups are held separately for children with ASDs and their parents with sessions focused on how to call friends on the phone and to set up get-togethers. Both parents and children report that the intervention is effective for increasing friendships. Thus, utilizing parent-mediated approaches should be further investigated and potentially included to augment school-based interventions.

A second related issue is the difficulty in meeting the needs of all children with ASDs given the heterogeneity of the disorder and variability in educational opportunities. One way to increase flexibility of treatments for individual children is to use a distillation and matching model for treatment (Chorpita, Daleiden, & Weisz, 2005). *Distillation* refers to finding the common element or technique in a particular set of treatment manuals, such as the use of visual feedback or conflict management techniques. *Matching* refers to the use of the element or technique for a particular child. For example, for children with an anxiety disorder, a common element in most treatment programs is the use of exposure therapy. Thus, using exposure therapy may be a critical element in a social skills program for a child who has high anxiety but may be less effective for a child who does not demonstrate anxiety. Developing a common elements approach to social skills treatments may assist clinicians in individualizing treatment for a particular child, and increasing the flexibility of evidence-based treatments to maximize dissemination.

Exposure therapy is a cognitive behavioral approach to reducing feelings of fear and anxiety in response to certain stimuli or situations. The patient takes part in a program of gradually increasing exposure to the anxiety-inducing factors and, if the approach is successful, eventually becomes habituated to the stimuli.

Future Recommendations

Although socialization deficits associated with ASDs can be severe and may require intervention across the life span, targeted social skills remediation may lead to more favorable prognoses (Scattone, 2007). To date, there are few data suggesting highly efficacious social skills treatments, but there are a number of promising strategies (Williams White et al., 2007).

Given the current state of knowledge, several areas of social skills programs require further research (McConnell, 2002; Rogers, 2000; Williams White et al., 2007). First, there is a need for documentation of the heterogeneity of social deficits for children with ASDs. In their meta-analysis of social skills training, Gresham, Sugai, and Horner (2001) concluded that the traditionally weak treatment effects of many social skills programs may be the result of assessment tools that fail to match identified skill deficits with treatment objectives. As such, the first step of any social skills program should be to identify the specific social skills of the targeted children and, more specifically, the skills that will be the treatment goals of intervention (Bellini, 2006). To determine individualized social skill strengths and weaknesses in children, it is critical that researchers observe children in their natural environments. Using only parent reports may not shed enough light on what the particular issues are for a child on the school playground. Typically, neither parents nor teachers are present on playgrounds. The best informants are likely the child's peers and the playground supervisors (often teaching paraprofessionals). The field needs social skill observational assessments that can be utilized by a variety of professionals and that can be easily implemented. Such information will better inform treatment goals and objectives.

Another essential element of high-quality social skills programming and program accountability requires efficient and effective measurement systems for assessing outcomes in natural environments and within spontaneous interactions (Rogers, 2000). Outcomes should reflect the content of the intervention and have some meaning for the construct under study (Kasari, 2002). Many times, social skills training programs have sought to remediate social skills in a contrived setting such as a clinic where children practice learned skills on adults, not peers. Another issue concerns how change is evaluated and whether the evaluators have access to children in the settings on which they are asked to report. Thus, without the use of meaningful outcome measures, interventions may be found to be inappropriate, insufficient, and/or ineffective (Rao et al., 2008).

Because autism is a spectrum disorder, each child may have vastly different social skills strengths and weaknesses. Some children with autism may need assistance developing social behaviors such as joining a game on the playground, whereas other children may need additional assistance with more subtle social cues like attending to a conversation with a friend. As such, it is imperative that social skills interventions are individualized to the child's developmental needs and target behaviors that can ultimately be used to foster high-quality relationships. One fundamental goal of many social skills training programs is to provide children with autism with the necessary social skills repertoire to be successful in social situations and foster meaningful and long-lasting relationships and friendships with others. Asking children to report on their perceptions of relationship quality has been increasingly utilized in friendship research and provides insightful information that may also address questions relating to children's social awareness. Therefore, it is important to tailor the goals of intervention to each child and provide the necessary skills for children with autism to establish and maintain quality reciprocal relationships, particularly friendships with peers.

Future social skills interventions should also address questions regarding the active ingredients of effective social skills programs (Kasari, 2002). These issues center on dose, content, methods, service delivery, and timing. Most studies of social skills programs have been of low dose (e.g., weekly meetings of short duration), content that is a standard curriculum of specific skills (e.g., greetings, starting conversations), methods that are behavioral in orientation, service delivery that is clinic-driven and typically not in the environment in which social skills need to be executed (e.g., school), and timing that is either late (e.g., when children already show significant distress) or early (e.g., before children are aware of potential peer relationships). The issue of timing raises a number of issues for future studies and requires systematic comparisons to determine when social skills programs may have their greatest impact.

Next, integrating typically developing children into the intervention paradigm has been a key factor in several existing interventions (Bellini et al., 2007; Chung et al., 2007; Laushey & Heflin, 2000; McConnell, 2002; Scattone, 2007) and is an essential component of social skills training for children with autism. Utilizing typical peers has an added benefit in that interventionists have access to social behaviors of agemates for children with autism so that expectations for the behaviors of children with autism can be realistic. In this way, treatment goals can be established according to the social context and culture of the targeted child with autism.

In many reviews, social skills interventions, treatments, and programs have been criticized for their lack of skills generalization across contexts, people, and time (Bellini et al., 2007; McConnell, 2002; Rogers, 2000; Williams White et al., 2007). Like any intervention program, social skills interventions should document the long-term effects of the intervention for children with autism. Specifically, it is important to evaluate the generalization and maintenance of specific components or social skills learned during the intervention (McConnell, 2002)

through follow-up observations, additional evaluations, and/or repeated outcome and/or assessment measures. Furthermore, the use of developmentally generative interventions, where skills and characteristics acquired in treatment lead to ongoing development of increasingly sophisticated social behaviors (McConnell, 2002), may be an effective approach to ensure the use of less intensive social skills training in the future.

Finally, the field needs to develop successful and efficient intervention approaches that are structured, manualized, and packaged for dissemination to a wide variety of community settings (Rogers, 2000). Structured interventions are essential for replication as well as ensuring treatment fidelity (Williams White et al., 2007); however, taking a distillation and matching approach (Chorpita et al., 2005) to treatments increases treatment flexibility, individualization, and potential application by a wide variety of treatment providers.

Conclusion

Much like the nature of ASDs, the existing literature on social skills intervention programs is extremely heterogeneous. Some interventions have shown positive outcomes in children's friendships and knowledge of social skills, but these tend to be poorly maintained and generalized. The future of our understanding depends on well-designed studies that incorporate some of the active elements of treatment. Although we are still at the beginning stages of social skills intervention research, we are hopeful that we can improve the current system so that all children with autism have the opportunities necessary to have rich social experiences.

Challenges and Future Directions

- There is a need to document the heterogeneity of social deficits for children with ASDs as well as to develop and utilize efficient and effective measurement systems for assessing outcomes in natural environments.
- Intervention programs should be individualized to fit the needs of the child, incorporate key active ingredients (i.e., dose, content, methods, service delivery, and timing), and multiple agents of change (i.e., typically developing peers, parents, teachers, and paraprofessionals).
- Finally, we need to document the long-term effects of interventions for children with autism and develop successful and efficient intervention approaches that are structured, manualized, and packaged for dissemination to a wide variety of community settings.

Adolescent Transition to Adulthood and Vocational Issues

Points of Interest:

- Entering puberty involves a number of physical, medical, and emotional issues that must be addressed so that the ASD adolescent is able to learn the life skills necessary to transition to adulthood.
- Achieving life skills necessary to enhance independence and quality of life requires targeted interventions for the individual with an ASD in the areas of communication, social behavior, and daily living.
- The few follow-up studies addressing the symptom impairment and abatement in adolescents and adults with an ASD suggest that these individuals can make improvements from childhood to adulthood; however, some experience periods of symptom aggravation and a majority continue to require support services.
- To learn necessary life skills, individuals with an ASD need to be able to attend and focus rather than be distracted by medical or psychiatric issues; therefore, an assessment of the underlying issues or ASD-specific deficits that cause or are driving the behavioral presentation is necessary.
- An understanding of the unique learning characteristics and behaviors of individuals with an ASD can enhance the implementation of interventions to improve their level of functioning in society.

Introduction

Adolescence brings unique challenges to individuals with an autism spectrum disorder (ASD), regardless of his or her level of intellectual ability or the amount and type of early interventions and school-age support services employed. The very fact that the child is now older, larger, and almost physically mature puts him or her at risk for being misunderstood and vulnerable in his or her community. Those unfamiliar with the complexities of autism may have difficulty understanding or ignoring the odd or seemingly rude behaviors of the mature-looking individual with an ASD. Caregivers are also less able to avoid addressing the socially immature behaviors and demands of their adult-sized child with an ASD. Such behaviors may have been tolerated when the individual with an ASD was a young child, but they bring a whole host of problems when the child enters adolescence. Heightened community expectations for increased cognitive, psychological, and social maturity also create challenges for these ASD adolescents. Additionally, entering puberty involves a number of physical, medical, and emotional issues that must be addressed so that the ASD adolescent is able to learn the life skills necessary to transition to adulthood.

Although there are many books related to teaching life skills to individuals with ASDs (*see* Suggested Readings), such teaching can be overwhelming because it is difficult to synthesize this information to address all the unique needs of a given individual with an ASD. Along with this, intervention strategies need to be adjusted to address the developmental strengths and needs of each child as they enter adolescence and continue on to adulthood. This chapter attempts to address this problem by providing a framework for understanding the unique obstacles to helping adolescents with ASDs acquire the life skills needed to enhance their independence and quality of life. The first section of this chapter reviews the current literature regarding the life-course of symptom impairment and abatement that adolescents and adults with ASDs continue to face. Such issues include *communication and social abilities, behavior challenges, daily living skills, and adaptation to community living/vocational environments*. The second section provides a suggested method for approaching life skill instruction with adolescents diagnosed with ASDs by *assessing underlying problems, recognizing the unique ASD learning styles, teaching survival life skills, providing case*

examples, and addressing issues related to transitioning to residential and vocational settings.

Life Skills Development for Individuals With Autism Spectrum Disorders

Life Skills

The World Health Organization (WHO, 1999; WHO, 2004) has defined life skills as adaptive and positive behaviors necessary for an individual to deal with the demands of life. Life skills involve problem-solving, decision-making, goal-setting, critical thinking, communication, assertiveness self-awareness, interpersonal skills, and an ability to cope with stress**.** These are psycho-social and reflective life skills that are particularly difficult for individuals with ASDs because of their qualitative impairments in three core areas: social, communication, and repetitive and stereotyped behaviors and interests (American Psychiatric Association, 2000).

To achieve life skills, the individual with ASD needs to develop specific adaptive living skills (e.g., communication, social behavior, and daily living) necessary to integrate into society. Klin et al. (2007) assert that a "critical indicator of an individual's progress is his or her ability to translate cognitive potential into real-life skills" (i.e., adaptive behaviors) (p. 748). Of concern is the unique and consistent finding that ASD individuals tend to have much lower adaptive functioning abilities compared to their levels of intelligence and that adaptive abilities appear to either level off or decrease as these individuals age (Lockyer & Rutter, 1969; Rumsey et al., 1985; Freeman et al., 1991; Bryson & Smith, 1998; Carter et al., 1998; Bolic & Pousika, 2002; Volkmar, 2003). Having speech by age 5 years and higher childhood intelligence tends to predict a lesser degree of impairment later in life for ASD individuals (e.g., Howlin, 2003; Billstedt et al., 2007; Shattuck et al., 2007). However, these higher functioning individuals can still be handicapped by their inappropriate or odd social behaviors and limited self-care skills (e.g., Ballaban-Gil et al., 1996; Howlin et al., 2004; Gabriels et al., 2007; Klin et al., 2007; Saulnier & Klin, 2007).

A major challenge to life skills intervention and planning for individuals with ASDs is the heterogeneity of symptom impairment across individuals. Individuals with ASDs display variability in the range and severity of the core ASD diagnostic symptoms in the areas of social communication and behavior. For example, some ASD individuals may have limited to no expressive language ability; whereas, others may have a large expressive vocabulary, but have difficulty engaging in reciprocal social conversations. Individuals with ASDs can also differ widely in their social and behavioral presentation from being socially interested but odd in their social interactions with others to engaging exclusively in their restricted interests or odd repetitive behaviors. Individuals with ASDs also display a variety of associated symptom deficits in intelligence and

adaptive ability levels, sensory sensitivities, and comorbid medical and psychiatric diagnoses (e.g., Mottron & Burack, 2001; Bolte & Poustka, 2002; Tuchman & Rapin, 2002; Gabriels et al., 2005; Leekam et al., 2006; Leyfer et al., 2006; Klin et al., 2007).

Life Skill Outcomes in Adolescents and Adults With Autism Spectrum Disorders

There have been a limited number of prospective follow-up studies of adolescents and adults with ASDs to assess how children with ASDs function as they enter adolescence and adulthood (Shattuck et al., 2007). The few studies addressing the symptom impairment and abatement in adolescents and adults with ASDs suggest that these individuals can make improvements from childhood to adulthood; however, some experience periods of symptom aggravation. The majority of individuals with ASDs remain significantly impaired and continue to require support services (e.g., Gillberg & Steffenburg 1987; Shattuck et al., 2007; Cederlund et al., 2008; *see also* Seltzer et al., 2004, for a research review). The following section reviews the prospective, retrospective, and cross-sectional studies of adolescents and adults with ASDs. Outcomes in the areas of *communication, social, behavior, and daily living skills* along with *community living and vocational environments will be reviewed***.**

Communication

Studies indicate that individuals with ASDs do make improvements in their ability to communicate during adolescence and adulthood; nonetheless, problems remain for ASD individuals with or without speech (*see* Seltzer et al., 2004 for a review). These communication problems involve reciprocal verbal communication and nonverbal communication impairments. For example, in a prospective follow-up study of 105 adolescents and young adults with ASDs and a range of intellectual ability levels, the most common communication problem for this group was a lack of reciprocal verbal communication behaviors such as providing both a response to others and leads for others to follow-up on, in conversations (Billstedt et al., 2007). In everyday life, these conversation difficulties can put the ASD adolescent at risk for social rejection if, for example, the adolescent insists on directing conversations back to their own special interests, without offering comments about what another person wants to talk about. The other common problem in this study's sample was impairment in the use of nonverbal communication skills such as using inappropriate or unvaried facial expression and abnormal voice intonation (Billstedt et al., 2007). A relatively high prevalence of nonverbal communication impairments were also found in a sample of 241 adolescents and adults with ASDs and a range of intellectual ability levels (Shattuck et al., 2007). Nonverbal communication impairments in this ASD population sample included limited use of pointing to express an interest or limited use of head nodding or shaking to communicate as well as restricted

use of conventional (e.g., waving) and instrumental gestures (e.g., reaching out for more). These particular nonverbal communication impairments have important implications for predicting the future social interactions of adolescents or adults with ASDs. For example, if an ASD adolescent or adult displays a lack of facial expressions, abnormal voice intonation, and minimal use of gestures, others are likely to misinterpret their intentions, resulting in the ASD individual inadvertently angering or threatening others such as an employer or landlord.

Social

Studies indicate that adolescents and adults with ASDs continue to have significant social problems as reflected by having limited to no friendships or acquaintances and difficulties understanding and engaging in romantic relationships. This difficulty with developing significant social relationships is influenced in part by their social and emotional reciprocity deficits such as their limited ability to share enjoyment or interests with others along with their limited understanding of other's emotional states (*see* Seltzer et al., 2004, for a review). More recent follow-up studies of ASD adolescents and adults with a variety of intellectual abilities similarly indicate persistent problems with social reciprocity in a majority of the individuals studied. These problems were evidenced by limited and inappropriate interactions with same-age peers such as having poor eye contact or unfocused gaze along with a lack of emotional responsiveness, shared enjoyment, understanding of others' emotions (Billstedt et al., 2007; Shattuck et al., 2007).

Studies of higher functioning ASD adolescents have found that higher levels of intelligence are not associated with equally high levels of adaptive social abilities necessary for relationships, college, employment, and independent living (Klin et al., 2007; Saulnier & Klin, 2007). These social impairments of individuals with ASDs may contribute to reports in the literature of the greater likelihood of becoming involved with law enforcement (Curry et al., 1993). For example, a follow-up study that included 70 adolescents and adults with Asperger's Syndrome (AS) found that although the majority of this group was considered law-abiding, 10% had been involved with the law for issues such as fraud, harassment of others, stealing, assault, and sexual abuse (Cederlund, Hagberg et al., 2008). A recent survey of parents of ASD adolescents and adults (ages 13–36 years) compared to parent reports of typical adolescents and adults indicated that along with the younger subset of this sample, older ASD individuals did not necessarily have increased levels of social competence, and that level of social functioning significantly influenced levels of romantic functioning, despite the fact that many of these ASD individuals still had a desire for social and romantic relationships (Stokes, Newton, & Kaur, 2007). In addition to these study findings, the ASD adolescents and adults tended to engage in more inappropriate (e.g., intrusive and threatening) behaviors when in pursuit of romantic relationships with a wider variety of people (e.g., friends, strangers, celebrities) than did the comparison group of typical individuals (Stokes et al.,

2007). The fact that problems with social reciprocity have been found to be the most central and persistent problem, regardless of intelligence level, highlights this as a critical area to address when preparing individuals with ASDs for adulthood (Shattuck et al., 2007).

Restricted and Repetitive Behaviors and Interests

Behaviors in this ASD diagnostic domain include stereotyped and repetitive body movements and manipulation of object parts, compulsions and rituals, insistence on things being the same, circumscribed interests, and self-injurious behaviors (Schultz & Berkson, 1995; Lewis & Bodfish, 1998; Bodfish et al., 2000). Studies of these behaviors in adolescents and adults with ASDs indicate mixed results regarding these behavior difficulties (*see* Seltzer et al., 2004, for a review). A recent follow-up study did not find significantly high levels of maladaptive or stereotyped behaviors in their sample of 105 adolescents and adults with ASDs and varying levels of intellectual ability; however, more than half of this sample had problems with engaging in repetitive activities or routines (Billstedt et al., 2007). Another finding was that a majority of this sample (93%) had sensory response problems such as aberrant behavior responses to being touched or when exposed to auditory or visual stimulation (Billstedt et al., 2007)**.** This finding of pervasive sensory response problems in adults with ASDs has been replicated in other studies (e.g., Leekam et al., 2006). Hypotheses have asserted that individuals with ASDs may engage in repetitive behaviors to induce a sensory experience or that repetitive behaviors are a response to a sensory experience (Liss et al., 2006).

A study by Shattuck et al. (2007) of 241 adolescents and adults with ASDs revealed significant improvements in all maladaptive behaviors measured, including improvements in the areas of repetitive activities and restricted interests, with greater likelihood of improvement in individuals age 31 years and older. However, individuals with ASDs and mental retardation (MR) had more maladaptive (e.g., aggression or self-injury) behaviors and less improvement in behaviors over time (Shattuck et al., 2007). An important situation for consideration is that if an ASD individual has communication difficulties and they experience pain related to medical issues or perceive an aversive sensory experience, then this may cause him or her to display an increase in self-injurious or aggressive behaviors. This possibility has implications for the determination of future adult living environments for these ASD individuals. For example, if an ASD individual does not learn more effective means of communicating and his or her behaviors escalate to the point of regularly displaying threatening or dangerous behaviors in response to activities or transitions, then they are not likely to remain in community-based programs (Cox & Schopler, 1993).

Daily Living Skills

As previously mentioned, ASD individuals tend to have higher intelligence levels compared to their levels of adaptive

functioning, and they tend to show less of an increase over time in acquiring adaptive skills as compared to typically developing peers (e.g., Lockyer & Rutter, 1969; Rumsey et al., 1985; Freeman et al., 1991; Schatz & Hamdan-Allen, 1995; Bryson & Smith, 1998; Carter et al., 1998; Gillham et al., 2000; Bolic & Pousika, 2002; Gabriels et al., 2007). In autism research, the Vineland Adaptive Behavior Scales (VABS; Sparrow et al., 1984) is often used to measure adaptive skills in the areas of communication, daily living, social, and motor skills. Specific deficits on the VABS have been observed in studies of adolescents and adults with autism with a wide range of intellectual abilities, including limited leisure interests, lack of awareness of the need to dress according to situation, poor motor coordination, problems with receptive and expressive language, difficulties with interpersonal social skills, and dependence on others for daily living activities (Billstedt et al., 2007; Klin et al., 2007; Saulnier & Klin, 2007; Shattuck et al., 2007). Notably, it is important for caregivers and service providers to be aware that adolescents with high-functioning autism or AS will also need formal instruction in life skills, because they may not naturally learn these skills from family members or peers.

Living and Vocational Environments

Over the past 30 years, several studies have examined the types of living and vocational environments that ASD adolescents and adults typically attain. Follow-up studies have revealed that although there is considerable variability in adult role outcomes in areas such as independent living, education, vocations, and relationships, a substantial number of individuals do not live independently, are dependent on their families and service providers for assistance with daily living activities, and have limited social networks. The few individuals who have jobs tend to be poorly paid. (*See* Seltzer et al., 2004, for a review.) There is, however, an estimated 15% to 25% of the ASD population with higher intellectual and language abilities, who have more favorable outcomes in these areas, but more research is needed to investigate the predictors of such outcomes (Seltzer et al., 2004).

Cederlund et al. (2008) conducted one of the first studies to prospectively examine the long-term (i.e., more than 5 years) outcomes of a group of 70 males (ages 16–34 years) diagnosed with AS with higher intellectual and language abilities compared to 70 males (ages 16–36 years) diagnosed with autism, the majority (93%) of whom functioned below the average range of intellectual ability. In the AS group, 27% had what was defined as a "good outcome" by *(1)* being employed or engaged in higher education or vocational training and *(2)* living independently if age 23 years or older or *(3)* having two or more friends if age 22 years or younger. Only 3% of those in the AS group were identified as having "poor outcomes" as defined by having obvious impairments in independent and social functioning but still having communication skills. There were no individuals in the autism group who had "good outcomes," and 56% had "very poor outcomes" as defined by an

inability to function independently and having limited communication skills. With regard to living environments, 64% of individuals in the AS group age 23 years and older were living independently, although they were all still dependent on caregivers for support. Only 8% of individuals in the autism group age 23 years and older were living independently, although all were still dependent on caregivers for support. These results support the need to consider providing life skills interventions to ASD individuals regardless of their level of intellectual functioning. In addition, for the ASD individuals who have lower intellectual abilities, it is important to consider the value of specifically targeting interventions to improve communication and independent living skills.

Promoting Optimal Functioning to Learn Life Skills

To learn necessary life skills, ASD individuals need to be able to attend and focus rather than be distracted by medical or psychological issues. For example, sometimes adolescents or adults with ASDs may engage in behaviors involving tantrums, self-injury, aggression toward others, and destruction of property. As a result, life skill teaching environments such as home and community-based school or vocational settings are likely to determine that these individuals are unmanageable. This can then lead to considering more restrictive placements for these individuals where the individual is not expected or allowed to develop life skills to their full capacity.

Behavior problems can affect the ability of an ASD individual to attend to and learn from interventions designed to develop life skills. Addressing an ASD individual's problem behaviors requires an exploration and understanding of the possible underlying *causes* related to such behaviors (e.g., medical or psychiatric co-morbidities). A process of active exploration to determine the underlying causes is warranted, because it is difficult for ASD individuals to spontaneously report or describe their experiences in a way that can be understood by others (Theory of Mind: Baron-Cohen et al., 2000). The iceberg metaphor has been used to provide a visual representation of the "tip-of-the-iceberg" problem behaviors and the underlying medical/psychiatric issues or ASD-specific deficits that may be causing or are driving the behavioral presentation (Cox & Schopler, 1993; Peeters, 1995). This iceberg metaphor serves as a reminder for interventionists to avoid simply attempting to change the visible tip-of-the-iceberg behaviors and instead consider seeking ways to understand and be understood by the individual with an ASD (Morgan, 1996). The following section provides an overview of the myriad of medical or psychiatric issues that are important possible causes or contributors to behavior problems in ASD individuals that should be considered and addressed. (*See* Gabriels & Hill, 2007; Gabriels & Van Bourgondien, 2007; and Goldson & Bauman, 2007, for further discussion about physical, medical, and emotional issues related to individuals with ASDs entering adolescence.)

Medical Health Issues and Autism Spectrum Disorders

Like individuals in the general population, ASD individuals face a wide range of health-care challenges. Deterioration in behaviors or sudden onset of behavioral and emotional disturbances should alert caregivers to the possibility of a physical illness (Wainscott & Corbett, 1996). Compared to the general population, there is a high rate of epilepsy (29%) in individuals with autism who also have lower intellectual functioning, and there is an increased risk of seizures during early childhood and adolescence (Volkmar & Nelson, 1990; Gillberg & Billstedt, 2000; Kielinen et al., 2004). Gastrointestinal (GI) symptoms are prevalent (24%), with chronic diarrhea being the most common (12%) concern in individuals with autism (Molloy & Manning-Courtney, 2001). Along with this, constipation can be a concern because of diet issues or medication side effects. GI symptoms should be taken seriously and investigated because they can cause significant discomfort for the ASD individual, which may result in significant behavior problems (e.g., severe aggression toward self or others) (Goldson & Bauman, 2007).

Abnormal response to sensory input has been documented in numerous studies, and this has implications for the behavioral presentation of ASD individuals (e.g., Baranek et al., 2005). Abnormal sensory responses in ASD individuals can include over- and under-responsiveness to sensory input as well as actively seeking sensory input in all sensory domains (auditory, visual, vestibular, tactile, and oral; Dunn, 1999). It has been hypothesized that along with an individual's perception of sensory information, his or her physical or emotional well-being can affect the intensity of his or her behavioral response (Ayres, 2005; Kerstein, 2008).

Sleep problems resulting from a variety of medical and psychosocial issues are common in ASD individuals and include problems falling asleep and staying asleep, sleeping too much, or experiencing events that interfere with sleep such as seizures (Malow, 2004; Allik et al., 2006). There is an indication that the sleep problems in individuals with ASDs may exacerbate issues such as stereotypic behaviors and communication problems observed during daytime activities (Schreck et al., 2004).

Individuals with ASDs may have more oral conditions (oral injuries, oral sensory defensiveness, and teeth-grinding) compared to children with general developmental delay. These factors can result from a combination of poor daily dental hygiene and inconsistent visits to the dentist, which might increase their risk of developing dental disease (DeMattei et al., 2007). Having dental or other medical problems that may result in general discomfort (e.g., oral sensitivities) or pain (e.g., jaw and headache pain from teeth-grinding), which can result in the ASD individual refusing to eat or engaging in self-injurious behaviors (e.g., head banging). Finally, it is important to help this ASD population access health care on a regular basis to monitor and proactively intervene with medical issues, which, if left untreated, may otherwise result in extreme behavioral exacerbations.

Mental Health Issues

Psychiatric Issues

Deterioration in the behavior functioning from an individual's baseline ASD symptom presentation can signal the onset or worsening of a psychiatric condition. As is the case with medical issues, elevated behavior symptoms can interfere with an individual's capacity to learn life skills and function as independently as possible. Higher rates of affective disorders, particularly depression, have been reported in the ASD population (Chung et al., 1990; Tantam, 1991; Abramson et al., 1992; Ghaziuddin & Greden, 1998; Leyfer et al., 2006). Affective disorders appear to peak in ASD adolescents and young adults and are signaled by behavior deterioration (e.g., increased irritability and aggression) (Gillberg & Billstedt, 2000; Ghaziuddin et al., 2002). Notably, ASD individuals with higher levels of intellectual functioning may be more acutely aware of their social and relationship difficulties, which can contribute to feelings of depression. Higher levels of anxiety disorders have been found in children and adults with ASDs compared to controls (e.g., Lecavalier et al., 2006; Leyfer et al., 2006; Gillott & Standen, 2007). The sources of anxiety for ASD individuals have included situation (e.g., being in a busy mall) and medical (e.g., blood draws) fears (Evans et al., 2005), along with specific phobias (e.g., loud noises) (Leyfer et al., 2006). There is growing evidence that symptoms of repetitive or obsessive behaviors can develop into a separate psychiatric obsessive-compulsive diagnosis in ASD children (Muris et al., 1998; Reaven & Hepburn, 2003) and adults (Szatmari et al., 1989; Tantam, 1991; Ghaziuddin, 2005).

Family Issues

The stress of caring for an ASD individual can impact both the individual and their family members. The unique family system, family life cycle (ASD child entering adolescence), and extended support systems are all important factors that can improve the understanding of an individual's behavior problems and identification of needed family service supports to relieve stress (e.g., respite care, parent training, or support groups) (Head & Abbeduto, 2007). Systems theory asserts that families are interactive systems with each member contributing to, influencing, and being influenced by all aspects of family life and their environment (Minuchin, 1974). Caring for ASD individuals can involve considerable expenditures of time, finances, and effort beyond the typical responsibilities of parenting. Parents of ASD children have reported higher levels of stress, depression, marital discord, and pessimism about their child's future than parents of children with other developmental disabilities. (*See* Head & Abbeduto, 2007, for a literature review.) Specific caregiver concerns that relate to having a child or adolescent with an ASD include the individual's behavior problems (e.g., defiance, disruption, aggression), social and communication deficits, and dependency

needs that can restrict family activities (e.g., Fong et al., 1993; Lecavilier, Leone, & Wiltz, 2006).

Parent and sibling factors as well as significant life events are important issues that can affect the behavior presentation of the individual with an ASD. Parents of ASD individuals tend to have elevated levels of psychiatric (Yirmiya & Shaked, 2005) and developmental difficulties (Piven et al., 1997) that can affect how they relate to and engage with the ASD individual. For example, if a caregiver struggles with cycling moods, then this parent may give mixed affective messages that can be extremely frustrating and confusing to the ASD individual, who tends to best understand situations when simple and clear-cut messages are provided. On-going exposure to this kind of environment may result in the ASD individual chronically experiencing high levels of anxiety linked with rage reactions. Sibling relationships (e.g., lack of sibling closeness or positive interactions) can also be a contributing factor to the behavioral expression of the sibling with an ASD, depending on the specific coping patterns (e.g., avoidance of the ASD sibling) adopted by the neurotypical sibling (*see* Orsmond & Seltzer, 2007, for a review.) Finally, exposure to negative life events such as a family move or the death of a family member can be associated with an increase in behavior and mood symptoms (e.g., crying spells, irritability, and sleep and appetite disturbance) expressed by the ASD individual (Ghaziuddin et al., 1995).

Autism Spectrum Disorder Symptom Variability: Hypothetical Case Examples

Individuals with ASDs can present with a wide variability of core ASD social, communication, and behavior symptoms combined with a range of intellectual functioning and associated issues. The following two hypothetical cases provide examples for considering how symptom variability requires an individualized life skill intervention approach. In the first case, AS is the diagnosis; however, it is important to note that current research has not provided evidence that there are clear-cut differences between the impairments and service needs of AS and high-functioning autism. (*See* Kasari & Rotheram-Fuller, 2005, for a review.) These case examples will be discussed again in the life skills intervention section to review possible solutions to address the issues presented here.

Case 1:

Joe is a 13-year-old adolescent male with AS or high-functioning autism with at least average intellectual ability and language skills. Although Joe's *communication* skills include a large vocabulary and ability to engage in conversations about his particular interests, he makes fleeting eye contact and speaks in a monotone voice slightly above the volume level of his peers; his peers are often confused by his facial expression because it rarely changes from looking "serious." When Joe's classmates try to involve him in conversations,

they become frustrated by his insistence on guiding conversations back to things of interest to him. *Socially*, Joe has been teased by peers because he sometimes forgets he is in public settings and puts his hands in his pants to touch his genitals. He desperately wants to fit in with a peer group at school and has tried to imitate the behaviors and dress of certain social groups, but he has done so to such an extreme that he has been further rejected. Joe's friendships are limited to a much younger girl in his neighborhood and an e-mail pen pal. Joe likes to figure out how mechanical things work, and sometimes this has resulted in his being accused by others of "breaking" their things. Joe's behavior becomes extremely agitated (e.g., he makes loud remarks or threatens to hurt others) when others try to talk to him about how his behavior impacts them. He also becomes significantly more resistant when he is asked to do something he does not want to do, does not get his way, or if the bell rings to signal time to transition to his next class. In the past, he has been suspended from school because he said he wanted to "blow up the school." At home, Joe has little interest or involvement in *activities of daily living*, including his self-care. He spends a majority of his time on the computer and tinkering with mechanical things around the house. Joe refuses to attempt or assist with simple chores or meal preparation. He prefers to eat variety of unhealthy snacks throughout the day. Joe refuses to shower on a daily basis and he often needs reminding to dress appropriately for weather changes because he prefers to wear shorts or pajama pants all of the time. Because of Joe's interest in tinkering with mechanical things and computers, his parents have considered future *living and vocational* environments that include being in a college living environment with supports to address his self-care and social skills deficits. Within such an environment, they hope Joe might learn skills necessary to work with information technology or mechanical engineering.

Case 2

Sarah is a 15-year-old adolescent female with autism and moderate MR. Sarah *communicates* by using sign language and some simple phrases. However, she uses only a few signs, is not precise in gesturing signs, and her verbalizations tend to be repetitive or echoed. If she is offered a choice, Sarah tends to echo the last thing said to her regardless of her preference. Sarah can also communicate her needs by writing simple sentences, but her primary mode of communication is to grab or throw things. Sarah can read simple words or phrases and understand expectations others have for her if provided with a demonstration or simple written instructions presented with pictures. Sarah enjoys swimming, jumping on the trampoline, and singing in *social* settings. Sarah can take turns with others to play simple board or card games but quickly loses interest. At school and in other community settings, Sarah tends to stand too close to others and will spontaneously touch others or smell their hair. She also tries to take her clothes off or

masturbate in public settings. *Behaviorally*, Sarah has a hard time waiting and will begin to bang her head when she is expected to wait too long. She can easily become angry and out -of control when she is simply told "No" or asked to do something. Sarah frequently chews holes in her shirts and hits her face, head, or neck repetitively. These behaviors worsen when she becomes emotionally distressed. Sarah tends to grind her teeth at night and at times during the day. She wakes up several times throughout the night. At home, Sarah's *activities of daily living* are limited to sitting in a rocking chair or swing, watching movies, completing 150-piece puzzles, tearing out magazine pictures and sorting them into piles, or listening to music. Her piles of pictures have cluttered many of the living spaces in her home, but her parents do not move them for fear she will become extremely upset. Sarah's parents also do not engage her in helping with simple chores around the house or cooking, because she needs too much supervision to complete such tasks. Sarah can use the toilet but sometimes needs to be reminded to go to the bathroom and needs help with wiping thoroughly. Sarah needs some assistance with completing the steps involved in bathing and brushing her teeth. She has not been to the dentist in several years because of related emotional distress. Sarah's parents have worried about what they will be facing in terms of finding appropriate *living and vocational environments for Sarah*. They are concerned that Sarah may eventually need to live in a very restricted setting with maximum staff assistance and wonder if she will ever be able to do vocational work.

The next sections review interventions that can be gleaned from the literature regarding the underlying learning styles and needs of individuals with ASDs. Following this, example strategies to address the individual needs and capabilities of these two case examples will be provided.

Teaching Survival Life Skills

What and When to Teach

To determine which survival life skills to teach in preparation for adulthood, it is crucial to identify which behaviors will be needed for the ASD individual to function in a future environment. Following this, it is necessary to systematically teach those behaviors throughout the child's life. During each life stage, systematic teaching of life skills should involve interventions that build on the individual's current behaviors, strengths, and interests while considering questions such as "*How will this skill assist the child in the future?*" Families can be valuable life teachers for ASD individuals by embedding the instruction of life skills into the daily activities of family life. This is an important strategy because ASD individuals have difficulties with skill generalization and function better with predictable routines.

Table 67-1 provides a list of suggested life skills to teach ASD individuals. Skills are summarized under core diagnostic

domains. For a more comprehensive guide to life skills for this population, see the Suggested Reading for a list of resources.

School settings should incorporate teaching life skills into the curriculum to prepare ASD individuals for vocational and adult living environments. The individuals with Disabilities Act of 1990 (P.L. 101-476) mandates state and local educational agencies to develop an Individualized Education Plan (IEP) for students with disabilities. The IEP maps out how an individual's unique needs can be met to prepare him or her for further education, employment, and independent living in state and local educational agencies. (*See* Steedman, 2007, for a thorough review of the laws impacting the treatment and long-term care of individuals with ASDs.) Assessment tools such as the *TEACCH Transition Assessment Profile–Second Edition (TTAP)* can assist the IEP intervention planning process by identifying the individual's life skill strengths and weaknesses (Mesibov et al., 2007). The TTAP evaluates the individual's life skills in home and school/work environments in areas such as vocational skills, independent functioning, leisure skills, functional communication skills, and social skills.

How to Teach

Parents may have implemented a variety of best practice behavioral and cognitive-behavioral intervention strategies when the child with an ASD was young but may have discontinued using these strategies when the child enters adolescence, assuming that the child has outgrown such techniques. However, these previously used strategies may still be very important and necessary, because the ASD adolescent is still learning and processing information in the unique ways

Table 67–1.
Suggested life skills to teach

Communication Life Skills	Social Life Skills	Behavior Life Skills
Expressive language skills	*Relationship skills*	*Understanding emotions*
Communication aids, pictures, sign language, or adaptive devices	Friendships (shared enjoyment)	Awareness of levels of internal states
	Sportsmanship	Understanding triggers
Conversation skills	Dating	Developing coping skills
Writing skills	*Self-care skills*	*Self-regulation skills*
Receptive language skills	Hygiene	Leisure and sensory-oriented recreation activities
Understanding nonverbal cues, figurative language, and sarcasm	Medical health care	*Safety*
	Diet and meal preparation	Sexuality issues
	Exercise routines	Respecting personal space and property
	Employment	
	Transportation	Understanding public versus private behaviors
	Housing-household chores	Dealing with emergencies
Reading skills	Managing money	
	Shopping	

particular to this ASD population. This section provides an overview of the unique ASD learning styles and identifies a few key behavioral intervention strategies. This section is not meant to provide an in-depth review or discussion of behavioral intervention theories or methods; rather, this section provides a way to consider extending intervention techniques to match the learning needs of the adolescent with an ASD.

Mesibov (2005) refers to the "culture of autism," which is an extremely useful approach to linking theoretical understandings of this ASD population to intervention approaches. Thinking of autism as a "culture" helps make the tremendous ASD symptom variability comprehensible by focusing on common learning characteristics and patterns of behavior. Such understanding can enhance the implementation of interventions to improve the functioning of ASD individuals in society.

Individuals With an Autism Spectrum Disorder Tend to Think Concretely

Concrete thinking can be evidenced in their difficulties with pragmatic language skills, which involve social, emotional, and cognitive factors that enable an individual to effectively communicate and receive messages (Twachtman-Cullen & Twachtman-Reilly, 2007). Concrete thinking can put an ASD individual at risk for not understanding things such as figurative language (e.g., "Give me a hand"). The ASD individual thus may respond in inappropriate ways or become confused by social situations, social conversations, or school lectures. Intervention techniques such as Social Stories™ (Gray, 2000) are frequently used to teach ASD individuals how to respond and manage their behavior during a variety of social situations. Social Stories™ provide concrete and well-defined social rules and socially appropriate behaviors that the individual can follow to engage more successfully. Social Stories™ have demonstrated some effectiveness in decreasing the negative behaviors in individuals with ASDs (Rust & Smith, 2006; Scattone et al., 2007). Social skills training groups also are an important intervention consideration because they have demonstrated skill improvements in ASD adolescents (e.g., Tse et al., 2007). Teaching ways to deal with bullying can be taught through organizations such as KIDPOWER (www.kidpower. org), an international organization that provides instruction regarding the practical skills needed to address confrontation and victimization (van der Zande, 2007).

Individuals With an Autism Spectrum Disorder Struggle to Understand Others' Intentions, Emotional States, and Behaviors

This struggle has been referred to as "mind-blindness" and described by the Theory of Mind (ToM) (Baron-Cohen, 1995; Baron-Cohen et al., 2000). This impaired mentalizing ability can make it difficult for ASD individuals to infer possibilities based on available information, reflect on how their own behaviors may affect others, and problem-solve ways to change their behaviors to improve their social relationships. For

example, an ASD adolescent may become extremely angry if his routine of being picked up by his mother at an appointed time is delayed. This adolescent may be unable to generate more than one possibility to explain why his mother is late; if he could, he may be more forgiving of things he cannot control. Social Stories™ or opportunities to learn by "doing" or role-play can be useful interventions to address this issue. Other techniques derived from behavior learning theory and principles of ABA have evidenced effectiveness with ASD individuals (*see* Matson et al., 1996, for a review of behavioral interventions in autism.) For example, highlighting (e.g., giving social praise) to the ASD individual's appropriate social behaviors whenever they occur serves to both increase the individual's awareness of desired social behaviors and motivate them to display these behaviors more frequently.

Individuals With an Autism Spectrum Disorder Tend to Focus on Details at the Expense of Seeing Things in Context or Getting the "Big Picture"

This difficulty integrating ideas affects the ASD individual's ability to generalize information across situations and has been described by Weak Central Coherence Theory (Frith, 2003). Unfortunately, success in the social world heavily depends on the integration of details such as facial expression, vocal intonation, gestures, body language, and words in context. For example, an ASD individual may not understand the nonverbal or verbal cues of someone else being frustrated with his or her inappropriate remarks; therefore, the ASD individual may continue to escalate his or her inappropriate behavior, misreading the nonverbal cues of another person. One helpful technique to encourage motivation and understanding with ASD individuals is to use the "*First do this, then get that*" behavior teaching strategy. For example, at the first signs the ASD individual is being socially inappropriate, the other person can tell the ASD individual that they will return to talk with them when the ASD individual is engaging in a specific socially desired manner and then immediately remove their attention and engagement. Although ASD individuals may have impaired social interactions, they are still are motivated to engage with others. Being told, "*First do this, than get that*" is a strategy that works well to motivate ASD individuals to do something they may be less interested in doing, such as a chore or a task for another person, because following this, they know they can engage in their preferred activity.

Individuals With Autism Spectrum Disorder Have Difficulty With Organization and Sequencing

This has been as described by the theory of Executive Dysfunction (Ozonoff, 1995; Russell, 1997). Executive functions include cognitive flexibility, an ability to apply social rules flexibly, control impulses, organize, and initiate activities. Individuals with an ASD may have difficulties completing a task unless the steps are clearly outlined for them. They also may have trouble completing activities in a timely manner

unless they are provided with specific cues to know when an activity is to be finished. Structured intervention methods such as those developed by Division TEACCH address the poor organization and sequencing skills of ASD individuals (Schopler et al., 1995). For example, the TEACCH approach offers strategies for modifying or structuring the physical environment to enhance comprehension of and cooperation with expectations using such techniques as visual schedules and breaking down multiple-step tasks (e.g., showering) or events (e.g., shopping) into more manageable parts (Krauss et al., 2003). Studies of individuals with ASDs in natural environments have demonstrated that the introduction of external structure (e.g., visual cues like pictures and physical organization) combined with predictable routines can help increase on-task behaviors and completion of work (MacDuff et al., 1993; Hume, 2005). There is also evidence to support alternating activity schedules between preferred (those activities not associated with challenging behaviors) and less preferred activities (activities that evoke challenging behaviors) to decrease the presence of behavior problems (Liptak et al., 2006). *See* previously mentioned "*First do this, then get that*" strategy.

Individuals With an Autism Spectrum Disorder Tend to Be Very Distractible, yet Able to Focus Intensely on Things of Particular Interest to Them (Dawson & Levy, 1989)

They can be abnormally aroused or distracted by sensory input such as sound, touch, smell, taste, or movement (Greenspan & Wieder, 1997; Hirstein et al., 2001; Baranek et al., 2005; Tomchek & Dunn, 2007). An ASD individual's focus on stereotyped or repetitive behaviors can distract him or her from being able to attend to teaching tasks. Preferred or "attractive" sensory stimulus conditions have resulted in a reduction in stereotyped movement behaviors in children with autism (Gal et al., 2002). In addition, it may be easier to motivate and teach new information to ASD individuals if the new skill can be linked to their particular interests or preferred activities (Delmolino & Harris, 2004). Given this information, important intervention strategies for ASD individuals include teaching life skills in learning environments free from aversive sensory input and linking new skills with things that are familiar to or preferred by the ASD individual.

Tables 67-2 and 67-3 provide examples of intervention solutions to some of the issues described in the hypothetical cases presented earlier in this section. Notably, these intervention solutions are not intended to be a comprehensive list of options to consider.

Transitions to Residential and Vocational Training Environments

Ideally, transitions to adulthood should be a gradual planned process that is originally considered when a child is diagnosed,

is reconsidered when the child enters puberty, and is then again considered when they reach adulthood. The transition to adulthood has been defined as an "… active process that attends to the medical, psychosocial, and educational-vocational needs of adolescents as they move from child-oriented to adult-oriented lifestyles and systems" (White, 1997, p. 698). Transitions can involve moving from educational to work settings from pediatric to adult health-care providers and from living with the family to living in community settings. Caregivers should make plans and adjustments in their perspectives of eventually having to "let go" during each of these life time periods to minimize having to make (haphazard) decisions in a crisis about issues such as where an ASD individual should live (White, 1997). Such prospective planning can help ensure that life-long social and financial support networks are identified and developed long before the individual reaches adulthood (Aman, 2005). For example, establishing a living will and advanced directives (or mental health plans) can provide guidance to future treatment providers about the child's strengths, needs, and problem behavior warning signs. Organizations such as the *National Alliance on Mental Illness (NAMI)* provides one of the largest network of supports and information for improving the quality of life for individuals with special needs, including supports for helping individuals with an ASD transition to independent living and college (www.nami.org).

Residential Environments

Individuals with ASDs are a diverse group, and although some may be able to live independently, other individuals may require supports to live in a safe and healthy manner. It may be difficult for parents to consider planning alternative living settings during their child's early years, because they may be distracted by the daily life struggles related to managing the ASD child's current needs. However, as early as possible, parents should begin considering future living environments for their child because government and private residential agencies are limited. The *National Association of Residential Providers for Adults with Autism (NARPAA)* is a good resource for finding U.S. agencies that provide residential services (www.NARPAA.org). Parents may consider supervised group homes or other supportive living arrangements. Supportive co-housing arrangements may include setting up an apartment with a hired caregiver or other living arrangements that include a peer roommate who has free or discounted rent in exchange for looking out for the ASD individual. After an ASD individual reaches age 18 years, they may qualify for Supplemental Security Income (SSI) to assist with living expenses, although the individual may still live with their parents (www.ssa.gov). Finally, it is important for parents to consider a special needs trust for their ASD child so that he or she can continue to be cared for after the death of the parents. Notably, some trusts or monies in the child's name may impact the child's continued eligibility for benefits such as SSI.

Table 67–2.
Hypothetical case I solutions for 13-year-old male with Asperger's syndrome

Life Skill Domain	Strengths and Needs	Suggested Interventions	Life Skill Goal
Communication	*Strength:* Interest in computers and how things work	1) After-school clubs involving his interests	Development of prevocational skills and friendships who share interests
	Need: Social conversation skills	2) Social skills groups 3) Individual or group therapy with a speech language pathologist	Increased awareness & understanding of survival social conversation skills
Social	*Strength:* Desire for friendships & ability to imitate others	1) See above social interventions. 2) Involve in a school job	1) See above 2) Provide a defined social engagement role with peers.
	Need: Lacks awareness of private vs. public behaviors, & maintaining appropriate social boundaries	1) Teach what are private vs. public and social boundary behaviors 2) School class addressing sexuality issues	Increased pro-social skills to decrease possible involvement with law enforcement
Behavior	*Strength:* Ability to vocalize frustrations *Needs:* Lacks awareness of levels of internal states, triggers, and coping skills	1) Teach to rate levels of internal states related to triggers on a rating scale. 2) Work with an occupational therapist to identify sensory-related calming/coping strategies.	1) Increased understanding, expression, and ability to cope with frustrations 2) Decrease the possibility of expulsion from community settings.
Activities of daily living	*Strength:* Motivated by computers and tinkering with mechanical things *Needs:* Lacks motivation and possibly an understanding of why or how to engage in variety of self-care and daily living activities	1) Daily written schedule alternating less preferred followed by preferred activity 2) Social story of why it is important to keep the body clean, exercise, and eat healthy food	Increased motivation and understanding to engage in adaptive daily living activities

Table 67–3.
Hypothetical case II solutions for 15-year-old female with autism and mental retardation

Life Skill Domain	Strengths and Needs	Suggested Interventions	Life Skill Goal
Communication	*Strengths:* Understands and uses some sign language and simple phrases. Pictures enhance her understanding *Needs:* Limited ability to consistently communicate in multiple settings	1) Expect and reinforce continued use of sign language and phrase speech 2) Introduce a talking device with pictures and use it with her in multiple settings. Use picture–word schedules. 3) Consult with speech language pathologist	1) Decrease frustrations resulting from a lack of ability to communicate needs or to understand others' expectations. 2) Increase ability to be understood by a variety of individuals in multiple settings.
Social	*Strengths:* Interest in others and in soothing self *Needs:* Lacks understanding of appropriate public vs. private behaviors	1) Teach to use specific location for identified private behaviors. 2) Teach to give handshakes for greetings and to ask to get close to or touch others. 3) Teach variety of leisure skills expanding on sensory and special interests.	Increase pro-social and leisure skills to decrease possible involvement with law enforcement and reduce risk of victimization.

(Continued)

Table 67–3. (*Contd.*)

Life Skill Domain	Strengths and Needs	Suggested Interventions	Life Skill Goal
Behavior	*Strengths*: Attempts to occupy self when waiting or soothe self when upset. *Needs:* Difficulty knowing what to do when waiting	1) Use timers (e.g., vibrating watch or hourglass) to signal how long she is to wait. 2) Teach to engage with "waiting" (e.g., sensory-oriented materials made available every time she has to wait.	Increase ability to wait in a pro-social and safe manner.
	Needs: May be experiencing headache and neck pain related to teeth-grinding behaviors	1) See dentist to evaluate condition of teeth. 2) Consult with medical professional about pain management strategies. 3) Consult with occupational therapist to define sensory relieving activities. 4) Provide socially appropriate items to chew such as rubber-type jewelry.	Improve dental health and identify pain management and self-regulation strategies to reduce negative behaviors.
Activities of daily living	*Strengths*: Motivated by swinging, movies, puzzles, and sorting pictures *Needs:* Lacks motivation, and ability to engage in activities of daily living	1) Daily picture schedule alternating less preferred followed by preferred activity 2) Mini picture schedule of the steps to do a skill. 3) Consult with occupational therapist to identify strategies to help engage in daily life activities. 4) Incorporate sorting skills into chore activities.	Increase motivation and ability to engage as independently as possible in a wider variety of daily living activities.

Supportive College Living Programs

There are several programs that provide supportive residential environments where ASD students can receive assistance to develop social and daily living skills while taking courses at a nearby community college. Two examples are The College Internship Program (http://www.collegeinternshipprogram.com) and the College Living Experience (http://www.cleinc.net/home.aspx). Such programs also provide academic assistance to complete college and assistance to prepare the individual for the transition to independent living. Assistance includes helping the ASD individual break down academic and daily living tasks into manageable steps, learn self-regulation stress management skills, develop appropriate friendships, and manage medications, as needed. Other programs provide support to ASD students outside of a residential environment. For example, the AHEADD Model (http://www.aheadd.org) provides continuum of professional staff and peer mentors who serve as liaisons, personal advocates, and coaches to the student with an ASD who is competitively admitted to a college of their choice. Finally, contacting the office for disability services on college campuses can be another resource for services and supports for the ASD individual. *See* Blumberg (2005) for a more in depth discussion of college, career, and residential supports.

Employment Training Programs

Project SEARCH is a high school transition program that provides work training experiences in an effort to increase employment opportunities for individuals with disabilities (http://www.cincinnatichildrens.org/svc/alpha/p/search/). Project SEARCH began at Cincinnati Children's Hospital Medical Center in 1996 and now has more than 106 replication sites across the United States. Although a majority of the SEARCH training programs are within health-care settings, other settings include banks, universities, and manufacturing sites. Project SEARCH provides unpaid year-long vocational preparation internships to high school students (ages 18–21 years) with disabilities. These internships involve hands-on experience in employment settings with highly trained job coaches. The internship focuses on teaching appropriate hygiene, social, and communication skills along with skills related to improving students' ability to take direction, change their behavior, and access public transportation. Admission into the internship program depends on the student's updated immunization record, desire to work, and ability to pass a drug screen and background check. Following the completion of this internship program, there is no commitment by the training site to hire the student, although students typically become employees (Personal Communication Project SEARCH co-founder Erin Riehle, March 13, 2009).

Conclusion

Expanding the possibilities for an optimal quality of life when ASD children grow up necessitates assessment and treatment their medical and psychological health as well as teaching necessary life skills that build on the current behaviors, skills,

and interests of the ASD individual. Families can be valuable life teachers for their ASD child by routinely embedding the instruction of life skills into activities of family life, making this teaching a part of routines that are practiced every day. The ASD learning style culture is an important consideration when developing life skills interventions to encourage skill acquisition and generalization across vocational and living environments.

Challenges and Future Directions

- Follow-up studies are needed to evaluate the outcomes of the next generation of adolescents and young adults with ASDs who received intensive early intervention services in the 1990s.
- Studies are needed to assess the actual implementation of life skills preparation in academic environments for ASD individuals along with the impact of these programs on social and vocational outcomes.
- More resources are needed to address the residential and vocational needs of the older adolescent and young adult with an ASD.

Family Adaptive Functioning in Autism

Points of Interest

- Families of children with autism spectrum disorders (ASDs) are recognized as being impacted by having a family member with an ASD. Impacts can vary widely and include both negative and positive experiences, ranging from increased resource needs, to higher levels of parenting-related stress, to positive personal growth for family members.
- Families are increasingly appreciated for their crucial role in implementing and supporting early autism intervention. Addressing the needs of children with ASDs thus requires including a focus on the family.
- Family adaptive functioning is proposed as an integrative term for the many specific activities families carry out to support improved outcomes for children with ASDs. These activities include examples such as family-orchestrated child experiences (e.g., summer camps, sports programs), parent–child interaction, and child health and safety functions.
- Early autism intervention can play a role in supporting family adaptive functioning. Evidence suggests intervention that improves child social functioning and decreases problem behavior associated with ASDs may support family adaptive functioning.
- Research is needed to clarify characteristics of intervention programs that lead to improved family adaptive functioning and ways in which family adaptive functioning is related to better outcomes for children with ASDs. Increased attention to measuring clear, well-defined constructs related to the family will support efforts to identify new targets for ASD intervention.

Families of children with ASDs have received increasing attention from autism researchers in recent years. There is a growing appreciation of the potentially daunting hurdles parents may face related to raising a child or children with ASDs. The time of initial diagnosis is often emotionally painful. This process can be complicated by the necessity of initiating early intervention services while concurrently facing the emotional reality of the diagnosis of an ASD. Services are often difficult to access and costly, adding burden to the family. The family context is increasingly understood as a crucial factor to consider in implementing early intervention. Thus, increased attention by research to families of children with ASDs is related in part to an appreciation of the difficulties they face but also to a growing understanding that the success of early intervention may be improved with the support of parents and families.

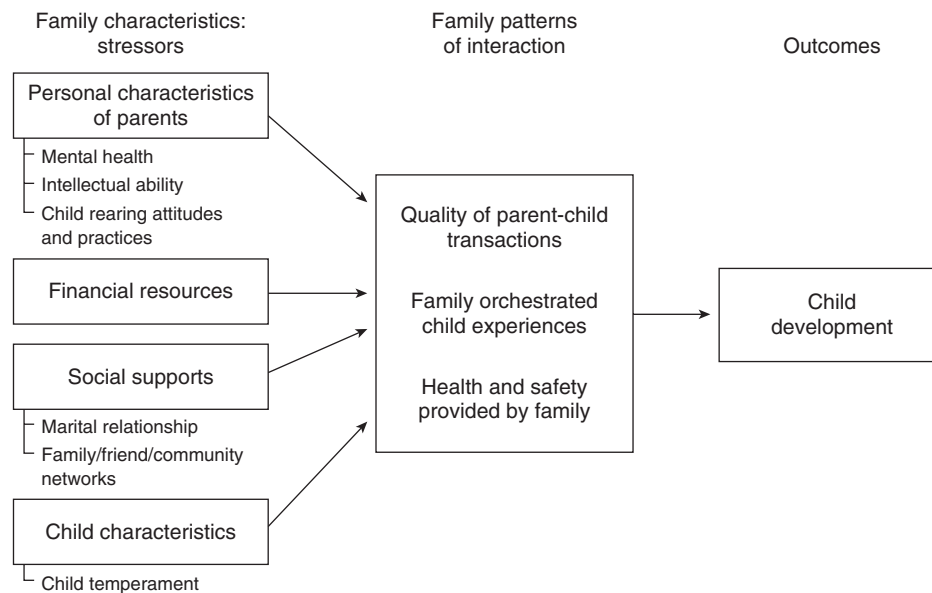
The Developmental Systems model (DS model; Guralnick, 1998, 2005) provides a framework for understanding the connection between family context, early intervention, and improved outcomes for children with developmental disabilities. This model is centered on developmental principles and places the family—particularly parents—at the center of early intervention programs. The DS model specifies parent–child interaction (e.g., verbal commenting on child play, responsiveness to child initiations, positive physical play), family-orchestrated child experiences (e.g., holiday celebrations, meal time, leisure activities), and child health and safety functions (e.g., medical care, regular sleep patterns, monitoring child whereabouts) as specific functions provided by the family that can improve child outcomes. Within this model, both threats and supports to these central family functions are identified. Family characteristics that may threaten or support family patterns of interaction include personal characteristics of parents (mental health, intellectual ability, and child-rearing attitudes), financial resources, and social supports for the family. Threats also include child characteristics that increase the demands on parents, family resource needs, and distress in the family, as well as decrease confident parenting.


Figure 68–1. Developmental Systems Model. From Guralnick, M. J. (2005). An overview of the developmental systems model for early intervention. In M. J. Guralnick (Ed.), *The developmental systems approach to early intervention* (p. 11). Baltimore: Paul H. Brookes Publishing, Reprinted by permission.

In addition to the functions identified in the DS model, the family system, especially parents, often plays a crucial role in early identification of difficulties for children with ASDs and may be part of an interdisciplinary team approach to implementing early intervention (e.g., Vismara, Colombi, & Rogers, 2009).

There are many complex and heterogeneous constructs that motivate and inform research related to families of children with ASDs. Family adaptive functioning is a concept we propose to use as a framework for the concepts discussed above. Adaptive functioning for an individual is considered the ability of an individual to carry out age-appropriate skills needed to function in daily life, such as dressing, eating, following rules, avoiding accidents, and making friends. The specific activities of families that contribute to improved outcomes for children with ASDs (parent–child interaction, family-orchestrated child experiences, and child health and safety functions in the DS model) can be considered "family adaptive functioning."

Parents are typically the single-most important contributors to family adaptive functioning. Therefore, the first section of this chapter will focus on four constructs related to parental contributors to family adaptive functioning: parenting-related stress, parental psychological distress, parental psychological functioning, and parent coping strategies. Research findings related to these constructs in families with children with ASDs will be discussed, and specific measures of these constructs will be presented. The second section of the chapter will present several key threats and supports to family adaptive functioning: family characteristics, stressful life events, spousal relations, social support, and child characteristics. Measures of each threat and support and relevance to families

of children with ASDs will be discussed. The chapter concludes with a discussion of connections between interventions for ASD and family adaptive functioning. Evidence regarding the impact of three types of intervention—early intensive behavioral intervention, parent training, and interventions directly targeting parent stress—on family adaptive functioning is discussed.

Parental Contributors to Family Adaptive Functioning

Parenting-Related Stress

In the extensive literature on parenting, the concept of stress has been used as an umbrella term, integrating a variety of phenomena that may affect parent functioning (Webster-Stratton, 1990). Research on parent stress may include factors that range from extrafamilial (e.g., negative life events), to interparental (e.g., marital distress), to child-related (e.g., difficult child temperament). Stress has also been defined phenomenologically as resulting from the parent's subjective appraisal of the demands placed on them in their role as a parent (Abidin, 1992). The scientific investigation of parent stress is challenging, given the wide variety of concepts the term stress covers. This complexity has resulted in many different constructs being measured, even though they purportedly all relate to parent stress. This has important ramifications for interpreting results of research in this area. For example, Rodrigue, Morgan, and Geffken (1990) found that stress was higher in parents of children with ASDs

compared with parents of children with idiopathic developmental delay (DD) and typical development, but only on certain dimensions of parental stress. Perceived parental competence and marital satisfaction were lower in parents of children with ASDs, but self-blame and perceived disruption of finances and activities were equivalent in the ASD and DD groups. In addition, no group differences in family cohesion and mother–child interaction were found between groups. Greenberg and colleagues (2004) found no differences in overall level of optimism, depression, well-being, or health among mothers of adult children with ASDs, Down syndrome, and schizophrenia. Mothers of adults with Down syndrome reported closer relationships with their children compared to mothers of adults with ASDs. The literature strongly supports the notion that parents of children with ASDs experience higher stress (e.g., Dumas et al., 1991; Estes et al., 2009), but it also appears that the way in which stress is defined and measured can offer a more complex picture.

We define *parenting-related stress* as the amount of stress a parent feels related specifically to aspects of parenting their child with ASD. The term parenting-related stress has been used by others (e.g., Abidin, 1992; Hodapp et al., 2003) but with a slightly different meaning. For example, some parenting stress scales include child characteristics, spousal relations, and social support, which we consider as separate constructs. We argue that it is important to attend to these measurement issues so that meaningful comparisons can be made between studies, and models can be objectively tested. In addition, our phenomenological approach emphasizes the parental experience of stress. An underlying assumption of this approach is that stress is subjective and thresholds for experiencing stress vary from person to person. It is important to distinguish between an individual parent's experience of stress (i.e., parenting-related stress) and an investigator's assumptions about the impact of child characteristics on the family. This is because a particular child characteristic may cause great stress for one parent but low stress for another parent. This level of measurement clarity is needed to allow systematic evaluation of the impact of ASD intervention on family adaptive functioning and to increase understanding of moderators of family adaptive functioning. We next review commonly employed rating scales that are used to measure parent-related stress.

One of the most commonly used rating scales to investigate parenting-related stress in families of children with ASDs is the Parenting Stress Index, (PSI; Abidin, 1995) and the PSI-Short Form (PSI-SF, Abidin, 1995). The PSI is based on the theory that the amount of stress a parent experiences is a complex interaction of certain child characteristics, parent characteristics, and situations related to the parenting role. Hence, to assess parent stress levels, the PSI is divided into two domains; the Child Domain and the Parent Domain. The Parent Domain is relevant to parenting-related stress but also taps into the domains of psychological distress (e.g., Depression) and social support (e.g., Isolation). It comprises seven subscales: Competence, Isolation, Attachment, Health,

Role Restriction, Depression, and Spouse. Example items from the Parent Domain are: "I often feel that I cannot handle things very well" and "I feel trapped by my responsibilities as a parent." The entire questionnaire consists of 120 items, rated on a 5-point scale (Strongly Agree to Strongly Disagree). The instrument yields a Total Stress Score, subdomain scores for each of the subscales, and an optional Life Stress score. Using a sample of 534 parents, the PSI demonstrated good reliability on the child domain (0.89), parent domain (0.93), and the Total Stress Score (0.95). Test–retest reliability on a subset of 37 mothers showed adequate reliability on the child domain (0.55) and good reliability on the parent domain (0.70) and Total Stress Score (0.65) after a 1-year interval.

Another frequently used scale is the Questionnaire on Resources and Stress (QRS; Holroyd, 1974). The most frequently used version of the QRS in ASD research appears to be the QRS–Friedrich Short Form (QRS-F; Friedrich, Greenberg, & Crnic, 1983). The QRS-F contains 52 true-false items comprising four subscales: Parent and Family Problems (e.g., "I can go visit with friends whenever I want" and "Other members of the family have to do without things because of ___"), Pessimism (e.g., "It bothers me that my son/daughter will always be this way" or "I worry about what will happen to ____ when I can no longer take care of him/her"), Child characteristics (e.g., "I feel tense when I take ____ out in public"), and Physical Incapacitation (e.g., "___can walk without any help"). It has demonstrated good reliability and validity (Honey et al., 2005).

A third questionnaire used in the parent stress literature is the Parenting Daily Hassles Questionnaire (Crnic & Greenberg, 1990). This questionnaire consists of 20 items, each stating a different event that commonly occurs in families with young children (e.g., "Being nagged, whined at, complained to" and "Difficulty getting kids ready for outings and leaving on time"). Each item is rated on a 4-point scale for how often they occur (rarely, sometimes, a lot, or constantly) and on a 5-point scale for intensity (1 being low and 5 being high) of hassle experienced by parents. In a sample of children with three comparison groups: ASD, intellectual disability or language disorder and no clinical concerns, internal consistency between the items on the Frequency and Intensity was 0.86 (Rutgers et al., 2007).

Plant and Sanders (2007) designed two scales that may be useful for investigating the subjective experience of parenting-related stress in families with children with ASDs. The first determines which caregiving tasks parents perceive as most stressful. The second assesses the degree of stress parents associate with each caregiving task. Parents are asked to rate on a 7-point Likert scale (1—not stressful at all, 7—extremely stressful) how stressful they find completing tasks associated with eight caregiving areas: *(1)* direct tasks (e.g., bathing, feeding); *(2)* in-home therapy (e.g., completion of special activities recommended by therapists); *(3)* attending medical appointments, therapy sessions, and educational programs; *(4)* supervision of their child's activities/whereabouts; *(5)* involvement in leisure/play activities; *(6)* education and

information about their child's disability; *(7)* advocating for services; and *(8)* managing their child's behavior. The parent's responses in each of the eight areas are added together for a total score, with higher scores indicating greater stress associated with caregiving activities. The authors reported good internal consistency ($r = 0.82$; Plant & Sanders, 2007).

Parental Psychological Distress

Psychological distress is a construct relating to an individual's experience of negative feelings or emotions. There is a wide range of symptoms and emotions investigated in studies of psychological distress, ranging from symptoms of depression and anxiety to pessimism. Research suggests parents of children with ASDs experience increased psychological distress. For example, compared to parents of children without developmental delays, parents of children with ASDs reported higher levels of anxiety (Hamlyn-Wright et al., 2007) and depression (Eisenhower et al., 2005; Hamlyn-Wright et al., 2007). A study by Orsmond and colleagues (2007) has suggested that mothers of adolescents with ASDs have a higher probability of reporting elevated depression and anxiety symptoms compared to normative samples. A variety of studies of parents of children with ASDs have reported increased levels of depression, anxiety, and/or pessimism compared to parents of children with other disabilities, such as Down syndrome, cerebral palsy, intellectual disability, and developmental delay without ASD (Abbeduto et al., 2004; Blacher & McIntyre, 2006; Estes et al., 2009; Hamlyn-Wright et al., 2007). However some, studies do not find elevated levels of psychological distress in parents of children with ASDs compared to parents of typically developing children (Allik et al., 2006; Toth et al., 2007) or children with Fragile X, communicative impairment, developmental delay, or schizophrenia (Abbeduto et al., 2004; Bristol et al., 1993; Herring et al., 2006; Eisenhower et al., 2005; Greenberg et al., 2004; Olsson & Hwang, 2001). Despite the lack of mean group differences, approximately one-third of the mothers of children with ASDs report clinical levels of depressive symptoms—a significantly higher proportion compared to the mothers of children with Fragile X (18.2%) or Down Syndrome (10.3%) (Abbeduto et al., 2004).

Within families affected by ASD, mothers are frequently reported to have higher levels of depressive symptoms (Hastings et al., 2005; Moes et al., 1992, Olsson & Hwang, 2001) and anxiety (Hastings, 2003) compared to fathers. Davis and Carter (2008) have suggested that fewer fathers report depressive symptoms within the clinical range, whereas proportions of mothers and fathers reporting high levels of anxiety were similar. However findings are mixed with regard to depressive versus anxiety symptoms (Hastings, 2003; Hastings et al., 2005; Allik et al., 2006).

Elevated scores on measures of psychological distress may be related to decreased parental quality of life and self-efficacy (e.g., Donenberg & Baker, 1993; Hastings & Brown, 2002; Rodrigue, Morgan, & Geffken, 1992). As such, these findings warrant serious attention from clinicians and researchers. However, it is important to bear in mind that high scores on measures of individual distress may not represent psychopathology (*see* Coyne & Downey, 1991). Furthermore, the relationship between parental psychological distress, parenting-related stress, and child characteristics remains to be delineated. Longitudinal studies investigating these interconnected effects across time will be essential for understanding this complex interaction.

One of the most commonly used measures of psychological distress is the Center for Epidemiologic Studies Depression Scale (CES-D; Radloff, 1977). The CES-D includes 20 items asking the respondent to rate on a scale of 0 (rarely or none of the time) to 3 (most or all of the time) the presence and persistence of depressive symptoms in the last week (e.g., "I had crying spells" and "I was happy.") Internal consistency is reported to range from 0.84 for the general population and 0.90 for the patient sample in the original study (Radloff, 1977) and 0.89 to 0.91 for mothers and fathers of children with ASDs, respectively (Davis & Carter, 2008).

Another frequently used measure is the Hospital Anxiety and Depression Scale (HADS; Zigmond & Snaith, 1983). The HADS consists of 7 items that assess depression (e.g., "I feel as if I am slowed down") and 7 that assess anxiety (e.g., "I get sudden feelings of panic."). Respondents are asked to rate their experience in the last week on a scale of 0 to 3, where higher scores indicate the presence of symptoms and scores greater than 11 suggest the probable presence of a mood disorder. In two samples of parents of children with ASDs, good reliability was reported for both the Anxiety (Cronbach's alpha = 0.86–0.87 for fathers and 0.89–0.90 for mothers) and Depression (0.72–0.74 for fathers, 0.82–0.86 for mothers) scales (Hastings & Brown, 2002; Hastings, 2003).

The Brief Symptom Inventory (BSI; Derogatis, & Melisaratos, 1983) is a 53-item parent self-report measure of psychological distress. Derived from the SCL-90-R (Derogatis, 1983, 1994), the BSI assesses presence of symptoms in nine areas: somatization, obsessive-compulsive, interpersonal sensitivity, depression, anxiety, hostility, phobic anxiety, paranoid ideation, and psychoticism. Respondents are asked to rate items such as "Trouble remembering things" and "Feeling inferior to others" on a scale of 0 ("not at all") to 4 ("extremely"). Scores result in three global indices: the Global Severity Index (level of overall psychological distress), Positive Symptom Distress Index (intensity of symptoms), and Positive Symptom Total (number of symptoms reported). In the original normative sample of 1002 psychiatric outpatients, 719 nonpatient subjects, and 313 psychiatric in-patients, the BSI was found to have good test–retest reliability and internal consistency (0.68–0.91 and 0.71–0.85, respectively, for the 9 dimensions; Derogatis & Melisaratos, 1983). This measure has been used in several studies of parents of children with ASDs (Estes et al., 2009; Toth, et al., 2007; Blackledge & Hayes, 2006).

The Beck Anxiety Inventory (Beck & Steer, 1990) is sometimes used to measure parental anxiety levels. This questionnaire was originally designed as an instrument that would

reliably discriminate anxiety from depression and contains 21 items, each representing a different symptom of anxiety (e.g., "Nervous," "Shaky/unsteady," and "Feeling hot"). On a scale from 0 ("not at all") to 3 ("severely bothered"), respondents are asked to rate how much each item has bothered him/her over the past week. Items are summed to produce a total anxiety score. In a sample of parents of toddlers with ASDs, good internal consistency was reported (alpha = 0.86 for mothers and fathers separately; Davis & Carter, 2008).

Parental Psychological Functioning

Parental psychological functioning encompasses facets of individual, psychological well-being or positive emotional functioning in parents. Taken as a whole, investigations suggest that well-being is not simply the opposite of psychological distress, akin to a low score on a Likert scale that ranges from positive to negative emotions. It appears that positive psychological functioning may function relatively independently from psychological distress. For example, parents of children with ASDs may undergo a grieving process related to their child with ASD that entails symptoms of depression and anxiety. However, simultaneously, they may feel personal growth, efficacy, and increased meaning as part of this same process. Greenberg and colleagues (2004) investigated the role of dispositional optimism in mothers of adults with Down syndrome, schizophrenia and autism. They found that maternal optimism was an important mediator of maternal well-being. Smith and colleagues (2008) found that problem-focused coping was associated with increased maternal well-being. Another study found that increased parenting self-efficacy was associated with maternal well-being (Kuhn & Carter, 2006). However, White and Hastings (2004) reported lower social support was associated with anxiety, depression, and parenting-related stress but found no association between social support and a measure of parental well-being. Higgins, Bailey, and Pearce (2005) reported no relationship between coping strategies and measures of self-esteem in parents of children with ASDs.

One measure of well-being that has been used is the Scales of Psychological Well-Being (Ryff, 1989). This measure consists of six subscales (self-acceptance, positive relations with others, autonomy, environmental mastery, purpose in life, and personal growth). Each subscale contains 20 items, divided equally between positive (e.g., "I like most aspects of my personality") and negative items (e.g., "I tend to worry what other people think of me"). Alpha coefficients for the six scales ranged from 0.82 to 0.90 (Schmutte & Ryff, 1997). Several revisions of the measure exist, with subscales ranging from three to six items each. Greenberg and colleagues (2004) used three subscales (personal growth, self-acceptance, and purpose in life) as a measure of positive psychological well-being in a sample of mothers of adults with Down syndrome, ASDs, and schizophrenia and found good internal consistency (0.80–0.88). Smith and colleagues (2008) used a five-item personal growth subscale (e.g., "New experiences are important"

and "Life has been continuous learning and growing") in a sample of mothers of toddlers and adolescents with ASDs and reported reliability coefficients of 0.63 and 0.68, respectively (Smith et al., 2008).

Sense of coherence is often measured using the Sense of Coherence Scale (SOC; Antonovsky, 1987). Among several different versions, the SOC-13 has been used in ASD research (Mak et al., 2007; Olsson & Hwang, 2002). The SOC-13 asks respondents to rate 13 statements on a scale of 1 ("very often") to 7 ("very seldom" or "never"). These statements assess cognition (e.g., "Do you ever have very mixed up feelings and ideas?"), emotions (e.g., "How often do you have feelings that you're not sure you can keep under control?"), and hope/meaning (e.g., "How often do you have the feeling that there's little meaning in the things you do in your daily life?"). Internal consistency of the SOC-13 has been reported between 0.78 to 0.87 in samples of parents of children with developmental disabilities and/or ASDs (Mak et al., 2007; Olsson & Hwang, 2002).

Optimism has been measured using a modified version of the Life Orientation Test (LOT; Scheier & Carver, 1992). Greenberg and colleagues used a modified version of the LOT consisting of eight items (e.g., "If something can go wrong for me, it will." and "In uncertain times, I usually expect the best."), rated on a 4-point scale (strongly disagree to strongly agree). In their sample of mothers of children with ASDs, Cronbach's alpha reliability was reported to be 0.87 (Greenberg et al., 2004).

Parental Coping Strategies

Coping is "the process by which individuals respond to threats of stress" (Smith et al., 2008). The style of coping that parents use has been examined in several studies. Many contrast problem-focused coping, which involves trying to solve the problem causing stress, with emotion-focused coping, which involves trying to alleviate the feelings that are a result of the stress. Orsmond et al. (2007) found higher emotion-focused coping in mothers of children with disabilities to be associated with higher anxiety. Stoneman and Payne (2006) reported fathers of children with disabilities who used more problem-focused coping viewed their marriages more positively. Abbeduto and colleagues (2004) found mothers of children with developmental disabilities who used more emotion-focused and less problem-focused coping had higher levels of pessimism and depression. Smith and colleagues (2008) compared coping strategies in mothers of toddlers with ASDs with mothers of adolescents with ASDs. In both groups, greater emotion-focused coping was associated with greater maternal depression and anger. Increased problem-focused coping was associated with decreased depression and increased personal growth. Taken together, these studies indicate that parents of children with disabilities who use more problem-focused coping and less emotion-focused coping may experiences less psychological distress.

The Coping Orientations to Problems Experienced or Multidimensional Coping Inventory (COPE; Carver, Scheier, & Weintraub, 1989) is a 52-item questionnaire used to assess how individuals respond to stressful events. Each item asks the respondent to rate, on a 4-point scale, the frequency with which a particular coping strategy is used during a stressful event. The COPE includes scales measuring emotion-focused coping strategies (e.g., denial, emotionality, disengagement) and problem-focused coping (e.g., active coping, planning, positive reinterpretation, growth). Studies have shown adequate to good internal consistency on the emotion-focused (0.60–0.78) and problem-focused (0.66–0.89) scales with mothers of children with ASDs (Abbeduto et al., 2004; Orsmond et al., 2007; Smith et al., 2008).

The Family Crisis Orientated Personal Evaluation Scales (McCubbin et al., 1991) contains 30 coping behavior items comprising five subscales: reframing (positively reframing events to make them more manageable); passive appraisal (minimization of response to problematic issues); acquiring social support; seeking spiritual support; and mobilizing the family to acquire and accept help from community resources. In a sample of parents of children with ASDs, internal consistency for each of the subscales was reported as follows: reframing (0.82), passive appraisal (0.48), acquiring social support (0.81), seeking spiritual support (0.88), and mobilizing the family (0.59; Honey et al., 2005).

Threats and Supports to Family Adaptive Functioning

Next we turn to several potential threats and supports that may moderate or mediate family adaptive functioning. These include family characteristics, stressful life events, spousal relations, social support, and child characteristics.

Family Characteristics

Particular family characteristics, such as family income and number of children with a disability, may moderate family adaptive functioning in ASD. For example, lower household income predicted higher reported levels of maternal depressive symptoms (Orsmond et al., 2007), whereas higher household income predicted lower parenting-related stress (Mak et al., 2007). Mothers who had one child with ASD and another child with a disability (ASD, ADHD, LD, or other psychiatric condition) reported higher levels of depressive and anxiety symptoms compared to mothers with just one child on the autism spectrum (Orsmond et al., 2007). Parents report less family adaptability and cohesion than U.S. norms (Higgins et al., 2005) and less adaptability than mothers of children with Down syndrome (Rodrigue et al., 1990). Mothers of two children with disabilities reported lower levels of cohesion and adaptability in the family compared to mothers with just one child with ASD (Orsmond et al., 2007). Compared to mothers

of children with Down syndrome, mothers of children with ASDs have also reported poorer quality mother–child relationships (Abbeduto et al., 2004). In a study by Greenberg and colleagues (2004), better quality relationships with their child were associated with lower levels of maternal depressive symptoms.

The Family Adaptability and Cohesive Evaluation Scales (FACES-II; Olson et al., 1982) is a 30-item parent-report questionnaire designed to measure the degree of emotional bonding between family members (Cohesion Subscale) and how flexible and able the family system is to change roles and relationships in response to stressors (Adaptability Subscale). The questions assess both positive and negative aspects of family life—for example, "It is easier to discuss problems with people outside the family than with other family members," and "Family members discuss problems and feel good about the solutions." Parents are asked to rate each statement on a 5-point scale ranging from 1 ("almost never") to 5 ("almost always"). In a sample of mothers of adolescent and adult children with ASDs, reliability alphas were 0.72 for both subscales (Orsmond et al., 2007).

The Positive Affect Index (PAI; Bengtson & Schrader, 1982) is a measure of affective closeness used to investigate parents' perceptions of their relationship with their child. This scale consists of 10 items on a scale of 1 ("not at all") to 6 ("extremely"). Parents are asked to rate five facets of positive affect: trust, intimacy, understanding, fairness, and mutual respect. Half of the items ask the parent to rate their feelings toward their child in these five areas, whereas the other five items ask the parent to rate the extent to which these five facets are displayed by the child toward the parent. In two samples of mothers with adult children with ASDs, reliability alphas were reported between 0.85 and 0.87 (Greenberg et al., 2004; Lounds et al., 2007).

Stressful Life Events

The occurrence of major life events may impact family adaptive functioning by increasing stress levels in parents of children with ASDs, which in turn may disrupt parenting practices and parent–child interaction. Stressful life events include events that all families may experience, such as the death of a family member, but some such events may be directly related to having a child with autism, such as relocating to access better services. Few studies have systematically explored the influence that life events may have on parents of children with ASDs. Toth and colleagues (2007) reported family changes and stressful events during pregnancy with a younger sibling to the child with autism did not differ significantly between parents of children with autism compared to parents without a child with an ASD. Whether or not life events occur at a higher level in families with a child with ASD, they may be an important consideration when evaluating family adaptive functioning. Furthermore, the impact of stressful life events on parents of children with ASDs may be moderated by social support and coping style (Dunn et al., 2001). The importance of measuring

stressful life events in other populations (e.g., Crnic, Greenberg, & Slough, 1986) suggests this is an area that warrants further investigation in families affected by ASDs.

One measure used to assess life events is the Life Experiences Survey (LES; Sarason, Johnson, & Siegel, 1978). The LES is a self-report questionnaire that asks individuals to evaluate the impact of 60 life events on a 7-point scale, ranging from –3 (extremely negative) to +3 (extremely positive). Test–retest reliability correlations were reported to range from 0.19 to 0.53 for the positive change score, 0.56 to 0.88 for the negative change score, and 0.63 to 0.64 for the total score (Sarason et al., 1978). The PSI also contains an optional 19-item Life Stress Scale that asks about the occurrence of potential stressors outside of the parent–child relationship and provides a context for interpreting the PSI scores.

Spousal Relations

There is a well-documented relationship between marital conflict and poorer child outcomes for typically developing children. For example, children exposed to marital conflict may be particularly vulnerable to behavioral and emotional disturbances, social and interpersonal problems, and poorer academic performance (e.g., Grych & Finham, 1990; Jenkins & Smith, 1991; Cummings, Davies, & Simpson, 1994). A small number of studies suggest parents with a child with ASD report lower levels of marital happiness and marital intimacy compared to parents of typically developing children or children with Down syndrome (Fisman et al., 1989; Higgins et al., 2005; Rodrigue et al., 1990). Past research suggested that parents of children with ASDs may be at a higher risk for marital discord (DeMyer, 1979; Donovan, 1988; Rodrigue et al., 1990). In light of studies demonstrating the adverse effects that marital distress can have on children, future research is needed to systematically investigate how the marital relationship is impacted by having a child with ASD.

The Locke-Wallace Marital Adjustment Test (Locke & Wallace, 1959) is a self-report questionnaire of marital adjustment consisting of 15 items, each weighted differently to yield a total possible score of 2 to 158. Total scores have been shown to discriminate between couples referred for intervention (<100) and those who were not at risk for marital difficulties (>100). Of the well-adjusted group tested in the original validation study, 96% achieved scores of 100 or more. Split-half reliability was 0.90.

The Dyadic Adjustment Scale (Spanier, 1976) is a 32-item, self-report measure assessing the quality of the current marriage or relationship with the partner. This scale has been found to have good criterion validity. Marital status (divorced vs. married) significantly correlated with each item ($p < 0.001$) and total scores for married versus divorced significantly differed in a sample of 218 married and 94 divorced individuals. High correlations between the Dyadic Adjustment Scale and the Locke-Wallace Marital Adjustment Test (0.86 for married respondents and 0.88 for divorced; $p \leq 0.001$) also indicated good construct validity. Cronbach's alphas ranged between

0.73 and 0.94 for each subscale and 0.96 for the total scale (Spanier, 1976).

Social Support

Social support may function as a protective factor for parents of children with ASDs. Honey et al. (2005) found that mothers' stress was lower when they rated the helpfulness of informal social support and accessibility of social support as higher. Another study found higher psychological distress in mothers of children with ASDs was associated with lower levels of family social support (Bromley et al., 2004). Parents of children with ASDs rate accessing social support as one of their top coping mechanisms (Luther, Canham, & Cureton, 2005) and report relying on multiple sources of support (Mackintosh, Myers, & Goin-Kochel, 2006). However, mothers of children with ASDs reported emotional support was less available compared with mothers of children intellectual disability and mothers of typically developing children (Weiss, 2002; Rutgers et al., 2007). Data obtained on a web survey from parents indicates that they rely on other parents of children with ASDs more frequently than any other source of support (Mackintosh et al., 2006). Parents reporting higher levels of social support also report lower levels of depression, anxiety, and anger (Benson, 2006; Benson & Karlof, 2008; Gray & Holden, 1994), and mothers with higher self-esteem and higher levels of social support report less depression (Weiss, 2002). Parents who do not seek and receive social support report more relationship problems with their spouse (Dunn et al., 2001). Siklos and Kerns (2006) found that parents of children with ASDs did not differ from parents of children with Down syndrome in the number of family needs. However, parents of children with autism were more likely to report needs relating to professional assistance and ASD intervention, indicating professionals can be an important source of support for parents of children with ASDs.

The Social Support Questionnaire (Sarason et al., 1983) consists of 27 items. For each item, the respondent lists people they can rely on for different aspects of social support (counted to yield N score for item) and rates their satisfaction with these supports on a 6-point scale (S score). Reliability coefficients for N and S scores were 0.97 and 0.94, respectively. This measure has also been used in samples of parents of children with autism (Rodrigue et al., 1990; Rodrigue et al., 1992).

The Family Support Scale (Dunst, Trivette, & Jenkins, 1984) is an 18-item questionnaire asking the parent to rate on a 5-point Likert scale the helpfulness of informal and formal sources of support for raising a young child. This measure can be used to identify the areas in a family's support network that need to be strengthened or accessed to better meet their needs. Based on revised scoring procedures by McConachie and Warings (1997), two scores may be derived from this measure: *(1)* a weighted score for the helpfulness of informal sources (spouse, family, friends, other informal supports) of support available to the family and *(2)* a weighted score for the

helpfulness of support from professionals and services available to the family. Dunst et al. (1984) have described good reliability in families of children with disabilities (internal consistency = 0.77, and test–retest reliability = 0.91).

Child Characteristics

Parents face unique challenges related to characteristics of children with ASDs as well as challenges that are common to all parents of children with developmental disabilities. Unlike some other types of developmental disability, ASDs impair social relatedness, which may be particularly emotionally painful for parents. Many children with ASDs also exhibit unusual language and communication patterns, such as stereotyped speech or language delays, and odd and ritualistic behaviors. Researchers have investigated the parents' perceptions of both the negative and positive impact of having a child with ASD on the overall family functioning (Lloyd & Hastings, 2008; Herring et al., 2006; Eisenhower et al., 2005; Hastings et al., 2005; Rodrigue et al., 1990). Problem behaviors, such as irritability, hyperactivity, and self-injury, have consistently emerged as an important child-related source of parental distress for parents of children with ASDs (e.g., Baker et al., 2002; Beck et al., 2004; Hastings, 2002; Hauser-Cram et al., 2001; Hodapp et al., 2003; Konstantareas & Homatidis, 1989). Estes and colleagues (2009) investigated the relationship between behavior problems, adaptive functioning, and maternal distress in preschool-aged children with ASDs and DD without ASDs. Despite the two groups being matched on developmental age, children in the ASD group demonstrated higher levels of problem behavior and lower daily living skills compared with the children in the DD group. Increased levels of child problem behaviors were associated with increased parenting stress and increased psychological distress. However, neither child diagnosis nor daily living skills were significantly associated with parenting stress. Interestingly, parenting stress and child problem behaviors were more strongly correlated in the DD group than in the ASD group, suggesting additional factors may be at play for parents of children with ASDs.

Smith et al. (2008) found that the presence of restricted and repetitive behaviors in adolescents with ASDs, was associated with maternal reports of lower personal growth and less problem-focused coping. Intellectual disability is a child characteristic that does not consistently appear to be associated with parenting stress and psychological function (Baker et al., 2002; Baker et al., 2003; Johnston et al., 2003). Although a common assumption is that increased intellectual disability is associated with increased parent stress, some research indicates that having a cognitively lower functioning child with developmental disabilities is actually associated with lower parental distress (Gallagher & Bristol, 1989). A related hypothesis is that lower independence (referred to as adaptive functioning) is source of distress for parents. However, results are mixed in terms of the relationship between adaptive function and parental distress, with two

studies finding better adaptive skills in children associated with maternal well-being (Fitzgerald, Birkbeck, & Matthews, 2002; Tomanik, Harris, & Hawkins, 2004) and three reporting no association with adaptive skills (Beck et al., 2004; Lecavalier, Leone, & Wiltz, 2006; Estes et al., 2009).

It is beyond the scope of this chapter to review measures of child characteristics. One measure used to assess the child's impact on family functioning is the Family Impact Questionnaire (FIQ; Donenberg & Baker, 1993). This scale measures a parent's perception of the "child's impact on the family compared with the impact other children his/her age have on their families." It comprises 50 items (e.g., "My child's behavior bothers me more," "I enjoy the time I spend with my child more") rated on a scale from 0 ("not at all") to 3 ("very much"). Subscales assess the parent's perception of the child's negative impact (social life, finances, siblings, marriage, and parenting) and positive impact (feelings about parenting) on the family. In a sample of typically developing children and children with various disabilities (including ASD), reliability alphas were reported to be 0.92 for the combined negative impact scales and 0.81 for the positive impact scale (Eisenhower et al., 2005).

The Kansas Inventory of Parental Perceptions Positive Contributions Scale (KIPP-PC; Behr, Murphy, & Summers, 1992) has also been used to assess the parent's belief that the child with disability has a positive impact on the parent (e.g., the child is responsible for the parent learning patience) and positive impact on the family (e.g., the child is responsible for bringing the family closer together). It also has a scale that measures parent belief that their child has positive characteristics (e.g., the child is kind and loving), which may be a measure of child characteristics rather than parent perception on the child's impact on the family. This measure has 50 items, rated on a 4-point scale. In a sample of parents of children with ASDs, the KIPP-PC was shown to have a high level of internal consistency (Cronbach's alpha = 0.95) for both mothers and fathers (Hastings et al., 2005).

Intervention for Autism Spectrum Disorders and Family Adaptive Functioning

Early Intensive Behavioral Intervention

Research has shown that early intensive behavioral intervention (EIBI) leads to improved outcomes for many children with ASDs. A less well-understood, but equally positive set of findings suggests that parents may also benefit from their child's participation in EIBI. It is likely that a complex, transactional relationship exists between parent stress, EIBI, and developmental progress in children with ASDs. Although the mechanisms of change are not well-understood, research does suggest that EIBI can serve to reduce stress in parents. In a study of 65 families with preschool children with ASDs,

more intervention hours were associated with a greater improvement in parent stress (Osborne et al., 2007). The children in the study received a variety of interventions, including preschool, speech, EIBI, and parent training for 2 to 40 hours per week. Although improvements in parent stress were reportedly a result of the number of intervention hours received, children with the highest number of intervention hours tended to be receiving EIBI. Thus, additional research is needed to disentangle these results. Schwictenberg and Poehlmann (2007) also found lower depression scores in mothers when their children were receiving more EIBI hours; however, mothers who provided more EIBI hours themselves reported higher levels of personal strain. Salt et al. (2002) compared families of children with ASDs receiving a social-developmental early intervention program with a waitlist control group and found that at follow-up 10 months later, parents of children in the intervention group had lower stress than the control group. However, this difference was not statistically significant, and the number of intervention hours differed between the two groups, making it difficult to reach a conclusion about the effects of the program on parent stress.

> EIBI is defined as intervention for children with ASDs that incorporates the behavioral learning principles of ABA, begins prior to age 5 years, and involves 20 to 40 hours per week of intervention.

In one study, parent stress was examined in families with young children (mean age = 28.35 months) with autism and typical development (Baker-Ericzen, Brookman-Frazee, & Stahmer, 2005). In this study, parents participated in an early intervention inclusion program utilizing Pivotal Response Training. Pivotal Response Training is an intervention approach developed and described elsewhere by Koegel and colleagues (e.g., Koegel, Koegel, & Schreibman, 1991; Koegel et al., 1989). Children with autism were enrolled in either a morning or afternoon session for at least 6 months, and each class had four children with autism and eight who were typically developing. Mothers of children with ASDs showed reductions in stress on the Child Domain but not on the Parent Domain on the Parenting Stress Index. Father stress did not change, however. Maternal stress on the Child Domain was predicted by child cognitive functioning and symptoms of autism. There was also a correlation between a child's level of social skills and maternal stress (Parent Domain). This study suggests changes in parent stress may be related specifically to changes in the child's behavior.

Hastings and Johnson (2001) conducted a survey of 141 parents participating in intensive in-home intervention based on Lovaas-style EIBI. The average age of the child was 4.98 years, with an average of 13.47 months of participation in the program. Parent stress was lower in parents who believed in the efficacy of the intervention. In addition, beliefs about treatment efficacy moderated the effects of ASD symptom severity on parents' pessimism. This study highlights the importance of parental beliefs about the effectiveness of their children's intervention services.

Parent stress may also have an impact on the effectiveness of EIBI. Osborne et al. (2007) reported that when children received high levels of intervention, they showed less improvement in educational and adaptive functioning when their parents had high levels of stress. Improvements in IQ were not related to parent stress. Also, a high level of parent stress was not associated with educational outcomes in children who received fewer hours of intervention. The mechanisms behind these reported patterns are not clear. Parenting style, level of treatment involvement, and factors associated with child behavior problems were not investigated but could underlie these findings. It is also important to note that the children with highly stressed parents also demonstrated improvement but not to the same degree as children with less stressed parents.

Parent Training

Several studies have focused on the impact of behavioral parent training programs on reducing parent stress. In one study, 28 mothers of preschool children with ASDs participated in a psycho-educational parent training program or a no-treatment control (Bristol, Gallagher, & Holt, 1993). The treatment consisted of parents and therapists working together to develop an early intervention program using behavior modification and educational techniques for the parents to deliver in the home. Mothers in the treatment group showed decreases in depressive symptoms over time. This was not a randomized trial, as mothers could choose whether or not to participate in the psycho-educational program and the results may be amplified by an uneven distribution of maternal characteristics between the groups. For example, mothers in the treatment group may have been more problem-focused or more efficacious in their problem solving than mothers in the control group.

There has been one randomized trial comparing parent education and behavior management intervention to a parent education and counseling control for parents of children with ASDs (Tonge et al., 2006). Children were 2.5 to 5 years old at the start of the study. All of the children had been diagnosed with ASDs within the previous month. The parent education/behavior management intervention included such topics as general education about ASDs, available services, behavior modification techniques, teaching skills, and stress management for parents. It included rehearsals, modeling, and homework tasks. The control group also received some educational information and discussion; however, the control intervention did not include skills training or homework assignments for the parents. Parents in both groups improved in overall mental health post-intervention and at a 6-month follow-up. The treatment group showed a greater reduction in anxiety, insomnia, somatic symptoms, and family dysfunction at follow-up, suggesting that learning and practicing specific

behavior management strategies may be important for reducing parent stress.

The way in which parent training treatment is delivered may be also be an important consideration. In a study using a repeated reversal design with three families with 2-year-old children with ASDs, clinician-directed parent training was compared to parent–clinician partnership parent training (Brookman-Frazee, 2004). Both groups were taught using Pivotal Response Training. In the partnership condition, the clinician asked for parental input and provided choices about target behaviors and how to teach skills. The clinician followed the parent's lead when the parent chose target behaviors or intervention opportunities. In the clinician-directed condition, the clinician chose activities and target behaviors without asking for parent input. Mothers showed decreased stress and increased confidence during parent/clinician partnership periods but not during clinician-directed periods.

Interventions Directly Targeting Parent Stress

Interventions designed to directly target parent stress have been developed and investigated. A review article on interventions for stress in parents of children with intellectual and developmental disabilities suggests that although interventions such as respite care, case management, and parent-led support networks likely reduce stress in parents, cognitive behavioral group interventions have best evidence for reducing stress in mothers (Hastings & Beck, 2004). For example, a support group designed to teach stress management was delivered to mothers of school-aged children with ASDs (Bitsika & Sharpley, 2000). Positive—although not statistically significant—changes were found on measures of anxiety, depression, and stress. A 2-day (14-hour) Acceptance and Commitment Therapy (ACT) workshop was evaluated with a group of 20 parents of children with ASDs and a wait-list control group (Blackledge & Hayes, 2006). ACT "emphasizes acceptance of unpleasant emotions, defusion from difficult thoughts, clarification of the client's personally held values and corresponding goals, and enhancement of the client's effectiveness in moving towards those values and goals" (p. 3). The approach is based on cognitive-behavioral therapy but focuses on mindfulness and acceptance as much as change. Parents in the treatment group showed small but statistically significant improvements in parent stress and depression as measured on the BSI, BDI, and General Health Questionnaire. It remains unclear whether interventions that directly target parent stress will be found to be as effective as interventions targeting child problem behavior, child development, or parenting techniques in families with a child with ASD.

Conclusions

A variety of factors contribute directly and indirectly to family adaptive functioning, but parents are typically the single-most important contributor. Parents of children with ASDs are consistently found to have elevated levels of parenting-related stress and psychological distress, even when compared with parents of children with non-ASD developmental disabilities. It is also the case that positive psychological functioning and effective coping strategies are also often reported in parents of children with ASDs. Potential threats and supports to family adaptive functioning, including socio-economic status, spousal relations, availability of social support, and specific child characteristics, should be considered when designing empirical studies and interventions for children with ASDs. Research on the relationship between family factors (e.g., parenting-related stress) and child-focused interventions (e.g., EIBI, parent training) is still in the early stages. However, it is evident that a child's treatment can have positive impact on parents. Findings suggest that gains in child social functioning and reduction of child problem behavior may reduce parent stress, which, in turn, may improve family adaptive functioning. Factors associated with intervention, such as the number of hours provided, parental beliefs about the efficacy of the intervention, and a collaborative approach to intervention, may also serve to support family adaptive functioning. Further investigation of positive contributors to family adaptive functioning holds promise for increasing the already impressive momentum toward greater understanding and improved outcomes for children with ASDs.

Challenges and Future Directions

- Increased attention to measuring clear, well-defined constructs related to family adaptive functioning is needed. Developing ASD-specific theoretical models of family adaptive functioning and outcomes for children with ASDs and measuring specific components of these models will support innovations in intervention for children with ASDs.
- Research is needed to clarify characteristics of intervention programs that contribute to improved family adaptive functioning. This is particularly challenging because of the transactional nature of the relationship between child behavior, child response to intervention, and family adaptive functioning. However, this line of research is promising and has already suggested intervention targets (such as child problem behavior) and intervention approaches (such as parent–clinician partnership) that may improve family adaptive functioning.
- More work is needed to understand the ways in which family adaptive functioning may positively influence outcomes for children with ASDs and their family members. It will be important to investigate whether these family factors can be targeted directly and whether this will contribute to positive longer-term outcomes for children with ASDs and their families.

Psychopharmacological Treatment of Autism

Points of Interest

- Psychostimulants, such as methylphenidate, are less efficacious and cause more adverse events in children with pervasive developmental disorders (PDDs) than in typically developing children with attention deficit hyperactivity disorder.
- The most efficacious class of drugs for the treatment of aggression and irritability in autism and other PDDs is the antipsychotics.
- Based on results from double-blind, placebo-controlled trials, selective serotonin reuptake inhibitors (SSRIs) appear to be more efficacious for improving interfering repetitive behavior and better tolerated in adults compared with children with autism.
- To date, double-blind, placebo-controlled studies have not identified a drug with consistent beneficial effects on the social or communication impairments of autism.

As awareness of autistic disorder (autism) and other pervasive developmental disorders (PDDs) increases, so does research regarding these conditions. The interfering symptoms of these disorders have been recognized for years. More recently, research regarding the treatment of target symptoms associated with PDDs has accelerated. These symptoms include hyperactivity and inattention, irritability and aggression, interfering repetitive behaviors, and social impairment, among others. This chapter focuses on the pharmacologic treatment of these symptom clusters that are commonly disabling in this population. At this time, risperidone and aripiprazole are the only U.S. Food and Drug Administration (FDA) approved pharmacologic agents to treat symptoms associated with autism. There are no other medications that have received FDA approval to treat any of the disabling symptoms of autism or other PDDs. However, in clinical practice, many different drugs are being prescribed to minimize some of the interfering

symptoms of PDDs. A priority is placed on discussing randomized, placebo-controlled trials when available, as well as side effects associated with these medications in this diagnostic group. Symptom areas for which controlled trials of medications have not been published, such as mood, anxiety, and sleep difficulties, will not be discussed in this chapter. Also, medications that have been found to be relatively ineffective (e.g., naltrexone and secretin) will not be reviewed in detail.

The "gold standard" design of a drug treatment study includes blinded conditions and placebo control. Random assignment to drug or placebo is critical and a parallel groups approach, rather than crossover approach, can minimize carryover effects. The duration of the trial will be influenced by the time to reach steady state with the particular drug. The choice of the minimum and maximum amount of drug to be administered is also important. The goal is to strike a balance between minimizing potential adverse effects and not missing potential symptom improvement resulting from too low a dose. A particular type or group of symptoms needs to be targeted and a threshold for symptom severity needs to be set. This will allow for the inclusion of a more homogeneous subject sample; age range and diagnostic subtype are also important in this regard. An open-label extension treatment phase is often needed. This allows for a determination of maintenance of response of the drug, as well as an assessment for longer-term adverse events. A blinded discontinuation phase can provide information related to necessary duration of treatment with the drug.

The current optimal approach to measuring symptom change in autism and other PDDs in drug treatment trials includes a variety of parent- and clinician-rated scales. The Aberrant Behavior Checklist (ABC) Irritability and Hyperactivity subscales are parent-rated scales that have been shown to be sensitive to drug treatment effects on symptoms of aggression/self-injury/tantrums and hyperactivity/noncompliance, respectively. The Children's Yale-Brown Obsessive Compulsive Scale for Pervasive Developmental Disorders

(CY-BOCS-PDD) is a clinician-administered scale used to measure change in interfering repetitive behavior. The ADHD Rating Scale is also a clinician-administered scale included because it better reflects inattentiveness and disorganization, which is particularly important in persons with higher-functioning PDDs. Although there are no ideal measures to monitor change in social impairment in autism, the Social Responsiveness Scale is promising, especially given that it only takes parents 20 minutes to complete. The Clinician Global Impression global improvement item score (CGI-I) is based on careful examination of all areas of possible improvement.

Hyperactivity and Inattention

Hyperactivity and inattention are symptoms many individuals with PDDs exhibit. Studies have estimated that as many as 40% to 59% of children diagnosed with PDDs also meet criteria for attention deficit hyperactivity disorder (ADHD) (Gadow, DeVincent, & Pomeroy, 2006; Goldstein & Schwebach, 2004). Interestingly, even with such a high prevalence of diagnosable ADHD within this population, the DSM-IV-TR includes PDD as one of its exclusionary criteria when making an ADHD diagnosis (American Psychiatric Association [APA], 2000).

> Controversy exists as to whether or not ADHD should be an allowable comorbid diagnosis with the PDDs.

Table 69-1 includes published placebo-controlled studies of drugs for motor hyperactivity and inattention in PDDs.

Psychostimulants

For typical children with ADHD, methylphenidate (MPH) and other stimulants are the psychopharmacologic treatments of choice (Greenhill et al., 2002). Response rates to MPH of 70% to 80% have been demonstrated in this population (Greenhill et al., 2001). The data regarding the use of stimulant medication to treat children with PDDs and ADHD symptoms is not as conclusive. Reviews of early studies indicate that children with mental retardation and autism do not respond well to stimulants. There is also a possible increase in stereotypy in this population with stimulant use (Aman, 1982). However, the more recent literature on this topic has come to different conclusions. Quintana et al. (1995) performed a study with 10 DSM-III diagnosed autistic children from the age of 7 to 11 years. The children were given two different MPH doses (10 or 20 mg bid twice a day) in a double-blind crossover study with placebo. Hyperactivity declined a modest but statistically significant degree with MPH. Side effects included irritability, headache, stomachache, lack of appetite, weight loss, and insomnia. Another study was performed with 13 autistic children with ADHD symptoms ages 5.6 to 11.2 years (Handen, Johnson, & Lubetsky, 2000). This was a double-blind, placebo-controlled trial of MPH dosed at 0.3 to 0.6 mg/kg body weight per day. Sixty-two percent of the treated children had a 50% or greater decrease on the Teacher Conners Hyperactivity Index. Improvements in stereotypies and inappropriate speech were also reported. Side effects included depression, irritability, decreased appetite, and drowsiness.

Stigler et al. (2004) performed a retrospective chart review within their clinic on all patients with PDDs treated with a

Table 69–1.

Published placebo-controlled studies of drugs for motor hyperactivity and inattention

Study	Drug	Subjects	Design	Results
Quintana et al., 1995	Methylphenidate	n = 10 Age = 7–11	2 weeks Crossover	Methylphenidate > PLA
Handen et al., 2000	Methylphenidate	n = 13 Age = 5–11	1 week Crossover	Methylphenidate > PLA 8/13 (62%) responders
RUPP Autism Network, 2005a	Methylphenidate	n = 72 Age = 5–14	1 week Crossover	Methylphenidate > PLA
Arnold et al., 2006	Atomoxetine	n = 16 Age = 5–15	6 weeks Crossover	Atomoxetine > PLA
Jaselskis et al., 1992	Clonidine	n = 8 Age = 5–13	6 weeks Crossover	Clonidine > PLA by teacher and parent, but not clinician 6/8 (75%) responders 2/8 (25%) responders at 1-year follow-up
Fankhauser et al., 1992	Clonidine (transdermal)	n = 9 Age = 5–33	4 weeks Crossover	Clonidine > PLA 6/9 (67%) responders

Note: All ages are in years. PLA = placebo. Each study included subjects with autism. RUPP Autism Network, 2005a and Arnold et al., 2006 included subjects with autism and other pervasive developmental disorders.

stimulant. Charts of 195 patients ages 2 to 19 years were reviewed. Sixty-one of the patients had more than one stimulant trial resulting in the analysis of 274 independent stimulant trials. The results indicated that 24.6%, 23.2%, and 11.1% of individuals with a history of one, two, or three stimulant trials, respectively, responded to their first stimulant trial. Patients with autism and PDD not otherwise specified (PDD-NOS) were less likely to respond to stimulants than those with Asperger's Syndrome. However, there was not a link between response and IQ of the patient. Side effects included irritability, dysphoria, weight loss, and agitation. Agitation was seen less often in those with Asperger's Syndrome. The investigators concluded that stimulants were ineffective and not tolerated well in most individuals with PDDs. However, the subtype of PDD may affect the response to stimulants.

The largest randomized, placebo-controlled trial with MPH in children with PDDs to date was funded by the National Institute of Mental Health (NIMH) and performed by the Research Units on Pediatric Psychopharmacology Autism Network (RUPP) (RUPP Autism Network, 2005a). The study included 5 sites throughout the United States. Seventy-two children (ages 5–14 years) with a DSM-IV diagnosis of autism, Asperger's Syndrome, or PDD-NOS and moderate-to-severe hyperactivity entered the study. Before the study began, the children were given test doses of the medication. One day of placebo and 2 days each of ascending low, medium, and high MPH doses were given. Sixty-six children remained in the study following the test dose phase and were able to be randomized to the crossover phase. The children were given placebo and the three doses of MPH, each for 1 week, in a randomized order. The patients that demonstrated a positive response to MPH entered a second phase of the trial. They were given 8 weeks of MPH (open-label) at the determined best dose. Forty-nine percent of the 72 initially enrolled subjects were deemed to be responders. Side effects resulted in 18% (13 of 72) of the subjects discontinuing MPH. Side effects seen more frequently with MPH than with placebo included irritability, decreased appetite, insomnia, and emotional lability. MPH led to lower response rates in autism than in children with Asperger's Syndrome or PDD-NOS. In this study, IQ, age, and weight were not found to be predictive of response. An analysis of the secondary measures of this study led to the conclusion that the medium and high doses were most efficacious, MPH decreased hyperactivity slightly more than inattention symptoms, and worsening of repetitive behavior was not common (Posey et al., 2007a).

The Multimodal Treatment Study of typical Children with ADHD (the MTA study) found that 69% (or 198) of the 289 participants who received MPH were classified as responders. The rate of side effects causing study discontinuation was 1.4% (or 4 of 289 participants) (Greenhill et al., 2001).

The data from the RUPP Autism Network study above combined with those from the MTA study lead to the conclusion that compared with typical developing children, children with PDD are less likely to respond and more likely to have side effects associated with MPH (RUPP Autism Network, 2005a).

Atomoxetine

Atomoxetine is a reuptake inhibitor that is selective for norepinephrine. It is also believed to exert an effect on dopamine in the frontal lobes (Stein, 2004). Atomoxetine is approved by the FDA for the treatment of ADHD. It has been found to be efficacious in treating ADHD symptoms in typically developing children, adolescents, and adults (Pliszka, 2007). There have been several studies performed to determine whether these findings can be extrapolated to individuals with PDDs. Posey et al. (2006) performed an open-label study of 16 children with PDD and ADHD symptoms. The children were given atomoxetine at an average dose of 1.2 mg per kg per day. Twelve of the 16 children (75%) were deemed to be responders. In addition to ADHD symptoms, there was also a more modest improvement in irritability, repetitive speech, social withdrawal, and stereotypy. Two of the 13 children (15%) discontinued the study early because of irritability.

A retrospective study at an outpatient registry identified 20 children with PDD who were placed on atomoxetine for 12 months (Jou, Handen, & Hardan, 2005). Most of these children were also taking at least one other medication. Twelve of the 20 (60%) children were deemed to respond to atomoxetine in the areas of hyperactivity, conduct, learning, and inattention. One patient stopped the medication because of mood swings.

Arnold et al. (2006) performed a double-blind, placebo-controlled, crossover study of atomoxetine in children with PDDs and symptoms of ADHD. Sixteen children were randomized to receive atomoxetine or placebo for 6 weeks. There was a 3-week titration phase, an additional 3 weeks of medication at the titrated dose, a 1-week wash-out period, and then a second treatment phase of atomoxetine or placebo (whichever the patient did not receive in the first phase). Fifty-seven percent of patients were judged to be responders. Three of the 16 stopped the study early—1 because of intolerable side effects and 2 because of efficacy while on placebo. Side effects in this study included appetite suppression and irritability. The authors concluded that similarly to MPH, atomoxetine has a smaller response rate in children with PDDs than in typically developing children. A 10-week, open-label study by Troost et al. (2006) with atomoxetine in 12 children with PDD found a higher rate of intolerable side effects. Five of the 12 children (42%) discontinued because of adverse effects. Sleep problems, fatigue, gastrointestinal symptoms, and irritability were the most common side effects in this study.

Alpha$_2$ Adrenergic Agonists

Clonidine and guanfacine are both central alpha$_2$ agonists that are often prescribed off-label to treat patients with ADHD (Pliszka, 2007). They are thought to work by agonism at the alpha$_2$ adrenergic receptors in the prefrontal cortex of the

brain. One of the potential causes of ADHD is dysfunction in this region of the brain (Posey & McDougle, 2007). Studies have been performed to attempt to extrapolate these data to individuals with PDD.

> Clonidine and guanfacine are also used to treat high blood pressure.

Clonidine

Two double-blind, placebo-controlled crossover studies have been performed with clonidine in children with PDD. The first involved eight male children with a diagnosis of autism and ADHD symptoms (Jaselskis et al., 1992). These were all children who had not been able to tolerate treatment with neuroleptics, MPH or desipramine. Improvement was found with some of the rating scales used, including the teacher ratings on the ABC and the Parent Conner's scale. Six of the eight children continued treatment after completion of the study. The authors concluded that clonidine was modestly effective for short-term treatment of hyperactivity and mood swings in some autistic children.

A second double-blind, placebo-controlled crossover study was performed with nine autistic males (ages 5–33 years) using transdermal clonidine (Fankhauser et al., 1992). Each individual was either given placebo or a weekly clonidine patch of 0.005 mg per kg per day for 4 weeks. This was followed by a 2-week wash-out period between the two treatment phases. During treatment with clonidine, there was a significant improvement on three (sensory responses, affectual reactions, and social relationships to people) of the five subscales of the Ritvo-Freeman Real Life Rating Scale and on the CGI scale. Sedation and fatigue were seen during the first 2 weeks of treatment.

Guanfacine

There are two published trials with guanfacine in children with PDDs. The first is a retrospective review of 80 children (ages 3–18 years) diagnosed with PDD and treated with guanfacine (Posey et al., 2004). Most children were dosed two to three times daily and were taking one or more other psychotropic medications. The mean dose was 2.6 mg per day. Nineteen of the 80 individuals (24%) were judged to be responders. Three of 6 children had a decrease in tics, 14 of 51 (27%) had an improvement in insomnia, hyperactivity improved in 20 of 75 (27%), and inattention improved in 16 of 76 (21%). Those who responded to treatment were less likely to have been treated with stimulants in the past, less likely to have been tried on multiple other psychotropics, and less aggressive at baseline. Side effects included transient sedation, irritability, constipation, headache, and nocturnal enuresis. No significant change in blood pressure or heart rate was noted. Individuals with PDD-NOS (39.3%) and Asperger's Syndrome (33.3%) were more likely to respond than those with autism (13%).

The second published study was an 8-week, open-label prospective study of guanfacine in 25 children (ages 5–14 years) with PDD and ADHD symptoms who had not responded to or were unable to tolerate MPH (Scahill et al., 2006). Children weighing less than 25 kg started at 0.25 mg at bedtime and were increased to twice the starting dose on day four. Doses were then increased by 0.25 mg every fourth day as tolerated. The maximum dose for this group was 3.5 mg divided three times a day. Children weighing more than 25 kg were given 0.5 mg at bedtime and were increased in 0.5-mg increments. Their maximum dose was 5.0 mg divided in three daily doses. Twelve of the 25 children (48%) were deemed to be responders. In doses ranging from 1 to 3 mg per day there were no serious adverse events and the drug was well-tolerated. Common side effects included sedation, irritability, sleep disturbance, decreased appetite, aggression, agitation, and perceptual disturbance. Three subjects stopped the study early because of irritability.

Irritability and Aggression

Irritability is a common symptom seen in individuals with PDDs (Stigler & McDougle, 2008). Studies have shown that approximately 30% of children and adolescents with PDDs suffer from moderate-to-severe irritability (Lecavalier, 2006). Frequently, the irritability can manifest as aggressive acts toward self or others. When directed toward self (i.e., self-injurious behavior [SIB], such as head banging), serious injury, including retinal detachment or subdural hematoma, can occur (McDougle et al., 2008). The most effective drugs used to treat these symptoms are antipsychotics (both typical and atypical). Clinicians also use mood stabilizers for this purpose. However, their use in this population has not been validated with controlled studies (McDougle et al., 2006). Table 69-2 includes published, placebo-controlled studies of drugs for irritability and aggression in PDDs.

Typical Antipsychotics

Initially, several studies were published using typical antipsychotics to treat children diagnosed as "schizophrenic," "disturbed," and some with "autistic features." Typical antipsychotics studied included chlorpromazine, trifluoperazine, thiothixene, trifluperidol, fluphenazine, and molindone. However, the diagnoses were unclear and the outcome measurements were not standardized, making the generalization of these findings difficult (Posey et al., 2007b).

Haloperidol

The high-potency antipsychotic haloperidol is associated with less cognitive effects and sedation than the lower-potency typical

Table 69–2.

antipsychotics. It is the most extensively studied of the typical antipsychotics for treating symptoms associated with autism.

The first to perform placebo-controlled studies of haloperidol in autistic children was Magda Campbell. An initial study published in 1978 (Campbell et al., 1978) had the purpose of evaluating the results of behavior therapy and/or haloperidol on behavioral symptoms and language acquisition. Forty autistic children ages 2.6 to 7.2 years were studied using a range of haloperidol dosing of 0.5 to 4.0 mg per day, with a mean dose of 1.65 mg per day. Haloperidol was superior to placebo and the combination of the two treatments was superior to haloperidol alone in acquiring imitative speech. The older children (older than 4.5 years) had a statistically significant response to haloperidol for the symptoms of withdrawal and stereotypy. In this study, side effects were dose-related sedation in 12 of 20 (60%) and dystonic reactions in 2 of 20 (10%).

After this study was performed, several subsequent studies were done to verify and further elucidate the findings. A small placebo-controlled study with nine autistic children was completed with haloperidol by Cohen et al. (1980). This study also found that children receiving haloperidol had significantly reduced rates of stereotypy and increased abilities to orient to the raters of the study. Anderson et al. (1984) subsequently performed a double-blind, placebo-controlled study with haloperidol in 40 children ages 2.3 to 6.9 years with DSM-III diagnosed autism. The haloperidol group (0.5–3.0 mg/day or 0.02–0.22 mg/kg/day) showed a significant decrease in maladaptive behaviors and a trend toward facilitated discriminatory learning. At the above dose range, no adverse effects were noted. Another double-blind, placebo-controlled crossover study with random assignment to treatment sequences with 45 autistic children ages 2.0 to 7.6 years was performed by Anderson et al. (1989). Haloperidol was given over 4 weeks at a dose of 0.25 to 4.0 mg per day. Haloperidol was associated with a statistically significant reduction of symptoms. However, no difference between haloperidol and placebo was found with regards to discrimination learning. No adverse effects were noted.

A secondary analysis performed on the Campbell et al. (1980) and two Anderson et al. (1984, 1989) studies presented

above revealed several predictors of response. Higher IQ was predictive of a greater reduction in behavioral symptoms, older children were more likely to respond to haloperidol, and the greater the initial severity of the illness (placebo or treatment group) the more likely there was to be a greater reduction in symptoms. Finally, reduction in symptoms with short-term haloperidol treatment was not related to whether children developed dyskinesias with long-term treatment (Locascio et al., 1991).

A study was performed to determine the long-term efficacy of haloperidol and the effectiveness of discontinuous versus continuous haloperidol administration in 82 autistic children ages 2.3 to 7.9 years (Perry et al., 1989). Sixty children completed the study with doses ranging from 0.5 to 4.0 mg per day. At the start of the study, the children were divided into two groups. Half the children were given continuous haloperidol administration daily. The other half were given haloperidol for 5 days and then placebo for 2 days in a random order for 6 months. After this phase there was a 4-week placebo withdrawal. Drug efficacy did not differ between the continuous and discontinuous haloperidol administration groups. Haloperidol remained effective throughout the placebo withdrawal. Baseline angry and labile affect, uncooperativeness and irritability were symptoms seen in the children that responded best to haloperidol. Twelve of the 60 children (20%) that completed the study had dyskinesias (3 while receiving haloperidol and 9 during drug withdrawal while given placebo).

A longitudinal study was performed to determine the safety of long-term haloperidol use and the risk for haloperidol-related dyskinesias (Campbell et al., 1997). One hundred and eighteen autistic children ages 2.3 to 8.2 years were given 6 months of haloperidol and then 4 weeks of placebo. This schedule was repeated for the children that continued to need haloperidol treatment. The average dose of haloperidol was 1.75 mg per day. Dyskinesias developed in 40 of the 118 children (34%), with 20 of the children developing more than one dyskinetic episode.

> Extrapyramidal symptoms (motor side effects) appear to be more common with typical antipsychotics, such as haloperidol, than the newer atypical antipsychotics.

The first episode was tardive dykinesia in 5 of the 40 children and for the other 35 subjects, the first episode was withdrawal dyskinesia. The authors of this study found that female gender may make autistic children more vulnerable to dyskinesias. It was also noted that there may be an increased risk for dyskinesias in those treated longer or with higher total haloperidol doses. The average total Rochester Research Obstetrical Scale score was also found to be significantly higher in those children who developed dyskinesias (Armenteros et al., 1995). Anesthesia use during delivery was also more common in these children. Thus, pre- and perinatal complications may also cause central nervous system dysfunction that may increase susceptibility to dyskinesias.

Pimozide

A double-blind, placebo-controlled study with haloperidol and pimozide (a typical antipsychotic similar to haloperidol) in 87 children with behavioral disturbance (34 of whom were autistic), ages 3 to 16 years, was conducted over 24 weeks (Naruse et al., 1982). Each medication (haloperidol, pimozide, and placebo) was given for 8 weeks with no wash-out period between medications. The dosing ranged between 1 and 9 mg per day for pimozide and between 0.75 and 6.75 mg per day for haloperidol. Response was measured by the Questionnaire on Behavior in Children for parents and guardians and the Rating Scale for Abnormal Behavior in Children for therapists. These were completed prior to the study and then every 4 weeks. The authors concluded that patients with autism respond to both treatments. Pimozide was superior to placebo in the cluster group "abnormal symptoms," especially in sleep disturbance and excretion disorders. This led to the possibility that pimozide could be helpful in social adjustment. There was no significant difference between haloperidol and placebo when measuring "abnormal symptoms." Adverse events seen with both medications included sleepiness.

Atypical Antipsychotics

As described above, there is a significant risk of dyskinesias when treating autistic children with haloperidol. In the United States, atypical antipsychotics have all but replaced the use of typical antipsychotics to treat behavioral disturbances in autism (Posey et al., 2007b). Atypical antipsychotics antagonize the serotonin receptor, in addition to dopamine receptor blockade, and lead to less extrapyramidal symptoms (EPS). They are also thought to be more effective than typical antipsychotics in treating the negative symptoms of schizophrenia, which in some ways resemble the social withdrawal of autism. Thus, there was the consideration that the atypicals could help with this core symptom domain of autism. To date, this hypothesis has not proved to be true (Posey et al., 2008).

Clozapine

There have only been three case reports of clozapine use in this population. All three were described in letters to the editor. One involved a 32-year-old autistic male who had repeat hospitalizations for harming himself as well as others and destroying property. He had been administered multiple treatments with poor responses and severe EPS. He was prescribed clozapine, and the dose was increased to 300 mg per day. Marked improvement was noted after 2 months, with benefits seen in aggressiveness and social interactions continuing beyond 5 years (Gobbi & Pulvirenti, 2001).

Zuddas et al. (1996) described three autistic children who had been treated with clozapine. Two 8-year-old boys and one 12-year-old girl who had been previously treated with

neuroleptics with minimal improvement were given increasing doses of clozapine (200–450 mg/day, modified for clinical response). After 3 months of treatment, all three children showed a marked improvement on the Children's Psychiatric Rating Scale.

A 17-year-old Hispanic male with autism and severe mental retardation with increasing aggression toward staff and patients was given clozapine after being administered typical and atypical neuroleptics, mood stabilizers, selective serotonin reuptake inhibitors (SSRIs), and beta blockers with little success (Chen et al., 2001). The clozapine was increased to 275 mg per day over a 15-day period, during which he became more compliant with staff and began to perform some activities of daily living.

Clozapine is not used often clinically for treating those with PDDs, as it has the potential to cause life-threatening agranulocytosis and requires frequent blood draws to monitor the white blood cell count (McDougle et al., 2008). These venipunctures can be very difficult for cognitively impaired individuals to understand and tolerate. There is also the possibility of a lowered seizure threshold when administering clozapine.

Risperidone

Risperidone is an atypical antipsychotic with dopamine and serotonin receptor antagonism. There have been several double-blind, placebo-controlled studies with risperidone in autistic individuals. In the first of these, 31 adults with PDDs received risperidone or placebo for 12 weeks (McDougle et al., 1998). Those that received placebo were then given a 12-week open-label trial of risperidone. Dosages ranged from 1 to 6 mg every day. At the end of the study, 8 of 14 adults (57%) were deemed to be responders to risperidone, whereas none of the adults in the placebo group responded. Of the subjects that initially received placebo and then the 12 weeks of open-label risperidone, 9 of 15 (60%) were found to respond to risperidone. Reductions in repetitive behavior, aggression, anxiety, depression, and irritability were all noted. No change was observed in social behavior or language. Side effects primarily included transient sedation.

A double-blind, placebo-controlled, multisite study of risperidone in autism was conducted with 101 children, ages 5 to 17 years, over 8 weeks by the RUPP Autism Network (RUPP Autism Network, 2002). Dosing ranged from 0.5 to 3.5 mg per day. The children receiving risperidone attained a 56.9% decrease in irritability on the Irritability subscale of the ABC, whereas the placebo-treated group experienced a 14.1% decrease. Of the children who received risperidone, 34 of 49 (69%) had a positive response compared to 6 of 52 (12%) in the placebo group. A positive response was defined as a 25% or greater decrease in irritability as measured by the Irritability subscale of the ABC and a rating of much improved or very much improved on the CGI-I. In the children who responded to risperidone, two-thirds of those who remained in the study maintained the positive response at 6 months. Side effects at 8 weeks included an average weight gain of 2.7 kg (compared to 0.8 kg in the placebo group), increased appetite, fatigue, drowsiness, dizziness, and drooling. It was also noted that there was improvement in the ABC subscales of Stereotypy and Hyperactivity. There was no significant difference between the drug and placebo groups for the subscales of Social Withdrawal and Inappropriate Speech.

Another 8-week double-blind, placebo-controlled trial of risperidone was conducted in Canada with 79 children with PDDs, ages 5 to 12 years (Shea et al., 2004). The dosing of risperidone was 0.01 to 0.06 mg per kg per day with a mean dose of 0.04 mg per kg per day (1.17 mg/day). At the end of 8 weeks, irritability as measured by the ABC Irritability subscale improved by 64% in the risperidone-treated group compared with 31% in the placebo group. Sixty-two percent of the children treated with risperidone showed statistically significant decreases in hyperactivity as measured by the ABC Hyperactivity subscale compared with 39.5% of the placebo group. Adverse effects included somnolence, upper respiratory tract infections, rhinitis, and increased appetite. However, the somnolence eventually resolved in 86% of the cases. There was a statistically significant increase in weight, heart rate (average increase of 8.9 beats per minute), and systolic blood pressure in the children treated with risperidone. There was no significant difference in EPS between groups.

A study to determine the longer-term efficacy of risperidone in 36 autistic children ages 5 to 17 years was performed with a double-blind discontinuation phase (Troost et al., 2005). The children were given an 8-week open-label trial with risperidone. Those children who responded received another 16 weeks of additional treatment. At the end of the 24 weeks, the average daily dose was 1.81 mg per day. After that time, the children were placed in two groups; half received a 3-week taper and then 5 weeks of placebo, and the other half continued to receive risperidone. Relapse occurred in 8 of the 12 subjects (67%) who received placebo and in 3 of the 12 subjects (25%) who continued with risperidone. Adverse effects included weight gain, increased appetite, anxiety, and fatigue.

A second multisite, double-blind discontinuation study to determine the longer-term efficacy and safety of risperidone in autistic children ages 5 to 17 years was performed by the RUPP Autism Network (2005b). Sixty-three children were given 4 months of open-label treatment with risperidone at an average dose of 1.96 mg per day. At the end of 4 months, 38 children who continued to meet response criteria were randomly assigned to continue risperidone at the current dose or receive a gradual placebo substitution. The substitution occurred at a decrease of risperidone by 25% of the original dose per week. The relapse rate for the gradual placebo substitution was 62.5% versus 12.5% for continued risperidone treatment. Side effects associated with risperidone during the 16-week risperidone extension included increased appetite, tiredness, and drowsiness. After 6 months of treatment, the average weight gain was 5.1 kg.

Based in part on the results of these controlled studies performed with risperidone, the FDA approved its use in children diagnosed with autistic disorder ages 5 to 16 years with

irritability. This is the first drug to be approved by the FDA for treatment of symptoms associated with autism (McDougle et al., 2008).

Olanzapine

Positive responses to olanzapine in individuals with PDDs have been noted in an open-label study, a case series, and one small placebo-controlled study. The open-label study included 25 children ages 6 to 16 years with PDDs given olanzapine for 3 months at a final average dose of 10.7 mg per day (Kemner et al., 2002). Clinical improvement was noted with the ABC subscales (Irritability, Hyperactivity, and Inappropriate Speech) and TARGET (a checklist of five target symptoms). However, only 3 children were determined to be responders on the CGI-I. EPS occurred in three children but improved with a lower dose. Other side effects included weight gain, increased appetite and loss of strength. The explanation for the low response rate in this study could result from the low average ABC Irritability subscale score (of 11) at study entry. In the two large, placebo-controlled studies of risperidone in children with PDDs, the Irritability subscale scores at study entry were 26 and 20, respectively (McDougle et al., 2008).

> Significant weight gain can occur with the atypical antipsychotics, particularly in children and adolescents.

A case series involving seven PDD patients ranging in age from 8 to 52 years that were followed for 52 weeks on olanzapine has been described (Stavrakaki, Antochi, & Emery, 2004). At the end of 6 weeks, four patients had improved (as noted by the CGI-I) and two were much improved (as noted by the CGI-I and the Global Assessment of Functioning scale). At the end of 52 weeks, all the patients had improved to some extent; one was improved, three were much improved, and three were very much improved. The mean dose of olanzapine was 7.1 mg per day. Side effects included sedation and one seizure that was likely not attributable to the medication. Significant weight gain was not experienced. However, all patients received dietary management, behavioral interventions, or both while taking this medication. This could account for the lack of weight gain noted in the study.

Eleven children ages 6 to 14 years with PDDs entered a small double-blind, placebo-controlled study with olanzapine for 8 weeks at an average dose of 10 mg per day (Hollander et al., 2006). The subjects were randomized into parallel treatment groups. Fifty percent in the olanzapine group were noted to be responders judged by the CGI-I compared to 20% in the placebo group. Significant weight gain was noted in the treatment group (7.5 lbs) compared to the placebo group (1.5 lbs).

Quetiapine

The results from studies of quetiapine (an atypical antipsychotic with a mechanism of action similar to clozapine) in the PDD population have been inconsistent. A 16-week open-label study was performed on six children with PDD (mean age: 10.9 years) (Martin, Koenig, Scahill, & Bregman, 1999). Medication dosages ranged between 100 and 350 mg per day (average dose: 225 mg/day). The 16 weeks of treatment were completed by two children who were deemed to be responders on the CGI-I. Three children dropped out early because of lack of efficacy and sedation. One child dropped out early because of a possible seizure. Other adverse effects included behavioral activation, increased appetite, and weight gain.

Another open-label trial was performed using quetiapine administered to nine patients with autism (ages: 10–17 years) for 12 weeks (Findling et al., 2004). Over the initial 6 weeks, the dose of quetiapine was increased to 300 mg per day; dosage could continue to be increased to 750 mg per day. The average dose was 292 mg per day. Six patients were able to finish the trial. Of those, only two patients were deemed to be responders as measured by the CGI-I scale. Side effects included sedation, weight gain, agitation, and aggression.

A retrospective analysis of quetiapine was conducted with a review of 857 charts to find 20 patients with PDD who had been treated for at least 4 weeks with quetiapine and no other antipsychotic or mood-stabilizing drug (Corson et al., 2004). The average dose of quetiapine was 249 mg per day and the average duration of treatment was 60 weeks. The average age of the patients was 12.1 years. Eight of the 20 patients were judged to be responders by the CGI-I scale. Side effects occurred in 10 of the patients and included weight gain, continued sedation, insomnia, and pain. An average weight increase of 5.7 kg was noted. Three of the patients discontinued quetiapine because of weight gain ($n = 2$) and tardive dyskinesia ($n = 1$), respectively.

A second retrospective study was performed with 10 PDD patients who were treated with quetiapine for a mean of 22 weeks (Hardan, Jou, & Handen, 2005). The average age was 12 years. The average dose of quetiapine was 477 mg per day. Six of the 10 patients were deemed to be responders by the CGI-I. The Conners Parent Scale was also used to track change. Improvement was seen in the dimensions of conduct, inattention, and hyperactivity. No significant improvement was noted on psychosomatic, learning, or anxiety dimensions. Adverse effects included sedation ($n = 3$), weight change (average 2.2 lb), mild intention tremor ($n = 1$), and increased sialorrhea ($n = 1$). Three children did gain more than 10 pounds with treatment. There were no EPS noted.

Ziprasidone

A case series has been published involving ziprasidone administered to 12 children and adults with PDDs (age range: 8–20 years) who received treatment for at least 6 weeks (McDougle, Kem, & Posey, 2002). The average daily dose was 60 mg with a range of 20 to 120 mg per day. Six of the 12 subjects were responders as judged by the CGI-I. Two of the patients who also had a diagnosis of bipolar disorder were rated as "much worse." The mean weight change for the group was a loss of 5.83 lb. Five of the individuals lost weight, five remained the

same weight, and one gained weight (6 lb). The weight loss was believed to be secondary to the discontinuation of prior treatment with other atypical antipsychotics that had resulted in significant weight gain. Transient (in most cases) sedation occurred in eight subjects. Oral dyskinesia was seen in one individual with a history of TD that resolved after ziprasidone was discontinued. No cardiovascular adverse effects were noted.

An open-label retrospective study was conducted in 10 adults with autism who had been switched from another atypical antipsychotic to ziprasidone (Cohen et al., 2004). The average age was 43.8 years, and the average dose was 128 mg per day. The subjects had been treated with ziprasidone for at least 6 months. The reasons for medication change included weight gain, hypercholesterolemia, behaviors, depression, and drowsiness. At the end of 6 months, six subjects were found to have improvement in their behavior, eight lost weight (average 13.1 lb), four of five available cholesterol levels had decreased, and three of five triglyceride levels were reduced. No significant side effects were associated with ziprasidone.

Two case reports have been published describing marked improvement with the use of ziprasidone in autistic children. The first was a 7-year-old male who had not responded to trials of amphetamine, guanfacine, sertraline, and divalproex for symptoms of agitation, impulsivity, irritability, hyperactivity, and intermittent nocturnal awakenings (Goforth & Rao, 2003). The boy responded to 10 mg of ziprasidone nightly. He had less agitation and impulsivity and improvement in his mood. After 8 weeks of treatment, a significant improvement was noted in his language and cognitive performance. He began to use two- to three-word phrases and follow directions. He was rated as "much improved" on the CGI-I. The behavioral and cognitive effects continued to be noted 8 months later. No side effects were reported.

The second case report involved a 15-year-old male with autism, mild mental retardation, and significant ADHD symptoms (Duggal, 2007). He exhibited multiple maladaptive behaviors as well. His symptoms did not respond to MPH alone. Therefore, he was administered risperidone (lack of efficacy) and quetiapine (gained 28 lb over 2 years). Subsequently, he was prescribed ziprasidone at a dose of 20 mg twice a day for the first day, 40 mg twice a day on the second day, and 60 mg twice a day on the third day. After 2 weeks, significant improvement was noted in all of his maladaptive behaviors, including aggressive and disruptive symptoms. His ADHD symptoms (inattention, distraction, hyperactivity, and impulsivity) improved as well. His CGI-I rating was "much improved." MPH was continued at 60 mg per day throughout the titration of ziprasidone. His improvement remained stable over 2 months with no weight gain.

A 6-week open-label study of ziprasidone was performed in 12 adolescents with autism (ages 12.1–18 years; Malone et al., 2007). The average daily dose of ziprasidone was 98 mg (range: 20–160 mg/day). Nine of the 12 individuals (75%) were deemed to be responders based on the CGI-I. There was a significant decrease in total cholesterol (net decrease of 10.2

mg/dl) but not low-density lipoproteins or triglycerides. There was no significant change in weight in this study. The most common side effect was transient sedation. Two patients had dystonic reactions. One was not witnessed by study staff and resolved on its own. The second dystonic reaction occurred after a dose increase, but resolved after 50 mg of diphenhydramine was administered. There was a mean QTc interval (a measurement on the electrocardiogram related to cardiac conduction) increase of 14.7 msec, which was determined to be clinically insignificant.

Aripiprazole

A naturalistic, open-label study of aripiprazole in five males with PDDs (ages 5–18 years) was performed for an average of 12 weeks (range: 8–16 weeks) (Stigler, Posey, & McDougle, 2004). The average dose was 12 mg per day (range: 10–15 mg/day). All five subjects were deemed to be responders as determined by the CGI-I. No EPS or cardiovascular changes were noted. One child gained 1 lb, two children lost weight (likely because of the discontinuation of other atypical antipsychotics), and two of the subjects' weight remained stable. Two of the five subjects demonstrated sedation. One child experienced dizziness.

> Unlike the other atypical antipsychotics, aripiprazole is a partial agonist at the dopamine D_2 and serotonin 5-HT$_{1A}$ receptors.

A retrospective chart review was done with 32 children ages 5 to 19 years with developmental disabilities who had received aripiprazole in an urban setting (Valicenti-McDermott & Demb, 2006). Twenty-four of the children were diagnosed with PDDs and 18 with mental retardation. Target symptoms included aggression, hyperactivity, impulsivity, and SIB. Twenty-eight of the participants had been receiving a different antipsychotic prior to aripiprazole. The average dose was 10.55 mg per day and was administered for 6 to 15 months. Response was noted in 18 of the 32 individuals (56%). However, the drug was reported to be helpful in only 9 of the 24 (37%) children with PDDs. Ten of the 18 (56%) children with mental retardation responded, but only 5 of the 13 (38%) children with both PDDs and mental retardation responded. Side effects were noted in 16 of the 32 (50%) children and caused 7 participants to stop the study. Discontinuation was caused by sleepiness ($n = 4$), tics ($n = 1$), increased aggression ($n = 2$), stiffness ($n = 1$), myalgias ($n = 1$), facial dyskinesia ($n = 1$), and diarrhea ($n = 1$). Weight gain also occurred with the average body mass index (BMI) increasing from 22.5 to 24.1. The changes in weight were most prominent in those younger than age 12 years, with an average increase in BMI of 21.3 to 23.

A 14-week prospective, open-label trial of aripiprazole (mean dose: 7.8 mg/day) in 25 children and adolescents (mean age: 8.6 years) with Asperger's Syndrome or PDD-NOS was recently reported (Stigler et al., 2009). Twenty-two of 25 subjects (88%), all of whom had significant irritability

(aggression, self-injury, tantrums), responded based on the CGI-I. Mild EPS were reported in 9 subjects. Age- and sex-normed BMI increased from a mean value of 20.3 at baseline to 21.1 at endpoint. Prolactin significantly decreased from a mean value of 9.3 at baseline to 2.9 at endpoint. No subject exited the study because of a drug-related adverse event.

Results were recently published from an 8-week, double-blind, placebo-controlled, parallel group, fixed-dose (5, 10, or 15 mg/day) study of aripiprazole in 218 children and adolescents (mean age: 9.7 years) with autism (Marcus et al., 2009). All doses of the drug were significantly better than placebo in reducing mean ABC Irritability subscale scores and improving CGI-I scores at week 8. Discontinuation rates resulting from adverse events were: 7.7% for placebo, 9.4% for 5 mg, 13.6% for 10 mg, and 7.4% for 15 mg. The most common adverse event leading to discontinuation was sedation. At week 8, mean weight change was: +0.3 kg for placebo, +1.3 kg for 5 mg, +1.3 kg for 10 mg, and +1.5 kg for 15 mg. Combined with results from another large placebo-controlled, flexible-dose study of aripiprazole in children and adolescents with autism, this drug was recently granted FDA approval for the treatment of irritability in patients ages 6 to 17 years.

Interfering Repetitive Behaviors

One of the core symptom domains of autism is repetitive and stereotypic behaviors. These can interfere with an individual's ability to function in several different realms. Studies have shown a proven benefit of SSRIs in other disorders such as obsessive-compulsive disorder (OCD) in helping these behaviors (Erickson et al., 2007). A study of 50 adults with autism and 50 age- and sex-matched adults with OCD was performed to compare repetitive thoughts and behaviors between the two diagnostic groups (McDougle et al., 1995). The repetitive thoughts and behaviors of those with OCD differed from what was seen in those with autism. In this study, autistic subjects were much less likely to experience obsessions of contamination, sexual, religious, symmetry, or somatic content. Autistic individuals were more likely to experience compulsions of ordering, hoarding, telling or asking, and touching, tapping, or rubbing when compared with the subjects with OCD. The subjects with OCD were more likely to experience compulsions of cleaning, checking, and counting compared with the autistic subjects.

> The repetitive thoughts and behaviors of individuals with autism differ from those with OCD.

There have been multiple studies suggesting significant serotonin abnormalities in those with PDDs. One Dutch study involving 230 patients with PDDs (ages 5–20 years) and their parents revealed an association between the serotonin transporter intron 2 polymorphism and rigid-compulsive behaviors (Mulder et al., 2005). Studies have also found platelet

hyperserotonemia in individuals with autism (McBride et al., 1998; Mulder et al., 2004). Another study has suggested that the capacity for autistic children to undergo the normal period of elevated serotonin brain synthesis in childhood is disrupted (Chugani et al., 1999). Although the types of compulsive behaviors may differ between those with OCD and PDD, studies have shown some abnormalities in serotonin function in individuals from both diagnostic groups. As a result, several investigations have assessed the efficacy of SSRIs in the PDD population for improving repetitive and stereotypic behavior. Table 69-3 includes published placebo-controlled studies of SRIs in PDDs.

Clomipramine

Clomipramine is a tricyclic antidepressant with potent serotonin reuptake blocking properties that has been demonstrated to be more effective for OCD than desipramine or placebo. A double-blind study comparing clomipramine, desipramine, and placebo in 30 DSM-III diagnosed autistic individuals ages 6 to 23 years was performed to determine if clomipramine was more effective than the other two for decreasing interfering repetitive and stereotyped behavior (Gordon et al., 1993). Each individual was given a 2-week single-blind, trial of placebo. The individuals with less than a 20% response as measured by the Children's Psychiatric Rating Scale, CGI, Modified NIMH Global OCD and Anxiety scales, Modified NIMH OCD Scale, and Modified Comprehensive Psychopathological Rating Scale OCD subscale were then given a 10-week double-blind, randomized crossover comparison of clomipramine and placebo or clomipramine and desipramine (5 weeks on each agent). The mean dosage of clomipramine was 152 mg per day and that of desipramine was 127 mg per day. At the end of the study, clomipramine was found to be superior to placebo and desipramine in decreasing abnormal behaviors (stereotypies and anger) and obsessive-compulsive behaviors and symptoms (compulsive, ritualized behavior). Hyperactivity improved with both clomipramine and desipramine as compared to placebo. Side effects for clomipramine included prolongation of the corrected QT interval and tachycardia (both improved upon dose reduction). One patient receiving clomipramine suffered a grand mal seizure. Eight of the 12 individuals receiving desipramine suffered from increased irritability, aggression, and temper tantrums.

An open-label study of clomipramine (mean dose: 103.12 mg/day), following a 1-week placebo lead-in, was performed with eight autistic children ages 3.5 to 8.7 years (Sanchez et al., 1996). A 3.5-year-old boy dropped out during the third week because of urinary retention. One child improved moderately and six had worsening behavior as measured by the Clinical Global Consensus Ratings. The authors concluded that clomipramine was not helpful and was associated with serious adverse effects in this young population. Adverse effects included acute urinary retention ($n = 1$), severe constipation ($n = 4$), insomnia ($n = 4$), increased aggression

Table 69–3.
Published placebo-controlled studies of SRIs for interfering repetitive behaviors

Study	Drug	Subjects	Design	Results
Gordon et al., 1993	Clomipramine	$n = 30$ Age = 6–23 Dx = AUT	5 weeks Crossover	Clomipramine > PLA Clomipramine > DMI 19/28 (68%) responders
Remington et al., 2001	Clomipramine Haloperidol	$n = 36$ Age = 10–36 Dx = AUT	7 weeks Crossover	Clomipramine = PLA Clomipramine = Haloperidol
Buchsbaum et al., 2001	Fluoxetine	$n = 6$ Age = 30.5 ± 8.6 Dx = AUT, ASP	8 weeks Crossover	Fluoxetine > PLA 3/6 (50%) responders
Hollander et al., 2005	Fluoxetine	$n = 45$ Age = 5–16 Dx = AUT, ASP	8 weeks Crossover	Fluoxetine > PLA repetitive behavior

King et al., 2009	Citalopram	$n = 149$ Age = 5–17 Dx = AUT	12 weeks Parallel groups	Citalopram = PLA

Note: SRIs = serotonin reuptake inhibitors. All ages are in years. AUT = autistic disorder. ASP = Asperger's Syndrome. Dx = diagnosis. PLA = placebo. DMI = desipramine.

and irritability ($n = 4$), drowsiness ($n = 7$), enuresis ($n = 1$), lip-licking ($n = 1$), and diarrhea ($n = 1$).

A 12-week open-label study of clomipramine (mean dose: 139 mg/day) was performed in 35 PDD-diagnosed adults ages 18 to 44 years (Brodkin et al., 1997). Two patients dropped out of the study, one because of agitation and one because of abdominal cramping. Of the 33 patients who finished the study, 18 (55%) were responders as judged by the CGI-I. In the individuals who responded to clomipramine, improvement was noted in repetitive thoughts and behaviors, aggression, and some aspects of social relatedness, such as eye contact and verbal responsiveness. Adverse events seen in 13 of the patients included seizures (2 patients with prior history and 1 with no prior history), constipation ($n = 3$), weight gain ($n = 3$), anorgasmia ($n = 1$), agitation ($n = 1$), and sedation ($n = 2$). No cardiovascular effects or EPS were noted during the study.

A double-blind, placebo-controlled crossover study was conducted to compare clomipramine, haloperidol, and placebo in 36 autistic individuals (ages 10–36 years) who were diagnosed with DSM-IV (Remington et al., 2001). Each individual was randomly placed in one of three sequential treatment groups (clomipramine-placebo-haloperidol, placebo-haloperidol-clomipramine, or haloperidol-clomipramine-placebo). Each medication was given for 7 weeks, with a 1-week wash-out period between medications. The mean daily dose of clomipramine was 128.4 mg and that of haloperidol was 1.3 mg.

Haloperidol and clomipramine were statistically comparable for improving irritability and stereotypy in those individuals who completed the trial. However, statistically only 37.5% (12 of 32) of individuals were able to complete the trial of clomipramine, compared with 69.7% (23 of 33) of those given haloperidol. In the clomipramine group, 12 discontinued because of side effects including fatigue ($n = 4$), tremor ($n = 2$), tachycardia ($n = 1$), insomnia ($n = 1$), diaphoresis ($n = 1$), nausea or vomiting ($n = 1$), and decreased appetite ($n = 1$). The other eight discontinued for "behavioral reasons." Seven of the 10 patients discontinued haloperidol because of fatigue ($n = 5$), dystonia ($n = 1$), and depression ($n = 1$). The other three discontinued because of behavior problems.

Fluoxetine

Fluoxetine is an SSRI that has been shown to decrease obsessive-compulsive symptoms in individuals with OCD. There have been several studies performed to determine whether fluoxetine will decrease perseverative, repetitive behaviors in individuals with PDDs. An open-label trial of fluoxetine was performed in 23 autistic individuals (ages 7–28 years) who were diagnosed with DSM-III (Cook et al., 1992). The subjects were started at a dose of 20 mg per day and doses were increased until side effects were seen or it was deemed that no further therapeutic effect would be reached. Ratings were performed after patients had been on medication for an

average of 189 days (range: 11–426 days). Fifteen of the subjects had an improvement in the CGI-I. A similar response was seen in the rating on the CGI-I for perseverative and compulsive behaviors.

An open-label study was performed with fluoxetine in 37 autistic children (ages 2–7 years) (Delong, Teague, & Kamran, 1998). Each individual's dosing was between 0.2 and 1.4 mg per kg per day. Twenty-two of the children responded to fluoxetine, with 11 having an "excellent" response that resulted in their being able to be maintained in regular classes. Improvements were noted in behavior, language, cognition, affect, and socialization. Another 11 children improved but not to the same extent.

A pilot study was performed with six PDD patients who had a mean age of 30.5 years to determine the effects of fluoxetine on regional cerebral metabolism in this population (Buchsbaum et al., 2001). Each patient received a 1-week placebo wash-out period. After this they were given fluoxetine for 8 weeks and then placebo for 8 weeks in a randomized crossover design. Doses began at 10 mg per day and increased to 40 mg per day. F^{18}-fluorodeoxyglucose positron emission tomography (PET) with co-registered magnetic resonance imaging was performed at baseline and again after 8 weeks of treatment with fluoxetine. The average Y-BOCS obsessions and Hamilton Anxiety Scale scores showed significant improvement with fluoxetine. The CGI-I was improved in three of the patients and unchanged in the other three. The PET scans revealed increased right frontal lobe metabolic rate after treatment with fluoxetine. The patients whose baseline PET scan showed higher metabolic rates in the medial frontal region and anterior cingulate were more likely to have improvement with fluoxetine.

A double-blind, placebo-controlled crossover study with liquid fluoxetine was performed in 45 individuals with PDD between the ages of 5 and 16 years (Hollander et al., 2005). The trial included two randomized 8-week phases of either fluoxetine or placebo separated by a 4-week wash-out period. The dosage of fluoxetine started at 2.5 mg per day for the first week and then increased if needed. The average dose at the end of the fluoxetine treatment period was 9.9 mg per day. Older children tended to receive higher doses. Fluoxetine was found to be superior to placebo for decreasing repetitive behaviors as measured by the CY-BOCS compulsion scale. Fluoxetine was found to be better than but not statistically superior to placebo on the CGI autism score. The composite measure of global effectiveness (CY-BOCS change and the CGI autism score) was found to be marginally statistically improved by fluoxetine. Adverse reactions were not significantly different between fluoxetine and placebo.

Fluvoxamine

Fluvoxamine has also been studied in subjects with PDDs. A 12-week double-blind, placebo-controlled trial of 30 adults with autism was performed (mean dose: 276.7 mg/day) (McDougle et al., 1996). Eight of the 15 (53%) patients who

received fluvoxamine responded as measured by the CGI-I. Improvements were noted in repetitive behaviors, maladaptive behaviors, aggression, and language use. Adverse effects included mild sedation and nausea. No cardiac events or seizures occurred.

As opposed to the preceding results, a 12-week double-blind, placebo-controlled study involving 34 children and adolescents (ages 5–18 years) with PDDs described limited response and poor tolerability with fluvoxamine (McDougle, Kresch, & Posey, 2000). Eighteen of the individuals received fluvoxamine at an initial dose of 25 mg every other day. The dose was increased in 25-mg increments every 3 to 4 days as tolerated. Only 1 child out of 18 responded to fluvoxamine. Side effects were seen in 14 of the children who received fluvoxamine: insomnia ($n = 9$), hyperactivity ($n = 5$), agitation ($n = 5$), aggression ($n = 5$), increased rituals ($n = 2$), anxiety ($n = 3$), anorexia ($n = 3$), increased appetite ($n = 1$), irritability ($n = 1$), decreased concentration ($n = 1$), and impulsivity ($n = 1$).

Another study in children and adolescents also showed disappointing results. A 12-week double-blind, placebo-controlled, randomized crossover study with 18 autistic children ages 3 to 8 years was performed with fluvoxamine (Sugie et al., 2005). In addition to testing the response to fluvoxamine, the serotonin transporter gene was also studied to find a correlation between response and serotonin transporter gene promoter region polymorphism (5-HTTLPR). 5-HTTLPR (long [l] or short [s] allele) was measured by the polymerase chain reaction method. Ten of 18 children improved, although "minimally improved" was included as response to treatment. When "much improved" or "very much improved" was used to indicate response, the rate was only 5 of 18 (27.8%) subjects. Superior response to fluvoxamine was noted in those children with the "l" allele.

Sertraline

A 12-week open-label trial with 42 adults (mean age: 26.1 years) with PDDs was conducted with sertraline (mean dose: 122 mg/day) (McDougle et al., 1998). Improvement was noted in 24 of the 42 (57%) patients in aggression and repetitive behaviors. Improvement in social relatedness was not observed. When the percentage was broken down by type of PDD and using the score from the CGI-I, 68% (15 of 22) of the individuals with autism, 0% of the individuals with Asperger's Syndrome (0 of 6), and 64% (9 of 14) of the patients with PDD-NOS improved. Adverse effects included anorexia ($n = 1$), headache ($n = 1$), tinnitus ($n = 1$), alopecia ($n = 1$), weight gain ($n = 3$), sedation ($n = 1$), and anxiety ($n = 2$). No cardiovascular symptoms, EPS, or seizures occurred.

An open-label case series of nine children (ages 6–12 years) with autism and transition-induced behavior deterioration (panic, anxiety, irritability, or agitation) was conducted with sertraline (Steingard et al., 1997). Eight of the nine (89%) children showed improvement in these symptoms, with sertraline at doses ranging from 25 to 50 mg per day. Response was noted within 3 to 8 weeks of treatment. Two children

showed worsening behavior when their medication was raised to 75 mg per day. In three children there was a noted loss of initial response after 3 to 7 months. Adverse effects included stomachache and behavioral activation.

Citalopram and Escitalopram

A retrospective assessment of citalopram (mean dose: 19.7 mg/day) in 14 children and adolescents (ages 4–15 years) with PDDs was performed to determine its efficacy for decreasing aggression, anxiety, stereotypies, and preoccupations (Couturier & Nicolson, 2002). Ten of the 17 subjects (59%) responded as determined by the CGI-I. Adverse events included increased agitation ($n = 2$), insomnia ($n = 1$), and possible tics ($n = 1$).

Another retrospective review of citalopram (mean dose: 16.9 mg/day) in 15 children and adolescents (6–16 years) with PDDs was done to test the effectiveness and tolerability of the drug (Namerow et al., 2003). Eleven of the 15 patients (73%) improved significantly as judged by the CGI-I. Anxiety symptoms improved significantly in 66% and mood symptoms responded in 47% of the individuals.

The NIMH STAART Network recently reported the results of a multisite, double-blind, placebo-controlled trial of citalopram for repetitive behavior in children and adolescents with PDDs (King et al., 2009). A total of 149 subjects (mean age: 9.4±3.1 years) received citalopram (maximum mean dose: 16.5±6.5 mg/day) or placebo for 12 weeks. There was no significant difference in the proportion of responders based on the CGI-I or in the reduction in the Children's Y-BOCS for PDD between groups. Citalopram was significantly more likely to be associated with adverse effects, particularly hyperactivity, increased energy level, impulsivity, and gastrointestinal symptoms.

A 10-week open-label study of escitalopram (mean dose: 11.1 mg/day) was performed in 28 children and adolescents (ages 6–17 years) with PDDs (Owley et al., 2005). There was a forced titration schedule (2.5, 5, 10, 15, and 20 mg) increased weekly unless criteria were met for a decrease in medication dose. All of the ABC subscale scores (Irritability, Social Withdrawal, Stereotypy, Hyperactivity, Inappropriate Speech)

and the CGI-I showed improvement. Twenty-five percent of the patients responded to doses less than 10 mg per day. Additionally, 36% of the individuals responded to doses higher than or equal to 10 mg per day. Tolerability and efficacy were not related to weight and correlated only marginally with age. Five children had to discontinue the study because of hyperactivity requiring stimulant use not allowed in this study ($n = 2$), no response ($n = 1$), or disinhibition and aggression ($n = 2$). Side effects seen in other children requiring dose adjustment included irritability ($n = 7$), hyperactivity ($n = 6$), and both hyperactivity and irritability ($n = 5$).

Social Impairment

Core social impairment is one of the distinguishing characteristics of PDDs. Several different theories on the pathobiology of social impairment in PDD have been proposed. One theory includes the brain opioid hypothesis. This idea stems from the similarities seen between the social withdrawal seen in individuals with opioid addiction and the social withdrawal seen in autism (Walters, Barrett, & Feinstein, 1990). A second theory relates to a hypothesized abnormality in the physiology of secretin and its receptors (Köves et al., 2002). This idea was proposed after children receiving secretin injections reportedly displayed improvements in social and behavioral skills (Horvath, 2000). Another theory suggests that autism is associated with hypoglutamateric function. This theory came from observations of the similarities in behavior of autistic individuals and healthy controls who were given an N-methyl-D-aspartate (NMDA) antagonist (Carlsson, 1998). Thus medication trials that address these theories have been performed. Table 69-4 presents selected published placebo-controlled trials of drugs for social impairment.

Naltrexone

Several double-blind, placebo-controlled studies of the opioid receptor antagonist naltrexone have been conducted.

Table 69–4.
Published placebo-controlled studies of drugs for social impairment

Study	Drug	Subjects	Design	Results
Belsito et al., 2001	Lamotrigine	$n = 28$ Age = 3–11	12 weeks Parallel groups	Lamotrigine = PLA
King et al., 2001	Amantadine	$n = 39$ Age = 5–19	4 weeks Parallel groups	Amantadine = PLA for primary outcome Amantadine > PLA on clinician-rated hyperactivity and inappropriate speech 9/19 (47%) responders
Posey et al., 2008	D-Cycloserine	$n = 80$ Age = 3–12	8 weeks Parallel groups	D-Cycloserine = PLA

Note: All ages are in years. All studies involved subjects with autistic disorder. PLA = placebo.

Although some of the studies revealed a decrease in hyperactivity and/or irritability, no change in core social impairment was noted (Campbell et al., 1990; Campbell et al., 1993; Willemsen-Swinkels et al., 2005; Feldman, Kolmen, & Gonzaga, 1999).

Secretin

Multiple case reports have described improvement in social skills after intravenous administration of secretin (Horvath et al., 1998). However, a review of 15 double-blind, randomized controlled trials of secretin injection in PDDs revealed that none found secretin to be effective (Sturmey, 2005).

Lamotrigine

Lamotrigine is a drug that modulates glutamate release. Because of its interaction with glutamate, it was hypothesized it could improve social relatedness in individuals with PDDs. A double-blind, placebo-controlled parallel groups study of lamotrigine was performed with 28 children ages 3 to 11 years with autism (Belsito et al., 2001). The children that were given lamotrigine received an increasing dose over 8 weeks to a final dose of 5 mg per kg per day. This dose was continued for an additional 4 weeks. There was a 2-week taper of the drug and then a 4-week drug-free period. Outcome measures after the maintenance phase of lamotrigine included the ABC, the Vineland Adaptive Behavior Scales, the Pre-Linguistic Autism Diagnostic Observation Schedule, and the Childhood Autism Rating Scale. Lamotrigine did not separate from placebo on any of these outcome measures. The most common adverse events included insomnia and hyperactivity. No children discontinued the study because of rashes.

Amantadine

Amantadine hydrochloride has some NMDA noncompetitive antagonist properties. Although it is normally prescribed to treat influenza, herpes zoster, and Parkinson's disease, it has been studied to treat autism. A double-blind, placebo-controlled study of amantadine was performed in 39 autistic children ages 5 to 19 years (King et al., 2001). Children in this study received 2.5 mg every day of either amantadine or placebo for 1 week and then 5 mg twice a day for the next 3 weeks. Results were measured by the ABC and CGI-I. The parent-rated ABC did not show a statistically significant improvement between the two groups. However, the clinician-rated ABC showed statistical significance in the amantadine-treated group for Hyperactivity and Inappropriate Speech. Twice as many patients in the amantadine group versus the placebo group were rated as responders on the CGI-I. Adverse events included insomnia and somnolence.

D-Cycloserine

D-Cycloserine is an antibiotic that is used to treat tuberculosis. It is a partial agonist at the glycine site of the NMDA glutamate receptor. A study with D-cycloserine in schizophrenia showed an improvement in negative symptoms (Goff et al., 1999). Because symptoms of autism have been compared to the negative symptoms of schizophrenia, the idea that D-cycloserine could improve the social impairment of autism was proposed. A pilot study of D-cycloserine was completed in 12 autistic individuals ages 5.1 to 27.6 years (Posey et al., 2004). The patients were given a 2-week placebo lead-in phase and then ascending doses of D-cycloserine of 0.7, 1.4, 2.8 mg per kg per day for 2 weeks each. The ABC and CGI were performed every 2 weeks. Two individuals discontinued the study because of noncompliance ($n = 1$) and increased stereotypic behavior ($n = 1$), respectively. Ten patients completed the study. According to the CGI-I scale, improvement was found to be 0%, 30%, 40%, and 40% for placebo, low, medium, and high doses of D-cycloserine, respectively. The ABC Social Withdrawal subscale also revealed statistically significant improvements. Side effects included increased echolalia and transient motor tics.

More recently, a large-scale 8-week double-blind, placebo-controlled trial of D-cycloserine (1.7 mg/kg/day) was completed in 80 children (67 boys, 13 girls) with autism (ages 3–12 years) (Posey et al., 2008). No significant differences between groups were found on the CGI, ABC Social Withdrawal subscale, or the Social Responsiveness Scale. The drug was well-tolerated. Additional subgroup analyses are being conducted to determine any subject characteristics associated with response.

Memantine

Memantine is FDA-approved for the treatment of Alzheimer's disease.

Memantine is a noncompetitive NMDA receptor antagonist. Open-label add-on treatment with memantine was given to 151 PDD patients ages 2.6 to 26.3 years (Chez et al., 2007). Individuals were started at 5 mg per day. The dose was increased or decreased according to patient response by 2.5 or 5 mg every 4 to 6 weeks. Final dosing ranged from 2.5 to 30 mg per day, with an average dose of 12.67 mg per day. Seventy percent of the patients responded according to the CGI-I scale for language. Seventy-one percent of the patients showed significant improvement in showing interest in others, making efforts in social interaction, and being more cooperative. Twenty-seven patients discontinued the trial, 22 because of an increase in poor behavior and five because of lack of response.

An open-label study of memantine to determine its effectiveness in improving cognitive functioning and behavioral symptoms was initiated in 14 subjects (ages 3 to 12 years) with a diagnosis of PDD (Owley et al., 2006). Memantine was administered at 0.4 mg per kg per day. Twelve subjects completed the study. Significant improvement was seen on memory tests (Children's Significant Scale Dot Learning Subtest) and on three of the ABC subscales: Hyperactivity, Social Withdrawal, and Irritability. There was no significant improvement noted in any subjects on the CGI-I.

A retrospective study of memantine was performed in 18 patients (ages 6 to 19 years) with a diagnosis of PDD (Erickson et al., 2007). Medication doses ranged from 2.5 to 20 mg per day with an average daily dose of 10.1 mg. Sixty-one percent of the patients were rated as responders according to the CGI-I. A significant change from baseline was seen on the CGI-Severity subscale. Side effects were seen in 39% of the patients and included irritability ($n = 4$), rash ($n = 1$), emesis ($n = 1$), increased seizure frequency ($n = 1$), and sedation ($n = 1$). Four of these patients stopped the trial early because of side effects. Two children discontinued the study because of lack of efficacy.

Conclusions

There has been significant progress in the development of pharmacological treatment strategies for target symptoms associated with autism and other PDDs. The large majority of the treatment trials have focused on one target symptom at a time. Utilizing this approach, MPH and alpha$_2$ adrenergic agonists have been shown to be efficacious, to some extent, for inattentive and hyperactive symptoms. The antipsychotics haloperidol, risperidone, and aripiprazole have proven to be even more effective for aggression and irritability. Improvement in interfering stereotypical and repetitive behaviors with SSRIs has been demonstrated to be affected by development, with adults showing more improvement and less adverse events than children. Preliminary work with drugs that affect glutamate function, such as memantine, hold promise for treating aspects of social impairment.

Challenges and Future Directions

The future of pharmacologic treatment development in autism will initially focus on conducting larger-scale, double-blind, placebo-controlled trials of drugs that have shown evidence of effectiveness and safety/tolerability in preliminary pilot studies. For the symptom cluster of hyperactivity and inattention, for example, a randomized controlled trial of atomoxetine is currently underway for children and adolescents with autism and other PDDs. A multisite, controlled study of guanfacine for the same subject population is also likely to begin soon. Preliminary unpublished data suggest that paliperidone, a metabolite of risperidone with purportedly fewer adverse effects than the parent compound, may be effective for treating irritability and aggression in autism. Considering that risperidone is currently one of only two FDA-approved drugs for the treatment of symptoms associated with autism, controlled studies of paliperidone appear to be warranted. Because of the relative lack of efficacy and poor tolerability of SSRIs for children and adolescents with PDDs and interfering repetitive behavior, alternative agents are

needed for this symptom cluster. Preliminary data have been published regarding encouraging effects of the glutamatergic drug riluzole in individuals with OCD. Exploratory studies of riluzole should be considered for targeting repetitive behavior in persons with autism and other PDDs. With regard to the more "core" symptom domains of autism (social and communication impairment), controlled studies of particular drugs with effects on glutamate function should be pursued. Based on published pilot data, the NMDA receptor antagonist memantine is one such compound, and a multi-site study is currently underway for this purpose. In light of results from systematic studies in adults with anxiety disorders, including simple phobia, social anxiety disorder, and OCD, a combined study of social skills training with intermittent, higher-dose D-cycloserine is also soon to begin. It may be that combining D-cycloserine, a drug with prominent effects on learning and memory, facilitates or enhances the effects of various cognitive therapeutic approaches, including social skills training. In addition, recent publications suggest that the neuropeptide oxytocin, which has been shown to have prominent effects on affiliative behavior in animals, may influence tests of social awareness/judgment in humans. Controlled studies of intranasal oxytocin are currently being pursued as a potential treatment for the impaired social behavior of autism. Beyond this, it will be important for our preclinical colleagues to continue to explore animal models of social impairment, as well as genetic contributions and other molecular approaches in the search for novel biological targets for drug development for the core symptom domains of autism.

Hyperactivity and Inattention
  - A double-blind, placebo-controlled trial of atomoxetine
  - A double-blind, placebo-controlled trial of guanfacine
Irritability and Aggression
  - Pilot study of paliperidone
Interfering Repetitive Behaviors
  - Pilot study of riluzole
Social Impairment
  - Double-blind, placebo-controlled trial of memantine
  - Double-blind, placebo-controlled trial of D-cycloserine + social skills training
  - Pilot study of intranasal oxytocin

Autism Spectrum Disorders: Identification and Implications of Associated Medical Conditions

⊞

Points of Interest

- Children, adolescents, and adults with ASDs, who experience common medical conditions, may not present with the same signs and symptoms as that exhibited by their neurotypical peers.
- Many nonverbal, sensory disordered persons with ASDs may not be able to express or demonstrate their discomfort or localize pain.
- Many of the medical conditions occurring in individuals with ASDs are treatable.
- Treating medical conditions can improve physical comfort and quality of life and allow the individual to better participate in and benefit from services and interventions.
- Some medical conditions may have genetic implications and may therefore aide in our ability to subtype groups of individuals on the autism spectrum.

⊞

Introduction

The autism spectrum disorders (ASDs) are identified by behaviorally defined clinical features characterized by core symptoms of impaired social interaction, delayed and disordered communication/language, and isolated areas of interest. It is now recognized that individuals affected with ASDs are heterogeneous in terms of the cause of their disorder and the degree to which each is affected functionally and neurobiologically. Since its initial description in 1943 (Kanner), a growing body of research has broadened our perspective of the disorder and has created an environment whereby early diagnosis and intervention has become the standard of care, with the realization that in many cases, early identification and intensive therapies can lead to more positive developmental

outcomes. With advancements in clinical care has come the observation and appreciation of the fact that many children with ASDs, adolescents and adults have medically relevant health-care issues that may go undetected because of atypical symptom presentation, the inability of the patient to describe or localize discomfort, and often behavioral issues that can make physical examination challenging. However, many of these medical conditions are treatable and, when identified and treated, may improve quality of life for the patient and his/her family and may broaden our understanding of the phenotypic expression of ASDs, leading ultimately to a better defined genotypic subtyping of individuals on the spectrum.

Etiology

Autism is now considered one of the most common disorders of development worldwide. Studies performed by the United States Centers for Disease Control (CDC) in selected communities in 2002 suggest that the current prevalence rates for ASDs are approximately 1 in 150 children (Kuehn, 2007). The increase in the reported prevalence of ASDs has been attributed by some to improved ascertainment, a broadening of the diagnostic definition, and improved public and professional awareness. Others have attributed this upsurge in diagnosis to the contribution of potential, as yet to be identified, environmental factors.

Numerous epidemiologic studies have provided compelling evidence for a genetic basis for autism (Bailey et al., 1995; Bolton et al., 1994). Beginning with the seminal twin study of Folstein and Rutter, published in 1977, the concept of ASDs as a largely genetic disorder has remained in the forefront of autism research. In this study, the authors identified a higher concordance in monozygotic twins than in dizygotic twins. Since that time, numerous linkage studies have been reported, with the most frequently replicated findings being associated with chromosomes 7q, 15q, 22q, and 2q (Schaefer & Mendelsohn, 2008). Additional candidate genes of promise

include γ-amino butyric acid (GABA) and serotonin transporter genes, engrailed 2, neuroligin, MECP2, WNT2, PTEN, and MET (Campbell et al., 2006, 2007). Many new loci and genes have been identified, and the reader is referred to the chapters related to genetics in this book for detailed data. Autism is four times more common in males than in females, with a higher ratio in milder forms of the disorder. Further, ASDs are associated with a significant familial recurrence, much higher than that seen in the general population. The reported recurrence risk has been estimated to be approximately 15% in families having one affected child (Landa et al., 2006, 2008; Lauritsen et al., 2005). If the family has two affected children, the recurrence rate for subsequent children increases substantially, up to 25% to 50% (Cook, 2001; Spence, 2004).

Despite modern technology and advanced research, only approximately 6% to 15% of individuals with autism will be found to have an identifiable genetic diagnosis. In addition, a number of syndromes have been associated with ASDs, including Fragile X Syndrome (FXS), tuberous sclerosis, Smith-Lemli-Opitz Syndrome, and Rett Syndrome (MECP2 mutations) (Schaefer et al., 2008; Geschwind, this book). Numerous genes have been investigated as possible candidate genes, but replicated findings are lacking. Current epidemiological studies of ASDs strongly suggest multifactorial inheritance, including genetic heterogeneity with multiple major gene effects, possible contributing environmental effects, and physiologically linked processes with multiple genes.

One of the many additional potentially important risk factors for ASDs that has gained increased interest is the role of advanced parental age. In a recent study, Durkin et al. (2008) noted that in a study of 1251 children with complete parental age information and who were defined as having ASDs based on DSM-IV criteria, both maternal and paternal age were independently associated with autism. The authors also noted that firstborn offspring of two older parents were three times more likely to develop autism than were later born offspring. A number of potential mechanisms for these effects have been suggested, including age-related chromosomal changes, complications of pregnancy, or possible environmental exposures during pregnancy that could have mutagenic effects. In addition, given the apparent importance of birth order, the authors speculate that these children may be more susceptible to autoimmune responses affecting neurodevelopment or may be affected secondary to maternal exposure to neurotoxic chemicals, passed to the offspring transplacentally or in breast milk, in combination with advanced maternal age. Whatever the mechanisms involved, these observations warrant further investigation in a larger population of children with ASDs.

Clinical Presentation

Although it is now recognized that autism is a clinically and biologically heterogeneous disorder, those affected share a triad of common features that include atypical social interaction, delayed and disordered language, and a markedly restricted repertoire of activities and interests (American Psychiatric Association, 1994). Symptoms can range from relatively subtle and mild to very severe. For example, there may be a qualitative impairment in reciprocal social interaction as opposed to an absolute absence of social interaction. Social behaviors can range from a seemingly total lack of awareness of others to inappropriate eye contact and atypical social responsiveness. Communication skills can span from a total lack of verbal speech and intentional use of gesture to the presence of speech that is associated with atypical intonation, prosody, syntax, and grammar. Although the normal development of single-word receptive and expressive vocabulary may be present, pragmatic language may be significantly impaired. Many affected individuals demonstrate poor eye contact, echolalia, pronoun reversals, stereotypic and repetitive behaviors, sensory processing dysfunction, difficulty dealing with novelty, an obsessive reliance on routine, and some level of cognitive impairment. In very young children, the lack of a pointing response and joint attention and limited pretend play are frequent characteristics as early as age 12 months. Many affected individuals have exceptional islands of rote memory and outstanding isolated talents in the face of otherwise general functional disabilities (Rapin & Katzman, 1998). Although it was initially believed that approximately 75% of those affected with autism functioned in the mentally retarded range, more recent studies have found that fewer than half of affected individuals have significant cognitive impairment (Newschaffer et al., 2007).

Typically, those individuals with nonsyndromic or "essential" autism demonstrate few, if any, dysmorphic features and are generally described as very attractive appearing children. For many years, these children were believed to demonstrate no abnormalities of motor function, or if present, these deficits were believed to be merely associated symptoms. It has now become apparent that gross and fine motor dysfunction is more common than previously appreciated. Numerous clinical studies indicate that children with autism exhibit deficits in skilled motor performance in response to command and with tool use, suggestive of a more generalized dyspraxia (Rogers et al., 1996; Mostofsky et al., 2006). Children with autism often show delays in learning novel complex motor skills such as peddling a tricycle or pumping on a swing with their legs (Gidley Larson & Mostofsky, 2007). Further, in a study of motor impairment in a group of 154 children with ASDs, Ming et al. (2007) noted that hypotonia was the most common motor symptom in this cohort, with motor dyspraxia being more prevalent in younger children than older children. Gross motor delay was reported in 9% and toe-walking in 19%. The etiology of motor dysfunction in ASDs remains uncertain, with abnormalities of the cerebellum, basal ganglia, and/or neural connections across distributed networks being hypothesized (Gidley Larson et al., 2008).

Examination of the autistic child, adolescent, and adult may be complicated by variable levels of cooperation, impaired communication and behavioral issues. Important factors during the physical and neurological assessments should include identification of potential dysmorphic features that

might suggest a specific diagnosis or syndrome. Measurements of head circumference throughout childhood has resulted in the observation that a subset of children with ASDs demonstrate a larger than average head circumference, with approximately 20% of these showing a frank macrocephaly of greater than 98% for age and sex. More recent work by Lainhart et al. (2006) highlights the fact that the distribution curve of head size in ASD is similar to that seen in typically developing children but is shifted to the left, suggesting that this unusual head growth may reflect an upregulation of as yet unknown growth factors. The clinical finding of macrocrania is, at this time, without a defined neuropathological correlate.

All patients with autism should have a formal audiogram. Many children with ASDs present with impaired receptive and expressive language and fail to respond to the spoken word, causing some parents to wonder if their child might be deaf. Impaired hearing could alter communication and socialization skills. There is a debate as to the role of electroencephalography (EEG) as part of the routine evaluation of a child with an ASD. Although there are reports of autistic-like symptoms in some children with seizure disorders and an acquired aphasia (Landau Kleffner Syndrome), this disorder is very rare. In general, EEG is probably not indicated as a routine part of the ASD evaluation unless there is a clinical history to suggest a possible seizure disorder. Similarly, cranial imaging studies are not routinely recommended unless abnormalities on neurological examination are observed (Filipek et al., 1999). Additional assessments should include high-resolution karyotype and Fragile X Syndrome studies as an initial step, along with assessments from a speech and language pathologist, an occupational therapist, and a cognitive developmental specialist.

Associated Medical Disorders

Until recently, much of the clinical and basic science research has been focused on the understanding of brain mechanisms that could explain the behavioral, cognitive, social interaction, and communication dysfunction associated with ASDs, with relatively little attention to the possible significance of accompanying medical conditions. Much of this relative neglect may be related to the fact that the physical examination of an individual with autism, particularly children, can be challenging and often limited by poor patient cooperation and difficult office behavior. Further, it now appears that ASD individuals, many of whom are nonverbal or hypo-verbal, may not be able to describe or localize their discomfort. In addition, there is a growing appreciation that persons with ASDs may not present with typical, easily recognized symptoms, making diagnosis in any one circumstance difficult, and therefore overlooked. Research indicates that children with ASDs are more likely than other children with special needs to have difficulty accessing medical care, further compounding the challenge of providing quality routine health care to this population of individuals (Kogan et al., 2008). The fact that a child has

autism does not rule out the possibility that he or she may have one or more other illnesses or disorders, similar to those experienced by typically developing children. Identifying and treating these disorders may improve behavior, developmental progress, and quality of life as well as provide leads into potential subsets of individuals with ASD who may have genetic and etiologic implications.

Pain and Discomfort

It is known from the general pediatric literature that typically developing children often show increased rates of problem behaviors in association with physical illness. For example, increased rates of head-banging behavior has been reported in infants who are experiencing middle ear infections (Lissovoy, 1962), and increased frequency of temper tantrums has been observed in toddlers in relationship to upper respiratory infections (Hart et al., 1984). Not surprisingly, physical illness is common in persons with developmental disabilities, and at least one study has suggested that the number of associated medical conditions may be higher for individuals with developmental disabilities than for the general population across the life span (Cooper, 1998). As is the case for typically developing persons, there also appears to be an association between physical illness and problem behaviors in the disabled population. Problem behaviors have been associated with illnesses such as allergies (Taylor et al., 1993), constipation (Lekkas & Lentino, 1978), premenstrual syndrome (Kennedy & Meyer, 1996), and urinary tract and ear infections (Gunsett et al., 1989). Documentation that problem behaviors may be causally linked to physical illness has been provided through studies showing that these behaviors can be significantly reduced as the result of appropriate medical diagnosis and treatment (Ghaziuddin et al., 1993; Peine et al., 1999). It has been suggested that this relationship between physical illness and problem behaviors is not the result of the illness itself but is more likely related to the degree of pain and discomfort experienced by the individual at any given time (Horner et al., 1996; Kennedy & Thompson, 2000).

Determining the causes and source of pain and discomfort can be challenging in nonverbal persons who may not process or localize sensory information accurately. Further, many persons with developmental disabilities, including individuals with ASDs, may not present with the typical signs and symptoms of illness familiar to most primary care physicians and specialists. For example, some ASD persons suffering from gastrointestinal disorders may present with aggression and self-injurious behavior without evidence of vomiting, diarrhea, constipation, or signs of abdominal discomfort (Buie, clinical observation). Thus, a high index of suspicion for some type of medical illness should be raised for any ASD or developmentally disabled patient who presents with an unusual onset or escalation of problem behaviors that have not responded to behavioral and environmental accommodations and that cannot be readily explained. Carr and Owen-DeSchryver (2007) have suggested the use of retrospective and prospective

questionnaires, administered by knowledgable informants, to assist in delineating a potential connection between problem behavior and physical illness. In a study of 11 individuals with ASDs, ages 4 to 21 years, the authors noted that retrospective questionnaires alone were often unreliable. The addition of a prospective questionnaire allowed informants to track the association between behaviors and illness-related pain over a period of months and on a daily basis. Informants were supplied with a list of motor and verbal pain indicators derived from the pediatric clinical literature. The resulting data proved reliable in that informants were able to agree among themselves with regard to their observations. Of further concern is the observation that without prevention and prompt intervention, problem behaviors may become more strongly established over time (Horner et al., 2002).

Space does not allow for a detailed description of the multiplicity of possible medical conditions that may affect a person with autism. Therefore, only some of the more common disorders will be briefly highlighted here. These include seizure disorders, sleep disturbances, gastrointestinal disorders, metabolic dysfunction, and hormonal imbalances. However, the primary care and specialty physicians serving persons with ASDs must be constantly alert to a wide range of medical possibilities at any one time.

Seizure Disorders

The prevalence of seizures in adults with autism has been estimated to be between 20% and 35% (Minshew et al., 1997; Tuchman, this book), and in children with ASDs, it has been estimated between 7% and 14% (Rapin, 1996; Tuchman et al., l991), with peak risk periods occurring in early childhood and adolescence (Volkmar & Nelson, 1990). Although regression of language and cognitive skills in association with seizures has been reported during the teenage years, little is known regarding its etiology or prevalence (Minshew et al., 1997). Seizures may be of any typ,e but partial complex seizures are most frequently reported. The clinical identification of partial complex seizures in autistic individuals can often be complicated by the presence of atypical behavioral patterns and body movements often seen in association with ASDs and frequently attributed to the autism *per se*. Alternatively, not all body movements or mannerisms observed in ASDs are seizure-related and may be manifestations of other medical conditions such as gastroesophageal reflux disease (GERD) (Buie, 2005). Further complicating diagnosis is the fact that there may be a lack of direct correlation between clinical seizures and EEG activity (Minshew et al., l997). However, any behaviors such as staring, cessation of activity, eye fluttering or aggressive behavior associated with confusion should raise the suspicion of a complex partial seizure and further evaluation pursued. Obtaining a high-quality EEG—especially in toddlers and young children—can be difficult but can be achievable. Prolonged or overnight EEG can often be helpful as well as the use of video tape review of the events recorded in the home or school. A growing number of anticonvulsant medications are now available, and these seizures can usually be brought under control with experienced medical management.

Gastrointestinal Disorders

Although gastrointestinal (GI) dysfunction is believed to be relatively common in autism, the true prevalence of these disorders is unknown (Buie, 2005; Campbell et al., 2009). Similarly, it is not known whether these disorders are more common in persons with ASDs than in typically developing individuals. However, a recent, well-controlled prospective study, using a structured interview, reported a significantly increased prevalence of GI conditions in ASDs as compared to controls (Valicenti-McDermott et al., 2006). Parents often report a number of symptoms in their babies and young children, including diarrhea, constipation, food intolerance, gas, bloating, abdominal pain/discomfort, and a history of reflux (Horvath et al., 1999; Quigley & Hurley, 2000).

Although many children with ASDs present with typical GI track symptoms, others may not and may instead exhibit aggressions and self-injurious behavior, facial grimacing, chest tapping, and the seeking of abdominal pressure (Buie, personal communication). It is well-known that typically developing children can and often do present with behavioral disruptions when not feeling well. There is no reason to believe that children with ASDs should do otherwise. The identification of GERD, gastritis, esophagitis, colitis, inflammatory bowel disease, Crohn's disease and celiac disease have been identified in autistic persons and treatment of these disorders have resulted in improved behavior and better developmental progress (Buie, personal communication), no doubt because the individual is more comfortable and physically well.

Recently, Campbell et al. (2009) have reported that disrupted MET gene signaling may contribute to increased risk for ASDs, including familial GI dysfunction. A functional variant in the promotor of the gene encoding the MET receptor tyrosine kinase has been associated with ASDs, and MET protein expression has been found to be decreased in the temporal lobe cortex in ASD postmortem brain tissue. MET is a pleiotropic receptor that is known to function in both brain development and GI repair. Thus, the identification of medical disorders in ASD individuals (in this case GI disorders) may not only improve quality of life for those affected with ASDs but may lead to improved or more precise definition of genetic and phenotypic subtypes in this complex heterogeneous disorder.

Sleep Disorders

The prevalence of sleep disorders in typically developing children is said to be approximately 30% and appears to be more common in early childhood (Ferber, 1996). In contrast, the prevalence rates among children with autism have been estimated to range from 44% to 83% (Richdale, 1999), and sleep disorders have been reported to be more severe in this population (Malow et al., 2006). It is known that disordered sleep affects daytime health, neurocognitive dysfunction, and

behavioral disruptions in a variety of psychiatric and neurologic conditions. In typically developing children, sleep disruption may lead to daytime sleepiness and may manifest itself as hyperactivity, inattention, or aggression (Owens et al., 1998). Insomnia, defined as having trouble initiating and/or maintaining sleep, is the most common feature reported by parents of autistic children. Additional sleep concerns include symptoms of disordered breathing associated with loud snoring, noisy breathing, or occasional pauses or apneas in breathing as well as leg movements and tooth grinding. Occasionally, nocturnal arousals associated with screaming, walking, or confusion have been reported. These sleep disturbances may have multiple causes. Trouble initiating sleep may be related to hyperactivity or medications used to treat hyperactivity. Anxiety, depression, seizure disorders, or abnormalities of circadian rhythm have also been associated with delayed sleep onset.

Although disorders of arousal and behavioral noncompliance may also be factors, one must also consider other medically based disorders. It is known, for example, that GE reflux can contribute to nighttime awakenings in infants as well as older children (Buie, unpublished data). Loud snoring and daytime mouth breathing may suggest enlarged tonsils and/or adenoids as possible factors (Owens et al., 2000). Further, both obstructive and sleep apneas have also been reported in some cases. Given that there is increasing evidence that poor quality and quantity of sleep can have a negative effect on daytime behavior and functioning (Malow et al., 2006), it is important to accurately diagnose and treat reported sleep disruptions in individuals with ASDs.

Metabolic Disorders

Metabolic disorders are considered a rarity among patients with neurodevelopmental disorders, a reported diagnostic yield after initial evaluation varying from 1% to 2.5% (van Karnebeck et al., 2005). Although rare, the effect of correct diagnosis and treatment of a metabolic disorder may have a substantial effect on the patient's developmental outcome. Engbers et al. (2008) performed repeated metabolic studies on a series of 433 subjects with neurodevelopmental disorders whose initial metabolic assessments were said to be normal and identified 12 metabolic diseases (2.8%), some of which were treatable. The prevalence of metabolic disorders in ASDs remains as yet largely unknown with the level of frequency no doubt varying with the specific disorder.

Smith-Lemli-Opitz Syndrome (SLOS) is one of the more common metabolic disorders associated with clinical features of autism (Bukelis et al., 2007). SLOS is an autosomal recessive disorder associated with an inborn error of cholesterol synthesis caused by mutations of the 7-dehydrocholesterol reductase gene (DHCR7) located on chromosome 11q12-13 (Kelley et al., 2001). Cholesterol is essential for neuroactive steroid production, growth of myelin membranes, and normal embryonic and fetal development. It is also believed to modulate oxytocin receptors, ligand activity, and G-protein coupling of

the serotonin-1A receptor (Aneia & Tierney, 2008). It has been hypothesized that a deficit in cholesterol may disrupt these biological mechanisms, thereby contributing to clinical features of ASDs as observed in SLOS. The syndrome has an estimated incidence of 1 in 20,000 to 1 in 60,000 births and a carrier frequency of about 1%. Clinical characteristics include developmental delay, facial anomalies (ptosis, upturned nares, small chin, bitemporal narrowing, and microcephaly), and abnormal webbing between the second and third toes. Additional symptoms can include irritability, hyperactivity, self-injury, temper tantrums, and aggression. In mild cases, the physical features may not be readily recognizable. It has been estimated that approximately 50% to 75% of individuals with SLOS may meet criteria for autism. A clinical diagnosis of SLOS can be confirmed by means of biochemical analysis, an elevated level of plasma 7-dehydrocholesterol relative to the cholesterol level establishing the diagnosis. This disorder is not only identifiable but partially treatable with cholesterol supplementation, thus increasing the importance of syndrome recognition.

A number of studies and case reports have suggested that mitochondrial disorders may be a causative factor in a subset of autistic individuals. In 2005, Oliveira et al. published a population-based survey among school-aged children with ASDs and found that 7% of those who underwent a complete metabolic evaluation were diagnosed with a mitochondrial respiratory chain disorder. Further, this group reported that the affected children were clinically indistinguishable from children suffering from ASDs without a mitochondrial dysfunction. More recently, however, Weissman et al. (2008) reported their findings on 25 ASD subjects with biopsy-proven mitochondrial disorder and found that a series of "clinical red flags" could distinguish the affected children from those with idiopathic ASD. These "red flag" characteristics included the involvement of at least one non-neurological organ system, significant gross motor delays, easy fatigability, and repeated regressions after age 3 years. Further, they noted a nearly even distribution between males and females. The authors concluded that with careful clinical and biochemical assessments, children with the co-occurrence of ASDs and mitochondrial dysfunction could be distinguished from those with idiopathic ASDs and that those affected with mitochondrial disorders may represent a significant subset of individuals with autism.

Osteoporosis

Decreased bone mineralization and osteoporosis, once believed to be health issues found in the elderly, is now being recognized with increasing frequency in younger populations, including in childhood. This process is driven to a large extent by nutritional status, calcium, and vitamin D intake (Lehtonen-Veromaa, 2002; Foo et al., 2009; Davies et al, 2005). Thus, conditions associated with poor nutrition during childhood and adolescence, a critical period for bone mass accumulation, may significantly impact on the attainment of healthy peak bone mass. Gastrointestinal disorders appear to be prevalent

among children with ASDs and may be more common in this population than among typically developing children (Valicenti-McDermott et al., 2006). Those with ASDs often demonstrate unusual eating patterns, frequently self-initiated, or may be placed on restrictive therapeutic or complementary alternative diets that limit the intake of calcium and vitamin D, the most common being the casein- and/or gluten-free diet. Additional factors may include impaired growth hormone secretion (Ragusa, 1993), low muscle tone (Ming, 2007), limited exercise (Pan, 2008), anticonvulsant medications (Chou et al, 2007; Pack et al., 2008), and the use of psychotropic or stimulant medications to control behaviors that may impact hormonal function, weight gain, and caloric intake (Bostwick et al., 2009; Ziere et al., 2008). Thus, although ASD individuals often have one or more of these well-documented risk factors, there are very few studies that have assessed the impact of any or all of these factors on bone density in ASD. A recent report of decreased cortical bone thickness in ASD children suggests that individuals with autism may be at high risk for the development of osteoporosis (Hediger et al., 2008). Given the potential risk of injury and fractures, as well as general health issues related to under-nutrition in this population, more research is needed.

Obesity

New evidence suggests that children with chronic conditions may be predisposed to being overweight and to obesity. In a recent study, Chen et al. (2009) analyzed reported height, weight, and body mass index (BMI) from 46,707 subjects, ages 10 to 17 years, with the goal of measuring the prevalence of obesity adjusted for demographic and socioeconomic factors. Obesity was defined as 95% or more of the sex-specific BMI for age growth charts. The prevalence of obesity among those without a chronic condition was 12.2%. Among those subjects with chronic conditions, the prevalence of obesity was highest among children with autism (23.4%), followed by those with asthma (19.7%), learning disabilities (19.3%), attention deficit/hyperactivity disorder (18.9%), and hearing/vision conditions (18.4%). The rising rate of obesity in the general population has been attributed to greater nutritional accessibility and more sedentary lifestyles. Although the causes of obesity are recognized to be heterogeneous, environmental and genetic factors have become the focus of intensive research. Numerous national studies have suggested that exposure to television is associated with obesity, lipid disturbances, and poor cardiovascular health during adulthood (Gortmaker et al., 1996; Robinson, 1999). The explanation for this correlation is the concept that television promotes significant lifestyle changes related to an imbalance of caloric intake and expenditure (Coon & Tucker, 2002). Medications that many children, adolescents, and adults with ASDs receive to control seizures, such as valproic acid (Verrotti et al., 2002), or disruptive behavior, such as risperidone (Saddichha et al., 2007), have been associated with excessive weight gain in some cases and may therefore also be contributing factors.

Earlier studies have found similar statistics. For example, a sample of 140 Japanese children with ASDs, ages 7 to 18 years,

revealed that 25% were classified as obese (Sugiyama, 1991). In a somewhat later study involving 20,031 children with mental retardation, ages 6 to 17 years, 413 of whom were children with autism, Takeuchi (1994) found the prevalence of obesity to be 22% in boys and 11% in girls. Curtin et al. (2005) more recently reported similar findings in which the overall prevalence for at-risk-for-overweight was 35.7%, and for overweight was 19% among children with ASD. When the data were stratified by age, the prevalence for at-risk-for-overweight and overweight appeared to be highest in the 12- to 17.9-year age group. These observations were echoed in a similar study of 380 boys and 49 girls with autistic disorder. However, the authors noted that at-risk-for-overweight/overweight in autistic children had no relationship to the core features of the disorder and that older age was a predictor of lower height and at-risk-for-overweight among these children (Xiong et al., 2005).

It is well-known that children with autism have different dietary patterns and lifestyles when compared to typically developing children. These factors can affect body growth and nutritional conditions. Although many reports have been directed toward the concern for obesity in ASDs, some studies have reported a tendency toward being underweight among children with autism and Asperger's Syndrome, often associated with delayed physical growth, and generally attributed to low appetite, narrow range of food choices, and digestive disorders (Bolte et al., 2002; Hebebrand et al., 1997; Lesinskiene et al., 2002). Thus, there is significant concern regarding diet, nutrition, physical activity, and therapeutic interventions, which—either separately or in combination—may contribute to serious health-related issues such as diabetes, hypertension, hyperlipidemia, anemia, and osteopenia, to name a few. The role played by potential genetic and environmental factors interacting with dietary and therapeutic approaches will be important topics for future research.

Hearing Impairment

Many children with autism present initially with delays in expressive and receptive language and it is not unusual for a parent to comment that they wondered whether their child might be deaf. Thus, the assessment of auditory abilities in children with ASDs is important in the diagnosis and treatment of this disorder. A small number of studies have investigated the prevalence of hearing impairment within the ASD population. In a study of 199 children with ASDs and adolescents who were audiologically evaluated, mild-to-moderate hearing loss was identified in 7.9% and unilateral hearing loss in 1.6% (Rosenhall et al., 1999). In this same study, profound bilateral hearing loss or deafness was found in 3.5% of all cases. These findings represent a prevalence significantly higher than that observed in the general population and was comparable to that found among individuals with mental retardation. Further, hearing deficits among the ASD subjects occurred at similar rates, regardless of intellectual functioning. Of additional note is the fact that hyperacusis was found in 18.3% of the autism group as compared to 0% in the

non-autism comparison group. Similarly, the rate of serous otitis media was found in 23.5% of ASD subjects with a related conductive hearing loss noted in 18.3%, both of which appeared to be increased in persons with autism. Similar concerns have been raised by the more recent study of Tas et al., (2007), raising the suspicion that hearing loss may be more common in children with autism than in typically developing children.

Gynecological Dysfunction in Adolescence

One of the many medical conditions that has not yet been well-studied relates to the potential effects of hormonal imbalance, especially during adolescence, which could be associated with precocious puberty, accelerated or reduced physical growth, and/or behavioral disruptions associated with menstrual pain or discomfort. These factors have been raised in a study published by Carr et al. in 2003, in which both physical discomfort and pain associated with the menstrual cycle were cited as possible causes of problem behaviors in adolescence. The authors, however, also raised the possibility that fluctuations in progesterone and estrogen levels might also be an important variable. This theme has been further expanded in a more recent study in which adolescent girls with autism, Down syndrome, and cerebral palsy were evaluated retrospectively regarding gynecological complaints. Girls with autism were significantly more likely to present with behavioral issues than the other two groups. Management included the use of non-steroidal anti-inflammatory drugs, oral contraceptives, and education (Burke et al., 2009). Further studies are needed in this important area to provide correct diagnoses and appropriate interventions.

Conclusion

Routine medical conditions frequently seen in typically developing individuals, as well as their behavioral implications, have yet to be fully investigated in children, adolescents, and adults with autism (Gilberg, this volume). The frequency and presence of recurrent ear infections, sinusitis, asthma, hypertrophied tonsils and adenoids, urinary tract infections, spastic bladder that be associated with new onset incontinence at any age, attention deficit disorder, disordered sensory processing, allergies, or any other medical condition commonly seen have yet to be carefully considered in autism. These conditions may not always present with the typical signs and symptoms that most physicians have been taught to recognize but should be considered in ASD individuals at any age who present with unexplained and/or changes in behavior. Defining and treating these medical conditions can improve quality of life for the patient as well as his or her family and can be associated with improved developmental gains as the result of better physical health. Further, there is a growing sense that at least in a subset of affected individuals, ASD may involve multiple organ systems. Thus, understanding the biological mechanisms

associated with these other organ systems, in addition to expanding our knowledge about the brain in persons with autism, could potentially expand our knowledge and provide insights into the underlying neurobiology of the disorder.

Much progress has been made in the identification and treatment of persons with ASDs, as well as our understanding of the etiologic and biological mechanisms that are or can be associated with the disorder. However, much remains to be unraveled and many questions remain unanswered. With advancing technology and improved medical and diagnostic assessments of those affected with ASDs and their families, it is hoped that diagnoses can be made earlier—potentially at or before birth—and that more effective therapies and interventions will become possible to improve the lives of those affected with autism.

Challenges and Future Directions

- Children, adolescents, and adults with ASDs may not present with the typical signs and symptoms easily recognized by most health-care professionals.
- ASD individuals who present with challenging behaviors such as aggression and self-injury, especially if they are nonverbal, should be evaluated for an underlying medical condition, before assuming that these disruptions are "just behavioral" or "just part of the autism."
- Health-care professionals and caregivers need to learn the signs and symptoms of pain and discomfort in nonverbal or hypo-verbal, sensory-impaired persons with ASDs.
- Some comorbid medical conditions may have genetic and biologic implications that may provide insight into some of the underlying mechanisms related to etiology and phenotypic expression of ASDs and could potentially aide in defining some treatment modalities in the future.

Dietary, Complementary, and Alternative Therapies

Points of Interest

- Complementary and alternative therapies are used by up to three-fourths of families for their children with ASDs. Up to half of children with ASDs take nutritional supplements and up to one-third use dietary therapies.
- Mind–body therapies like yoga may have an effect on regulating anxiety; music therapy might have a role in encouraging language.
- Biologically based therapies are based on hypotheses related to atypical oxidative stress, gastrointestinal dysbiosis, immunologic dysfunction, and removal of environmental toxins. The potential for side effects of biologic therapies have not been adequately studied.
- Manipulation and body-based therapies like chiropractic are popular, although there are not data to support effectiveness for symptoms of ASDs. The use of massage has been associated with subjective benefits but has not been adequately studied.
- Energy medicine therapies like Qi Gong are being studied for use for symptoms of ASDs.

Although the goal of interventions for autism are to target core and/or concurrent symptoms, conventional medical, psychological, and educational practice have evidence to support their ability to ameliorate only some of the core and concurrent symptoms. The only prescription medications with a package insert with indication for autism treatment are risperidone and apiprazole. Although the effect size for treatment is large, risperidone addresses irritability and not the core symptoms of autism spectrum disorder (ASD) (Scahill et al., 2007). Similarly, conventional educational and behavioral interventions such as early intensive behavioral intervention (Lovaas, 1993) result in improvements by teaching skills but do not address underlying biologic differences. It is not surprising that families of children with ASDs have become increasingly interested in therapies outside conventional treatments to attempt to symptomatically improve, or even cure, their child with ASD.

Complementary and Alternative Medicine Use in Children with Autism Spectrum Disorders

The National Center for Complementary and Alternative Medicine defines complementary and alternative medicine (CAM) as "… a group of diverse medical and health care systems, practices, and products that are not presently considered to be part of conventional medicine." Complementary refers to the use of novel therapies together with conventional medicine. The term *alternative* refers to interventions used in place of conventional practice. Most families of children with ASDs utilize multiple therapeutic approaches simultaneously (Levy & Hyman, 2008). National health information survey statistics (Barnes, 2004) indicate that 20% to 38% of adults and 11% to 21% of children in the United States use CAM therapies. If prayer is included, the overall rate of CAM use in adults increases to 62%. The rates of general CAM use are increasing with availability of information on the internet (V. A. Green et al., 2006) and a culture of increasing participation in medical care decision making (Levy & Hyman, 2008). In 1994, 11% of children were reported to have used CAM (Spigelblatt et al., 1994). By 2003, 45% of children taken for emergency department care had used CAM (Lanski et al., 2003). Little is known, however, of harm that might come from the use of nutritional supplements or other CAM therapies because adverse event reporting is not mandated for products regulated as foods in the case of supplements and not regulated at all for other types of interventions.

Complementary or alternative treatment use is higher among people with chronic illnesses and special health-care

needs. Surveys of parents of children with ASDs suggest that reasons for CAM use are similar among families of children with ASDs (Hanson et al., 2007; Wong & Smith, 2006). A survey of CAM use in different chronic disorders reported rates of 9% to 70% (Ernst, 1999). Families of children with ASDs attending a specialized clinic for ASD reported rates of 30% to 70% (Hanson et al., 2007; Levy et al., 2003) The reasons given for pursuing therapies outside of the conventional medical and educational recommendations included fear of side effects (of standard medication treatments), perception of CAM treatments as "natural," hope for cure, belief in theories of disease causation that differ from conventional medicine, and the desire to participate in the choice of therapies (Levy & Hyman, 2008). An internet survey of 552 families of children with ASDs reported an average of seven different treatments, with 27% using a special diet and 43% treating their child with supplements (V. A. Green et al., 2006) CAM use has become so widely used that at one clinic, almost one-third of families had instituted nutritional or other CAM interventions purported to aide symptoms of ASDs before the time of official diagnostic evaluation (Levy et al., 2003).

Reasons Families Pursue *Complementary and Alternative Medicine* Therapies

Although genetic factors are important to the etiology of ASDs, there is increasing evidence that environmental factors may either interact with a genetic predisposition or independently lead to symptoms of ASDs (Bello, 2007). Extrapolation of this line of scientific reasoning leads many proponents of CAM to therapies that purport to remove environmental toxins or modify the effect of environmental agents. Another reason CAM therapies have attained popularity is the slow and tedious progress that may accompany traditional educational approaches and the stepwise approach scientists demand to demonstrate effectiveness of interventions. The symptoms of ASDs change over time with developmental progress and are heterogeneous, so it is often difficult to attribute change to any specific intervention or interventions in clinical practice. It may be difficult to determine which intervention, if any, resulted in perceived improvements. In addition, CAM therapies are perceived as safe by their proponents. This belief is promulgated because many interventions are nonprescription (and thus unregulated by the FDA), are perceived as having an absence of side effects or involve manipulation, or other nonbiologic interventions that many people would see as having no potential for adverse effects. A fourth factor supporting CAM use is the desire by families for more control over treatment choice. Choosing treatment options empowers the family at a time that they may feel that they have little control over the course of their child's diagnosis, treatment, or course. Professionals who counsel families about treatments and the future outcome may be pessimistic regarding resolution of the ASDs, and CAM therapies allow families to hope for a cure for their child. CAM therapies for ASDs purport to treat both core symptoms of autism and medical symptoms such as sleep disruption and gastrointestinal distress that families are concerned about. Finally, CAM therapies may be supported and recommended by celebrities and others in the popular press, sometimes using anecdotal testimony, rather than analysis of scientific evidence, to support safety and efficacy. A culture of distrust has evolved where conventional practitioners may be accused of misleading families by not advocating CAM therapies and being dismissive of observations by families regarding the effectiveness of these therapies. Despite (and perhaps because of) this phenomenon, there is an increasing awareness of CAM practices and an increasing number of clinical trials to examine the safety and efficacy of the interventions.

Integrative Medicine, Pluralism, and Agreeing to Disagree

As therapeutic strategies that were initially popularized as complementary and alternative medicine are examined using scientific techniques, they are making their way into conventional practice as integrative medicine. Integrative medicine is defined as relationship-based care that combines conventional and complementary therapies that have scientific evidence of safety and effectiveness to promote health for the child and family (Kemper, Vohra, Walls, the Task Force on Complementary and Alternative, & the Provisional Section on Complementary, 2008). One alternative treatment that has gained the acceptance of conventional medicine and is often covered by insurance is acupuncture for pain management (Sherman et al., 2006). Some interventions popularized as CAM and integrated into conventional practice have been disproven, such as Gingko Biloba for dementia (Birks & Grimley Evans, 2009) and Vitamins C and E for cardiovascular disease prevention (Sesso et al., 2008). Some CAM therapies may actually have harmful effects. A meta-analysis of antioxidant therapy for prevention of gastrointestinal cancers demonstrated that supplementation was not only not helpful but actually increased mortality (Bjelakovic et al., 2008). There is insufficient scientific data to support many currently used and popular CAM therapies related to ASD treatment. There are no long-term data to know how significant alteration in nutrition might affect health in the future. In 2001, the American Academy of Pediatrics published guidelines to support the respectful discussion of therapies that families wish to investigate while keeping the best interests of the safety of the child as the focus of the medical care provider (American Academy of Pediatrics & Committee on Children With Disabilities, 2001). There are contradictory societal presses: support for the role of families in therapeutic decision making and the desire to advocate for the health of the child; the conflict between tolerance of alternative explanations for conventional theories of pathophysiology and the need for evidence-based practice. A pluralist approach allows for the discussion of therapeutic approaches with the understanding that there may not be agreement among scientists, and clinicians supporting evidence-based practices, and proponents of CAM therapies.

How to Evaluate Therapies

The same standard of evidence-based support should apply for all interventions for children with ASDs. Although CAM therapies are often referred to as "unproven," many of the commonly used treatments for symptoms of ASDs also have modest evidence to support their use (Guyatt et al., 2008). Families and primary care providers need to be educated how to evaluate the information that supports any therapeutic intervention they might elect to pursue. Factors to be considered in examining claims for a therapy include study design, whether the sample size was adequate to support the claims, characterization of the participants, use of valid outcome variables, and standardized implementation of the intervention (Guyatt et al., 2008). The use of placebo-controlled study design is important because caregiver observation may be altered unconsciously by the desire for an effect. Although randomized controlled clinical trials may be the most convincing design in evidence-based practice, useful information for hypothesis generation and clinical care can also be obtained from quasi-randomized design, prospective and retrospective cohort studies, open trials, case series, or systematic reviews.

Complementary and Alternative Medicine Therapies for Autism Spectrum Disorders

Examples of CAM used for ASDs will be discussed for each of the four general areas of CAM categorized by NCCAM. Although extensive, this list is not inclusive of all CAM therapies investigated and implemented for the symptoms of ASDs. The text is organized according to conceptual areas within CAM; however, on a practical level, clinicians and families want to know which therapies are safe and which have data to support their use. Table 70-1 summarizes the CAM therapies discussed in this framework based on the current peer-reviewed literature. Some therapies have insufficient evidence to comment on because lack of data is different than data demonstrating lack of effect.

Mind–Body Therapies

This category of treatments includes combinations of treatments that promote health through the interaction between the mind (psychosocial and physiologic factors) and physical symptoms. Some treatments are less structured and may be individually administered (e.g., relaxation or visual imagery), whereas others may require administration or training in a more procedural fashion. Symptoms such as pain, stress, and anxiety may be more amenable to mind–body therapies (MBTs) using techniques that permit relaxation (Astin, 2004). This hypothesis is in need of confirmation in appropriate clinical trials.

Yoga

Yoga encompasses a system of breathing practices, postures, and physical exercises. Specific controlled trials of yoga in children with autism have not been completed, but there are reports of improvement of symptoms of depression (Kemper, Vohra, Walls, the Task Force on Complementary and Alternative, & the Provisional Section on Complementary, 2008) and improved behavior in a small sample of boys with ADHD who participated in yoga sessions who were also treated with medication (Jensen & Kenny, 2004).

Music Therapy

Music therapy may be administered individually or in a group, with the goal of providing an effective medium for nonverbal social exchange. Core features such as eye contact, joint attention, and social reciprocity (e.g., with turn taking) are features of shared music making (Gold, Wigram, & Elefant, 2006). A recent Cochrane review (Gold, Wigram, & Elefant, 2006) included three small studies (n between 4 and 10 subjects) of young boys (age 2–9 years) who received individual music therapy and were compared with a comparison group. The studies described improved gestural and verbal communication skills. It is not clear whether the effects on communicative skills can be generalized to functional use. Kim and colleagues (Kim, Wigram, & Gold, 2008) reported a recent study of the effects of improvisational music therapy on joint attention behaviors in 15 children ages 3 to 5 years. The authors reported improved eye contact duration, turn taking and social approach behaviors in the 10 children who completed the study. This is a promising treatment that is often provided in educational settings, about which more research and data are needed. It is plausible that the imitation, repetition, nonverbal cuing, and use of nonlanguage elements of rhythm and music may render this a plausible therapy (Heaton et al., 2007).

Biologically Based Practices

The CAM therapy most commonly reported by parents are biologically based practices. The Interactive Autism Network (IAN, 2009) reports that more than 50% of the families responding to their online survey reported use of nutritional supplements and almost one-third reported the current use of dietary therapies for treatment of symptoms of autism. Many therapies are used simultaneously. Although little is known regarding effectiveness, less is known regarding the potential for side effects or the effect on conventional medication. Practitioners who advocate biologically based therapies often have claims relative to multiple disorders. They increasingly organize the interventions to fit alternative biologic theories of causation. These theories often extend hypothesis beyond the accepted scientific basis on which they are based.

Table 70–1.
CAM therapies

Treatments	Examples	No Risk and/or Proven to be Effective	Little Risk and/or Possible Benefit	Little Risk and/or No Proven Benefit	Moderate Risk and/or Unclear Benefit and/or No Evidence	High Risk and/or No Benefit an/or Proven Ineffective

Treatments to Decrease Oxidative Stress

Basic to cellular function is the detoxification of oxygen radicals produced when cells use energy in aerobic metabolism. Oxidative phosphorylation in the mitochondria of cells produces reactive oxygen species that the cell must detoxify. If cellular antioxidant functions do not appropriately regulate production of reactive oxygen species and peroxides, damage can occur to DNA regeneration. This can alter gene function or even lead to cell death. Several CAM therapies are promoted to compensate for suggested abnormalities in metabolic pathways related to the regulation of reactive oxygen species. James et al. (S. Jill James et al., 2004; S. J. James et al., 2006) have reported the observation that children with autism have elevated levels of intermediate compounds in the pathway metabolizing S-adenylhomocysteine (SAH) to adenosine and homocysteine. If adenosine is not removed, then it will inhibit methyltransferase reactions necessary for DNA replication and neurotransmitter production. The SAH is formed from methionine. SAH is transulfurated in another pathway to produce cysteine and glutathione, the primary intracellular antioxidant. The observation of abnormal levels of each of these

compounds in children with ASDs compared to controls has led to the hypothesis that there is a primary abnormality in metabolic pathways dealing with oxidative stress in children with ASDs. Several biologic interventions advocated as CAM therapies are intended to address this observation. The progression from biochemical observation to evidence-based treatment requires appropriate clinical trials.

Vitamin B$_{12}$

Cobalamins are important for nucleic acid metabolism, methyl transfer, blood cell formation, and myelin synthesis and repair. The natural sources of methylcobalamin (Vitamin B$_{12}$) in the diet include dairy products, meat, and eggs. Folinic acid is typically rapidly reduced to tetrahydrofolate and functions as a folic acid derivative. It is often used as a supplement with cancer chemotherapeutic agents that interfere with the enzymes necessary to metabolize other forms of folate. Subcutaneous administration of Vitamin B$_{12}$ (75 micrograms/kg twice weekly) with 400 micrograms of folinic acid twice daily over 3 months has been reported to significantly increase the cysteine, cysteinylglycine, and glutathione concentrations in 40 children with autism while decreasing the oxidized disulfide form of glutathione (S. J. James et al., 2009). The levels of these transmethylation/transsulfuration metabolites and the glutathione redox status were lower in children with ASDs than control children at baseline and, although increased, remained lower than controls after treatment. Based on the initial observation of this finding (S. Jill James et al., 2004; S. J. James et al., 2006), Vitamin B$_{12}$ administered as an injection, nasal spray, or orally is a popular complementary therapy. James et al. (2004) reported subjective improvement in an open trial. However, the preliminary data on 14 subjects in one small double-blind, placebo-controlled crossover clinical trial did not document behavioral improvement using standard outcome measures (Deprey, 2006). Vitamin B$_{12}$ has no published tolerable upper limit, the amount at which side effects are probable. Folinic acid, on the other hand, is available only by prescription at doses greater than 1 mg because of concerns for abdominal distention, nausea, sleep disturbance, irritability, psychomotor excitation, and increased seizure activity. High doses can also mask a B$_{12}$ deficiency. Dietary sources of *folic acid* which is metabolized to tetrahydrafolate, include leafy green vegetables, fruits, and legumes and peas as well as breads and cereals supplemented with folic acid. The biochemical observation of altered oxidative stress intermediates, and improvement in laboratory values with B$_{12}$ and folinic acid supplementation requires replication and further study to determine if there is an observable therapeutic effect.

Vitamin C

In addition to being an antioxidant, Vitamin C has a role in promoting immune function and the intestinal absorption of iron and potentially affects dopamine binding. It has been evaluated as a treatment for symptoms of ASDs in 18 students in a residential school in a double-blind, placebo-controlled crossover trial. At high doses (8 g/70 kg/day), statistically significant improvements in sensorimotor and stereotyped behaviors were demonstrated (Dolske et al., 1993). This observation has not been replicated to date. Side effects at high doses may include gastrointestinal discomfort, acidification of the urine, or possible negative impact on physiologic antioxidant functions.

Hyperbaric Oxygen Therapy

Increasing ambient air pressure at the same time that oxygen concentration is increased (hyperbaric oxygen therapy [HBOT]) is a conventional treatment for carbon monoxide poisoning, divers who ascend too rapidly (the Bends), and to augment wound healing. It has been examined for the treatment of disorders that are associated with prenatal hypoxic brain injury, such as cerebral palsy. A well-designed trial was unable to identify benefit from HBOT compared to a sham procedure in children with cerebral palsy (Collet et al., 2001). The hypothesis that children with ASDs have areas of hypoxic brain injury stems from single proton emission tomography (SPECT) data demonstrating areas of decreased blood flow in individuals with ASDs (Ohnishi et al., 2000). Although there are children with ASDs and cerebral palsy who experienced hypoxic brain injury, hypoxic brain injury is not a cause of idiopathic autism. A secondary hypothesis suggests that there can be an improvement in oxidative stress by upregulation of enzyme systems related to superoxide dismutase and glutathione peroxidase and increased lipid peroxidation with HBOT treatment (Rossignol et al., 2007). Rossignol and colleagues performed an open trial of HBOT with subjective benefit in 18 participants with ASDs who underwent an average of 40 sessions at either 1.5 or 1.3 atmospheres of pressure and either 100% or 24% oxygen (Rossignol et al., 2007). Blood drawn before the first and after the last session did not identify worsening of oxidative stress in terms of plasma oxidized glutathione levels but did note significantly decreased C reactive protein, which might suggest diminished inflammation. The parents subjectively reported improvement. One child needed alteration of the regimen because of ear pain. The risk for seizures appears to be low. Other potential side effects not observed in this trial include stress with the procedure and the risks inherent in isolating an individual in a chamber. Two double-blind, placebo-controlled trials of HBOT in children with ASDs have been completed with conflicting results. Rossignol et al. (2009) reported improvement in analysis of within-group differences of children with ASDs randomized to HBOT or sham therapy. When the groups were compared, there were no differences on the Aberrant Behavior Checklist (Rossignol et al., 2009). Greenspesheh et al. (2009) found no improvement in a study of children, all of whom had ABA therapy, using similar HBOT procedures. They used valid outcome measures that were corroborated by direct observation data (Greenspesheh et al., 2009). Although ear pain, exacerbation of seizures, and anxiety with the procedure appear to be

infrequent, a significant side effect of controversial CAM therapies that is particularly relevant for HBOT is cost. A course of 40 sessions can be $20,000 or more.

Heavy Metal Toxicity

A second but related biologic hypothesis addresses the concern that environmental toxicants from vaccines or other sources lead to the neurologic insult in ASDs. The proposed mechanism includes both disruption of immune function and oxidative stress.

Chelation

Chelating agents bind to heavy metals in the body, such as lead and mercury, and permit elimination of these compounds through the kidney. Chelation is medically indicated in documented occupational and environmental exposures. In pediatric use, this therapy is most commonly indicated for the treatment of elevated lead levels from environmental exposure to lead paint in dust and in older buildings. Although not substantiated by epidemiologic data, there remains a popular belief that children with ASDs could have had neurologic injury from exposure to heavy metals other than lead. This is suggested to be via ethylmercury preservatives and aluminum adjuvants in vaccines and other environmental sources. Proponents of this theory report that individuals with ASDs have an abnormality in the capacity for metal excretion that leads to increased tissue concentrations (Holmes, Blaxill, & Haley, 2003) or have altered metal excretion because of altered gut flora (Adams et al., 2007). Elevated levels of mercury in baby teeth have been reported in children with ASDs. The authors relate this finding to the hypothesis of altered excretion of mercury in children with ASDs (Adams et al., 2007). However, plasma levels are not increased in infants after immunizations preserved with the ethylmercury derivative Thimerosal, suggesting rapid clearance by excretion (Pichichero et al., 2008). Thimerosal has not been used as a preservative in single-use pediatric vaccines since 2001, but environmental sources of elemental mercury include air pollution, and sources of methyl mercury include fish ingestion. Bernard et al. (2001) proposed an etiologic link with mercury exposure and autism. The symptoms of neurologic damage are not convergent with those of autism (Nelson & Bauman, 2003). Heavy metals, if present in an uncomplexed form, may donate electrons to create reactive oxygen species, leading to increased oxidative stress. Urinary excretion of porphyrins was reported to be elevated in children with ASDs compared to siblings with subsequent decrease after chelation therapy (Geier & Geier, 2007). Urinary porphyrins reflect disruption in one potential step in heavy metal excess affecting heme metabolism. Further studies are indicated to explain this observation that includes nutritional and medical characterization of participants. Use of a chelating agent to mobilize mercury as a means of determining the presence of toxicity is not supported by data from studies in unaffected volunteers (Archbold, McGuckin, & Campbell, 2004). Oral agents used for chelation of known heavy metal toxicity include dimercaptosuccinic acid (DMSA) and 2,3-dimercapto-1-propanesulfonic acid (DMPS). Although DMSA has clinical utility in lead poisoning and other heavy-metal toxicity, Na EDTA results in excessive elimination of calcium and has no current clinical indications (Brownet al., 2006). One death of a child with autism has been ascribed to chelation with Na EDTA. The only FDA-approved agent for intravenous chelation of lead is Disodium EDTA Calcium. There are no published randomized clinical trials of chelation for symptoms of ASDs. In rats, it was demonstrated that animals that did not have elevated lead levels had lasting cognitive and affective dysfunction after chelation with succimer, whereas improvement was identified in animals with elevated lead levels (Stangle et al., 2007). A real risk for depletion of iron, calcium, and other metals necessary for routine cellular function exists with chelation treatment. Although proponents often prescribe minerals and other supplements in conjunction with oral, rectal, or topical chelating agents, the efficacy of chelation is unknown and the potential risks great. The unregulated and medically unmonitored use of over-the-counter topical, oral, and rectal chelating agents has never been studied and may be dangerous. Intravenous chelation for symptoms of ASDs is costly and not covered by insurance. The real risk for side effects necessitates medical monitoring if this popular CAM therapy is pursued. There is no evidence in the peer-reviewed literature to support the clinical use of chelation for symptoms of ASDs at this time.

Gastrointestinal

There are several hypotheses regarding the role of intestinal function in the etiology of ASDs or occurrence of symptoms related to discomfort.

Secretin

Secretin is a peptide produced in the pancreas and released into the small intestine to enhance intestinal motility. Secretin receptors have been identified in the brain with potential roles in brain development (Chu, Yung, & Chow, 2006). The popularity of secretin began with a case series of three children with ASDs who were subjectively reported to have improved symptoms after receiving intravenous secretin during endoscopy to evaluate pancreatic function. This report and the resultant publicity led to widespread treatment of children with ASDs with intravenous secretin. Clinical trials ultimately studied more than 600 children with ASDs. None of these trials demonstrated clinical benefit for the core symptoms of ASDs or demonstrated clinical benefit (Williams, Wray, & Wheeler, 2005). Proponents of secretin treatment still maintain that a subgroup of children with GI symptoms may derive benefit from it, although the evidence from well-designed clinical trials overwhelmingly negates claims of clinical effect. The placebo effect may be very potent when there is hope for

symptomatic response (Sandler, 2005). Side effects include decreased intestinal motility and the stress and cost of the infusion. Clinical trials data resoundingly refute the use of intravenous, sublingual, or transcutaneous secretin for symptoms of ASDs.

Dietary Intervention

Green et al. (2006) report that almost one-fourth of the respondents to their internet survey were using specialized diets for their children with ASDs. The IAN (2009) reported that almost one-third of their sample reported current use of therapeutic diets for symptoms of ASDs. The most popular therapeutic diet at this time is the gluten-free and casein-free (GFCF) diet. This diet is based on the hypothesis that people with ASDs have a "leaky gut" that permits increased absorption of gluten- and casein-related opiate peptides that function as opioids in the central nervous system and produce symptoms common to autism and opiate exposure (Christison & Ivany, 2006). Increased urinary peptide peaks in the areas expected for caseomorphin and gluteomorphin initially supported this hypothesis. However, recent studies using mass spectroscopy did not identify opioid compounds in the urine to support this hypothesis (Cass et al., 2008). The most recent Cochrane review of the efficacy of the GFCF diet (Millward et al., 2008) reported on two trials with adequate scientific methodology. A single-blind trial compared 10 children with ASDs randomly assigned to a GFCF diet in the community to 10 who were not treated with diet (Knivsberg et al., 2002). General improvements in symptoms related to autism in these subjects suggest the need for further study; however, this study did not examine concurrent therapies or nutrition. Elder et al. (2007) reported a double-blind, placebo-controlled crossover trial in 15 children with ASDs. No behavioral effect could be documented using the Childhood Autism Rating Scale. The nutritional effects of eliminating dairy products may include decreased calcium and Vitamin D intake (Hediger et al., 2007; Johnson et al., 2008).* Risk includes decreased bone density (Herndon et al., 2009). Attention to general nutritional needs is important if a family elects a trial of a restricted diet. Additional studies to examine safety and efficacy are indicated, given the popularity of this intervention and the common use of nutritional supplements in an attempt to compensate for dietary restriction.

Yeast Overgrowth

The hypothesis that yeast overgrowth in the intestine occurs in children with ASDs has resulted in several therapies. Although no excess of candida colonization has been documented by endoscopy in series of children with ASDs (Horvath et al., 1999; Wakefield et al., 2000), there has been one case report of increased urinary organic acids attributed to yeast overgrowth (Shaw, Kassen, & Chaves, 1995). The subjects of the case report had an atypical presentation for idiopathic autism with ataxia and a waxing and waning course. Several approaches are used

by proponents of this theory to address yeast production such as decreasing sugar in the diet and treatment with probiotics to alter the intestinal flora. Other approaches are used by proponents of this theory to eliminate yeast already in the intestine, including prescription of the medications nystatin and diflucan. Side effects of this may include altering gut flora to select for resistant strains of yeast and, for diflucan, hepatotoxicity. There are no clinical trials in the literature to support or guide the use of these treatments. There is no biologic basis to support the underlying hypothesis at this time.

Dysbiosis

Alteration of intestinal immune function and gut flora are the basis of the hypothesis that pathologic bacterial species either produce toxins or act in some other way to result in symptoms of ASDs. Finegold et al. (2002) reported different clostridial species in the stool, stomach, and duodena of children with ASDs compared to controls. Bowel inflammation was investigated using two biomarkers: rectal nitrous oxide and fecal calprotectin (Fernell, Fagerberg, & Hellstrom, 2007). Only one (a child who had a history of *C. difficile* infection) of 24 consecutive patients with ASDs studied had elevation of both markers, suggesting that bowel inflammation is infrequent in children with ASDs. A trial of vancomycin was reported to result in subjective improvement in a group of children with ASDs (Sandler et al., 2000). The subjective improvements did not persist. Vancomycin has significant potential side effects when used orally, including pseudomembranous colitis and selection for resistant species of bacteria. In many hospitals, it can only be prescribed after an infectious disease consultation. Off-label use this antibiotic for symptoms of ASDs may contribute to the community selection of bacteria unresponsive to available antibiotics.

Inflammation

Immune and auto-immune phenomena are being investigated by conventional scientists related to both the neurobiology and GI pathology of ASDs. Several complementary therapies in addition to antibiotics and antiyeast agents are purported to affect immune function, including chelation and omega-3 fatty acids. The immune system uses production of reactive oxygen species as part of the mechanism to kill pathogens. Therapies addressing immune-mediated disorders include the approach of replacement of components of the immune system, treatment with interferon to enhance the body's ability to produce an immune response to a known antigen, and the use of anti-infective medications.

IV-IG

Popular interest in infusion of IvIG for symptoms of ASDs followed an initial report of an open trial of pooled human serum immunoglobins to enhance general immune function in children with ASDs, whose authors reported subjective

improvement in the participants (Gupta, Aggarwal, & Heads, 1996). Other investigators using more specific clinical trial methodologies have not confirmed the initial positive reports (DelGiudice-Asch et al., 1999; Plioplys, 1998). Autism is not an indication for IvIG administration. Although there is always a small risk in pooled plasma products, mild side effects such as fever and headache are not infrequent. Less common but significant side effects include aseptic meningitis, thrombotic events, and altered renal function. Common immunologic disorders such as atopy, asthma, and food allergy have not been documented to be more common in children with ASDs. Examination of specific alterations in immune function that might affect neurologic development is an active area of current research (Jyonouchi et al., 2005) and is addressing a neurobiologic question related to etiology of altered brain development

Antiviral Agents

Chess (1971) made the observation that children exposed to the rubella virus *in utero* had an increased risk for ASDs. In addition, there are cases of ASDs associated with herpes simplex encephalitis and cytomegalovirus infection. Prenatal bornavirus infection and prenatal maternal influenza infection alter behavior in mice without evidence of a conventional inflammatory response in brain, suggesting that prenatal infection of the mother might result in an immune response that alters fetal brain development (Libbey et al., 2005). In combination with neuropathologic findings of neuroinflammation in isolated brain samples (Vargas et al., 2005), there has been interest by some CAM providers in off-label treatment of children with ASDs with antiviral agents. No clinical trials have been published to judge safety or efficacy of this practice. Side effects of antiviral agents used off label to treat neuroinflammation in children with ASDs include headache, nausea, and abdominal pain. Renal complications can be minimized with adequate hydration. As with antibacterial agents, community use may result in the emergence of viruses with drug resistance. Therefore, in the absence of data to support their use, the public health recommendation would not support off-label use of these agents.

Other Neurobiologic Processes

Because vitamins and herbal products contain ingredients that affect central nervous system function, there is significant interest among families to manage symptoms of ASDs with products that they perceive as safe because they are available over the counter.

Melatonin

As discussed in Chapter 26, sleep disturbances are common among individuals with ASDs. Preliminary studies suggest that children with ASDs may have altered production or release of the hormone melatonin (Tordjman et al., 2005) that is produced by the pineal gland to regulate the sleep–wake cycle. Open-label studies report that treatment with 0.75 to 6 mg of melatonin prior to bedtime improves both sleep-onset and night wakings in children and adolescents with ASDs (Andersen et al., 2008). Observed side effects of melatonin include morning sleepiness and enuresis. No increase in seizures was reported. Melatonin appears to be a safe supplement with a physiologically sound explanation for proposed sleep effect that is currently being evaluated in controlled trials.

Omega-3 Fatty Acids

Omega-3 fatty acids—particularly the long-chain fatty acids eicosapentaenoic acid (EPA) and docosahexaenoic acid (DHA)—have been investigated as treatments for inattention, obsessive compulsive disorder, and other neurologic and psychiatric disorders (Ramakrishnan et al., 2009). Western diets are typically low in this nutrient found in fish and vegetable sources such as flax seeds. Although supplementation has been promoted by CAM providers as a treatment in ASDs to correct dietary deficiency, it is also hypothesized to improve cell membrane fluidity and function, alter neurotransmitter binding, and alter cytokine production to modify inflammatory response. A small double-blind trial in 8 children demonstrated significant improvement in stereotyped behaviors at a dose of 1500 mg/day (Amminger et al., 2007). An open trial in 19 adults with ASDs did not lead to behavioral improvement (Politi et al., 2009). Randomized clinical trials are ongoing to evaluate the effect of treatment. Known side effects are mild and include loose stools, decreased appetite, and aftertaste.

Vitamins and Nutritional Supplements

Vitamins, used as single agents or as combinations, are among the most commonly used complementary therapies for symptoms of ASDs. Green et al. (2006) reported supplement use in 43% of their sample. Various supplements are given to children with ASDs in hopes of enhancing function like Vitamins C and E, minerals such as zinc and selenium, and nutritional supplements such as trimethylglycine (TMG). One of the earliest CAM therapies studied in clinical trials for symptoms for ASDs remains one of the most popular. Vitamin B_6 (pyridoxine) may enhance transulfuration of methionine to cysteine and glutathione; modulate enzyme systems responsible for production of neurotransmitters such as GABA, dopamine, and serotonin; and is involved with immune function because of its role in protein metabolism. Studies to date are inconclusive as to the benefit given the small sample sizes and problems with study design (Nye & Brice, 2005). CAM providers administer this to children with ASDs at high doses with magnesium to decrease hyperactivity and enhance language. Vitamin B_6 is found in a wide variety of foods, including fortified cereals, meat, poultry, fish, and some fruits and vegetables. Potential side effects of excess B_6 include numbness and tingling of the hands as manifestation of a peripheral neuropathy. Magnesium is found in nuts, legumes, whole grains, and green vegetables such as spinach. Excess intake of magnesium

may result in decreased appetite, nausea, diarrhea, low blood pressure, cardiac arrhythmias, and changes in mental status. The clinical trials to date do not support recommendation of B_6/magnesium supplementation beyond the RDA.

Clinical trials typically attempt to understand the effect of discrete interventions. Because families of children with ASDs employ seven interventions on average (Green et al., 2006), effectiveness studies will need to examine the interaction of multiple treatment approaches used simultaneously. Adams et al. (Adams & Holloway, 2004) reported subjective improvement in sleep and gastrointestinal function in 20 children with ASDs treated with a multivitamin combination compared to controls. Further research is necessary to examine the safety and efficacy of supplements used concurrently at doses above the Recommended Dietary Allowance. Research in other disorders has cautioned that excess supplementation may be harmful rather than helpful (Bjelakovic et al., 2008). There can be too much of a good thing. For example, it is known that chronic excess intake of Vitamin A can result in fatigue, GI symptoms, and irritability. Excess supplementation with Vitamin E over time is associated with a general increase in mortality and congestive heart failure in adults and is associated with fatigue and GI symptoms. It is difficult to study the effects of nutrient excess as noted previously because the effects occur over long periods of time, the supplements are not regulated so the specific dosage may not be either consistent or known, and multiple agents are often used in conjunction with traditional medications.

Manipulative and Body-Based Therapies

Chiropractic Care

Chiropractic care is the most frequently provided CAM practice in the general population, with children making up 11% of patient visits (Lee, Li, & Kemper, 2000). This care focuses on spinal alignment and body manipulation and its relationship to health (Kemper et al., 2008). The majority of adults who pursue chiropractic care do so for pain or musculoskeletal complaints, with some suggestion of subjective or objective improvement (Kaptchuk & Eisenberg, 1998). A recent review of chiropractic care for non-musculoskeletal conditions (Hawk et al., 2007) summarized results of randomized controlled trials and/or systematic reviews of the efficacy of treatment for medical conditions such as asthma, hypertension, infantile colic, otitis media, and others. Many of the studies suffered from methodologic difficulties and reported some subjective, but few objective, benefits. Similar data about chiropractic treatment of autism are not available. Although very rare, adverse results include delay in appropriate medical care and rare adverse events such as spinal fluid leak (Mathews et al., 2006) or vertebral artery dissection (Chen et al., 2006). Chiropractic care, although not evidence-based or rooted in current scientific understanding

of pathophysiology of disease, is covered by most health insurances.

Massage and Therapeutic Touch

Massage is another type of biomechanical treatment that is administered by massage therapists or parents who have been instructed in the techniques. The goals of treatment include addressing sleep difficulties, sensory abnormalities (hyper and hyposensitivity), and improving attention (Escalona et al., 2001). Massage has been demonstrated to be helpful in preterm infants, facilitating growth and earlier discharge (Field, 2002). Hypothesized mechanisms of action include alterations in epinephrine, norepinephrine, serotonin, and cortisol levels (Field et al., 2005) or alteration in vagal tone. Escalona and colleagues (2001) completed a randomized controlled trial of massage versus attention (reading a book to the child) in 20 children with ASDs ages 3 to 6 years. Children randomized to massage therapy had less stereotypic behavior, improved social relatedness, and improved sleep. Further work is needed regarding specific physiologic mechanisms of action and replication of these results using more rigorous study design. No untoward side effects have been reported, and parents reported a feeling of closeness with the children (Cullen, Barlow, & Cushway, 2005). The cost of therapy, time for visits, and direction of resources away from other types of therapies are the potential side effects.

Craniosacral Manipulation

Craniosacral manipulation is another mechanical treatment, which proposes manipulation of bones of the skull to correct the flow of cerebrospinal fluid and promote health. There is no evidence that external manipulation results in alteration of spinal fluid dynamics. Craniosacral manipulation is administered by certain osteopathic physicians, physical therapists, massage therapists, chiropractors, and others. A systematic review of available evidence-based studies revealed few studies, all of which had methodologic difficulties (C. Green et al., 1999) and no support for efficacy for treatment of symptoms of autism beyond the massage component.

Auditory Integration

Auditory integration training is an environmentally administered treatment that was introduced to the United States in the early 1990s, around the time of publication of a book in the popular press describing a "cure" of ASDs using this methodology (Council on Children with Disabilities, 1998). The hypothesis behind this treatment asserts that abnormal sensitivity to certain frequencies of sound are associated with behavior and learning problems (Sinha, et al., 2006) and that training sessions with electronically modified music will improve or cure symptoms. No physiologic mechanism of action has been proposed. A systematic Cochrane review of studies of AIT (Sinha et al., 2004) reported no difference

between control and treatment conditions in the larger, more robust studies but suggested improvement in less methodologically sound studies. Potential side effects include exposure to high-output levels of sound and the cost to families in time and money for the therapy.

Vagus Nerve Stimulation

Vagus nerve stimulation is an increasingly accepted treatment for management of intractable epilepsy, despite the fact that the specific mechanism for effectiveness is not known. To administer the treatment, a stimulation system is implanted under general anesthesia. Daniellsson and colleagues (2008) described a case series of 8 children with epilepsy and autism who underwent treatment with vagal stimulation for their intractable epilepsy. They had extensive pre- and post-neuropsychological evaluations. In this open-label pilot study, no child had diminished seizure frequency. Three showed minor improvement in general functioning with no positive cognitive effects. Potential side effects are significant, related to need for general anesthesia and the unknown long-term impact of implantation of the device.

Energy Medicine

Qigong

Qigong is a form of ancient Chinese medical practice used to enhance health with energy realignment of the body with breathing and movement exercises. It has been compared to a moving form of meditation. It is considered a bioenergentic therapy because the technique addresses management of "qi" or specific aspects of energy associated with the body. Silva and colleagues (Silva & Cignolini, 2005; Silva et al., 2007) described several observational case series of children who received medical qigong massage. The authors reported decreased autistic behaviors as well as increased language and sensory function, but methodologic problems include lack of appropriate controls and unblinded analysis of treatment effects.

Reiki

Reiki is a biofield therapy that purportedly affects energy fields that surround and penetrate the human body (Kemper et al., 2008). Reiki grew out of a Japanese tradition where the healer places hands on the subject's body, thus transmitting a healing force (McLean & Kemper, 2006). There are no studies evaluating its effectiveness in treating children with autism.

The Business of Therapy

It has been documented that the annual cost of health care for children with autism is more than seven times greater than

children with typical development ($6132 vs. $860) (Liptak, Stuart, & Auinger, 2006). These calculations do not include the significant expense that families of children with autism spend out of pocket on CAM therapies. More than $34 billion dollars are spent annually on CAM therapies in the United States. Cost, however, includes more than the dollar value of the product purchased. It factors in all of the direct costs of the intervention (product, practitioner fees, diagnostic costs, equipment and facility fees), additional nondirect costs (transportation, parents time off from work), indirect costs (parental time off related to the intervention separate from the direct visit, childcare for siblings, lost leisure time), and additional intangible personal costs (discomfort related to the procedures, disappointment if not successful) (Herman, Craig, & Caspi, 2005). Analysis of the cost effectiveness of CAM therapies includes economic, humanistic, and clinical outcomes (Herman, Craig, & Caspi, 2005). Humanistic outcomes are less easily quantifiable than clinical outcome measures and include quality of life, autonomy, safety, comfort, and sense of well-being. Few studies on the cost-effectiveness of CAM have been published. This may be in part because some practitioners are not motivated to examine the cost of therapy. It has also been suggested that demonstration of effectiveness might result in incorporation of these interventions into conventional care and diminish the autonomy of CAM practice (Kelner et al., 2002). The process of CAM itself may have therapeutic benefit in terms of more difficult-to-measure outcomes such as patient empowerment and sense of well-being that are not easily captured in cost–benefit analyses (Herman, Craig, & Caspi, 2005).

The number of uninsured Americans increased from 20% to 23% between 1988 and 1999 and was projected to approach 30% by 2009 (Pagan & Pauly, 2005). These authors reported an increase in CAM use among adults who had decreased access to conventional care because of cost. By extension, CAM use among families of children with ASDs might be increased by difficulty in accessing effective behavioral, and educational therapies. Similarly, emotional or financial investment in CAM therapies may postpone or limit involvement with potentially beneficial therapies.

Research Needs

Families and clinicians need unbiased, well-designed clinical trials that can address both safety and efficacy to inform treatment decisions. This is challenging, given the imperative to treat children during the potential therapeutic window for response, although well-designed studies may take years to be productive of informative results. As with any new pharmacologic or educational intervention, the data from case series and open trials provide information regarding the promise of a therapy that may merit study and may be used to inform sample size determination, choice of valid outcome measures, and study design. Clinical trials are expensive and typically

require assessment of each treatment component individually. Commonly used CAM protocols may implement multiple interventions simultaneously. To advance knowledge regarding CAM treatments requires investigation of scientific theories hypothesized as responsible for desired therapeutic effect, commitment of funding for well-designed clinical trials, and education of both families and practitioners about appropriate scientific study design and interpretation of data. A collaborative approach by proponents of CAM and conventional scientists to examine the science and practice of CAM therapy will ultimately benefit the children affected by ASDs and move some therapies from CAM to conventional and others from CAM to history.

Challenges and Future Directions

The challenge to the conventional practitioner is the popular acceptance of many CAM therapies without the evidence that would support their use. This results in mistrust of the medical and scientific establishment by families who find hope in the claims made. It places people with ASDs at potential risk for unanticipated side effects from unregulated therapies. An additional challenge is the defense of conventional therapies that are not supported by the strength of evidence either. To be able to advise patients regarding the safety and efficacy of intervention they might elect, all therapies used for children with ASDs should be examined using the same criteria.

It is plausible that some current therapies considered to be CAM will be demonstrated to have biologic plausibility and will be proven to be effective for specific symptoms of ASDs. It is also plausible that long-term sequelae of CAM intervention not currently thought to have side effects might be identified. Coincident with scientific study of CAM, there needs to be educational efforts for consumers so that family empowerment to participate in the choices for care for their children is done in an informed fashion.

The mGluR Theory of Fragile X Syndrome

Points of Interest

- Fragile X Syndrome (FXS) is a single-gene disorder associated with mental retardation and autism that is caused by loss of expression of the fragile X mental retardation protein (FMRP).
- The "mGluR theory of fragile X" postulates that FMRP and group I metabotropic glutamate receptors (mGluRs) act in functional opposition to regulate protein synthesis at the synapse, with mGluRs activating and FMRP repressing translation of FMRP target mRNAs.
- Antagonism of mGluRs is expected to reverse many of the phenotypes resulting from the loss of FMRP and may thus provide a valuable strategy for the treatment of FXS and other autism spectrum disorders (ASDs) linked to excessive synaptic protein synthesis.
- Preclinical studies in animal models of FXS have shown that genetic or pharmacological antagonism of mGluR5 signaling can reverse many of the structural, physiological, and behavioral phenotypes related to FXS.
- Clinical studies are underway to test the efficacy of mGluR5 antagonists in treating patients with FXS.

Synaptic plasticity is an alteration in the strength of synaptic connections between neurons that is believed to be important for long-term information storage in the brain. Several forms of synaptic plasticity exist, including **long-term potentiation** (**LTP**), a persistent enhancement of synaptic strength, and **long-term depression** (**LTD**), a persistent decrease in synaptic strength. Many different molecular mechanisms are thought to contribute to synaptic plasticity, one of which is the **internalization**, or **endocytosis**, of a class of glutamate receptors known as **AMPA receptors**. The removal of these receptors from the synapse results in a decrease in glutamatergic transmission that may be particularly important for metabotropic glutamate receptor-induced LTD, or **mGluR-LTD**.

Synaptic protein synthesis: also known as **translation**, is the process by which cells generate proteins based on genetic information encoded in the form of messenger RNA, or **mRNA**. Protein synthesis is carried out by large structures called **ribosomes**, which can cluster on mRNAs to form **polyribosomes**. In neurons, the bulk of protein synthesis occurs in the cell body, but certain mRNAs can be translated locally at synapses to generate protein products that are likely to be involved in synapse-specific structural and functional plasticity. These mRNAs are transported into dendrites and stored at synapses in the form of RNA-protein complexes known as **ribonucleoprotein particles** or **RNA granules**. Translation of individual mRNAs can be regulated by proteins that act as **translational activators** or **translational repressors**, and these proteins, in turn, can be regulated by processes such as **phosphorylation** and **dephosphorylation** in response to extracellular signals.

***Fmr1* knockout mice:** Given the difficulty in obtaining information at the molecular and cellular level from human FXS patients, the vast majority of the knowledge summarized in this chapter has been gained from studies conducted in animal models of FXS. The most widely used animal model in fragile X research is an ***Fmr1* knockout mouse**, or ***Fmr1* KO**, that was generated by disrupting exon 5 of the mouse *Fmr1* gene, resulting in loss of expression of the FMRP protein (The Dutch-Belgian Fragile X Consortium et al., 1994).

Introduction

Fragile X Syndrome (FXS) is the most prevalent form of inherited mental retardation, characterized by cognitive and behavioral deficits that include developmental delay, attention

deficits and hyperactivity, impulsivity, aggression, sensory hypersensitivity and withdrawal from touch, abnormalities in language and communication, social anxiety, and stereotyped behaviors and interests (Penagarikano et al., 2007; Reiss & Hall, 2007). Approximately 18% to 33% of individuals with FXS are also diagnosed with autism, and the prevalence of FXS in autism is 2% to 4% (Belmonte & Bourgeron, 2006; Zafeiriou et al., 2007), making it one of the most common single-gene disorders associated with autism. Based on this overlap in phenotypes, it has been proposed that there may also be an overlap in the neural mechanisms underlying the two disorders and that understanding how the single-gene alteration in FXS results in autistic-like behaviors may provide valuable insights into potential targets for the research on idiopathic autism (Belmonte & Bourgeron, 2006).

The "mGluR theory of fragile X syndrome" provides a useful example of how basic research into the molecular consequences of such single-gene alterations may produce insights that can be directly translated into therapeutic strategies (Bear et al., 2004). It originated from three basic findings: *(1)* the discovery that activation of a class of neuronal receptors known as metabotropic glutamate receptors, or mGluRs, resulted in the synthesis of new proteins at the synapse (Weiler et al., 1997); *(2)* the subsequent observation that a form of mGluR-induced synaptic plasticity, known as mGluR-dependent long-term depression (LTD), was protein synthesis-dependent (Huber et al., 2000); and *(3)* LTD was exaggerated in a mouse model of FXS (Huber et al., 2002). Together, these findings suggested that FMRP may be a crucial regulator of mGluR-mediated protein synthesis at the synapse and that in the absence of FMRP, mGluR-dependent synaptic maturation and plasticity may be disrupted, resulting in some or all of the phenotypes observed in FXS (Bear et al., 2004). Based on this model, it was proposed that by pharmacologically targeting mGluR function, it might be possible to reverse these phenotypes and develop a treatment strategy for FXS. Since its introduction in 2002, the mGluR theory of fragile X has been extensively investigated, and the results emerging from this research continue to support the notion that mGluRs and their downstream effectors may be promising therapeutic targets for the treatment of FXS.

In this chapter, we first briefly introduce FMRP and metabotropic glutamate receptors. Subsequently, we review the current state of knowledge on the mGluR theory at the level of basic, preclinical, and clinical research. Finally, we discuss the questions that remain to be addressed to ensure that pharmacological interventions based on the mGluR theory have the greatest possible chance of succeeding in clinical trials and providing safe and effective treatments for patients with FXS.

The Fragile X Mental Retardation Protein

Fragile X Syndrome received its name from the observation that individuals with this disorder show a characteristic constriction, or fragile site, at the end of the long arm of chromosome X (Penagarikano et al., 2007). This fragile site was found to result from a CGG trinucleotide repeat expansion located in the first exon of a gene subsequently named *FMR1*, or fragile X mental retardation gene 1 (Verkerk et al., 1991). The triplet repeat expansion causes hypermethylation of the repeat itself and of the surrounding DNA sequence, leading to transcriptional silencing of *FMR1* and hence loss of the *FMR1* gene product FMRP, or fragile X mental retardation protein. Since the initial characterization of this protein 15 years ago (Verheij et al., 1993; Devys et al., 1993), extensive research has focused on identifying its cellular function and the mechanisms by which its disruption results in mental retardation and autism. In this section, we summarize the current understanding of FMRP function and its role in synaptic plasticity and behavior.

Fragile X Mental Retardation Protein Structure and Function

FMRP is expressed widely throughout the body, but it is particularly enriched in the brain and testes. Within the brain, FMRP is expressed almost exclusively in neurons, localizing both to the cell body and to dendrites and synapses (Feng et al., 1997; Christie et al., 2009). Structural analysis of FMRP revealed that it is an mRNA binding protein, containing several characteristic RNA binding motifs, including two KH domains and an RGG box (Siomi et al., 1993; Ashley, Jr. et al., 1993). A comprehensive list of mRNAs targeted by FMRP has yet to be established, but it was estimated that FMRP binds to approximately 4% of all mRNAs present in the brain (Ashley Jr. et al., 1993), and a number of candidates have been identified that will be discussed in more detail in the section on target proteins regulated by FMRP and mGluR signaling.

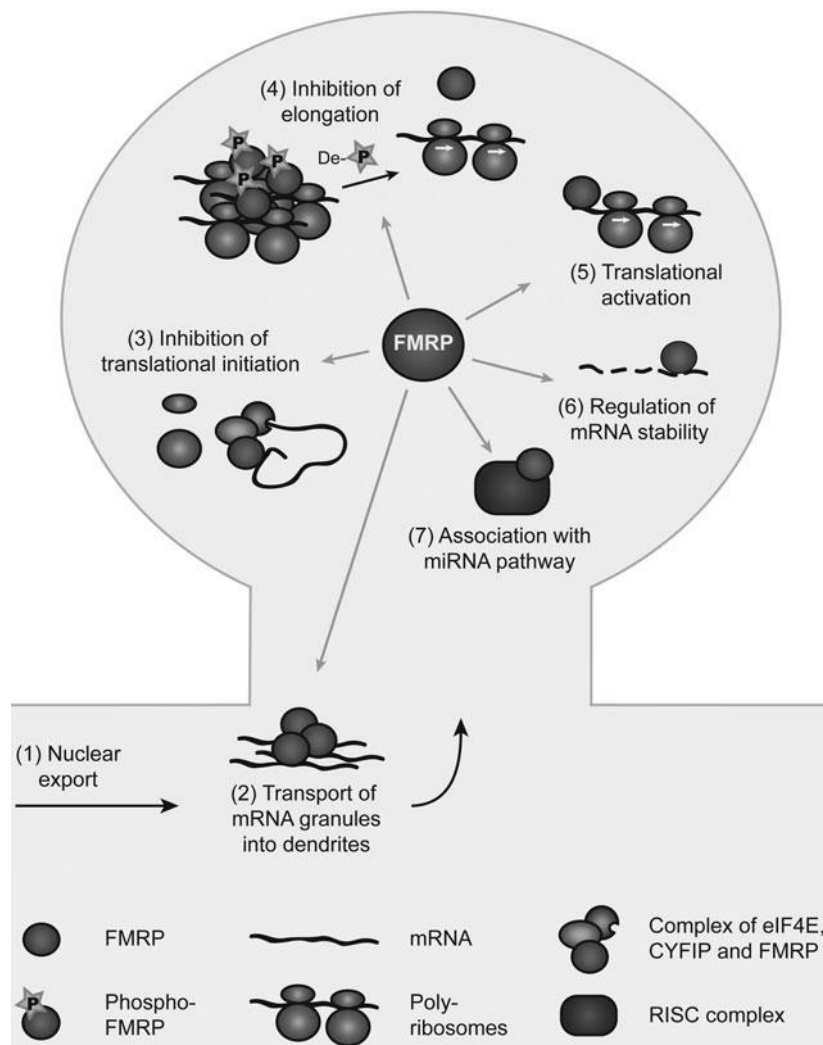
One important clue regarding the function of FMRP came from the observation that it is associated with polyribosomes, implying a role in the regulation of protein synthesis (Tamanini et al., 1996; Khandjian et al., 1996; Corbin et al., 1997). Based on in vitro assays, FMRP was proposed to function as a repressor of protein synthesis (Laggerbauer et al., 2001; Li et al., 2001), and this is consistent with findings in animal models of FXS showing that basal protein synthesis is increased in the absence of FMRP (Qin et al., 2005; Dolen et al., 2007; Bolduc et al., 2008). Several mechanisms have been proposed by which FMRP may regulate translation (Figure 72-1). In one study, FMRP was found to be associated with stalled, translationally inactive polyribosomes when phosphorylated at residue serine 499, whereas dephosphorylated FMRP was associated with actively translating polyribosomes (Ceman et al., 2003). These findings led to the hypothesis that FMRP-bound mRNAs may be positioned on stalled ribosomes until the arrival of a signal resulting in FMRP dephosphorylation and translational derepression. It has also been proposed that FMRP may be involved in sequestering mRNAs into RNA granules, structures that are thought to represent pools of translationally silent mRNAs that may or may not also contain stalled polyribosomes (Mazroui et al., 2002; Aschrafi et al., 2005). In support of this hypothesis, a decrease in the total number of RNA granules was observed


Figure 72–1. Putative roles of FMRP at the synapse. A number of different mechanisms have been proposed by which FMRP may regulate synaptic function and plasticity. These mechanisms include *(1)* Export of target mRNAs from the nucleus, *(2)* Trafficking of mRNA granules into dendrites and synapses, *(3)* Inhibition of translation initiation, *(4)* Inhibition of elongation in response to FMRP phosphorylation, possibly by sequestration of stalled ribosomes into translationally inactive mRNA granules, *(5)* Activation of translation of certain target mRNAs, *(6)* Regulation of stability of target mRNAs, and *(7)* Association with the microRNA pathway. To date, the relative contribution of each of these mechanisms to the regulation of synaptic structure and function remains unknown. It is conceivable that several of these functions occur in parallel at the same synapses or that different mechanisms may play differential roles depending on brain region, Developmental stage, species, or other unknown factors. (See Color Plate Section for a color version of this figure.)

in a mouse model of FXS, consistent with the notion of de-repression of mRNAs and increased protein synthesis in the absence of FMRP (Aschrafi et al., 2005). Another more recent model postulates that FMRP may repress translation initiation by recruiting the cytoplasmic FMRP interacting protein 1, or CYFIP1, which in turn was suggested to inhibit the function of the translation initiation factor eIF4E (Napoli et al., 2008). Finally, it has been proposed that FMRP may also regulate protein synthesis by activating, rather than repressing, translation of certain targets (Bechara et al., 2009), by altering the stability of individual mRNAs (Zalfa et al., 2007), and through association with the microRNA pathway (Cheever & Ceman, 2009). Together, these findings imply that FMRP may regulate translation at several levels in parallel or that

different mechanisms may be involved under different conditions.

In addition to its role in regulating protein synthesis, FMRP has also been implicated in the transport and localization of mRNAs to dendrites and synapses (Figure 72-1). FMRP contains nuclear import and export signals, and it was proposed to be required for nuclear export of its target mRNAs in ribonucleoprotein particles (Eberhart et al., 1996; Kim et al., 2009). Moreover, FMRP-containing RNA granules were found to be trafficked into neurites in PC12 cells (De Diego Otero et al., 2002) and into dendrites and spines in hippocampal cultures in an activity-dependent manner (Antar et al., 2004; Antar et al., 2005). FMRP was found to interact with kinesins, a class of motor proteins that mediate

transport of cargos along microtubules, and this interaction was required for trafficking of FMRP-containing RNA granules to dendrites (Davidovic et al., 2007; Dictenberg et al., 2008). FMRP may thus serve a dual role in the regulation of synaptic mRNAs, first by mediating active transport of RNA granules along microtubules to synapses, and subsequently by repressing translation at synapses until the latter is activated by synaptic stimulation (Wang et al., 2008). It should be noted, however, that one study found no dysregulation of the dendritic localization of putative FMRP target mRNAs in *Fmr1* knockout mice, suggesting either that this mechanism only applies to a subset of FMRP target mRNAs, or that compensatory mechanisms may occur in *Fmr1* knockout mice to replace this function (Steward et al., 1998).

Role of Fragile X Mental Retardation Protein in Synaptic Structure and Plasticity

The identification of a role for FMRP in regulating protein synthesis at the synapse was particularly interesting in light of the increasing evidence linking local protein synthesis to synaptic maturation and plasticity. Given these findings, loss of FMRP expression might be expected to result in disruptions of synaptic structure and function. Consistent with this hypothesis, one of the most prominent morphological phenotypes observed in both patients with FXS and *Fmr1* knockout mice is an increase in dendritic spine density and the presence of abnormal long and tortuous spines (Hinton et al., 1991; Comery et al., 1997; Irwin et al., 2000). Cultured neurons from *Fmr1* knockout mice mimic this phenotype, displaying an increase in the number of structural synapses (Pfeiffer & Huber, 2007). Interestingly, acute replacement of FMRP in these cultures was found to reduce the number of synapses without affecting the function or maturation state of the remaining synapses. Similarly, acute replacement of FMRP in a Drosophila model of fragile X was able to at least partially rescue synaptic structural phenotypes (Gatto & Broadie, 2008). These findings imply that the abnormal increase in spines and synapses observed in the absence of FMRP is not solely an irreversible developmental effect, raising the possibility that acute postnatal manipulations may be able to rescue these deficits and hence provide a viable treatment strategy.

In addition to these effects on synaptic structure, loss of FMRP in animal models has also been shown to affect synaptic plasticity. *Fmr1* knockout mice show exaggerated forms of LTD in hippocampus (Huber et al., 2002) and cerebellum (Koekkoek et al., 2005), consistent with the notion of excess protein synthesis in these mice that underlies the expression of certain forms of LTD (discussed in further detail below). Moreover, several groups have reported a disruption in long-term potentiation (LTP) in the cortex of *Fmr1* knockout mice (Li et al., 2002; Zhao et al., 2005; Desai et al., 2006; Wilson & Cox, 2007), possibly because of an alteration in the threshold for LTP induction (Meredith et al., 2007). Together, these findings suggest that the absence of FMRP causes alterations

in synaptic plasticity at synapses throughout the brain, which may be important in the pathogenesis of FXS.

Summary

Evidence to date suggests that the protein disrupted in fragile X syndrome, FMRP, is an RNA-binding protein that regulates mRNA localization and translation at the synapse. In the absence of FMRP, excess protein synthesis occurs at the synapse, causing alterations in synaptic structure and plasticity, which are likely to underlie at least some of the behavioral phenotypes observed in FXS. This hypothesis is supported by recent data showing that administration of low levels of protein synthesis inhibitors reverses memory deficits in a dFmr1 mutant fly model of FXS (Bolduc et al., 2008). Future research on the precise mechanisms by which FMRP regulates synaptic mRNAs and causes excess synaptic protein synthesis will be crucial for the development of therapeutic agents aimed at restoring normal synaptic structure and function in patients with FXS.

Group I Metabotropic Glutamate Receptors

Glutamate receptors are transmembrane receptor proteins that bind to glutamate, the principle excitatory neurotransmitter in the mammalian central nervous system. They can be divided into two major categories: *(1)* ionotropic glutamate receptors (iGluRs), ion channels that open in response to glutamate binding and induce fast excitatory responses, and *(2)* metabotropic glutamate receptors (mGluRs), G-protein coupled receptors that link to intracellular signaling pathways and hence modulate neuronal function. To date there are eight known mGluR subtypes that can be divided into three groups based on sequence homology, pharmacology, and signal transduction mechanisms: group I (mGluR1 and mGluR5), group II (mGluR2 and mGluR3), and group III (mGluR4, mGluR6, mGluR7 and mGluR8). This section will focus on a description of group I mGluRs because of their implication in the pathogenesis of FXS.

Distribution of Group I mGluRs in the Brain

Both mGluR1 and mGluR5 are expressed widely throughout the central nervous system, but they show distinct patterns of enrichment in specific brain regions. mGluR1 expression is most abundant in the cerebellum and the olfactory bulb, as well as in the hippocampus, lateral septum, globus pallidus, thalamus, substantia nigra, and superior colliculus (Martin et al., 1992; Shigemoto et al., 1992). mGluR5 is present at highest levels in cortex, hippocampus, striatum, lateral septum, olfactory bulb, and inferior colliculus (Shigemoto et al., 1993; Romano et al., 1995). In addition to these spatial differences, mGluR1 and mGluR5 show distinct patterns of temporal regulation during postnatal development: mGluR1 expression

starts at low levels at birth and increases steadily over the first three postnatal weeks, whereas mGluR5 is highly expressed in the neonatal brain but subsequently decreases in all brain regions except the hippocampus (Catania et al., 1994). Both receptors are found predominantly in dendritic shafts and spines, suggesting a mostly postsynaptic function for group I mGluRs, although some examples of presynaptic expression and function have also been reported.

Function of Group I mGluRs

The discovery of metabotropic glutamate receptors in the late 1980s caused a major shift in the perception of the function of glutamate in the brain (Conn, 2003). Previously, it was believed that glutamate was associated only with fast excitatory neurotransmission, whereas slower modulation of activity in glutamatergic circuits was ascribed to separate neuromodulators such as various monoamines and neuropeptides. The presence of G-protein coupled glutamate receptors at synapses throughout the brain suggested that glutamate itself may also act as a neuromodulator, simultaneously fine-tuning the fast excitatory responses it elicits. This notion became particularly interesting in light of the diversity of mGluR subtypes being identified, implying that these receptors may be involved in a variety of forms of glutamate-induced synaptic modulation. By now, it is known that mGluRs can indeed regulate synaptic plasticity by a plethora of mechanisms throughout the brain (Valenti et al., 2002; Xiao et al., 2006). Here, we will focus on those forms of plasticity that are induced by group I mGluRs and that depend on protein synthesis—that is, those that are potentially most relevant for FXS.

The most thoroughly understood function of group I mGluRs lies in the induction of LTD, a persistent decrease in synaptic strength that occurs in response to prolonged low-frequency stimulation (Figure 72-2). mGluR-dependent LTD is observed in several brain regions, including the hippocampus, cerebellum, striatum, ventral tegmental area, and bed nucleus of the stria terminalis. The molecular mechanisms of this mGluR-induced depression in synaptic strength have been extensively studied in the CA1 subregion of the hippocampus, where LTD can be induced either by specific synaptic stimulation protocols (Oliet et al., 1997; Huber et al., 2000) or by application of the group I mGluR agonist (S)-3,5-dihydroxyphenylglycine (DHPG) (Palmer et al., 1997; Huber et al., 2001). Using these induction protocols, it has been shown that activation of mGluRs causes a rapid internalization of postsynaptic AMPA receptor subunits (Snyder et al., 2001; Xiao et al., 2001), which is believed to underlie, at least in part, the observed decrease in synaptic strength. Both mGluR-LTD and the maintenance of mGluR-induced AMPA receptor internalization are dependent on local protein synthesis at the synapse (Huber et al., 2000; Snyder et al., 2001; Huber et al., 2001), suggesting a mechanism in which mGluR activation leads to the translation of specific proteins required for stabilization of the internalized AMPA receptors. The exact nature of these "LTD proteins" has remained elusive, but one candidate that has recently sparked much interest is the activity-regulated cytoskeletal protein Arc, which is known to be associated with the endocytic machinery (Shepherd et al., 2006; Park et al., 2008; Waung et al., 2008). mGluR-LTD in brain regions other than area CA1 of the hippocampus also appears to be dependent on postsynaptic protein synthesis and AMPA receptor internalization (Karachot et al., 2001; Naie & Manahan-Vaughan, 2005; Yin et al., 2006; Mameli et al., 2007). However, it has been proposed that the nature of the proteins that need to be synthesized and the mechanisms of regulation of local protein synthesis may be specific for each brain region (Bellone et al., 2008). It has also been suggested that the mechanisms of mGluR-LTD are regulated developmentally within the hippocampus and that presynaptic mechanisms that are not protein synthesis-dependent may play a role during certain stages of development (Rammes et al., 2003; Nosyreva & Huber, 2005; Moult et al., 2008).

In addition to mGluR-LTD, several other forms of group I mGluR-induced plasticity have been reported. In area CA1 of the hippocampus, application of subthreshold concentrations of group I mGluR agonists prior to induction of LTP leads to an enhanced magnitude and stability of that LTP, a phenomenon known as LTP priming (Cohen & Abraham, 1996). Conversely, application of the mGluR agonist DHPG to synapses that have already been potentiated by high-frequency stimulation results in loss of that potentiation, a process known as depotentiation (Zho et al., 2002). Like mGluR-LTD, both of these effects are dependent on protein synthesis, and depotentiation also requires AMPA receptor internalization (Raymond et al., 2000; Zho et al., 2002). There have also been reports that certain forms of LTP in hippocampus and cortex may be dependent on mGluR activation (Wilson & Cox, 2007), although the role of protein synthesis in these forms of plasticity is less clear. Finally, DHPG can cause long-lasting alterations of nonsynaptic synchronous neuronal activity in hippocampal slices (Piccinin et al., 2008). The protein synthesis dependence of this effect has not been investigated.

Signaling Pathways Activated by Group I mGluRs.

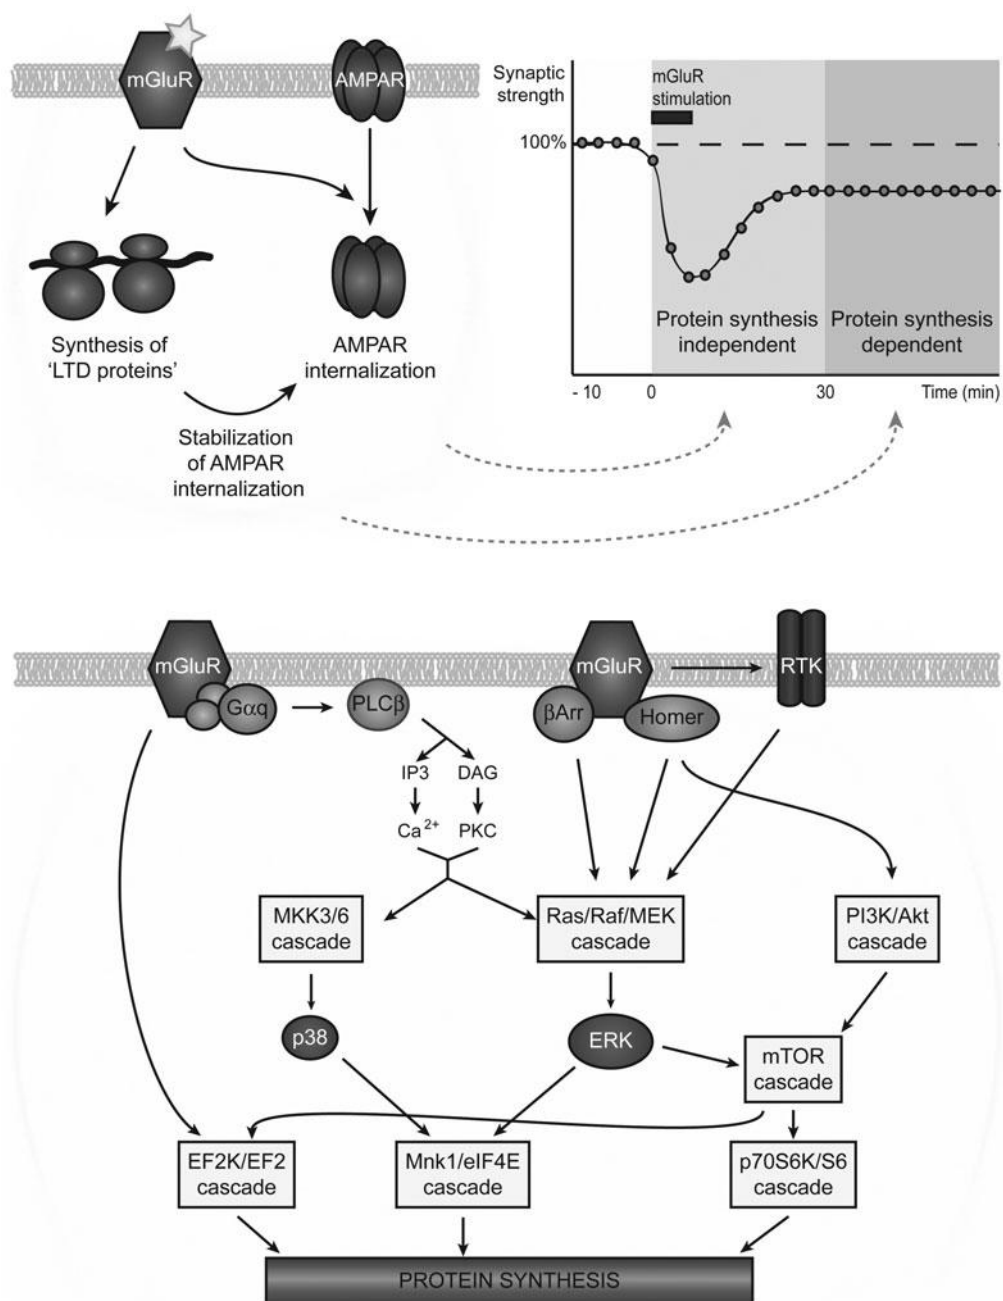
How does binding of glutamate to group I mGluRs trigger the protein synthesis necessary for mGluR-LTD and other forms of synaptic plasticity (Figure 72-2)? All mGluRs are G-protein coupled receptors, and group I mGluRs are specifically coupled to G proteins containing a $G\alpha_q$ subunit (Hermans & Challiss, 2001; Gerber et al., 2007). Binding of glutamate to the extracellular domain of group I mGluRs results in activation of the $G\alpha_q$ subunit, which in turn results in activation of phospholipase C β (PLCβ), an enzyme that releases the intracellular messengers inositol-1,4,5-trisphosphate (IP$_3$) and diacylglycerol (DAG). IP$_3$ binds to IP$_3$ receptors in the endoplasmic reticulum, leading to release of calcium from intracellular stores, whereas DAG (in concert with the released calcium) initiates signaling through the protein kinase C


Figure 72–2. Function and signaling of group I mGluRs. *Upper Panel*: Stimulation of group I mGluRs can result in the induction of long-term depression (LTD), a persistent reduction in synaptic strength. Activation of mGluRs causes a rapid internalization of postsynaptic AMPA receptor subunits, which is thought to underlie the initial, protein synthesis-independent, decrease in synaptic strength. Activation of mGluRs also stimulates synaptic protein synthesis, which results in the synthesis of "LTD proteins" that are believed to be required for stabilizing the internalized AMPA receptors. This stabilization of AMPAR internalization is believed to be the basis for the persistent, protein synthesis-dependent, decrease in synaptic strength following induction of LTD. *Lower panel*: Signaling pathways proposed to be activated upon group I mGluR stimulation. To date, the relative contribution of each of these signaling pathways to synaptic protein synthesis remains unknown and is likely to vary depending on factors such as brain region and developmental stage. It should also be noted that research into these signaling pathways is still actively ongoing, and that this schematic may therefore be incomplete. (See Color Plate Section for a color version of this figure.)

(PKC) pathway. The increase in cytosolic calcium levels and the activation of PKC can result in the activation of a number of different downstream signaling pathways (Marinissen & Gutkind, 2001), the details of which appear to somewhat depend on the cell type and preparation under investigation.

Both calcium and PKC can initiate a Ras/Raf1/MEK cascade that leads to activation of the extracellular signal-regulated kinase (ERK), and ERK activation has been shown to be required for hippocampal mGluR-LTD and for mGluR-induced activation of global protein synthesis (Gallagher et al., 2004;

Banko et al., 2006; Osterweil et al., 2010). Moreover, the Gα_q subunit can activate a MKK3/6 cascade, resulting in activation of p38 MAPK, and this cascade may also be required for mGluR-LTD in area CA1 in adult rats (Moult et al., 2008).

In addition to the canonical G-protein-mediated signal transduction pathway, other signaling cascades have more recently been identified that may also be relevant for group I mGluR-dependent protein synthesis and plasticity. In particular, ERK can be activated by several G-protein- and calcium-independent mechanisms involving interactions with the Homer family of postsynaptic scaffolding proteins, interactions with β-arrestins, or transactivation of receptor tyrosine kinases (Gerber et al., 2007; Wang et al., 2007). Moreover, a transient activation of the PI3K/PDK1/Akt/mTOR pathway was reported to be necessary for mGluR-LTD in area CA1 (Hou & Klann, 2004), and activation of this pathway by group I mGluRs is likely to occur through G-protein-independent mechanisms such as interactions between mGluRs and Homer proteins (Ronesi & Huber, 2008b). Interestingly, activation of the PI3K/Akt/mTOR pathway by mGluRs does not occur under all conditions, and it does not appear to be necessary for mGluR-stimulated global protein synthesis (Osterweil et al., 2010). The functional importance of this pathway thus remains an area of active investigation.

Another important question that remains to be answered concerns the downstream pathways linking mGluR-mediated activation of ERK, p38 MAPK, or Akt to the stimulation of local protein synthesis. Candidates to date include the Mnk1/eIF4E pathway (Banko et al., 2006), the p70S6K/ribosomal protein S6 pathway (Antion et al., 2008), and the EF2K/eEF2 pathway (Park et al., 2008). The relative contribution of each of these pathways remains to be determined and may vary between brain regions and experimental preparations.

Group I mGluRs in Central Nervous System Disorders

In accordance with their key role in regulating synaptic function and plasticity, group I mGluRs have also been implicated in several neurological and psychiatric disorders. Because of their modulation of neuronal excitability, group I mGluRs facilitate epileptiform activity, and administration of pharmacological group I mGluR antagonists has antiepileptogenic and anticonvulsant effects in rodent models of epilepsy (Tang, 2005; Alexander & Godwin, 2006). These antagonists also produce anxiolytic behavioral responses in rodents, as well as decreasing reactivity of the autonomic nervous system to stressful conditions, suggesting a potential use in the treatment of anxiety disorders (Spooren et al., 2000; Pietraszek et al., 2005; Swanson et al., 2005). Similarly, pharmacological or genetic inhibition of mGluR5 results in antidepressant-like effects in rodents (Pilc et al., 2008). Striatal group I mGluRs may play an important role in drug addiction: Reduction of mGluR5 signaling by pharmacological or genetic manipulations abolishes preference for cocaine, morphine, nicotine, and ethanol in rodents, suggesting that group I mGluRs may

positively regulate brain reward function (Kenny & Markou, 2004). In one study, a mutation in mGluR5 was linked to a familial case of schizophrenia (Krivoy et al., 2008). Inhibition of group I mGluRs—particularly mGluR1—has been implicated in the treatment of neuropathic pain (Schkeryantz et al., 2007). Finally, aberrant forms of mGluR-dependent striatal plasticity have been described in rodent models of Huntington's disease and Parkinson's disease, suggesting that mGluRs may be a useful target for the treatment of these disorders (Gubellini et al., 2004).

Pharmacological Agents Targeting Group I mGluRs

Because of their potential involvement in several disorders of the CNS, significant efforts are underway to develop pharmacological agents that target group I mGluRs and that may be of widespread therapeutic relevance. The most commonly used antagonist in preclinical research is 2-methyl-6-(phenylethynyl)-pyridine (MPEP), a potent noncompetitive antagonist of mGluR5 that crosses the blood–brain barrier and can be applied in studies both in vitro and in vivo (Lea & Faden, 2006). However, it was subsequently discovered that high doses of MPEP can result in off-target activity at other glutamate receptors, providing a potential caveat to some of the preclinical research on mGluR5 and decreasing its relevance for clinical applications. The more recently developed structural analog 3-((2-methyl-1,3-thiazol-4-yl)ethynyl) pyridine (MTEP) appears to show fewer off-target effects and better CNS penetrability, but it has been less well-characterized in preclinical models to date. Recently, the anxiolytic drug fenobam was shown to be a potent, selective, and noncompetitive antagonist of mGluR5 function (Porter et al., 2005). This important discovery confirmed the role of mGluR5 in anxiety disorders and provided access to a clinically available mGluR5 antagonist. In addition, development of novel modulators of group I mGluR function is underway, and targeting these receptors may soon be a viable treatment strategy for a range of clinical applications.

Summary

Group I mGluRs—particularly mGluR5—play an important role in activity- and protein synthesis-dependent synaptic plasticity throughout the brain, including in areas relevant for the behavioral phenotypes of FXS, such as hippocampus, striatum, cerebellum, and possibly cortex. Dysregulation of group I mGluR function has been linked to several neurological and psychiatric disorders, making these receptors important putative targets for the development of therapeutic interventions. The molecular mechanisms by which group I mGluRs induce protein synthesis and synaptic plasticity are beginning to be elucidated, but further research will be necessary to fully understand these mechanisms and identify potential additional drug targets for mGluR-related disorders.

Basic Research: Fragile X Mental Retardation Protein and mGluR Interactions at the Synapse

The observation that FMRP is a regulator of synaptic protein synthesis, and that mGluR activation induces synaptic protein synthesis that is required for mGluR-dependent plasticity, raised the intriguing possibility that there might be a functional interaction between these two synaptic elements and that the disruption of this interaction in FXS may play a major role in the pathogenesis of the disorder. In this section, we review the evidence that FMRP and mGluR signaling are indeed inter-related at the synapse and summarize what is known about the molecular mechanisms by which this functional interaction occurs.

Regulation of Fragile X Mental Retardation Protein Levels and Localization by mGluR Activation

The initial impetus for studying a role for mGluRs in FXS came from a biochemical screen looking for synaptic mRNAs that change their association with the translational machinery in response to neurotransmitter stimulation. It was shown that chemical stimulation of group I mGluRs in rat cortical synaptoneurosomes (an in vitro preparation that is enriched for synaptic terminals) resulted in an increased association of FMRP mRNA with actively translating ribosomes, as well as an increase in FMRP protein levels (Weiler et al., 1997). Subsequently, this finding was replicated in other experimental preparations, including mouse hippocampal slices (Hou et al., 2006), cultured cortical neurons (Todd et al., 2003a), and in vivo in rat barrel cortex (Todd et al., 2003b). In addition to FMRP synthesis, mGluR activation was also found to regulate the localization of the FMRP mRNA and protein within neurons. In response to stimulation of cultured hippocampal neurons with the group I mGluR agonist DHPG, both FMRP mRNA and protein were shown to translocate from the neuronal cell body into the dendrites, placing them closer to the site of synaptic protein synthesis (Antar et al., 2004). Interestingly, however, there appears to be some debate about the localization of FMRP in dendritic spines, with conflicting reports suggesting that FMRP either moves into spines (Ferrari et al., 2007) or out of spines (Antar et al., 2004) in response to DHPG stimulation. Further research will be required to resolve this issue, but overall it appears clear that the function of FMRP is regulated by mGluR stimulation, although some of the details remain to be investigated.

mGluR-Dependent Plasticity in the Absence of Fragile X Mental Retardation Protein

Following from the observation that FMRP function is regulated by mGluR stimulation, it was hypothesized that this regulation may be a key mechanism in the initiation of mGluR-dependent protein synthesis and plasticity. By this logic, it was proposed that many of the mGluR-induced protein synthesis-dependent plasticity processes described above would be altered in the absence of FMRP. The first evidence in support of this hypothesis was obtained in a study investigating mGluR-LTD in a mouse model of FXS, showing that mGluR-LTD in area CA1 of the hippocampus is exaggerated relative to wild-type controls (Huber et al., 2002). Even more strikingly, mGluR-LTD in the *Fmr1* knockout mice is no longer dependent on protein synthesis, persisting in the presence of the general translation inhibitors anisomycin and cycloheximide, which completely abolish mGluR-LTD in wild-type mice (Nosyreva & Huber, 2006). A similar phenomenon was observed for cerebellar mGluR-LTD in the *Fmr1* knockout mice (Koekkoek et al., 2005). Because one of the mechanisms by which mGluR activation is thought to induce LTD in wild-type animals is by triggering a protein synthesis-dependent internalization of AMPA receptor subunits, it was hypothesized that the excess LTD in the *Fmr1* knockout mice might result from an excess internalization of AMPA receptors. This hypothesis was confirmed using knockdown of FMRP levels by short interfering RNAs in rat hippocampal cultures, resulting in an excess AMPA receptor internalization at prestimulation baseline, which occludes further internalization in response to DHPG stimulation (Nakamoto et al., 2007). Recently, it was shown that another form of mGluR-dependent plasticity, LTP priming, is protein synthesis-independent in *Fmr1* knockout mice (Auerbach & Bear, 2010). The combination of these data led to the theory that under wild-type conditions, FMRP represses the synthesis of certain "plasticity proteins" required for AMPA receptor internalization and other plasticity-related processes until mGluR stimulation relieves this FMRP repression by an unknown mechanism. In the absence of FMRP, it was proposed, these proteins would be synthesized in excess at baseline, eliminating the need for further protein synthesis upon mGluR stimulation and leading to excess protein synthesis-independent plasticity (Figure 72-3). It should be noted that certain forms of synaptic plasticity, such as cortical LTP, appear to be decreased in *Fmr1* knockout mice, arguing against a general exaggeration of all forms of plasticity. It is possible that the coupling mechanisms between group I mGluRs and FMRP may differ between brain regions and synapses or that the decrease in cortical LTP may be a secondary effect of other consequences of FMRP loss.

Overall, the above studies have established a critical role for FMRP in regulating mGluR-dependent synaptic plasticity, presumably through the regulation of mGluR-induced protein synthesis that is required for the subsequent plasticity. Two major questions now arise that will be of fundamental importance in the development of novel therapeutic strategies for FXS: *(1)* At which step does FMRP regulate mGluR-induced protein synthesis, and how is this regulation achieved at the molecular level? and *(2)* What are the "plasticity proteins" and other targets that are synthesized in response to mGluR stimulation and that mediate the mGluR-dependent plasticity? Our current understanding of these questions will be summarized below.
Figure 72–3. Model for the Interaction Between FMRP and Group I mGluRs in Translational Regulation and LTD. *Upper Left Panel*: Under basal conditions in wild-type mice, FMRP acts as a repressor of protein synthesis. As a result, no protein synthesis occurs, despite low levels of basal mGluR signaling. *Upper right panel*: mGluR stimulation in wild-type mice is thought to trigger three events: *(1)* internalization of AMPA receptors, *(2)* upregulation of protein synthesis signaling pathways, and *(3)* relief of FMRP-mediated translational repression by dephosphorylation of FMRP, degradation of FMRP, or translocation of FMRP out of the synapse. This leads to the synthesis of "LTD proteins," which stabilize the internalized AMPA receptors, resulting in protein synthesis-dependent LTD. *Lower left panel*: In *Fmr1* KO mice, FMRP is not present to repress translation, and basal mGluR signaling is therefore sufficient to induce synthesis of LTD proteins. In the absence of AMPA receptor internalization, however, these proteins alone do not result in LTD. *Lower right panel*: Upon mGluR stimulation in *Fmr1* KO mice, AMPA receptors are internalized just as in wild-type mice. However, the LTD proteins are already present in excess, resulting in stabilization of internalized AMPA receptors and hence LTD that is both exaggerated compared to wild-type mice and independent of new protein synthesis. (See Color Plate Section for a color version of this figure.)

Mechanisms of Fragile X Mental Retardation Protein Regulation of mGluR-Induced Protein Synthesis

As discussed above, the details of the molecular function of FMRP remain to be elucidated, and it has consequently proven challenging to determine how FMRP may respond to mGluR activation and participate in the regulation of mGluR-induced protein synthesis. However, a number of recent discoveries have yielded some important clues. Phosphorylation of FMRP was shown to influence the translation state of associated ribosomes (Ceman et al., 2003). Based on this observation, it was proposed that phosphorylated FMRP may act as a translational repressor and that dephosphorylation of FMRP in

response to mGluR signaling may be an important switch that leads to the derepression of translation. In accordance with this hypothesis, it was recently shown that stimulation of mGluRs with DHPG in hippocampal cultures results in rapid and temporary (<5 min) dephosphorylation of FMRP by the phosphatase PP2A, and this was proposed to initiate translation (Narayanan et al., 2007). Other potential mechanisms by which FMRP-mediated translational repression may be relieved in response to mGluR activation include the mGluR-induced ubiquitination and degradation of FMRP (Hou et al., 2006) and the translocation of FMRP out of the synapse (Antar et al., 2004). The detailed mechanisms by which dephosphorylation, degradation, or translocation of FMRP are initiated in response to mGluR signaling remain an area of active

investigation. Interestingly, it appears that derepression of protein synthesis following mGluR stimulation is a very short-lasting event, because FMRP is rephosphorylated (Narayanan et al., 2007; Narayanan et al., 2008) or newly synthesized (Hou et al., 2006) within 5 minutes of mGluR activation. This implies that it may be important to limit the time window during which protein synthesis can occur following the induction of plasticity, although the extremely brief nature of this time window is somewhat surprising.

Another intriguing phenomenon is that loss of FMRP also appears to cause alterations in the mGluR signaling pathways upstream of FMRP, presumably through complex feedback loops. One study showed that in *Fmr1* knockout mice, mGluR5 receptors are less tightly coupled with synapses and Homer scaffolding proteins, implying an increased lateral motility in the membrane and thus presumably leading to altered signaling properties (Giuffrida et al., 2005). Consistent with this hypothesis, the Homer-dependent activation of mTOR signaling in response to mGluR5 stimulation was absent altogether in *Fmr1* knockout mice (Ronesi & Huber, 2008b). At the same time, basal activation of the PI3K/Akt/mTOR signaling pathway was found to be elevated in *Fmr1* knockout mice (Sharma et al., 2010; Gross et al., 2010). Other groups have reported a slight basal increase in ERK activity (Hou et al., 2006) as well as an aberrant mGluR-induced inactivation of ERK (Kim et al., 2008) in *Fmr1* knockout mice, although these effects are not observed under all conditions (Osterweil et al., 2010).

Target Proteins Regulated by Fragile X Mental Retardation Protein and mGluR Signaling

One of the major areas of focus in fragile X research has been the identification of target mRNAs of FMRP that are dysregulated in the absence of FMRP. Using micro-array studies and other approaches, it was determined that 2% to 4% of all mRNAs in the brain can bind to FMRP via its KH domains and/or its RGG box (Brown et al., 2001; Darnell et al., 2001; Bassell & Warren, 2008). To date, no comprehensive list of all of these targets is available, but we will discuss a number of candidates here based on their potential relevance to mGluR-dependent plasticity (Table 72-1).

Two of the most widely studied FMRP targets are the microtubule-associated protein MAP1B and the elongation factor eEF1A. MAP1B is highly expressed during early postnatal development, where it plays an important role in neurite outgrowth through modulation of microtubule dynamics. MAP1B mRNA binds to FMRP via its RGG domain, and its developmental expression profile is disrupted in *Fmr1* knockout mice, resulting in abnormal microtubule stability

Table 72–1.

List of mRNAs believed to be translationally regulated by both FMRP and group I mGluRs

Protein	Link to FMRP	Link to mGluRs	References
MAP1B	mRNA binds to FMRP Developmental expression time-course is altered in *Fmr1* KO Genetic interaction between dFMR and MAP1B homolog in Drosophila	Synthesized in response to mGluR activation Involved in mGluR-dependent AMPAR endocytosis	Zhang et al., 2001; Lu et al., 2004; Davidkova & Carroll, 2007; Menon et al., 2008
EF1A	mRNA binds to FMRP	Synthesized in response to mGluR activation	Sung et al., 2003; Huang et al., 2005; Antion et al., 2008
Arc	Upregulated in *Fmr1* knockout mice mGluR-stimulated synthesis is abolished in *Fmr1* KO *Fmr1* x Arc double knockout mice have reduced mGluR-LTD	Synthesized in response to mGluR activation Required for mGluR-LTD and AMPAR trafficking	Zalfa et al., 2003; Shepherd et al., 2006; Park et al., 2008; Waung et al., 2008
CaMKII	Upregulated in *Fmr1* KO	Synthesized in response to mGluR activation	Zalfa et al., 2003; Muddashetty et al., 2007
PSD95	mGluR-stimulated synthesis is absent or occluded in *Fmr1* KO Levels downregulated in *Fmr1* KO caused by decreased mRNA stability	Synthesized in response to mGluR activation mGluR stimulation increases mRNA stability	Todd et al., 2003a; Muddashetty et al., 2007; Zalfa et al., 2007
SAPAP3	Upregulated in *Fmr1* KO	Synthesized in response to mGluR activation	Narayanan et al., 2007; Narayanan et al., 2008

(Lu et al., 2004; Menon et al., 2008). In Drosophila, loss of dFmr1 leads to synaptic structural defects, and these defects are reversed in double mutants also lacking Futsch, the Drosophila equivalent of MAP1B (Zhang et al., 2001). Recently, it was also shown that MAP1B is synthesized in response to DHPG stimulation in hippocampal cultures, and it is required for DHPG-induced AMPA receptor endocytosis (Davidkova & Carroll, 2007). These findings suggest that alterations in MAP1B regulation may play a role in disrupting axon targeting and synaptogenesis and synaptic plasticity in FXS. eEF1A is a component of the protein synthesis machinery that is responsible for delivering amino acids bound to transfer RNAs to the ribosome. It has been shown that eEF1A mRNA binds to and is repressed by FMRP (Sung et al., 2003) and that eEF1A protein is synthesized in response to DHPG stimulation in hippocampal slices (Huang et al., 2005; Antion et al., 2008). Thus far, the importance of eEF1A synthesis for synaptic plasticity or FXS has not been investigated, but it is conceivable that by expanding the translational machinery, it may contribute to the basal increase in protein synthesis observed in *Fmr1* knockout mice.

Two other candidates that have received much attention are the activity-regulated cytoskeleton-associated protein Arc and the Ca^{2+}/calmodulin-dependent kinase CaMKII α. Arc plays an important role in AMPA receptor trafficking and LTD (Shepherd et al., 2006). *Fmr1* knockout mice reportedly have increased levels of Arc protein, as well as an increased association between Arc mRNA and polyribosomes (Zalfa et al., 2003). Arc is also rapidly upregulated in response to neuronal activity and mGluR-LTD (Waung et al., 2008), and this upregulation (but not a slower, presumably transcriptional event) is abolished in *Fmr1* knockout mice (Park et al., 2008). In *Fmr1* x Arc double knockout mice, mGluR-LTD is reduced (but not abolished). Similar data have been obtained for CaMKIIα, a kinase known to play a crucial role both in synaptic plasticity and in learning and memory. As with Arc, CaMKII α protein levels were found to be increased in *Fmr1* knockout mice, and CaMKII α mRNA showed an increased association with polyribosomes (Zalfa et al., 2003). DHPG stimulation also results in CaMKII α protein synthesis (Muddashetty et al., 2007). Together, these data imply that Arc and CaMKII α may be involved in the altered plasticity observed in *Fmr1* knockout mice.

A somewhat more complicated story has been reported for the regulation of PSD-95, a scaffolding protein that is a major component of the postsynaptic density and that is thought to anchor glutamate receptors and intracellular signaling proteins at the synapse. Like the above candidates, PSD-95 is synthesized in response to DHPG stimulation in cortical cultures and synaptoneurosomes, and this increase is absent or occluded in *Fmr1* knockout mice (Todd et al., 2003a; Muddashetty et al., 2007). However, another study found that in hippocampus of *Fmr1* knockout mice, levels of PSD-95 mRNA are lower than in wild-type mice, and that this results from a decrease in PSD-95 mRNA stability (Zalfa et al., 2007). Moreover, DHPG was shown to increase stability of PSD-95

mRNA in hippocampal cultures from wild-type mice but not from knockout mice. Thus, FMRP may be able to act by several different mechanisms, translationally repressing some mRNAs but increasing the stability of others. Interestingly, another postsynaptic scaffolding protein, SAPAP3, was found to be upregulated both by DHPG stimulation and in the *Fmr1* knockout mouse (Narayanan et al., 2007; Narayanan et al., 2008), indicating that there might be differences in mechanisms of regulation even within categories of similar proteins.

Recently, another target of FMRP was identified in the amyloid precursor protein (APP) that is associated with Alzheimer's disease (Westmark & Malter, 2007). APP levels were increased in synaptoneurosomes and cortical cultures from *Fmr1* knockout mice, and this occluded the further DHPG-induced increase observed in wild-type mice. The physiological function of the APP protein remains somewhat unclear, but it has been implicated in synapse formation and plasticity, and it is conceivable that dysregulation of these events in FXS results in cognitive deficits by mechanisms paralleling those involved in Alzheimer's disease.

Finally, unpublished observations from our laboratory suggest that the AMPA receptor subunit GluR2 may also be an interesting candidate in the search for relevant FMRP targets. Levels of GluR2/3 were found to be increased by DHPG stimulation in hippocampal slices, and this increase was mimicked and occluded in the *Fmr1* knockout mice (Osterweil et al., unpublished). These data are consistent with previous findings showing that the rapid translation of GluR2 is required for mGluR-LTD in the ventral tegmental area (Mameli et al., 2007), suggesting that an excess of mGluR-induced GluR2 synthesis in *Fmr1* knockout mice may contribute to the exaggerated mGluR-LTD phenotype.

Summary

Twelve years after publication of the first study demonstrating a link between FMRP and group I mGluRs, a large body of evidence now supports the model that these two players act in functional opposition to regulate protein synthesis at the synapse, with mGluRs activating and FMRP repressing translation of the majority of target mRNAs. Loss of translational repression by FMRP in FXS appears to result in excess synthesis and dysregulation of target proteins that are required for mGluR-dependent synaptic plasticity, leading to aberrant plasticity that may underlie the behavioral phenotypes observed in FXS. Significant progress has been made in identifying the mechanisms by which mGluR signaling leads to derepression of FMRP-associated protein synthesis and the nature of the relevant target mRNAs. However, it has also become increasingly clear that the interplay between FMRP and mGluRs is far more complex than initially anticipated and that multiple different mechanisms and many essential target proteins may be involved. Further research will be necessary to address both of these crucial questions to fully understand the potential of targeting mGluRs as a pharmacological treatment for FXS and related disorders.

Preclinical Research: Reversal of Fragile X Syndrome Phenotypes by mGluR Antagonism in Animal Models

In light of the growing literature implicating a dysregulation of mGluR signaling in FXS, research efforts have been increasingly aimed at directly testing whether mGluRs might provide a viable therapeutic target for the treatment of FXS. To address this question at the level of preclinical research, a number of groups have used various animal models of FXS to manipulate mGluR signaling and assess whether these manipulations can reverse the deficits observed in these animal models (Table 72-2).

Pharmacological Manipulations in the *Fmr1* Knockout Mouse

One of the first pieces of evidence that mGluRs may indeed provide a promising target for pharmacological interventions in FXS came from a study showing that administration of the mGluR5 antagonist MPEP to *Fmr1* knockout mice reversed the abnormal response of these mice in an open-field test, an experimental measure that is commonly used to assess anxiety-like phenotypes in mouse models (Yan et al., 2005). In addition, *Fmr1* knockout mice show an increase in the probability of audiogenic seizures, a model for the epilepsy frequently observed in fragile X patients, and MPEP administration significantly reduced the probability of these seizures. Consistent with this observation, another group found that *Fmr1* knockout mice showed prolonged epileptiform discharges in area CA3 of hippocampal slices in response to persistently increased synaptic activity and that these prolonged discharges were both protein synthesis-dependent and could be reversed by the application of MPEP (Chuang et al., 2005). These initial studies provided important evidence that mGluR antagonists may at least be able to ameliorate the epilepsy and anxiety phenotypes observed in FXS. More recently, another group was able to reverse a deficit in prepulse inhibition of startle in *Fmr1* knockout mice by acute administration of MPEP (de Vrij et al., 2008). Prepulse inhibition of startle is a functional measure of sensorimotor gating, a process by which sensory information entering the brain is filtered prior to reaching conscious perception.

At the molecular level, *Fmr1* knockout mouse brains were shown to have a decreased number of mRNA granules, which are thought to represent translationally repressed mRNAs,

Table 72–2.

List of studies showing reversal of *Fmr1* knockout phenotypes by antagonism of mGluRs

Study	Animal Model	*Fmr1* Manipulation	mGluR Manipulation	*Fmr1* Knockout Phenotype Studied
Yan et al., 2005	Mouse	*Fmr1* KO	MPEP	Increased exploration in open-field test Increased audiogenic seizures
Chuang et al., 2005	Mouse	*Fmr1* KO	MPEP	Prolonged epileptiform discharges in hippocampal slices
Aschrafi et al., 2005	Mouse	*Fmr1* KO	MPEP	Decrease mRNA granules
McBride et al., 2005	Drosophila	dFmr null	MPEP and others	Deficits in courtship-related behaviors and memory
Tucker et al., 2006	Zebrafish	*Fmr1* knockdown (morpholino)	MPEP	Disruptions in neurite morphology and craniofacial development
Dolen et al., 2007	Mouse	*Fmr1* KO	Cross with mGluR5 heterozygote	Exaggerated ocular dominance plasticity; excessive hippocampal LTD; increased global protein synthesis; increased spine density; increased audiogenic seizures; e3nhanced inhibitory avoidance extinction; increased body weight in young mice
Pan & Broadie, 2007; Pan et al., 2008; Repicky & Broadie, 2009	Drosophila	dFmr null	Cross with dmGluRA knockout	Phenotypes in glutamate receptor trafficking, synaptic plasticity, presynaptic ultrastructure, and coordinated motor behavior
de Vrij et al., 2008	Mouse	*Fmr1* KO	MPEP and fenobam	Deficit in prepulse inhibition: increased dendritic filopodia in hippocampal cultures
Bolduc et al., 2008	Drosophila	dFmr null	MPEP	Deficits in olfactory memory
Chang et al., 2008	Drosophila	dFmr null	MPEP	Increased lethality caused by excitotoxicity
Min et al., 2009	Mouse	*Fmr1* KO	MPEP	Increased GSK3 activation
Osterweil et al., 2010	Mouse	*Fmr1* KO	MPEP	Increased global protein synthesis

and this decrease was reversed by administration of MPEP (Aschrafi et al., 2005). Similarly, the excess protein synthesis observed in hippocampal slices from *Fmr1* knockout mice was corrected by a brief application of MPEP (Osterweil et al., 2010). Hippocampal cultures from *Fmr1* knockout mice showed an abnormal increase in the density of dendritic filopodia, thought to represent aberrant immature synaptic connections, and this increase was reversed by treatment with MPEP or fenobam, another mGluR5 antagonist (de Vrij et al., 2008). Recently, another group reported that glycogen synthase kinase-3, a key signaling enzyme involved in the regulation of many neuronal functions, was hyperactive in *Fmr1* knockout mouse brains and that this hyperactivity could be reversed by acute administration of MPEP (Min et al., 2009).

Genetic Manipulations in the *Fmr1* Knockout Mouse

A complementary strategy to testing whether manipulations of mGluR signaling are able to reverse fragile X-related phenotypes is by genetically decreasing the levels of mGluRs in the *Fmr1* knockout mice. This is particularly important in light of the fact that MPEP has been proposed to have some off-target activity, potentially confounding studies relying solely on this drug. Thus, to take advantage of the specificity of a genetic approach, *Fmr1* knockout mice were crossed with mice heterozygous for the *Grm5* gene—that is, those that had a 50% decrease in mGluR5 levels (Dolen et al., 2007). Using this strategy, seven out of eight fragile X-related phenotypes assessed were reversed in the *Fmr1* x Grm5 crossed mice. In accordance with the data obtained from the above pharmacological approach, genetic reduction of mGluR5 signaling causes a significant decrease in the induction of audiogenic seizures. In addition, this approach reversed the increase in dendritic spines seen in visual cortex of fragile X mice, the increase in protein synthesis in the hippocampus, and the increase in total body weight observed in young fragile X mice. Moreover, the genetic reduction of mGluR5 reduced the excessive hippocampal LTD, as well as an alteration in ocular dominance plasticity, a model for activity-dependent changes in the brain. Finally, the cross rescued an enhanced extinction phenotype in an inhibitory avoidance paradigm, a mouse model for learning and memory. The only phenotype not rescued in this study was macroorchidism, suggesting that other pathways (possibly mGluR1) must be involved in the testicular phenotype.

Manipulation of mGluRs in Other Animal Models of Fragile X Syndrome

Mice are commonly used in the generation of animal models for cognitive disorders because they represent the most highly developed species in which it is currently possible to specifically target and manipulate a gene of interest. However, despite significant progress in the development of techniques for genetic manipulation in mice, it still takes months to years to produce a knockout mouse model for a particular disorder. Moreover, studies are often limited by the spatial requirements for housing large colonies of mice. In contrast, manipulations in invertebrate species such as Drosophila are rapid and require far less space, making them very useful models for initial large-scale screens of mutations or drug effects. This approach was used successfully in the assessment of the effects of targeting mGluRs in a Drosophila model of FXS, in which the Drosophila homolog of the *Fmr1* gene, known alternately as dFmr1 or dfxr1, was disrupted. Male dFmr1 mutant flies showed abnormalities in several behavioral and structural measures of courtship-related learning and memory, and these deficits were reversed by administration of MPEP or other independent mGluR antagonists (McBride et al., 2005). Interestingly, MPEP reversed the deficits in courtship behaviors regardless of whether it was administered during the larval stage, the adult stage, or both, indicating that mGluRs may play a key role both in the development and in the acute function of mGluR-containing synapses. In a subsequent series of studies, another group took a genetic approach in Drosophila using a double knockout of dFmr1 and the only Drosophila mGluR, known as dmGluRA, to assess mechanistic links between these two molecules (Pan & Broadie, 2007; Pan et al., 2008; Repicky & Broadie, 2009). It was shown that dFmr1 and dmGluRA pathways converge to regulate multiple phenotypes, including glutamate receptor trafficking, synaptic plasticity, presynaptic ultrastructure, and coordinated motor behavior, leading the authors to conclude that loss of the receptor at least partially corrects defects caused by impaired translational regulation and vice versa. In other studies, MPEP administration in dFmr1 mutant flies was also able to ameliorate deficits in olfactory memory (Bolduc et al., 2008) and decrease embryonic lethality resulting from excitotoxicity (Chang et al., 2008).

Next to Drosophila, zebrafish embryos are used frequently in developmental studies because they are also easy to manipulate but have the advantage of being a vertebrate species. One group generated *Fmr1* knockdown zebrafish embryos using the morpholino antisense oligonucleotide technology (Tucker et al., 2006). This knockdown of *Fmr1* causes disruptions in neurite morphology in the hindbrain and spinal cord of the embryos, as well as in craniofacial development, including alterations in the cranial cartilage and number of neurons in the trigeminal ganglion. By developing these embryos in medium containing MPEP, the authors were able to restore normal neurite morphology and significantly reduce the number of neurons in the trigeminal ganglion. Together, these data provide evidence that manipulating mGluR signaling can reverse fragile X-related phenotypes across species, indicating that mGluRs may indeed provide a viable target for the treatment of FXS.

Summary

Preclinical studies using diverse animal models and techniques for manipulating group I mGluRs have demonstrated

that reductions in signaling through mGluRs—particularly mGluR5—can reverse or ameliorate several phenotypes associated with FXS. These data provide an important proof of concept to indicate that targeting mGluRs may be a valuable strategy for the treatment of FXS. Further research will be necessary to expand the list of phenotypes examined, especially with regard to the many cognitive phenotypes that have thus far received little attention. Moreover, it will be crucial to determine whether there is a specific developmental window of opportunity for targeting mGluRs in FXS and how chronic administration of group I mGluR antagonists would compare to acute treatments in terms of efficacy and potential side effects.

Clinical Research: Targeting mGluRs and Their Downstream Effectors in Fragile X Syndrome Patients

Encouraged by the exciting findings arising from preclinical research, a number of clinical trials have been initiated to test the efficacy of compounds directly or indirectly related to mGluR signaling in treating FXS (Berry-Kravis, 2008; Hagerman et al., 2009). To date, none of these compounds are specifically approved for the treatment of FXS, but promising preliminary results have been obtained, which are summarized below.

mGluR5 Antagonists

The first group I mGluR antagonist to be tested in clinical trials was fenobam, a compound that was originally developed as an anxiolytic with an unknown molecular target and that was subsequently demonstrated to be a selective mGluR5 antagonist (Porter et al., 2005). A phase II clinical trial was recently completed, in which 12 adult patients with FXS received a single dose of fenobam to assess drug safety, pharmacokinetics, and a small number of cognitive and behavioral effects. In this trial, fenobam was found to reduce anxiety and hyperarousal, as well as improving prepulse inhibition of startle and accuracy on a continuous performance task (a measure of sustained attention and impulsivity) in a subset of patients (Berry-Kravis, 2008; Berry-Kravis et al., 2009). Based on these favorable findings, it was concluded that future trials are warranted once the results of this trial have been fully analyzed. Similarly, a recent small open-label trial with acamprosate, a drug with mGluR5 antagonist properties, yielded promising results in 3 young adult patients with FXS (Erickson et al., 2010). In all 3 patients, acamprosate was associated with improved linguistic communication and global clinical benefit as assessed by the CGI-I (clinical global impression-improvement) scale. Other mGluR5 antagonists that have shown promising results in preclinical studies and are currently entering clinical trials include STX107 (Seaside Therapeutics, phase I trial initiated in the United States), AFQ056 (Novartis, phase II trial recently completed in France, Italy, and

Switzerland), and RO4917523 (Hoffman-LaRoche, phase II trial initiated in the United States).

Compounds Related to mGluR Signaling

In addition to targeting mGluRs directly, another approach to reducing excessive mGluR-mediated plasticity is to target the signaling pathways downstream of mGluRs. This approach is exemplified by the recent interest in lithium, which is already clinically approved for the treatment of mood disorders. The precise molecular mechanisms of lithium treatment are unclear (Williams et al., 2004), but it is thought to target the phospholipase C pathway, which plays a key role in group I mGluR signaling, as well as glycogen synthase kinase-3, which was found to be hyperactive in *Fmr1* knockout mouse brains in an mGluR5-dependent manner (Min et al., 2009). In a pilot trial on 15 patients with FXS, lithium treatment for 2 months was found to have positive effects on behavioral adaptive skills and one cognitive measure, suggesting that larger-scale clinical trials of this treatment strategy are warranted (Berry-Kravis et al., 2008).

Another study investigated the effects of treatment with the Ampakine CX516, a compound that enhances function of AMPA receptors and may thus counteract the excessive AMPA receptor internalization that underlies the exaggerated mGluR-dependent LTD observed in animal models of FXS (Berry-Kravis et al., 2006). Unfortunately this study did not yield clear positive results on any of the behavioral or cognitive measures tested, although a subset of patients who were also on antipsychotic treatment showed some improvement. This suggests that the dosing may have been inadequate or that targeting AMPA receptors alone may not be an optimal strategy for the treatment of FXS.

General Conclusions and Remaining Questions

Since its inception in 2002, the mGluR theory of FXS has been extensively investigated and validated, based on data ranging from basic in vitro research through in vivo studies in animal models to clinical trials in human patients with FXS. The encouraging nature of these findings, as well as the rapidity with which they have been translated from the bench to preliminary clinical testing, have engendered much excitement in the field, and it is hoped that additional trials may result in effective and clinically approved treatments for FXS in the reasonably near future.

There are a number of important remaining questions that need to be addressed at the preclinical level to direct clinical research toward the most effective intervention strategies. One significant issue is whether the effects of FMRP on synaptic structure and function are largely developmental or whether there is an ongoing acute requirement for FMRP, and hence an opportunity for correction of the synaptic phenotype, throughout adulthood. In the former case, it might be critical to target mGluR signaling as early as possible in post- or even prenatal development. Another major area of active research is

the identification of alternative targets for pharmacological intervention that may arise from the mGluR theory. As discussed above, these include signaling pathways downstream of mGluRs, as well as proteins whose mGluR-induced synthesis may be dysregulated as a consequence of the absence of FMRP. In addition, recent studies have suggested that other G_q-coupled receptors (Volk et al., 2007) or indeed any receptors that couple to synaptic translation (Osterweil et al., 2010), may contribute to the excess protein synthesis observed in FXS, and hence may be of interest as therapeutic targets. Finally, it will be of great interest to determine whether the treatment paradigms developed for FXS may also be beneficial to patients with other forms of mental retardation and autism. Several of the single-gene disorders characterized by mental retardation and autism have been linked to protein synthesis pathways at the synapse (Bear et al., 2007; Kelleher & Bear, 2008), and it is conceivable that idiopathic autism in a subset of patients may result from similar disruptions. The mGluR theory may thus have the potential to go far beyond its original scope and provide novel treatment options for a wide range of neurodevelopmental disorders associated with synaptic translation and plasticity.

Challenges and Future Directions

- Identification of developmental versus acute roles of FMRP at synapses: If loss of FMRP function during brain development causes irreversible alterations in synaptic structure and connectivity, then this has significant implications for any therapeutic approaches to FXS, including those based on the mGluR theory.
- Identification of additional drug targets based on the mGluR theory: By increasing our understanding of mGluR signaling pathways and other pathways contributing to synaptic protein synthesis, it may be possible to identify alternative targets for pharmacological intervention that will expand and improve treatment options for FXS.
- Comparison between FXS and other disorders: To determine whether treatment paradigms developed for FXS may also be beneficial to patients with other forms of mental retardation and autism, it will be essential to identify similarities and differences in the molecular and cellular mechanisms underlying these disorders.

Future Directions in the Treatment of Autism Spectrum Disorders

The past couple of decades have witnessed a dramatic growth in research on the efficacy of interventions for individuals with autism spectrum disorders (ASD). As described in the chapters in this section, there are now data to support a variety of treatment approaches for individuals with ASD, ranging from pharmacological to behavioral interventions. The state of knowledge pertaining to pharmacological interventions was thoughtfully summarized by the authors in this section. Current data provide support for the use of certain classes of medication for specific target symptoms, such as stimulants and nonstimulants for difficulties in attention/hyperactivity and atypical neuroleptics for irritability and impulsive aggression. Conflicting data were also discussed regarding the efficacy of certain medications, which challenge our current clinical practice and views. The remarkable progress that has been shown in our understanding and treatment of Fragile X was also described, providing an exciting example of the translation of data and insights derived from an animal model to preclinical and clinical research on pharmaceuticals in a relatively brief period of time. Results of studies on behavioral and psychosocial interventions reviewed in the chapters in this section support the efficacy of interventions targeting social skills, sensory motor dysfunction, and the early cognitive and language development of young toddlers with ASD. Thus, some progress in the treatment of ASD has clearly been made. The question before us is: Where do we go from here? In this commentary, we consider current challenges, gaps, and future directions of ASD treatment research, including research on neuropsychopharmacological and behavioral/psychosocial interventions for ASD.

Current Challenges and Gaps in ASD Treatment Research

Neuropharmacological Treatments

The history of neuropsychopharmacology of ASD is characterized by a symptom-focused rather than syndrome-based approach. Symptom domains of ASD that have phenotypic similarity with symptom domains of other neurodevelopmental/neuropsychiatric disorders have been assumed to have similar underlying neurobiology. As such, medications known to have favorable efficacy/safety profiles in other disorders have been "borrowed" and tested in ASD. This approach has had mixed success. The case of risperidone, the first medication to obtain FDA indication for the treatment of a symptom domain associated with ASD, is an example of the success of this approach. Similarly, the positive results of trials testing the efficacy of stimulants and atomoxetine for the treatment of attention-deficit/hyperactivity (ADHD)-like symptoms in autism support such an approach, although the effect sizes for ASD studies are smaller than those observed in ADHD studies. On the other hand, recent data questioning the efficacy of selective serotonin reuptake inhibitors (SSRIs) for the treatment of repetitive behaviors in ASD challenges the notion that phenotypic similarities reflect common neurobiological substrates. As molecular genetics and neuroscience analyses of ASD mature, new approaches are emerging. The exciting development is that for the first time we are in a position to identify novel molecular targets for autism based on the basic science of ASD. Although it is

too early to evaluate the ultimate success of such an approach, it is promising that our understanding of the neurobiology of ASD is becoming sophisticated enough that it allows the translation of basic science findings to the development of treatments that target core ASD symptoms and potentially facilitate responses to behavioral interventions. The hope is that by combining autism-specific pharmacological intervention with behavioral interventions, it will be possible to modify the developmental trajectories of individuals with ASD. Still, a series of challenges remains.

Measuring Outcomes

The valid and reliable measurement of outcomes of clinical trials of medications used with individuals with ASD poses significant challenges for the field. Perhaps the biggest challenge is that ASD is a developmental disorder with highly heterogeneous presentation, and as such, it requires measurement of symptom domains across different abilities, developmental and chronological age levels, and symptom severities. Cognitive abilities vary substantially and can influence symptom severity, such as communication ability. Within symptom domains, different behaviors can reflect an underlying core symptom domain. For example, an impairment in social relatedness can be reflected by difficulties in establishing eye contact, peer relationships, and social discourse, and each individual with ASD may have impairments in one or all of these domains. The nature of symptoms, such as an impairment in communication ability, will vary substantially according to developmental level. Even with a relatively small developmental window, such as the elementary school period, children's social abilities can range from just beginning to initiate social contact to engaging in complex social games, for example. In addition to the heterogeneity of symptom expression, another thorny issue is that many of the available outcome measures assess specific skills in a controlled environment, and it is often unclear how to measure performance of the same skills in community settings. There is debate about whether standardized tests, although reliable, correlate with spontaneous use of the skills that they intend to measure.

Another challenge in developing appropriate outcome measures is related to the type of skills we measure. Early intervention researchers have focused on developing measures that target skill acquisition in the areas of cognitive, social, and language abilities, as this is the goal of early intervention. On the other hand, neuropsychopharmacology researchers have focused on developing measures that reflect reduction in maladaptive behavior, since this has been the target of most medications so far. Given that most pharmacological research has targeted school-age children, we lack valid and reliable measures that focus on skills acquisition for this age group that can be used in clinical trials.

Lastly, we lack measures that target the many comorbid psychiatric conditions that are associated with ASD, such as depression and anxiety, which have been validated for use in individuals with autism. The limited availability of outcome measures validated in this population to assess psychiatric comorbidity has also translated into lack of efficacy data on the treatment of psychiatric comorbidities. Similarly, there is a lack of research on effects of such comorbidities on treatment response and side effect generation. Given that the prevalence of anxiety and depression (Ghaziuddin et al., 2002) and ADHD-like symptoms (Gadow et al., 2006) are higher in ASD than the general population, we need to consider the impact of such comorbidities in treatment studies that target core ASD symptoms. In addition, certain comorbid conditions have the potential to produce symptoms that may imitate or contribute to the behavioral symptoms of autism. As such, clarifying the role of such comorbidities in the phenotypic variability of ASD and its effect on treatment response may significantly impact the choice of agents available for the treatment of ASD related symptoms.

Medical Comorbidities

As described in Chapter 74, children with ASD experience a variety of medical issues, including GI disturbance and sleep difficulties. Although the exact link between these medical issues and the pathophysiology of autism remains unclear, there is an urgent need to develop effective treatments for these medical conditions to alleviate suffering, improve behavior, and possibly decrease the amount of psychotherapeutic agents used unnecessarily.

There is emerging evidence to suggest that a wide range of medical conditions or dysfunctions may be conferring risk or even possibly causing an ASD phenotype. Such areas include increased oxidative stress, mitochondrial dysfunction, immune dysregulation, and metabolic disorders. Several rare metabolic syndromes are associated with ASD-like phenotypes (e.g., central folate deficiency, creatine deficiency, Smith-Lemli-Opitz syndrome, PKU), although the incidence of such disorders in children with autism is reported to be low (Zecavati et al., 2009). Research is needed to explore the role of dysfunction in certain systems, such as mitochondrial function or oxidative stress, to determine whether, even in the absence of a diagnosable disorder, such metabolic disorders confer risk for autism, impact treatment response to psychopharmacologic agents, and whether treatment of such conditions improves ASD symptoms (Zecavati et al., 2009).

Alternative and Complementary Treatments

A thorough discussion of alternative treatments is included in Chapter 75. As mentioned by the chapter authors, the data are very limited in regard to both efficacy and safety, but the use of alternative treatments by the ASD community is widespread. The challenges are significant on multiple fronts. With few exceptions, many parents do not have faith in the Western concept of randomized controlled trials. The Western medical community has not invested in testing alternative approaches. Funding to do so has been limited. However, the scientific rationale for many of the alternative

treatments needs more rigorous research. Moreover, we know very little about the neurobiological effects of many of the complementary and alternative approaches. An organized effort on all fronts is required to properly test efficacy and safety of alternative approaches and move the field toward integrative, multitradition practice.

Treatments for Adults with ASD

As the first cohorts of children who have received intensive early intervention are crossing into adulthood, it is becoming apparent that we have minimal data on the efficacy of pharmacologic interventions for adults with autism. As such, there are few evidence-based guidelines to help clinicians make informed choices regarding the use of pharmacologic agents in this population. The few available studies are based on very small sample sizes. As mentioned in Chapter 71, the few follow-up studies addressing symptom impairment and abatement in adolescents and adults with an ASD suggest that these individuals improve from childhood to adulthood, but that they still experience periods of symptom aggravation, and a majority continues to require support. The reported rising figures of prevalence of ASD in children will soon reflect increased prevalence of ASD in adults. We are currently not prepared to address their needs given the lack of data for adult oriented interventions, limited understanding of the needs of adults with ASD, and the crucial lack of therapists and physicians with ASD expertise that care for adults.

Heterogeneity of ASD

As described in almost all chapters in the volume, one striking difficulty with developing interventions for ASD is the large individual differences in symptom severity and expression. At this point, we know very little about which characteristics/biomarkers identify distinct subgroups that will respond well to a particular biologic treatment. As such, researchers have found it very difficult to meaningfully stratify the ASD population in intervention studies. Most often, clinical trials try to address this issue by enrolling children who score poorly for the target domain symptom. Other analyses involve examining, and sometimes controlling for, the effect of age and IQ on treatment response. Although such approaches are helpful, they do not fully address the amount of individual variability observed in this population.

We also struggle with how to translate basic science findings that may apply to very small subgroups of children with ASD. The most obvious example is related to rare but causative mutations recently identified. The question arises regarding how the clinical scientist should use the information provided by genetics to develop clinical interventions for a well-known molecular target, when the available sample size for testing this clinical intervention may not allow randomized controlled designs. Suggestions have included grouping mutations that affect similar pathways together, or exploring single subject designs traditionally used by behavioral researchers, but

this is a new territory and it will require multidisciplinary input.

Behavioral and Psychosocial Intervention Research

Over the past several decades, we have made tremendous progress in the development of effective behavioral interventions for young children with ASD (Rogers & Vismara, 2008). It is generally agreed that comprehensive, early intensive behavioral interventions can significantly improve the outcomes of preschool aged children with ASD (Reichow & Wolery, 2009). Recently, an early intervention appropriate for toddlers at risk for ASD was shown to be efficacious (Dawson et al., 2009). A randomized controlled trial with children with ASD less than 2 ½ years of age demonstrated that an intensive early intervention that integrates applied behavioral analysis with developmental-relationship approaches, can improve IQ, language, and adaptive behavior, and reduce the severity of diagnosis in young children.

Although progress has been made, significant challenges and gaps in developing behavioral and psychosocial interventions remain. First, similar to neuropharmacological interventions, there is large individual variability in response to behavioral interventions across the life span. For example, although virtually all individuals appear to benefit from early intensive behavioral interventions, some children make extremely rapid progress, while others make slower progress. For those with slow progress, the need for effective alternative or augmented behavioral interventions is great. With the exception of pretreatment IQ, we still have no robust, reliable, and valid clinical or biological indices that predict level of response to behavioral interventions. There is an early literature that provides clues regarding which children with ASD respond well to different types of early behavioral interventions (Sherer & Schreibman, 2005), but there is a great need for more research in this area. Furthermore, the phenomenon of "recovery" or loss of diagnosis, occurring in approximately 10% of children with ASD (Helt et al., 2008), is poorly understood. The biological and/or environmental variables, including treatment variables, that predict recovery from ASD are unknown.

A second challenge is that few studies have yet identified the critical ingredients (mediators) that are responsible for the efficacy of behavioral interventions. For example, although studies have shown that early intensive behavioral intervention is effective for improving outcomes of children with ASD, basic questions pertaining to the optimal dose, age of onset of intervention, and specific treatment modality have not been answered. To date, no study has tested head-to-head whether one approach to early comprehensive behavioral intervention is more effective than another (e.g., ABA using discrete trials teaching versus developmental behavioral approaches).

Third, very few studies have documented the longer-term effects of behavioral intervention. There is a great need for longitudinal studies that examine whether the gains obtained

through early intervention are sustained, and if so, what factors account for maintenance of gains. Virtually all randomized controlled trials of comprehensive interventions have been conducted with preschool age children. It is unclear whether children who respond well to these interventions and enter general classroom environments continue to do well during elementary school. It is unknown what specific kinds of ongoing support are needed and what types of residual behavioral challenges these children typically face. The clinical literature suggests that many children who make significant cognitive and language gains as a result of early intensive intervention often experience continued difficulties in the areas of peer relationships, attention, and anxiety. Studies of programs designed to mitigate these difficulties are needed so that early investments in intervention can be of maximum benefit for individuals with ASD.

Fourth, most of the behavioral intervention studies have been conducted by university-based clinical staff, and many of the intervention programs have thus far been developed and evaluated primarily with children with European American backgrounds. To achieve the goal of providing appropriate intervention to all individuals with ASD, it will be important to understand cultural issues pertaining to language barriers, stigma, differences with respect to parenting style, and access to and use of medical and educational services, among others. There is a need to adapt many existing intervention programs to make them more scalable and exportable to the broader community. Mechanisms from training community professionals on a large scale also need to be developed. The use of Web-based and other remote training modalities will need to be tested for their effectiveness.

While progress in the area of early behavioral intervention has been steady, relatively fewer clinical trials designed to test the efficacy of interventions appropriate for school age, adolescent, and adult individuals have been conducted. Reviews of the state of the science regarding social skills interventions (Rao et al., 2008; Reichow & Volkmar, 2009; Williams, et al., 2007) indicate that some promising techniques have been evaluated and manualized. Several studies have shown that social skills during middle and late childhood can be improved through behavioral and psychosocial interventions. It is unclear, however, whether these improvements, which are often taught and assessed in clinic settings, lead to clinically significant improvements in social relationships at home and in the community. Some studies suggest that generalization of learned skills to more complex environments continues to be a challenge. It is unknown, furthermore, whether elementary school–age children who receive social skill interventions are more likely to have satisfying intimate relationships as adolescents and adults. Like other areas of ASD treatment research, research on social skills interventions has been impeded by a lack of valid, reliable measures of social skills that are sensitive to change in treatment studies. In fact, there currently is little consensus on what are the best available measures.

Finally, there is a paucity of research on effective behavioral and psychosocial interventions that can be employed for individuals with ASD during late adolescence and adulthood. A variety of treatment approaches is being used with adults, ranging from social skills groups to job coaching, but the number of published studies that examine the efficacy of such approaches is small. Given the increased prevalence of ASD with many children soon to enter adulthood, it is crucial that more attention be directed toward developing and evaluating behavioral and psychosocial interventions for adults with ASD.

Future Directions in ASD Treatment Research

We have described some of the current challenges and gaps in research on neuropharmacological and behavioral interventions for individuals with ASD. In this section, we highlight some of the future directions in ASD treatment research.

Animal Models to Inform Biological Interventions

Psychiatry has a poor record of translating animal research into new treatments for humans. The traditional approach has been to develop a model in which the animal displays some phenotypes that resemble human symptoms (e.g., depressed mood), and then to validate it by showing that effective treatments in humans can also have beneficial effects in the animal (e.g., fluoxetine). The obvious limitation is that a behavioral phenocopy does not indicate a shared etiology or pathophysiology. Furthermore, showing that a known treatment can be effective in the animal renders the model useful mainly for identifying additional treatments that work by the same mechanism(s) as the known treatments. This approach has not led to new medical breakthroughs in psychiatry. Most existing treatments for neuropsychiatric disorders resulted from a combination of serendipity and astute clinical observation, not animal research. Animal models of ASDs that rely solely on the attempt to phenocopy aspects of the human disease (e.g., impaired social interactions) are not likely to fair any better in furthering discovery of new treatments.

The explosion of knowledge about the human genome and genetic variations that cause or confer risk for disease will change this situation, dramatically (Cowan et al., 2002). Although we are still far from understanding the genetic architecture of ASD, the pace of discovery is quickening. The path from gene discovery to treatment must utilize animals in which the causative mutations can be engineered. It is reasonable to expect that the disruption in brain function by a mutation may manifest differently at the behavioral level in flies, mice, and humans. Yet understanding how neurons function differently in the genetically defined animal model has great potential to reveal core pathophysiological mechanisms and suggest ways that they can be corrected.

Fragile X provides a case in point. Fragile X syndrome (FXS) is manifest in humans in myriad ways—mental

retardation, repetitive and autistic behaviors, altered gastrointestinal function, childhood epilepsy. Modeling any one of these behavioral manifestations in wild type mice would not likely reveal the core pathophysiology of Fragile X, or lead to development of a disease-modifying treatment. However, FXS is caused by transcriptional silencing of a single gene, *FMR1*. The homologous gene has been knocked out in both mice and flies, and these Fragile X animal mutants have been studied extensively to understand the functional consequences of the loss of the gene product, FMRP (D'Hulst & Kooy, 2009). Although the story continues to evolve, many of the core deficits in the animal models appear to be caused by excessive downstream consequences of activating metabotropic glutamate receptor 5 (mGluR5). Remarkably, pharmacological or genetic reduction of mGluR5 signaling has been shown to ameliorate or correct a wide array of Fragile X mutant phenotypes in both mice and fruit flies. These findings suggest an evolutionarily conserved relationship between metabotropic glutamate receptors and FMRP. In the absence of FMRP., the consequences of mGluR5 activity are excessive, and this excess can be corrected by reducing mGluR5 activity (Dolen & Bear, 2008). Currently, several human clinical trials are underway using compounds that either reduce glutamate release in the brain or target selectively mGluR5. Preliminary results might be available by the time this book publishes.

Understanding the basic neurobiology in mice of other single gene disorders associated with human autistic behavior and cognitive impairment has also borne fruit. Examples are CNS changes in tuberous sclerosis, which may be ameliorated by inhibitors of the protein kinase mTOR (Ehninger et al., 2009); neurofibromatosis, which may be ameliorated by statins (Acosta et al., 2006); and Rett syndrome, which may be ameliorated by insulinlike growth factor 1 (Tropea et al., 2009); to name a few. Clinical trials based on findings in the animal models are planned or underway.

Single gene mutations that produce behavioral changes on the autism spectrum are rare, and any treatments that derive from these studies may apply to a small fraction of individuals on the autism spectrum. However, there are hints that the mutations responsible for these rare syndromes fall within pathways or networks of proteins with related functions (Kelleher & Bear, 2008). It is entirely possible that a substantial fraction of cases of autism of (currently) unknown etiology may be "Fragile X–like," sharing with FXS excessive glutamate signaling through mGluR5. Others might be "TSC-like" with altered mTOR signaling, and so on. Perhaps the autisms are caused by disruptions of a limited number of functionally related pathways, in which case treatments developed for a rare, genetically defined syndrome may be broadly beneficial. Expansion of ongoing clinical trials for Fragile X, etc, into nonsyndromic autism will be extremely important, as will tests of the "shared pathophysiology" hypothesis in the extant animal models.

We anticipate that the approach of creating a genetically engineered animal model, followed by intensive neurobiological analysis of pathophysiology will be repeated as additional highly penetrant mutations are discovered. One example of this approach is the neuroligin 4 mutant mouse (Jamain et al., 2008). Genetically defined animal models allow neurobiologists to examine how the brain functions differently in autism at a cellular level. This understanding has suggested potential therapeutic targets, and we will soon know how well these insights translate into the clinic. Animal models also allow additional, critical questions to be addressed. These include the degree to which altered brain development and function can be corrected when treatment is initiated in adults, the persistence of benefit if treatments are initiated during early critical periods of development, and the interactions of genes and experience.

Novel Pharmacological Targets

Glutamate System

The glutamate system has become the focus of translational work in recent years. As is described above in detail, the Fragile X model of autism illustrates that manipulation of aspects of this system can lead to a phenotype that includes autistic-like features. In addition to mGluR5 inhibition, there are other possible molecular targets within this system for pharmacologic manipulation. Patients with autism or Asperger's syndrome were found to have raised levels of glutamate in plasma compared to healthy controls in multiple studies (Rolf et al., 1993, Moreno-Fuenmayor et al., 1996, Aldred et al., 2003, Shinohe et al., 2006). Glutamic acid decarboxylase protein, the enzyme responsible for normal conversion of glutamate to GABA in the brain, has been noted to be reduced in the brain of autistic subjects in postmortem studies, suggesting increased levels of glutamate or transporter receptor density in autistic brains (Fatemi et al., 2002). In addition, further postmortem studies have revealed decreased AMPA-type glutamate receptor density in the cerebellum of autistic individuals. In the same study, the mRNA levels of several genes involved in the glutamatergic pathways were significantly increased in autistics, including the excitatory amino acid transporter 1 and the glutamate receptor AMPA 1 (Purcell et al., 2001). Genetic findings are still very preliminary but have so far revealed a mutation in the glutamate receptor gene GRIK2 in 6q21 that is present in 8% of autistic subjects and 4% of controls and seems to be transmitted from mothers to autistic males (Phillipe et al., 1999), a susceptibility mutation in linkage disequilibrium with variants in the metabotropic glutamate receptor 8 gene on chromosome 7 (Serajee et al., 2003), and a single nucleotide polymorphism of the GR1N2A subunit of the NMDA receptor associated with autism (Barnby et al., 2005).

A few medications affecting the NMDA receptor have produced preliminary evidence that encourage further studies in this system. Amantadine, which has NMDA noncompetitive inhibitor activity, was used in a double blind placebo controlled trial in autistic children, was well tolerated, and had modest effects on irritability and hyperactivity (King et al., 2001). Dextromethorphan is an NMDA receptor

antagonist. In a series of case studies of children with autism, it was reported to improve problem behaviors such as tantrums and self-injurious behaviors, as well as anxiety, motor planning, socialization, and language (Woodard et al., 2005, Welch et al., 1992, Phillips et al., 1999).

Memantine is a noncompetitive NMDA inhibitor. There have been four open-label studies of this compound reporting on a total of 186 children with autism. Effects of memantine included improvements in irritability, lethargy, hyperactivity, inappropriate speech, stereotypy, memory, and language (Owley et al., 2006, Chez et al., 2007, Niederhofer et al., 2007, Erickson et al., 2007).

The above discussion is encouraging in terms of suggesting that aspects of the glutamate system are possible targets for pharmacological manipulation in individuals with ASD. Well-controlled studies in this area are necessary.

Oxytocin/Vasopressin

Oxytocin (OXT) and the similar peptide vasopressin have been linked to modulation of social cognition and function in both animal models and in humans (see Chapter 34). A number of researchers have hypothesized that OXT may be implicated in autism given that repetitive behaviors and deficits in social interaction are core features of autism, and that this neuropeptide is involved in the regulation of repetitive behaviors and social cognition. Insel et al. (2004) postulated that abnormalities in the neural pathway for OXT could account for many features of autism including the early onset, predominance in males, genetic loading, and neuroanatomical abnormalities. The data for oxytocin involvement in the pathophysiology of autism is still limited although emerging (see Chapter 34). Still, children with autism have lower average levels of blood OXT level in comparison to typically developing children matched for age (Modahl et al., 1998) and may fail to show the normal developmental decrease with age (Green et al., 2001). Differences in OXT peptide processing pathways may result in inactive or less active forms of OXT. Neuropeptide synthesis genes may also be candidates for genetic susceptibility in this disorder. Recent studies suggest a genetic association between the OXT receptor gene and autism (Wu et al., 2005; Ylisaukko-oja et al., 2006; Jacob et al., 2007). Polymorphisms in the AVP receptor have also been linked to autism (Kim et al., 2002; Wassink et al., 2004; and Yirmiya et al., 2006) These findings are consistent with animal studies showing that both OXT and AVP genes are involved in many aspects of social behavior. Hollander et al. (2007) reported that intravenous administration of oxytocin facilitated the retention of social cognition in autism spectrum disorder patients.

Given the above, well-controlled studies manipulating the oxytocin system are warranted. Questions to be still addressed in preparation for large clinical trials are related to the pharmacokinetics/pharmacodynamics of the compound, the mode of administration, and the choice of social cognition outcome measures to be used.

Immune Modulation

Active and ongoing neuroinflammatory process in the cerebral cortex and white matter and cerebellum have been reported in postmortem brain tissue of subjects with ASD. The abnormalities included activation of microglia and astroglia (Vargas et al., 2005). Both microglia and astroglia are integrally involved in cortical organization, neuronal transmission, and synaptic plasticity. Activation of neuroglial cells can produce significant neuronal and synaptic changes that are likely to contribute to CNS dysfunction observed in autism. Increase in CSF proinflammatory factors, including IL-6, interferon-gamma, and MCP-1, have also been reported (Vargas et al., 2005; Pardo et al., 2005; Zimmerman et al., 2006). The changes are consistent with a dysregulated immune response and likely a skewed T helper cell type 1 (TH1/TH2 cytokine profiles), decreased lymphocyte numbers, decreased T cell mitogen response, and the imbalance of serum immunoglobulin levels. Many studies have documented elevated levels of proinflammatory cytokines in patients with ASD, including TNF-alpha/IL-12 (Jyonouchi et al., 2005a, 2005b, 2001); tumor necrosis factor receptor II (Croonenberghs et al., 2002a); IFN-Gamma and IL-1RA (Zimmerman et al., 2005); MCP-1, a macrophage chemoattractant protein (Vargas et al., 2005); and IgG2 and IgG4 (Croonenberghs et al., 2002b). Other studies have found that patients with ASD produce lower levels of IL-10, an important counterregulatory cytokine.

Other evidence possibly linking autism to the immune system comes from immunogenetic studies of the HLA genes, which are important determinants of immune function (Pardo et al., 2005). For example, a particular MHC haplotype (B44-Sc 30-DR4) associated with immune dysfunction has been shown to occur significantly more frequently in individuals with autism or their mothers as compared to unrelated controls (Daniels et al., 1995). Other immune-based genes including HLA-DRB1, complement C4 alleles (Ashwood et al., 2006), and HLA-A2 alleles (Torres et al., 2006) have also been shown to occur with significantly greater frequency in autistic subjects. Finally, evidence is accumulating that autoimmune disorders occur with significantly greater frequency within families of autistic individuals (Sweeten et al., 2003).

There are multiple agents available that may modulate the immune system of children with ASD in favorable way. Of note, this is an area where alternative compounds such as omega 3 fatty acids may be showing as much early promise as Western medications, such as pioglitazone. However, the evidence for any of these is preliminary at best and well-controlled studies are urgently needed.

Back Translation

In this commentary, we have discussed the importance and progress in the translation from basic science to research on treatments. However, "back translation" is also an important strategy for making progress in developing treatments. Findings from clinical trials have the potential to elucidate the

pathophysiology of autism. For example, as discussed above, a clinician scientist may consider not only studying the effect of an immune modulating agent on behaviors, but linking such improvements to specific inflammatory biomarkers, thus contributing to our understanding of the nature of possible immunologic abnormalities in this population.

Individual Differences

A significant challenge that needs to be addressed is understanding and predicting individual differences in responses to pharmacological interventions. ASDs are a heterogeneous group of disorders associated with multiple etiologies, clinical presentations, and comorbidities. There is a great need for identification of biomarkers that can predict which individuals will respond to which medications. Genetic and other biomarkers can potentially help predict individual differences in treatment efficacy, pharmokinetics, and side effects profiles.

Future Directions in Early Behavioral Intervention

Intervention with Infants and Toddlers

New advances in very early detection of ASD offer the possibility of intervening before the full syndrome of ASD is present. Thus, for the first time, prevention of ASD is plausible (Dawson, 2008). Genetic and environmental risk factors contribute to an atypical trajectory of brain and behavioral development in ASD that influences the early patterns of interaction between the child and his/her environment, particularly the social environment. Studies of infant siblings of children with ASD have found that many infants who later develop ASD begin to exhibit symptoms during the second half of the first year of life (see Zwaigenbaum, Chapter 5, this volume). Among the earliest symptoms are a lack of attention to other people and a failure to engage in social imitation and communicative babbling. These symptoms influence early interactions between the infant and the social world, thereby limiting the amount and quality of linguistic and social input that may be necessary to promote brain and behavioral development. Thus, early risk factors contribute to *risk processes* resulting in secondary effects of the early symptoms that may contribute to the development of the full ASD syndrome. By intervening early before the full syndrome is present, it might be possible to mitigate the downstream effects of early symptoms on later brain and behavioral development. In this way, prevention of the full syndrome of ASD, at least in some cases, might be possible (Dawson, 2008).

As described by Rogers and Wallace (Chapter 61 in this volume), early interventions that are appropriate for infants at risk for ASD as young as 12 months of age are currently being developed and tested (Dawson et al., 2009). Furthermore, six randomized clinical trials of early interventions for infants and toddlers, funded by Autism Speaks, are currently underway. Although the interventions vary, comparable pretreatment and outcome measures are being used, which will allow for comparing and combining data across the studies. Notably, there are several similarities among the six interventions being tested. They all are parent-delivered, involve individualized approaches that tailor the targeted skills to the developmental level of the child, and address early pivotal skills such as imitation and joint attention that set the stage for later social and communication development. The fact that the interventions are parent-delivered makes these interventions scalable and exportable to the broader parent community.

Combined Behavioral and Pharmacological Interventions

As described above, studies are currently being conducted that examine whether the mechanisms involved in single gene disorders such as FXS (namely, excessive glutamate signaling) may be similar in nonsyndromic ASD. If it is found that there is shared pathophysiology across different genetic subtypes of ASD, it is possible that medications that improve neural signaling would become available for a larger percentage of the ASD population. If such medications become available, it is likely that these will be used in combination with behavioral interventions. Early intensive behavioral interventions facilitate the formation of new connections in the brain that support the development of social behavior and communication. The hope is that medications that improve neural functioning will help individuals with ASD become even more responsive to behavioral interventions. In one of the first randomized clinical trials to examine the efficacy of a combined pharmacological and behavioral approach, Aman and colleagues (2009) found that, in combination, the use of medication and parent training was more effective for reducing serious behavioral problems in children with ASD than medication alone.

In conclusion, emerging data from basic science (neuropathology, genetics/genomics/proteomics, animal models) have made it possible to start identifying neurochemical systems involved in the pathophysiology of autism that can be specifically targeted with neuropsychopharmacological interventions. It is anticipated that, ultimately, pharmacological agents targeting systems involved in the pathophysiology of ASD will be used to facilitate existing behavioral interventions. Research reflecting the reality of providing multimodal interventions will have the largest impact in the care of individuals with autism. Such studies are fairly difficult to do and require significant commitment on the part of funding agencies, researchers, and the autism community. Early data has provided encouragement regarding the feasibility and value of such an approach (Scahill et al., 2009).

Best Practices: Early Diagnosis and Psychological Assessment

Points of Interest

- Early diagnosis of ASD provides children and families with more opportunities for accessing specialized intervention services that may promote improved functional outcomes.
- The diagnosis of ASD is often an intense emotional experience for caregivers, and an important aspect of the assessment process involves supporting families and promoting engagement with recommended services.
- In the absence of definitive medical and genetic etiologies, early diagnosis is reliant on understanding a child's behavioral profile in relation to the core symptoms of ASD.
- Additional research is needed to determine the reliability and stability of ASD diagnosis in children under 2 years old.
- Integrative and multidisciplinary approaches hold promise for refining the diagnostic assessment process and enabling service systems to meet the growing needs for appropriate diagnosis at younger ages.

An ever-growing body of scientific literature supports the fact that autism spectrum disorders are not rare. In fact, at an estimated prevalence of 1 in 110, ASD is among the most common of all developmental disabilities (Centers for Disease Control and Prevention [CDC], 2009). At the same time, there is little certainty regarding its etiology, the earliest clinical markers, course, optimal intervention practices, and outcomes for young children with ASD. Complicating this substantially limited scientific knowledge base is the fact that there has been unprecedented popular scientific, political, and media attention paid to ASD in the past decade. Although this attention has in many instances provided substantial benefits on individual, family, and system levels, in the face of scientific uncertainty, this attention has also contributed to a context of confusion and conflict for caregivers and professionals alike in understanding, pursuing, and obtaining appropriate and meaningful diagnostic assessment for ASD at young ages.

> **Key Point**
>
> - Early diagnosis of ASD can improve functional outcomes for children and families as well as reduce service system demands.

At present, the diagnostic evaluation of young children for ASD represents a public health issue of critical importance. Earlier diagnosis of ASD provides children and families with more opportunities for optimal benefit from intensive and specialized intervention services. Children who enter into autism-specialized intervention services at younger ages may show greater gains in cognitive and adaptive functioning and may be more likely to achieve fully integrated classroom placements at school age than children diagnosed at later ages (Cohen et al., 2006; Dawson & Osterling, 1997; Harris & Handleman, 2000; Remington et al., 2007; Rogers, 1996, 1998; Smith et al., 2000). An early diagnosis may lead to improvements in the quality of life for the child with ASD. When linked with intensive autism-specific intervention, early diagnosis may improve family functioning and ultimately reduce substantial service system demands.

Individuals with ASD were once thought to display comorbid intellectual disabilities and to fail to achieve adaptive independence as adults (Filipek et al., 2000; Howlin et al., 2004). However, recent work suggests that these poor outcomes may not be as prevalent as once thought (Chakrabarti & Fombonne, 2001, 2005). Such changes in the conceptualization of outcomes are complex and are likely to be associated with many factors, including major shifts in diagnostic processes. Thus, we cannot attribute better outcomes solely to the benefits of early diagnosis and intervention. However, all available evidence suggests that early diagnosis and intervention can play a meaningful role in improving outcomes for children

with ASD in the short- and long-term. As such, from a public health perspective, early intervention may ultimately reduce the considerable lifetime cost and service system demands associated with providing care and support to individuals with autism and their families (Jacobson & Mulick, 2000; Jarbrink & Knapp, 2001).

> Key Points
>
> - Although concerns about ASD are often noticed in the first years of life and professional groups consistently advocate for early screening and intervention, numerous barriers contribute to a significant time gap between first concern and diagnosis.
> - There are unique challenges for generating definitive diagnoses of ASD for very young children (i.e., children under 2 years of age).

Despite the public health need and mounting evidence that caregivers of children with ASD are able to identify and report concerns about development to medical professionals by the age of 12 to 18 months (Coonrod & Stone, 2004; DeGiacomo & Fombonne, 1998; Rogers & DiLalla, 1990; Wimpory et al., 2000), currently the average age of diagnosis is around 4 years of age or older in underserved communities and subgroups of children with higher IQs (CDC, 2009; Croen et al., 2002; Mandell et al., 2002; Yeargin-Allsopp et al., 2003). To address the gap between time of first concern and diagnosis and to take advantage of the potential impact of early intervention, several consensus panels involving numerous professional groups—including the American Academy of Neurology (AAN) and American Psychological Society (Filipek et al., 2000), the American Academy of Child and Adolescent Psychiatry (Volkmar et al., 1999), and the American Academy of Pediatrics (AAP) (Johnson & Myers, 2007)—have issued practice parameters endorsing early ASD screening in clinical practice settings. Most notably, recent AAP guidelines endorse formal screening for ASD at 18 and 24 months of age, as well as at any point when caregiver concerns are raised. This mandated screening, in combination with increased caregiver and public awareness of the earliest "red flags" of ASD, are creating a pressing need for diagnostic assessment of very young children (i.e., under 2 years of age). This situation presents a significant challenge to clinical diagnosticians, since the available "gold-standard" diagnostic tools and the judgments of even the most experienced clinicians have been applied in a limited manner to this age group. The field is now facing the critical question of whether and how ASD can be identified and addressed at ages that were not previously thought possible.

It is within the context of unprecedented public awareness, increased mandates and desires for definitive diagnoses of ASD at earlier and earlier ages, and limited empirical evidence surrounding the fundamental early features, course, and treatment of ASD that clinicians and diagnosticians are now operating. This chapter summarizes a wide range of considerations related to the diagnostic assessment process in young children that can optimize our ability to help children with ASD and their families. These issues include not only those related to obtaining an accurate diagnosis in young children, but also those related to the assessment process in general and the provision of optimal clinical care to children and families alike.

Function of Diagnostic Assessment

> Key Point
>
> - A meaningful diagnostic assessment of ASD involves understanding a child's unique behavioral profile as well as recommending appropriate interventions based on this profile.

A primary function of a diagnostic assessment for ASD is to understand the child's strengths, challenges, behavioral profile, and their implications for intervention. Ideally, a meaningful diagnosis of a neurobehavioral disorder such as ASD would be tied not only to a specific etiology, but also to specific medical, behavioral, and/or educational interventions, as well as reasonable predictions about the likely individual responses to these interventions (Lord & Richler, 2006). At present, the diagnosis of ASD in young children is not yet sufficiently backed by a body of etiological or intervention research that can reasonably claim to approach this goal. In the vast majority of cases, the field is not yet able to pinpoint specific causes of ASD that can be linked to specific treatments or cures. Likewise, the active ingredients underlying successful ASD treatments have not yet been identified, nor has the field determined whether specific treatments are superior to others, or discovered which treatments are better for whom and when. In the face of this uncertainty, a critical function of the diagnostic assessment process is to link families to individually tailored intervention plans that can be realistically implemented. In this regard, the diagnostic assessment process in young children can often expedite access to services, describe characteristics (e.g., the nature and intensity) of effective treatments, identify key intervention areas, and specify concrete measurable goals for children with ASD and their families.

> **Key Points**
>
> - An important aspect of the diagnostic assessment of ASD involves providing family support and facilitating access to specialized services.
> - Parents of young children with ASD often find themselves serving in the role of advocate and resource specialist for their child.
> - The diagnostic assessment process can be conceptualized as the initiation of intervention for the child and family.

Apart from providing information about how the child's unique behavioral profile relates to ASD and which services appear appropriate based on such a profile, a meaningful diagnostic assessment should also serve the function of supporting families (Bailey, 2008). The reality of the diagnostic assessment process is that it is often an intense emotional experience that can be quite confusing, frustrating, and frightening for many caregivers. The clinician is not simply focused on establishing a definitive behavioral profile and diagnosis, but is ultimately working toward conveying information about this profile in a manner that promotes optimal understanding, acceptance, and movement toward specific goals. The formal diagnosis of ASD, even when suspected for lengthy intervals of time, contributes to an array of reactions—from relief, to guilt, to loss, to action—in caregivers both in the short- and long-term (Hutton & Caron, 2005). In addition, personal experiences and the increasing variety of accounts of autism in popular media formats often contribute to an array of thoughts and beliefs about the nature of autism (Harrington et al., 2006). The diagnostic assessment process can help address these thoughts and reactions in a manner that helps the family engage proactively in the pursuit of intervention services that available science suggests will benefit the child as well as the family. For example, important components of the diagnostic assessment process include understanding parental beliefs about the causes of their child's ASD and potential attributions of blame and guilt, as well as helping families negotiate the complex landscape of various behavioral, educational, and complementary and alternative treatments. In this regard, the assessment itself may be understood as the initiation of intervention. Specifically, this intervention is provided in the form of helping elucidate and/or reframe the individual strengths and challenges of the child with ASD within larger contexts of what is important to the family to promote optimal developmental trajectories.

Another important aspect of the diagnostic process is the implication a diagnosis holds for obtaining access to desired services. In many instances, a specific ASD diagnosis is required for access to specialized programs, funding, and intervention opportunities (Lord & Richler, 2006). Conversely, the inability to provide a definitive diagnosis because of limitations in our diagnostic methods and understanding at very young ages may prevent families from obtaining certain services. Unfortunately, there is often a gap between the guidelines and laws surrounding interventions, and the availability of community resources and services (Bayley, 2008). As such, families often face significant barriers to accessing interventions. Caregivers are often placed in the extremely difficult role of having to act as expert advocates and resource specialists for their child to secure services that their child needs. Given this situation, the diagnostic assessment represents an entry point for assisting parents in developing effective advocacy and resource procurement skills. Thus, the assessment process not only presents families with overwhelming information about their child's developmental disability, but also conveys the importance of becoming the primary agents for facilitating

and implementing service recommendations within complex bureaucracies of existing service systems. Effective diagnostic assessment must balance presentation of information to aid in efficient utilization of available resources in the most time sensitive manner possible (Mash & Hunsley, 2005).

The Assessment Process

> Key Points
>
> - Families may have very different experiences, emotions, and expectations that they bring with them to the assessment.
> - Incorporating family experiences and input into the assessment from the initial point of entry is critical for establishing a productive working relationship.

Many families seeking a diagnostic evaluation for ASD have already had numerous formal and informal experiences, opinions, and/or evaluations offered by professionals, family, and friends that impact their desire, or lack thereof, for a formal diagnosis of ASD (Goin-Kochel et al., 2006; Mansell & Morris, 2004). Optimally, caregivers have expressed concerns to professionals and individuals within their support networks who have, in turn, been sensitive and supportive in listening to and validating their concerns as well as assisting them in securing a comprehensive diagnostic assessment explicitly for ASD. Even in this ideal circumstance, such support and validation does not eliminate the often intense distress and anxiety that caregivers experience in anticipating an evaluation that might confirm the fears they have about their child. Regrettably, many caregivers do not receive support for their concerns and instead are met with dismissive attitudes by professionals and individuals within family support systems (DeGiacomo & Fombonne, 1998; Goin-Kochel et al., 2006; Liptak et al., 2008). In other circumstances, caregivers may in fact have very limited knowledge or specific concerns about ASD, but have been asked to pursue services by professionals in their care systems. In each of these circumstances, careful attention to the nature and development of the caregivers' concerns—and the reactions of others to these concerns—may promote optimal engagement in the assessment process itself and provide an important springboard to the initiation of treatment.

Whether the caregivers' concerns have been validated, disregarded, or have been minimally present prior to the assessment, it is very important to understand how this mix of experiences and emotions caregivers carry into and through the assessment can impact the primary goal of promoting optimal outcomes for children with ASD. Failure to adequately attend to, discuss, and address such concerns may contribute to potential dismissal, or suboptimal understanding, of the findings and recommendations from the evaluation. This situation may lead to delays in accessing potentially beneficial services, which in turn may impact the child's outcome,

disrupt the family system, and increase demands on service systems at later time points. It is therefore extremely important to establish a meaningful working relationship with families from the initial point of contact, and to nurture this relationship throughout the assessment process, the discussion of clinical impressions and recommendations, and the follow-up.

Initial Contact

Key Point

- Conveying appropriate expectations for the assessment process in advance can facilitate the family's comfort and engagement.

The assessment process itself starts with the family's first contact with those affiliated with the clinical assessment system. This contact is not necessarily with the clinician, but more often with nonclinical intake or resource personnel who collect the basic referral information required to determine: *(1)* the appropriateness of a diagnostic evaluation for ASD; and *(2)* the fit between the caregiver's concerns and the resources of the clinical setting. During this process it is critical to balance the need for caregivers to express their concerns and ask questions about the nature of the assessment, with the recognition that they are not usually communicating at this point with the clinicians who will be performing the assessment. This initial contact can be very challenging for intake staff, as caregivers may wish to provide very detailed accounts about their child's history in a manner that may be more specific than necessary at this entry point of the evaluation. Thus, intake staff should make attempts to listen attentively, compassionately, and patiently to caregiver concerns and questions, while also indicating to families which information is actually needed at the time, and what their own limitations are in terms of providing definitive answers to the caregiver's questions.

An important consideration in this initial contact is the emotional state and functioning of the caller. It is a powerful understatement to note that it is quite distressing for caregivers to pursue an evaluation when the question is often explicitly, "Does my child have autism?" Many caregivers are in intense emotional or crisis states when asking this question, and intake personnel should be familiar with strategies for: *(1)* providing reassurance and support to caregivers while gathering the necessary information; and *(2)* offering concrete, pragmatic answers to the most common questions caregivers have about diagnostic evaluations. It can be quite helpful to provide caregivers with specific expectations for the nature of the assessment process, to reduce the uncertainty and distress surrounding this situation (cf., Stone & DiGeronimo, 2006). Specific information may relate to the qualifications of who will perform the assessment, when the assessment will take place, what will happen during the assessment, how long the assessment will last, whether the caregiver(s) can be with the child during the evaluation, whether they should bring along family members and/or

support persons, when they will receive the results, and what information they will receive at the end of the evaluation. Family members can also use this information to prepare their children for the evaluation. Specific advance information about the physical nature of the assessment area, including potential difficult situations (e.g., crowded waiting rooms, elevators, parking garages) can avoid unnecessary confusion and facilitate optimal levels of success on the part of the child.

Child and Family Assessment

Key Points

- A good assessment will provide opportunities for the child to demonstrate skills and strengths as well as experience success.
- Families should be active participants in the assessment process.

Optimally, caregivers arrive for comprehensive assessment already having a good understanding of what will happen on that day as well as who will be present during the assessment and why. Even in this circumstance, caregivers are often uncertain as to how they should act and why certain activities are occurring through the course of the assessment day. It is important to make caregivers as comfortable as possible by detailing the main focus of the evaluation, the structure of the day, each assessment tool and its purpose, as well as introducing the members of the assessment team and encouraging caregivers to seek clarification and alert team members to their own or their child's needs whenever they feel necessary.

Many caregivers are concerned about how their child will behave in the assessment environment. For example, they may be worried that their child's behavior will be different than it is in more familiar settings, or that the assessment results may either over- or underestimate the child's true level of skills. Likewise, caregivers may be concerned or embarrassed if the child exhibits challenging behaviors and they may be uncertain about what role they should play in these situations. It is often helpful to let caregivers know that the assessment will be geared toward obtaining optimal performance from the child. Further, it can be beneficial to let caregivers know that all observed behavior will be matched with information from the caregivers themselves about whether these observations are consistent across circumstances that the caretaker observes. Finally, when challenging behaviors manifest themselves, it is helpful to reassure caregivers that the assessment team is comfortable with and adept at addressing these behaviors, and, moreover, that the opportunity to observe such behaviors provides valuable information to the assessment team.

Inviting caregivers to join their children in the assessment room to observe, comment on, and (when appropriate) participate in the assessment process itself can be helpful for many reasons. Their presence often provides the child with a sense of familiarity and comfort, and may also serve a similar

function for caregivers themselves. Caregiver participation can offer excellent opportunities to facilitate meaningful discussion about behaviors that both parties have observed. These shared observations provide a framework for discussing behaviors and understanding their significance and impact on family interactions. Some caregivers may be overeager to assist their child in completing activities during the assessment process, but simple reminders about the nature of their participation usually limits any substantial interference in the process (Bailey, 2008). In other circumstances, observations can be quite distressful when caregivers perceive that their child is not passing items or is behaving in a manner that other children might not. In these situations it is important that the clinician provide reassurance to the caregiver and explanations about what they are doing and why, as well as to ensure that the child is given opportunities to experience success and demonstrate positive skills within the context of the assessment. This approach conveys to caregivers that the clinician is not only looking for areas of deficit, but also interested in identifying areas of strength and competence.

Maintaining transparency in the diagnostic assessment process whenever possible can help families understand the assessment from a functional perspective, alleviate any unnecessary uncertainties, and establish a goal-driven alliance between caregivers and clinicians from the outset. When families are included as active participants in the assessment, when their expertise in knowing their children better than anyone else is labeled as critical and important, and when the functions of assessment are clearly explicated, many caregivers will be primed for hearing and accepting information that can be quite difficult to receive. First and foremost, this transparency comes in the form of talking to families about ASD itself. When the referral question relates to the diagnosis of ASD, caregivers should be informed that specific assessment procedures geared toward evaluating the presence or absence of ASD will be conducted. This procedure invites caregivers to start talking about their own concerns and/or preconceptions from the outset, helps alleviate anxiety that could potentially grow over the course of the assessment, and prepares parents for later discussion about ASD diagnosis. Sometimes it is difficult for families themselves to mention the word "autism" as an explicit concern, even when they have sought a referral to an autism-specialized clinic. When this is the case, clinicians should attempt to facilitate the family's discussion of autism at the outset of the assessment process and discuss the term themselves with comfort.

When discussing explicit concerns about autism and the diagnostic process, it can be helpful to provide families with a framework of how and why a diagnosis is established. In the absence of a specific biological or genetic marker for the majority of cases of autism (*See Chapter 40 for details on clinical genetic assessment and Chapter 74 for a description of best practices in medical assessment*), the diagnosis essentially involves creating a behavioral profile of the child's skills and vulnerabilities in the areas of social interaction, communication and language, and repetitive interests and activities. In addition,

strengths and challenges in areas not specific to the diagnosis of autism, such as cognitive, motor, and adaptive behavior skills are evaluated to provide a more comprehensive view of the child and help identify areas and target goals for intervention. In circumstances where a specific genetic or biological etiology of ASD is indicated, assessment aims at indexing these same skill areas and the variability related to core ASD symptoms that exist within specific subgroups of children.

Ideally, families should be informed that the assessment will be based on information that they provide as well as behaviors that are observed directly. Explaining that the goal of the assessment is to spend enough time with the child and family to gather an impression of the child's strengths and weaknesses that fits with the family's own experiences can reassure parents about the nature of the process and help create a powerful working alliance. Likewise, describing the often complex names and terms used to refer to specialized clinical tools and procedures can further demystify the assessment process. For example, explaining that the Autism Diagnostic Observation Schedule is a gold standard measure in the assessment of ASD and that it involves talking to and playing with the child so that the clinician can personally experience the child's social and communication skills, can be quite effective in helping families understand a procedure that may otherwise not be transparent. Further, informing families that the behavioral profile of ASD is not characterized merely by the presence or absence of specific behaviors, but also by inconsistencies in displaying developmentally appropriate behaviors across settings, can also be important in facilitating eventual understanding of the diagnostic process. Many families have ideas and stereotypes of individuals with ASD from popular media and personal circumstance that are often focused on the exceptional both in terms of areas of deficit and strength. Finally, conveying information that the ultimate goal of the diagnostic assessment is to provide the family with assistance in ensuring that their child's needs are being met appropriately—regardless of whether a diagnosis is confirmed or disconfirmed—can help those families who may be struggling with the concept of "labeling" and its potential negative effects over time.

Diagnostic Feedback

> **Key Points**
>
> - Disclosure of ASD diagnosis is often an intense emotional experience for families and addressing the varied reactions of caregivers is an important element of successful disclosure.
> - Successful feedback must balance the provision of caregiver support with the need to encourage action toward appropriate interventions for the child.

In many circumstances, immediate feedback subsequent to the assessment itself is thought to be ideal. Certainly long

delays—and the resulting uncertainty and discomfort associated with waiting—may be extremely difficult to tolerate, and should be minimized whenever possible. However, there may be a number of circumstances under which it might be appropriate to delay feedback. For example, some families may be exhausted from the evaluation day, some may prefer to have other family or supportive individuals with them, and still others may prefer to receive feedback when their child is not with them. It is important to take into account the fact that disclosure of ASD is an event that can have a profound emotional impact for families as well as profound implications for clinical outcomes. Many families may be overwhelmed by disclosure of ASD diagnosis and may benefit from more comprehensive feedback about recommendations and interventions at a later date. Other families may wish to have all the information they can possibly have delivered immediately, so they can move forward with pursuing interventions. It may be hard for families and clinicians alike to know this preference at the outset of the appointment. However, families should be asked explicitly about their preferences, and clinicians should take these preferences into account and be as flexible as possible in offering a follow-up visit to discuss the evaluation results.

Unfortunately, very little empirical work has been conducted regarding effective disclosure of diagnoses of ASD. The existing literature has linked parent satisfaction with ASD diagnosis to factors that are primarily unrelated to the disclosure itself. Specifically, factors such as earlier age at diagnosis, fewer referrals prior to diagnosis, and prior acceptance of concerns by other professionals have been associated with increased satisfaction of disclosure of ASD (Brogan & Knussen, 2003; Mansell & Morris, 2004). A larger body of literature exists regarding the disclosure of diagnostic information about other developmental and physical disabilities (Hasnat & Graves, 1999), but there remain questions as to the applicability of this literature to ASD-specific samples. Notably, a diagnosis of ASD is often delivered later than diagnoses of other physical and developmental disabilities, and there are no specific biological or medical markers of ASD to aid in the diagnosis. With this caveat in place, factors in the disability literature attributed to the successful disclosure of a diagnosis include: interpersonal style, empathetic support and sensitivity, discussion of the whole child, up-to-date knowledge, provision of written material, and opportunities to ask questions (Brogan & Knussen, 2003).

Successful disclosure in many ways should be an end point of an assessment process that has been building from the first point of contact. If families have been prepared for the assessment day itself, the assessment process has been transparent and clearly explained, and families have been involved throughout, then disclosure of a diagnosis can involve revisiting the experiences and observations of the day, reaffirming that the clinician's impression fits with the caregivers' experience of their own child, and placing these impressions within or outside the bounds of a formal ASD diagnosis. Even under ideal circumstances, it is still critical to ask parents about their specific reactions to the diagnosis and their concerns about how and why the diagnosis was made, prior to embarking on a discussion of specific recommendations and resources.

For many parents the emotional reaction of the disclosure necessitates significant pause and/or clinical reassurance. Many parents benefit from the support and validation of their assessment team when clinicians acknowledge the difficulty of considering that their child might have ASD, reinforce the parents' willingness to pursue a diagnostic evaluation, and recognize the impact that disclosure of ASD diagnosis can have on parents. Messages that "normalize" the parents' reactions to this experience, and acknowledge that they have asked perhaps one of the scariest questions possible for the ultimate benefit of their child, should be conveyed. In addition, it is important to convey information to indicate that the diagnosis has not changed their child in any way, but will enable them to access resources that would otherwise have been unavailable. Finally, discussion centering around the numerous areas of child and family strength, in addition to vulnerabilities related to ASD, can assist many families in receiving subsequent information about recommendations and interventions for their children.

Along with providing reassurance and support, effective feedback will also address the specific limitations and vulnerabilities of the child in a manner that promotes involvement with clinically indicated intervention services. Many families will seek reassurance that their child's level of functioning will not necessarily impact or limit them from moving forward. Specifically, many families hold attributions that their child with ASD is "high-functioning," when clinical indicators suggest that there may be significant areas of delay. Although it is important to deliver feedback about strengths and to reassure families experiencing acute distress, ultimately it is important to note the areas of impairment that warrant attention and action in order to help move families toward appropriate resources. Questions regarding level of functioning, including ideas of "recovery" and overcoming challenges, are often driven by projections about the child's future, and the fundamental parental hope for the most positive outcome possible for their child. As such, these questions are ultimately some of the most important for parents, but are very difficult for clinicians to answer for individual children. The ability to predict long-term outcomes for very young children with ASD is quite limited (Chawarska et al., 2007; Lord, Risi, et al., 2006; Stone & Turner, 2007) and this is particularly true for children under 2 years of age. Providing families with quality information about the best group-level predictors and the realistic limitations surrounding diagnostic stability can be quite helpful for families of young children. Currently, these predictors for young children include language capacity, nonverbal abilities, and response to interventions. In addition to child characteristics and intervention factors, it may be that parental and familial factors such as hope, coping strategies, and specific reactions to diagnosis may be strong predictors of outcomes as well, particularly when coupled with clinically informed action. This area is certainly one that warrants significant additional attention, both in terms of research and clinical practice.

Resources and Recommendations

> Key Points:
>
> - Accessing appropriate interventions can be challenging for many families and likely requires substantial clinical guidance and follow-up.
> - Specific intervention recommendations should be framed within the broader context of best practices for ASD as well as within the community-specific context of what is available.

In addition to seeking answers about long-term implications of ASD diagnosis for their child's development, parents are often looking for more immediate guidance and explicit instruction in garnering help for their child. Unfortunately, even when the results of the diagnostic assessment are quite clear-cut and delivered with certainty, concrete information about how caregivers can best help their child is often lacking. Not only are there limits in terms of the empirical understanding of interventions, but differences in availability of community services and family resources unfortunately impact the quality, intensity, and type of services that many children with ASD will receive. In this context, it falls upon the clinician to deliver realistic information about what the field knows and does not know about effective intervention approaches, which interventions are available through community service systems and which require financial resources, and how parents can augment the impact of interventions via their own expertise and motivation to help their children.

It is beyond the scope of the current chapter to provide an explicit review of specific intervention recommendations for children with ASD; rather, the reader is referred to existing practice parameters (e.g., Myers & Johnson, 2007; National Research Council (NRC), 2001; *See also Chapters 12 and 13 that review interventions for preschool age and infant-toddler age children*). However, several points about conveying such information in the context of the diagnostic assessment process warrant attention. First, it is important to consider that the complex nature of negotiating service systems immediately following ASD diagnosis is overwhelming for most families, even families of substantial means and with copious support. As such, provision of follow-up services aimed explicitly at helping families of young children with ASD secure appropriate intervention appears crucial. When service coordination is lacking in the community, clinicians who schedule follow-up meetings and review intervention programming over time will likely be better able to help families access appropriate services.

It is also extremely important that families be given concrete information about resources, including written materials whenever possible. In addition to supplying timely and understandable evaluation reports, families can often benefit from receiving immediate recommendations or action checklists, in which critical next steps are laid out specifically and concretely. Written materials about ASD and related interventions that are targeted explicitly for parents can be quite helpful for

reinforcing action toward clinically indicated services. In the current climate of ASD awareness, many parents have already done copious internet and/or other informal research prior to pursuing a diagnostic evaluation. Although beneficial and empirically supported information is abundant, it is unfortunate that a multitude of information of a much lower quality is widely available as well. Failing to provide families with information or resources for accessing or evaluating this information will leave them in the difficult position of trying to sort out this complex information to make decisions about what may or may not be best for their child. Offering parents a core set of information and encouraging families to seek additional information as needed from other sources can reinforce a model of persistent engagement balanced with clinical support.

In providing feedback about interventions, it must be recognized that in addition to the behavioral and educational interventions recommended in current practice parameters (Myers & Johnson, 2007; NRC, 2001), most parents have questions about complementary and alternative medical (CAM) treatments as well. At present, a majority of children with ASD participate in CAM treatments, with the number of different treatments and their rate of use growing over time (Harrington et al., 2003; Wong & Smith, 2006). Caregivers are often eager to try any potential treatment in search of positive outcomes for their children, and CAM treatments may be more salient, attractive, and alluring than educational and behavioral interventions that actually have more scientific backing (Smith & Wick, 2008). As more children with ASD become involved with CAM treatments, it is important for clinicians to be familiar with these interventions and address them within the context of the assessment. If clinicians hope to assist families more fully in making autonomous, empirically informed decisions about treatments, then they must address questions about CAM treatments in a manner that allows families to feel comfortable reapproaching this issue on an ongoing basis. Materials that provide information in lay terms about the complexity of evaluating treatment effectiveness are sorely needed.

> Key Point:
>
> - Addressing the medical complexity of children with ASD is imperative and warrants multidisciplinary collaboration and follow-up.

Finally, young children with ASD are often medically complex and have a variety of needs that go beyond the scope of behaviorally based evaluations for ASD. Diagnostic evaluations should be multidisciplinary in nature, and should include assessment of associated medical conditions (e.g., seizures) and etiologies (e.g., Fragile X Syndrome). Ideally, a pediatrician, neurologist, or psychiatrist should participate in the evaluation to address these medical issues. Although team-based assessments are the ideal, they are not common, and pragmatic challenges related to reimbursement have

shifted care systems away from multidisciplinary team models. As such, when evaluations are primarily conducted by a behavioral provider, it is of extreme importance that core medical assessment and consultation be recommended and coordinated as part of that child's ultimate clinical care. In addition, when indicated, referrals should be made to specialists in the areas in which children with autism often have medically related problems (e.g., pediatric sleep specialist, pediatric gastroenterologist, specialist in genetic and metabolic conditions). It is becoming a standard of care to address and discuss issues of genetic vulnerability with families affected by ASD for their own family planning purposes, for the medical care and surveillance of their children, as well as to alleviate parental guilt and/or false attributions about etiology (Johnson & Myers, 2007; Myers & Johnson, 2007). The Autism Treatment Network, a program funded by Autism Speaks, was initiated with the specific goal of developing standards of care for identification, evaluation, and treatment of common medical conditions in children with ASD, such as sleep disorders, seizures, gastrointestinal disorders, and genetic/metabolic disorders. The Autism Treatment Network sites have medical specialists and subspecialists who are experienced in working with children with ASD, and thus represent excellent resources for comprehensive medical care.

Diagnostic Assessment for Children under 2 Years of Age

Key Point:

- Although some children with ASD can be diagnosed under age 2 years, there remain significant questions concerning the reliability and stability of such an early diagnosis using currently available assessment methodologies.

As numerous forces push for accurate ASD diagnoses to be made at younger and younger ages, it is important for those conducting ASD assessments to be aware of the potential limitations that exist regarding our current understanding of the diagnosis in children under 2 years of age. A growing body of work suggests that diagnoses of autism (i.e., autistic disorder) delivered by an expert clinician employing ASD-specific parent report and clinical observation assessment tools at age 24 months are generally reliable and stable up to school age in predicting continued ASD diagnostic classification (Charman et al., 2005; Eaves & Ho, 2004; Lord, Risi, et al., 2006; Stone et al., 1999). However, there appear to be limits to diagnostic stability even at this age. Specifically, there is evidence suggesting that ASD diagnoses fail to achieve optimal stability until 30 months of age (Turner & Stone, 2007) and there is considerable work suggesting that broader ASD classifications (i.e., Pervasive Developmental Disorder – Not Otherwise Specified (PDD-NOS)) are much less stable in young children

(Lord et al., 2006; Turner & Stone, 2007). Far less research has been conducted to date examining ASD diagnoses in children under 2 years of age. Consequently, knowledge of the limits of diagnostic classifications is extremely important to understanding optimal assessment practices for ASD in children in this age range.

Accuracy in clinical diagnosis of ASD for children under 2 years of age is, in part, impeded by limitations in our knowledge about specific behavioral manifestations of ASD itself at this time in development. Retrospective studies (see Palomo et al., 2006), prospective studies utilizing at-risk siblings of children with ASD (see Zwaigenbaum et al., 2007 for overview), as well as prospective studies of children failing development screens (Wetherby et al., 2007), have started to identify specific areas of delay that may be characteristic of ASD in the first years of life. This literature suggests that early behavioral markers predictive of a later ASD diagnosis may be present in *some* children as early as the first or second year of life (Bryson et al., 2007; Gamliel et al., 2007; Landa & Garrett-Mayer, 2006; Zwaigenbaum et al., 2005). However, there remain limitations in our certainty resulting from: *(1)* substantial individual variability related to these same markers and subsequent diagnostic outcome, as well as *(2)* mounting evidence for the presence of multiple distinctive developmental trajectories of ASD—characterized by early regressions, decrements, plateaus, slowings, and/or significant improvements—with some children more readily identifiable at specific time points than others (Bryson et al., 2007; Landa et al., 2007). Moreover, there is not yet sufficient evidence that the presence of early social communication vulnerabilities predicts specific ASD-related impairments at all later time points, irrespective of effects of maturation and intervention (Turner & Stone, 2007). Thus, there is sufficient variability in the nature, onset, intensity, and course of these early behavioral markers in young children that the implications for providing a definitive ASD diagnosis or recommending autism-specialized interventions for children under 2 years of age are unclear.

Available tools for detecting symptoms of ASD in children under 2 years old also have serious limitations. Currently, the "gold standard" clinical assessment tools utilized for diagnostic classification are less robust psychometrically for children with a mental age below 24 months, and decline in utility as mental age decreases (Chawarska et al., 2007; Lord, Risi, et al., 2006). Specifically, there are concerns that the Autism Diagnostic Observation Schedule (ADOS) (Lord et al., 2000) and the Autism Diagnostic Interview–Revised (ADI-R) (Rutter et al., 2003)—the leading diagnostic tools with well-established psychometric properties for school-aged children—have questionable diagnostic validity in children under 2 years of age. These tools exhibit tendencies to overclassify nonverbal children and children with mental retardation and to underidentify more verbal children and children without significant repetitive behaviors in their profiles at younger ages (Chawarska et al., 2007; Lord et al., 2006). New algorithms and a toddler module for the ADOS (i.e., ADOS–Toddler Version), may likely improve the utility of this instrument with children

below 24 months of age (Gotham et al., 2007), but currently these tools are not widely available, nor is there corresponding empirical work examining the diagnostic validity of these instruments. In addition to instrumentation, there is also a significant discrepancy between the diagnostic classification symptoms as currently described in Diagnostic and Statistical Manual of Mental Disorders (DSM-IV) and markers of ASD in young children (Zwaigenbaum et al., 2007). The DSM-IV symptoms of ASD are most often indicative of ASD symptoms seen in preschool, school-age, and adolescent populations, and their specific extension and application to symptoms of ASD in infancy and toddlerhood is unclear.

Despite these limits, emerging work suggests that ASD can be diagnosed in some children under 2 years old. Specifically, research performed exclusively within the context of high-risk infant sibling samples has, in fact, documented subgroups of children meeting criteria for autistic disorder at 12 to 25 months of age who have retained diagnosis up to a year later (Chawarska et al., 2007; Landa et al., 2007). Again, there appears to be less stability when initial clinical diagnoses are of the broader ASD spectrum, explicitly PDD-NOS (Charwarska et al., 2007; Gamliel et al., 2007). This research offers hope that meaningful, stable ASD diagnosis can be made during the second year of life, at least for certain small groups of children by leading experts in the field of ASD research. However, there remain numerous questions about how such early diagnoses relate to longer-term outcomes and how sensitive early measurements and diagnosis are for larger populations of young children. Specifically, questions remain about whether and how the diagnosis can be made with similar levels of stability, meaning, and impact within broader community settings. This issue is particularly pertinent as current professional guidelines and popular attention push clinicians to screen for and presumably diagnose ASD outside the realm of prospective research studies of high-risk populations and within the context of traditional community pediatric settings.

> Key Point:
>
> - The diagnosis of ASD in children under 2 years old should be accompanied by discussion of the limits of our knowledge in terms of diagnostic stability and the need for continued monitoring and follow-up.

In the absence of consensus guidelines of how to interpret DSM-IV criteria for children in this age group, how to utilize early behavioral markers of ASD, as well as how (or whether) to extend available ASD assessment tools to this population, clinicians are left in the challenging position of testing the limits of appropriate classification and diagnosis. At the same time, the existing early intervention and corresponding public health literature make strong arguments that diagnostic classifications, if tied to effective ASD-specific interventions, should be made. Because of the unique challenges of identifying children with ASD under 2 years old, the diagnostic process should be led by a clinician not only experienced with infants and toddlers, but also with symptoms of ASD in infants and toddlers. Ideally, ASD diagnosis in children under 2 years of age should be based on the clinical best judgment of an experienced multidisciplinary team, carefully taking into account a vast array of biopsychosocial information about the child's developmental history and current functioning. The scope of such assessments has been detailed previously (see AAN, 1999; Bishop et al., 2008; Johnson & Myers, 2007; Lord & Richler, 2006) and includes: a medical assessment and physical exam, including evaluation of normal hearing; thorough assessment of developmental level (i.e., evaluation of cognitive, speech/language, communication, and adaptive functioning); direct assessment of spontaneous social communication, play skills, and atypical behaviors matched with extensive clinical interviewing about these same skill domains.

Unfortunately, the current state of our science is that even when such comprehensive methods are undertaken, it may not necessarily be clear that the observed and reported behavioral markers are indicative of the presence or absence of ASD. Even for expert clinicians, it is much more difficult to distinguish ASD from other developmental disorders, including broader spectrum difficulties related to social and communication delays, in children under age 2 years. This fact has been particularly evident within high-risk sibling samples, where subtle and clear differences in social and communication development are clearly present in many children at early ages, but the link between these difficulties and later ASD occurs in a minority of cases (Gamliel et al., 2007; Merin et al., 2007; Presmanes et al., 2007; Stone et al., 2007; Zwaigenbaum et al., 2007). In addition, very young children may present with a range of additional medical and regulatory concerns whose impact on development may be challenging to tease apart in relation to social and communication vulnerabilities. When social-communication impairments are present in very young children, but clinical best estimate diagnostic certainty of ASD is lacking, the constructs of "at risk" and "prevention" may prove useful in acknowledging this developmental uncertainty, while at the same time conveying the needs for immediate intervention services related to core areas of deficit, and for systematic follow-up.

This uncertainty concerning the development of ASD in very young children exists within a context in which parents, clinicians, and service systems want (or need) definitive classifications and answers in order to access specialized services. As such, clinicians are not only confronted with the specific challenge of how to best provide information about how the child's unique behavioral profile relates to the ASD, but also how best to support families in promoting their child's optimal developmental outcome. Clinical best practices dictate that maintaining transparency in the diagnostic assessment process with families is often the ideal. For children under age 2 years, this process includes explicit discussion of the real predictive limits of our science, assessment tools, and diagnostic classification process itself. This presentation of assessment and diagnostic uncertainty can be a particularly challenging

process if parents and service systems are expecting clear, authoritative diagnoses on the basis of a one-point-in-time assessment. However, specific value can come from highlighting the limitations of diagnostic assessment within the context of providing reassurance that the assessment process will ultimately result in a richer understanding of the child's behavioral profile of strengths and challenges that can guide specific interventions regardless of whether a definitive diagnosis is issued. Even when primed for and presented with such reassurance during the assessment, it can ultimately be challenging to approach diagnostic ambiguity for families. In assigning concerns of ASD risk, families will likely experience confusion and differing interpretation of whether such assignment warrants specific action or simply increased surveillance and monitoring. As such, it becomes critical for clinicians working in this context to explicitly highlight the warranted interventions to be pursued in the short-term as well as to provide a specific rationale and methods for providing diagnostic clarity as children develop.

Conclusions

All existing evidence powerfully suggests that early diagnoses of ASD and appropriate intervention play a significant role in improving outcomes for children and families. Meaningful diagnostic assessment not only attempts to index ASD-specific concerns in the context of the developmental profile, but also recognizes the critical importance of supporting families to promote engagement in clinically indicated interventions. Ideally, diagnostic assessment also focuses on the complex medical profiles and needs of children with ASD and is multidisciplinary in nature. Currently, limited access to team-based assessments, and limitations of our diagnostic tools themselves for children at very young ages, present potent barriers to early diagnosis and intervention.

Challenges and Future Directions

- The reliance on observable behavioral assessment profiles limits our ability to identify core ASD vulnerabilities at the youngest ages.
- Integrative multidisciplinary tools and procedures may provide an improved assessment methodology for early diagnosis.
- As the limits of ASD diagnosis are pushed younger and younger, it is critical to understand the implications for families and for service systems related to diagnosis and intervention.
- An empirical understanding of the assessment process itself (e.g., how a diagnosis is delivered, family perceptions/attributions) may be powerful in advancing outcomes for individuals with ASD and their families.

The earlier we are able to identify the core vulnerabilities associated with the development of ASD, the closer we will come to understanding the neuroscience, genetics, and etiology of the disorder as well as implementing interventions that promote optimal developmental outcomes for children and their families. Looking ahead, diagnostic assessment may involve the identification of specific genetic and medical etiologies that have direct implications for specific interventions. In absence of such markers at present, provision of exceptional clinical care must balance pressures for definitive diagnoses of ASD at earlier and earlier ages with acknowledgement of the empirical limitations of diagnoses for very young children.

In pushing the limits of ASD diagnosis to include assessments conducted within the first 2 years of life, the viability of the concept of ASD risk may also be important to consider within the realm of community clinical practice. Specifically, regardless of geography and availability of high-quality diagnostic assessment services, the wait for such services is often quite extensive. It is not uncommon for parents of young children to be told that there is a 6-month wait list for services (Zwaigenbaum & Stone, 2006). Waits for evaluations conducted by subspecialists for infants and toddlers would likely prove even longer. As such, the development of assessment tools and pragmatic methods for promoting identification of risk for ASD hold promise. For example, interactive screening tools such as the Screening Tool for Autism in Two-Year-Olds (STAT) (Stone et al., 2000, 2004, 2008) may provide information about risk status as well as immediate intervention goals (Zwaigenbaum & Stone, 2006). The ability to identify risk status and initiate appropriate intervention (or prevention) services has advantages for families faced with long waits for diagnostic evaluations, as well as for clinicians faced with providing definitive diagnoses at a time when it is premature to expect clear-cut meaningful classifications.

Finally, in searching to refine the diagnostic assessment process for young children, researchers must look not only at the earliest social and communicative behavior of ASD in marking atypical development from typical development, but to potential new collaborative methodologies for obtaining diagnoses that incorporate additional sources of information. The inclusion of psychophysiological, functional neuroimaging, and medical and genetic data with early behavioral markers may provide ways for advancing the assessment of ASD in young children. As we wait for such research to add value to our diagnostic process, great care should be taken to utilize our current knowledge to more efficiently identify and serve larger groups of children at risk for ASD as soon as possible. In this regard, benefits will likely come not only from pragmatic revision of assessment, eligibility, and service models for at-risk children, but also from more fully exploring the roles of how diagnostic assessment services can optimally serve families.

Diagnosis and Assessment of Autism Spectrum Disorders: A Medical Perspective

Points of Interest

- Autism spectrum disorders are associated with several medical syndromes and genetic disorders, and their identification can impact diagnosis, prognosis, and treatment.
- Medical concerns, such as gastrointestinal symptoms and sleep problems, occur commonly and warrant evaluation and management as part of the overall treatment plan.
- Genetic testing consisting of high resolution chromosome analysis and testing for Fragile X syndrome is recommended in all diagnostic evaluations.
- Newer medical treatments have potential to greatly improve core symptoms of ASDs.
- The comprehensive treatment of a person with an ASD can be best provided through the family-centered, coordinated care received in a medical home.

Leo Kanner's original report of what he called "autistic disturbances" in 1943 continues to serve as not only an accurate depiction of the classic form of the disorder now known as autism, but also as a model for reporting the medical and behavioral aspects of psychiatric disorders . His original description of 11 children with similar problems of communication, social relatedness, and repetitive behaviors included careful examination of their progress over an extended period of time. During this ongoing observation, Kanner considered potential underlying medical factors that might have caused the disorder as well as family and social factors. He was most impressed with the parents, who were uniformly highly intelligent but at the same time displayed features similar to their children but in a milder form, and he commented that they were not "warm-hearted." He noted that six of the 11 children had "presented severe feeding difficulty from the beginning of life." He also noted that five of the 11 had relatively large heads. One child had seizures with an abnormal EEG, and the

other ten had normal EEGs. One child had a supernumerary nipple, but otherwise there was little in the way of dysmorphic features. As a result of these observations, he concluded that although he could not deny the possible influence of the family unit on the formation of this disorder, he felt that these children came into the world with an innate inability to form typical social relationships. Since that first description, much has been learned regarding the medical or biologic basis for many psychiatric disorders including autism. This chapter will discuss the medical aspects of autism spectrum disorders, and their influence on diagnosis, assessment, and treatment, beginning with a description of the medical evaluation in the context of the autism diagnostic process.

The Medical History

As part of a multidisciplinary diagnostic evaluation for autism, which typically includes a pediatrician, psychologist, speech-language pathologist, and occupational therapist, the medical evaluation is a key component that can inform not only diagnosis but treatment. A thorough developmental and family history should be taken with the goal of identifying risk factors for developmental disorders including autism. The developmental history should include prenatal conditions that affect the developing fetus, perinatal experiences, and conditions or illnesses encountered in infancy and childhood.

Prenatal: A careful history should be obtained of any illness or problems during the pregnancy, such as infections or eclampsia. For example, maternal rubella infection during pregnancy is associated with congenital rubella syndrome, a disorder associated with intellectual disability and potential autistic symptoms (Chess et al., 1978). Other maternal infections, such as flu, have also been shown in rats to increase the risk for behavioral changes similar to those seen in autism (Shi et al., 2003). Toxemia of pregnancy or eclampsia can result in

uterine blood flow abnormalities and decreased oxygen supply to the fetus. Preexisting maternal conditions, such as diabetes, can also have effects on the unborn fetus. Maternal seizure disorders requiring treatment with anticonvulsants run the risk of exposing the fetus to potential teratogens such as valproic acid (Rasalam et al., 2005). Exposure to other drugs or alcohol should also be determined. Mothers with preexisting nutritional or metabolic disorders such as hypothyroidism or phenylketonuria (PKU) have increased risks of a child having medical complications. Any unusual maternal dietary habits should also be noted as these may expose the fetus to inadequate or excessive amounts of certain vitamins or minerals.

Perinatal: Premature birth carries many risks of health problems, including respiratory and neurologic sequelae. Recent studies (Kuban et al., 2009; Limperopoulos et al., 2008) have indicated an increased risk of displaying symptoms associated with autism among graduates of neonatal intensive care units. Intrapartum fetal distress, birth asphyxia, intraventricular hemorrhage, sepsis, and meningitis are a few of the disorders affecting developmental outcome in this age group. Early feeding problems may be associated with later diagnosis of an ASD, perhaps reflecting early motor problems often associated with ASDs.

Postnatal: Medical difficulties during the first year of life can have significant effects on the developing central nervous system. Evidence of adequate growth and nutrition should be obtained through past growth charts or identified dates with heights and weights. Head growth trajectory should be noted, as it has been shown that atypical head growth characterized by accelerated growth beginning at about 4 months of age has been associated with ASDs (Webb et al., 2007). Deceleration of head growth after a period of normal growth has been associated with Rett syndrome (Huppke et al., 2003). Hospitalizations and surgeries should be documented. Reports of early developmental milestones are useful in considering first signs of a problem. Descriptions of social behavior during infancy, such as vocalizations, smiling, and interacting are important, as are difficulties noted with feeding or cuddling. Reports of any potential head trauma resulting in loss of consciousness should be noted.

Developmental History: The child's attainment of typical developmental milestones is an important part of the diagnostic process (*see Chapters 5 and 73 in this volume for detailed information about developmental signs often observed during the first and second year of life*). Delays in language can be caused by several conditions other than autism, such as hearing loss, specific language delay, or as part of a global developmental delay. The child's progress in social, communication, and motor domains should be queried as well as observed during the assessment. A history of developmental regression, or loss of skills, is of concern when reported by parents. This can suggest either a specific condition such as childhood disintegrative disorder, or a progressive metabolic or neurodegenerative disorder.

Family History: A family history focused on developmental and behavioral disorders should be elicited. A family history of autism spectrum disorders is of value, as the risk is increased significantly in subsequent children if a sibling has an ASD (Muhle et al., 2004). ASDs have also been found to be associated with a family history of autoimmune disorders (Ashwood & Van de Water, 2004). Other disorders associated with ASDs include Fragile X syndrome, Rett syndrome, and tuberous sclerosis. A family history of several males affected by mental retardation may suggest Fragile X syndrome; a history of several members with epilepsy, brain tumors or other tumors can be indicative of tuberous sclerosis complex. Early infant mortality in siblings or first-degree relatives can be seen in some metabolic disorders. Apart from the emphasis on disorders associated with autism, the history should inquire about usual family medical history concerns such as autoimmune, cardiac, gastrointestinal, pulmonary, endocrine and renal disorders, and cancer.

Review of Systems

In addition to assessing the primary concern leading to evaluation of a child or adolescent for ASDs, the medical assessment also should address any coexisting functional complaints. Concerns seen most frequently in children with ASDs include gastrointestinal (GI) and related nutritional status, sleep issues, innate immunity or risk for infectious diseases, and general behaviors such as stereotypies or hyperactivity. Psychiatric comorbidities such as ADHD, anxiety, and depression are very common, especially in older children and adolescents. Although the behavioral concerns usually are related to ASD diagnostic criteria, the other symptoms are more likely to be seen by many physicians as problematic but not related to the diagnostic visit. Medical problems such as GI distress, sleep disturbances, and so on, have been found to be significant problem areas for the child and family (Limoges et al., 2005; Nikolov et al., 2009; Tuchman & Rapin, 2002). Moreover, many of these problems have successful treatments and can, therefore, have a significant and immediate impact on quality of life and behavioral functioning. Best medical practice dictates that these should be reviewed and assessed accordingly as part of a thorough evaluation.

Gastrointestinal Concerns

Gastrointestinal symptoms including abdominal pain, diarrhea, gaseousness, and constipation are frequently reported by parents of children with ASDs. Numerous studies have examined these complaints through a wide range of surveys and with varying attempts at comparison or control groups. Reports of the incidence of gastrointestinal symptoms range from 17% (Taylor et al., 2002), to 85% (Horvath & Perman, 2002). A recent study of a well-characterized sample from the Research Units on Pediatric Psychopharmacology

(RUPP) reported a 22.7% incidence rate (Nikolov et al., 2009). Most frequent among the symptoms are diarrhea and constipation, often reported as alternating episodes in the same child. Abdominal pain may be clearly communicated by the child, or may be interpreted by the family to be present based on the child's behaviors. For example, a child experiencing pain may be more irritable, aggressive, or self-injurious. Parents may note certain behaviors occurring within a short time period of eating or elimination, and identify these as indicative of discomfort or of food intolerance or allergy. Their child's limited diet or food preferences may be interpreted as the child's response to food intolerances in an effort to reduce discomfort. Conversely, parents often describe implementing a variety of dietary changes in response to their child's gastrointestinal symptoms. In addition to diet manipulations that any parent might make in response to their child's complaints or symptoms, there are many nontraditional approaches parents may elect to use directed at treating these gastrointestinal symptoms, such as a gluten-free, casein-free diet, digestive enzyme supplementation, or probiotics.

Sleep Concerns

Sleep problems in individuals with autism spectrum disorders are frequently seen. They include delayed sleep onset, night waking, early awakening, obstructive sleep apnea, sleep epilepsy, and reduced need for sleep. A large population-based, case-controlled study of young ASD children (ages 2 to 5 years) found that 56% of children had at least one frequent sleep problem, with night waking and sleep onset problems the most prominent, a rate similar to children with other developmental disorders, but higher than typically developing children (Hansen et al., 2008). Although there are many reported sleep problems, difficulties with obtaining proper polysomnographic studies in this population have resulted in fewer studies using objective measures to define the sleep disorder. Studies using these methods frequently do find sleep abnormalities confirming what is commonly reported by parents (Richdale, 1999; Malow, 2004).

The Physical Examination

Although the diagnosis of an ASD continues to be a behavioral diagnosis at this time, there are medical conditions that may predispose to its development or that may occur as comorbidities. The medical evaluation is important in helping to ascertain etiology of the patient's ASD, and in the establishment of a comprehensive treatment plan that addresses all medical conditions along with the nonmedical treatment of the patient's ASD.

General: The child's affect, gait, and interactions with parents and staff should be observed as the child and parent

are brought back to the examining room. Reports by the parents of a change or worsening in gait or mobility should be correlated with these observations. Any special concerns, such as extreme responses to loud noises or marked fearfulness, should be noted. The child's responses to office staff, to others in the waiting room, and to requests to come to the exam room can give initial clues as to ability to hear and understand requests and questions, and verbal language in responses, as well as willingness to comply and ability to transition from waiting room to exam room. The child's responses to recording of height, weight, and vital signs should be similarly observed. Throughout these early minutes in the assessment visit, attention should be paid to the child's ability to make and maintain eye contact, to communicate appropriately for age, and any obvious patterns of behavior or stereotypies.

Head and Neck: Head circumference should be recorded, as a large percentage of children with ASDs have macrocephaly. Recent findings suggest a correlation of macrocephaly in patients with autism and mutations in the phosphatase and tensin (PTEN) gene (Varga et al., 2009). If macrocephaly is identified, the head circumference of both parents should also be obtained, as the most common cause of macrocephaly is familial and nonpathologic. Attention should be paid to the presence of any dysmorphic features—eyes, ears, nose, oral cavity—that would suggest a specific medical syndrome. Limited ability to abduct the eyes or presence of facial asymmetry may suggest Moebius syndrome, which may accompany autism in 25 to 40% of cases (Gillberg & Steffenburg, 1989; Johansson et al., 2001). A flattened appearance to the nose and face may indicate midfacial hypoplasia, which can be seen in several syndromes. The prominence of the philtrum and upper lip may be clues to fetal alcohol exposure.

Skin: There should be an examination for café au lait spots (hyperpigmented) or ash leaf marks (hypopigmented), as may be seen in neurofibromatosis and tuberous sclerosis, respectively. A Wood's lamp may be useful in this process. *Wood's light*, or ultraviolet light, is used to highlight pigmentary changes in the skin. It can help differentiate hypomelanotic macules from similar appearing lesions caused by topical fungal infections. Inspection for shagreen patches on the trunk, or adenoma sebaceum on the face should be made, as these are seen in tuberous sclerosis. Palpation of the skin for fibromas should be done as part of screening for neurofibromatosis.

Abdominal: Examination should be done for enlargement of the liver or spleen, as this may be seen in certain metabolic disorders. Attention should be paid to palpating for stool to support a history of constipation.

Genito-Urinary: The presence of hyperpigmented macules on the penis may suggest PTEN mutation. Macro-orchidism may indicate Fragile X syndrome.

Neurologic: The neurologic examination should document status of reflexes, muscle tone, and strength. Any abnormalities of muscle size or lateralizing findings should be noted. Examination of the cranial nerves may be done as part of the

head and neck exam, and may be difficult to fully ascertain if the patient is uncooperative.

Extremities: Documentation should be made of range of motion and any dysmorphic features—syndactyly, arachnodactyly, contractures, etc.—which might suggest a specific syndrome.

Cardiac and pulmonary exams should be completed as the child allows. Although there are no specific findings associated with autism in these portions of the physical, their inclusion is part of a thorough medical exam.

An important point to note is that many children with ASDs are difficult to examine in comparison to typically developing children. If the child is tired and uncooperative, some components of the examination may be deferred to a second visit. Although oppositional behavior may limit the documentation of physical findings, the type of resistance the child displays during the medical exam process often contributes to the diagnostic process in terms of documenting behavioral criteria for an ASD. A patient and gentle approach is usually best, and much appreciated by both patient and parents, and can set a positive tone for other parts of the diagnostic process and ongoing care. A child's sensitivity to touch, sound, and lights can influence the willingness of the child to be cooperative with the exam.

Associated Medical Conditions

There are several medical conditions for which their association with ASDs is clearly higher than that of the general population. Although the developmental-behavioral phenotype for these medical conditions may include symptoms meeting the diagnostic criteria for autism, such cases are often referred to as "secondary" autism; that is, their medical condition is believed to play a role in the causation of their autism. This etiology has been estimated to occur in up to 10% of cases (Barton & Volkmar, 1998; Battaglia & Carey, 2006). Improved understanding of these associated disorders can shed light on the underlying pathophysiology seen in the more common idiopathic ASDs.

Fragile X Syndrome

Fragile X syndrome is caused by a trinucleotide repeat on the X chromosome (Oberle & Rousseau, 1991; Verkerk et al., 1991). The gene defect occurs at the 5' end of the gene for FMR-1 protein. This repeat segment results in hypermethylation of the gene and subsequently failure to produce the FMR-1 protein. The syndrome is characterized by mental retardation, short stature, large ears and long face with prominent jaw, and macro-orchidism. Language development is particularly affected, and can be affected in female carriers (Bennetto et al., 2001). This is related to the number of trinucleotide repeats and the proportion of inactivated affected X chromosomes; the spectrum of the phenotype is related to the total amount of FMR-1 protein production.

Fragile X syndrome occurs in approximately 1 in 4,000 males in the general population (Sherman, 2002). Studies of Fragile X in autism populations suggest an incidence of up to 5%. Conversely, estimates of the rate of ASDs in Fragile X syndrome has been reported to be as high as 15 to 33% (Rogers et al., 2001). Although Fragile X is not a major cause of autism, autism or autistic symptomatology is a common complication of Fragile X. The autistic phenotype seen with Fragile X syndrome males tends to feature significant gaze aversion, hyperactivity, and increased sensory sensitivity. In affected females there is a tendency toward severe social anxiety. Both have a common pattern of "cluttered" speech, with episodes of rapidly speaking and verbal perseverations.

Beyond the behavioral and neurocognitive phenotype, individuals with Fragile X syndrome have an increased rate of other medical conditions. Joint laxity is seen in the majority, and hypotonia is common in the early years. As a result, complications such as scoliosis and hernias may occur. Seizures are reported in approximately 20% of cases, and there is an increasing identification of cardiac problems as they mature into adulthood. Most commonly this presents as mitral valve prolapse, and is seen in up to half of cases (Hagerman, 2002). Identification of medical complications of the disorder is important to the provision of comprehensive care to the patient.

Tuberous Sclerosis

Tuberous sclerosis complex (TSC) is an autosomal dominant disorder with primary manifestations in the nervous system. The textbook presentation is one of angiofibromas on the face, epilepsy, and mental retardation. The disorder is named for the cortical tubers that develop, which are assumed to be the principal cause for the patient's epilepsy. Epilepsy is the most common component, occurring in up to 90% of individuals with TSC. The TSC gene function is related to regulation of cell growth and proliferation, along with abnormal organogenesis. Loss of function of the gene, as happens in tuberous sclerosis complex, leads to uncontrolled cellular growth and the development of hamartomas throughout the body. The most easily identified dermatologic manifestations include angiofibroma of the face, hypomelanotic macules (often referred to as *ash leaf spots*), and a shagreen patch. Angiofibroma of the face, seen in 75% of cases, typically develop from about age 4 or 5 years onward, and are frequently mistaken for acne. The shagreen patch is less frequent, occurring in less than one-fourth of patients, and gives the skin an orange-peel texture. It is usually seen on the trunk or back, and may appear in children as young as age 2 years. Hypomelanotic macules are present on the trunk in nearly 90% of patients and can be identified in the first year of life, thus encouraging a thorough inspection of the skin in the diagnostic assessment of a young child for autism. A Wood's lamp, or ultraviolet lamp, is often useful in highlighting these lesions in infants and toddlers. Presence of hypomelanotic macules is not diagnostic of TSC, but is one of the findings that, when assembled, may point to this diagnosis.

It has been thought that the cortical tubers are the primary cause of epilepsy and mental retardation in cases of TSC. However, newer research suggests that cognitive and neurobehavioral aspects have a much more complex etiology than this.

If diagnosed, TSC has significant implications for ongoing medical management and monitoring. The pathognomonic hamartomatous lesions can occur in numerous organs and tissues. Brain manifestations such as cortical tubers, subependymal nodules, and giant cell astrocytomas can cause significant neurological symptoms. Although these are rarely malignant, their presence and growth can impinge on other brain structures and result in hydrocephalus or other complications. Rhabdomyomas of the heart and retinal phakomas occur in more than half of subjects, and angiomyolipomas frequently occur in the kidney.

15q 11q13 Duplication Syndrome

The region of chromosome 15 q11q13 has received significant attention since the mid-1990s. Various deletions, insertions, inversions, and duplications have been identified (Battaglia, 2005). Deletions are associated with Angelman's syndrome and Prader-Willi syndrome (Christian et al., 1999). The duplication referred to as inv dup (15) presents a consistent pattern of intellectual disability and hypotonia. A strong association has been found between isodicentric chromosome 15 and autistic features (Rineer et al., 1998; Borgatti et al., 2001). These children present with extreme gaze avoidance and social withdrawal, with a range of self-stimulatory behaviors directed at objects in their vicinity such as spinning objects, shiny objects, and water. Expressive language is poor and stereotypies are very common. Cognitive function is usually overall delayed, and significant hypotonia is present from birth and contributes to late acquisition of motor milestones. Although these children have some mild dysmorphic features, they do not have a characteristic appearance. Epilepsy appears to be a common complication (Battaglia et al., 1997).

Differential Diagnosis and Laboratory Workup

Laboratory studies and ancillary testing and consultation should be conducted to confirm or rule out conditions and diagnoses suggested by the history and physical examination. Some studies are recommended in all cases because of the significance of the result in formulating a diagnosis and treatment (e.g., obtaining an electrocardiogram (ECG) in any person over age 50 years with chest pain). Other studies are conducted only when the presentation—presenting concern, detailed history, and physical examination—suggests potential diagnoses that may rule out the presenting concern (e.g., not an ASD but a communication disorder) or that may need to be addressed as part of the overall treatment

plan. Recommendations for laboratory evaluations in ASD assessments are changing rapidly as new information is acquired and new technologies become available.

Audiology: The presentation of a child who does not speak or seem to listen, as seen in suspected ASD, requires evaluation of hearing in all cases. This is currently recommended as part of the evaluation of any child with developmental delay.

Lead Screening: The known effects of lead exposure on development, the increased risk of exposure associated with younger children who examine much of their environment through the mouthing of objects, and the potential to provide treatment that can improve function all support the screening for lead with a blood lead level.

Genetic Screening: The yield for genetic testing continues to increase as newer techniques are introduced and genetic correlates of medical conditions are identified. Current recommendations are for high resolution chromosome studies and for DNA analysis for Fragile X syndrome in all children with developmental delay. Newer techniques such as microarray technologies are developing rapidly. These methods are capable of locating copy number variants (CNVs) of smaller and smaller size, and of screening for larger and larger numbers of these CNVs on a single array—well over 5 million and quickly rising. However, many of the CNVs identified through this process are of no known significance. Performing this testing at this time often leads to uncomfortable discussions with the family about finding an abnormality and not knowing what it means. Until more is known, this procedure is not considered routine or mandatory, but this field is rapidly advancing and recommendations could change in the near future.

Metabolic Screening: Mandatory screening for numerous inborn errors of metabolism is done in most developed countries. In the United States, all states screen for 27 different disorders and vary in their requirements to screen up to a total of 51 disorders. Although children with some metabolic disorders such as PKU can display symptoms of an ASD, the majority of metabolic conditions present earlier in life with significant medical symptoms such as failure to thrive, seizures, and recurrent infections. There is no recommendation for routine metabolic screening in an ASD evaluation. Testing should be done only if clinically indicated, such as abnormal state of consciousness, repeated episodes of vomiting, dysmorphic features, and family history of a metabolic disorder. Questionable screening at birth, as in an immigrant child, is another indication.

Electroencephalography (EEG): Children and adolescents with ASDs do have an increased incidence of epilepsy, and studies have shown a rate of EEG abnormalities higher than the general population. However, these abnormalities are largely nonspecific and do not impact on care. Similarly, at this time there is no evidence to support treating EEG abnormalities in the absence of clinical seizure activity. There is no recommendation for routine EEG testing in ASD evaluations. Testing should be done in any child with a history of suspicious spells or episodes. It is also recommended in cases with

a history of regression, particularly language, because of the possibility of identifying Landau Kleffner syndrome, a treatable disorder.

Neuroimaging Studies: Similar to EEG findings, computed tomography (CT) and magnetic resonance imaging (MRI) studies have shown an increased incidence of intracranial abnormalities compared to more typically developing children. Again, these abnormalities have failed to accumulate into recognizable ASD phenotypes and rarely require any specific intervention. The presence of macrocephaly alone, with normal neurologic findings and no indication of intracranial process are not adequate to justify neuroimaging. There is no recommendation for routine neuroimaging in ASD evaluations but this field also is rapidly progressing and this may change in the near future.

Other Studies: The laboratory evaluation of a number of other minerals, hormones, and micronutrients, urinary peptides, food allergy testing, and hair analysis and heavy metal exposure are not recommended. Immunologic testing for celiac antibodies or signs of inflammation, stool analysis for yeast, and other neurochemical testing for glutathione disorders are also not recommended. The scientific evidence for conducting these studies fails to support them at this time.

Psychological and Speech-Language Testing: These evaluations are recommended as a required component of a diagnostic workup for ASDs. Psychologists routinely administer the standardized behavioral diagnostic tests, such as the Autism Diagnostic Observation Schedule (Lord et al., 2000). In addition, psychological testing is needed to establish levels of intellectual disability and pinpoint specific patterns of cognitive strengths and weaknesses, such as specific problems in auditory processing, memory, attention, and social comprehension. Speech-language evaluations are important for understanding the causes and nature of language delay, such as problems in the areas of oral motor functioning, phonemic discrimination, verbal memory, receptive versus expressive language, gestural development, and pragmatic language. These assessments are necessary for confirming the diagnosis and for establishing the treatment plan. More detailed neuropsychological testing should be done if standard testing fails to provide adequate detail regarding the child's cognitive abilities and if concerns about educational progress and strategies are present.

Medical Treatments

Treatment of Gastrointestinal Symptoms

It is possible that gastrointestinal symptoms can contribute to behavioral disturbance and can exacerbate the child's ASD symptoms (e.g., self-injurious behavior that may increase in response to pain). Thus, treatment of the gastrointestinal problem can have positive effects on reducing ASD-related symptoms and improve the child's ability to engage in and profit from behavioral and educational interventions. Some have theorized that core ASD symptoms can be directly related to GI-related problems (Reichelt, Ekrein, & Scott, 1990). The theory postulates that ASD symptoms are a manifestation of food intolerance, with gluten and/or casein sensitivity the most commonly identified culprit. This theory suggests that peptides from gluten and casein have a significant role in the origins of autism and that some of the physiology and psychology of autism might be explained by excessive opioid activity linked to these peptides. Frequently there is no traditional laboratory or research evidence of celiac disease or casein sensitivity to support the use of a gluten-free, casein-free diet in these children, with some having no gastrointestinal symptoms, but the diet is safe and effective for use in patients with celiac disease. Proponents also point out that some cases of celiac disease also fail to have traditional laboratory-supporting evidence. As a result, the diet can be followed as a therapeutic trial. It is important to help parents understand that it can be difficult to determine whether the diet is actually helping their child, especially if it is initiated along with other interventions. Thus, it is helpful to identify a person, such as the child's teacher or therapist, who is unaware of when the trial was initiated who can provide objective feedback regarding whether the child's behavior has improved.

Reichelt, Ekrein, and Scott (1990) identified 15 children with autism and abnormal urinary protein patterns. These were hypothesized to reflect gluten or casein protein absorption abnormalities, with more protein absorption and subsequent increased urinary excretion. A gluten-free and casein-free diet was implemented for these children for several years in an open-label fashion. The authors reported improvement in the children's behavior over time as rated by both parents and teachers. Similar findings were reported by several small studies (Knivsberg et al., 1995; Knivsberg et al., 2002; Knivsberg et al., 2003). Ratings from families participating in the Autism Research Institute collection of data regarding use of diets report improvement of symptoms in 66%, no change in 31%, and worsening in 3% (Autism Research Institute, 2009).

Many studies of the gluten-free casein-free diet that have reported improvement in areas other than the gastrointestinal tract suffer from methodologic problems including inconsistent diagnostic criteria, small numbers of children treated, lack of an appropriate comparison group, and failure to control for other therapies the child might be receiving for their autistic disorder (Reichelt et al., 1990; Knivsberg et al., 1995; Lucarelli et al., 1995; Whiteley et al., 1999; Knivsberg et al., 2002). As a result, it is difficult to clearly discern the true efficacy or lack thereof for this treatment, as noted in a recent review (Christison & Ivany, 2006). A recent Cochrane review was unable to compare the studies identified in their literature review because of a lack of common outcome measures, making a meta-analysis impossible. The reviewers were only able to identify two small, randomized, controlled trials,

totaling less than three dozen subjects. Their review concluded that evidence for efficacy of this treatment is poor and that larger, randomized, controlled trials were needed (Millward et al., 2008). When there has been evidence of celiac disease, dietary changes have reduced gastrointestinal symptoms, but not the core behavioral symptoms of the child's autistic disorder (Barcia et al., 2008).

The gluten-free, casein-free diet most often includes a regimen of vitamin and other nutritional supplements as a comprehensive approach to treating autism. To consider it as solely a treatment for gastrointestinal symptoms as described here does not give credit to the overall intent of the therapy. It is discussed in further detail in Chapter 71.

The presence of gastrointestinal symptoms in children with autism spectrum disorders may someday have diagnostic or prognostic benefit and should be evaluated. Recent genetic studies into potential causes for autism spectrum disorders has indicated a role for the autism spectrum disorder met receptor tyrosine kinase (MET) promoter variant rs1858830 in individuals with co-occurring autism spectrum disorder and gastrointestinal conditions (Campbell et al., 2009). The authors examined 918 individuals from 214 families to determine the association of MET alleles with autism spectrum disorder and the presence of gastrointestinal symptoms. They found an association in 118 families with at least one child with both an ASD and gastrointestinal conditions, but no association in the 96 families lacking this association. More recently, it has been seen that the MET gene is also associated with the social and communication domains of ASDs in these cases (Campbell et al., 2009). Further research in this area may someday characterize a clinical phenotype, which may then lead to a more specific treatment regimen. Studies such as this help emphasize the significance of family histories in better defining clinical phenotypes of ASDs, and as an important part of the medical assessment.

At the present time, the existence of a distinct gastrointestinal condition occurring in ASDs has not been clearly documented. There is heated controversy regarding what has been called autistic enterocolitis and how it should be managed if it indeed exists. What has been clearer is that families report many gastrointestinal symptoms but frustration with the evaluation and treatment these symptoms receive by the managing physician. In developing best practices for the management of gastrointestinal symptoms in children and adolescents with ASDs, at this time the recommendation is to follow existing best practice parameters for the symptom in question. Heeding parental concerns and addressing them in the same manner one would for a typically developing child will likely serve the child and family well in the majority of cases (Buie et al., 2010). The Autism Treatment Network (ATN) was founded in 2005 with a goal of expanding knowledge and expertise in the treatment of medical conditions associated with autism spectrum disorders. This network now consists of over a dozen autism centers across the United States and Canada, each following a multidisciplinary philosophy of evaluation and treatment for patients on the autism spectrum. Part of the work of these medical centers is focused on establishing and testing clinical guidelines for the assessment and treatment of various medical comorbidities seen in children and adolescents with autism. Guidelines for assessment and treatment of GI and other medical problems are being developed by these clinicians, along with testing of these recommendations in clinical practice (Coury et al., 2009).

Treatment of Sleep Problems

Johnson and Malow (2008) have noted that most sleep problems are multifactorial, and have strongly recommended that behavioral interventions be instituted prior to any trials of pharmacotherapy. Reed and colleagues (2009) have examined the use of behavioral interventions to promote sleep in 20 children ages 3 to 10 years with autism. Direct parental instruction was given covering effective daytime and nighttime habits, initiating a bedtime routine, and optimizing parental interactions at bedtime and during night wakings. Actigraphy documented an improvement in sleep latency, and insomnia symptoms showed improvement on several subscales of a standardized questionnaire. An important point of this study was its addition to available evidence that sleep problems can often be managed through nonpharmacologic methods, even in children with significant developmental disorders.

Melatonin, a sleep-promoting chemical secreted by the pineal gland in response to levels of darkness, is viewed by many as a natural and safe treatment for sleep latency problems, where delayed or reduced melatonin release may be present. Melatonin use in treating insomnia in children with developmental problems has been described in several studies with improvement reported in the majority of patients (Anderson et al., 2008; Johnson & Malow, 2009). It has also been shown effective in adults with autism and chronic sleep problems, most frequently sleep latency concerns (Galli-Carminati et al., 2009). However, delayed or reduced melatonin release is rarely confirmed or documented in clinical practice, so melatonin use is largely empiric. Ideally, it should be initiated following a formal sleep evaluation with polysomnography and carefully monitored. Difficulties obtaining such studies in children with ASDs tend to limit this practice.

Failure to improve sleep symptoms with melatonin often leads clinicians to use other medications to promote sleep onset and maintenance. In the general pediatric population and in children and adolescents with ASDs, the medications that are FDA-approved and indicated for treatment of sleep disorders are typically not used as first-line treatments. Physicians report the practice of prescribing medications such as antihistamines (diphenhydramine, brompheniramine), alpha agonists (clonidine, guanfacine), benzodiazepines (clonazepam, lorazepam), and trazodone for their sedating side effects to treat the sleep issues rather than for the medications' primary indications. In some circumstances, clinicians report prescribing other medications such as risperidone with a goal of treating other

symptoms associated with autism, such as irritability or repetitive behaviors, as well as the sleep problem.

A major concern in this area is the use of pharmacotherapeutic agents, some of which have significant potential adverse effects, without a clear definition of the underlying etiology of the child's sleep problem. Moreover, there are very few systematic studies of the use of these treatments specifically for sleep problems. For example, there is one open-label study of the use of clonidine for sleep disturbance (Ming et al., 2008). Work by the Autism Treatment Network to improve evaluation and understanding of the pathophysiology underlying sleep problems in children and adolescents with autism spectrum disorders, and the Network's capacity to conduct multi-site research will hopefully lead to better and more specific treatments. Early work done by Network investigators (Reed et al., 2009) has demonstrated the benefit of educating parents by providing direct instruction in sleep hygiene, as opposed to simply providing written information regarding bedtime routines. Additional research into the underlying causes of sleep problems could help avoid unnecessary medication as well as identifying what medications might be appropriate and in which situations.

Psychopharmacology for Associated and Core Symptoms of ASDs

Many of the core symptoms of ASDs bear resemblance to other known disorders—stereotypies are reminiscent of obsessive-compulsive behaviors, gaze aversion appears to manifest anxiety symptoms, unfocused overactive behavior looks much like the hyperactivity seen in attention deficit hyperactivity disorder (ADHD). Furthermore, it is recognized that individuals with ASDs suffer from comorbid psychiatric conditions, such as ADHD, obsessive-compulsive disorder, anxiety, and depression. When behavioral and other therapies are not sufficient in treating these manifestations, or when these behaviors severely limit the effectiveness of behavioral and other therapies, pharmacologic treatments are often considered. These tend to be used empirically, based on the patient's major symptom presentation. The stimulant medications typically used to treat attention difficulties and hyperactivity in individuals with ADHD can be effective in treating these same symptoms in ASDs, although they tend to have a lower efficacy rate and a higher rate of adverse effects (Aman et al., 2008; Posey et al., 2007). The same is true for anxiolytic medications for anxiety symptoms (Kolevson, 2006). The antipsychotic class of medications has been used for decades, and is known for reducing overactive behavior and aggression. The newer atypical antipsychotics have had significant study and are often effective for symptoms such as self-injurious behavior, aggression toward others, and repetitive behaviors. Their well-known calming effect has also been shown efficacious in treating the

irritability seen in many children with ASDs (McCracken et al., 2002; Filipek et al., 2006).

Future Medical Treatments

The tremendous heterogeneity in symptom presentation among individuals with ASDs suggests multiple causes and multiple neurobiologic pathways. Although behavioral and educational treatments have been shown to be most effective for promoting development and decreasing symptoms of autism, improved understanding of etiology and biological mechanisms and the resulting medical treatments have great potential to accelerate improvement for ASDs. Research in this area offers promise that eventually medications will be available that can: *(1)* treat core ASD symptoms, *(2)* treat more specific neurotransmitter pathways, and *(3)* alter the expression of specific target genes found to be involved.

Treatment of Core ASD symptoms

Various medications currently used in mainstream medical practice are focused on symptomatic treatment of specific ASD-associated target symptoms such as repetitive behaviors. There is continued progress in pharmacologic compounds with more specific neurotransmitter targets, better-defined therapeutic effects and fewer adverse effects. There will be new and improved stimulants, antipsychotics and anxiolytics. One novel approach being investigated is aimed at treatment of core symptoms, such as those in the social domain (Andari et al., 2010). Oxytocin, a naturally occurring neuropeptide, is known to promote social behavior and its deficiency in mouse models results in abnormal social behaviors similar to those seen in autism. A medication that is able to ameliorate the core social domain would have a tremendous impact on the efficacy of behavioral treatments. Reduction of social deficits could allow greater focus on language therapy and management of repetitive and perseverative behaviors. An enhancement in the social domain would likely improve the important factor of innate motivation and desire to please others, key elements of success in promoting positive behavior and learning.

Fragile X Syndrome

The GABAergic and glutamatergic neurotransmitter systems have been implicated in autism (Fatemi, Folsom, et al., 2009; Fatemi, Reutiman, et al., 2009). Gamma-amino butyric acid (GABA) receptors play a role in inhibitory neurotransmission, and influence the developmental and functional plasticity of the brain. Recent work in animal models has shown that

blocking GABA-B receptors can inhibit glutamate signaling and subsequently reduce metabotropic glutamate receptor (mGluR) mediated protein synthesis, which is increased because of lack of Fragile X mental retardation -1 (FMR-1) protein-suppressing production (Bear et al., 2004). Multiple aspects of Fragile X syndrome appear to be related to this excess activation. Treatment with GABA-B receptor agonists in drosophila fly models of Fragile X have shown significant improvement in courtship behavior and impaired memory (McBride et al., 2005). Treatment given to drosophila during development resulted in correction of neuroanatomical defects seen in the untreated group. Studies in adult drosophila demonstrated improvement in social behavior and memory also, but no correction of neuroanatomic structures. Clinical trials in humans are underway.

Tuberous Sclerosis Complex (TSC)

Research in the genetics of TSC has led to better understanding of how the normal protein complex TSC1 functions to inhibit the mammalian target of rapamycin (mTOR) cascade, which is known to govern cell growth (O'Callaghan et al., 2004). When the TSC genes fail to function as is seen in TSC, the result is continuous oversignaling, resulting in cell overgrowth and the characteristic tumors. This increased signaling appears to also be involved in the modification of synapses that occurs during learning, and leads to memory impairments (Goorden et al., 2007). Studies in mouse models have shown that rapamycin have shown clear improvement in cognitive abilities even in adult mice (Ehninger et al., 2008).

Other Disorders

The recent advances in our understanding of the neurochemical and molecular basis of ASDs and related conditions, and the subsequent development of novel treatments for the specific disorders mentioned above, represent a massive shift in the medical treatment paradigm. Similar discoveries have been made in mouse models for phosphatise tensin homolog (PTEN) mutants and Rett syndrome (methyl CpG binding protein 2 (MECP2) mutation) (Kwon et al., 2003; Shabazian et al., 2002). Even more exciting is the experimental work in these animal models demonstrating significant improvement in adult animals, and the potential for reversing many cognitive and social symptoms (Zhou et al., 2009; Guy et al., 2007). Most research geared toward acquiring better understanding of the etiology of a disorder is done with the hope of identifying a way to eventually prevent the disorder. The findings in these adult animal models hold hope for effective treatments for humans with ASDs and a variety of neurodevelopmental disorders. Given the evidence supporting these multiple—and

not always overlapping—etiologies, it is likely that personalized treatments incorporating several modalities will be developed for each person with an ASD.

The Need for Comprehensive Care: The Medical Home

Diagnosis and assessment of the child, adolescent, or adult with an ASD requires multidisciplinary evaluation. Most commonly involved are psychologists, psychiatrists, neurologists, and developmental pediatricians, as well as speech and language pathologists and occupational therapists. Various medical specialists may also be consulted for specific aspects, such as pediatric sleep specialists, gastroenterologists, and medical geneticists. The treatment plan is built around appropriate behavioral therapy and educational programming, with medical treatments as necessary for associated symptoms or conditions.

Health care expenses for families with a child with an ASD are higher than those for typically developing children (Mandell et al., 2006). Costs can be as much as ten times that of other families. Much of this is because of costly inpatient psychiatric care. When this inpatient care is excluded, the remaining ambulatory care costs suggest that children with ASDs are not receiving additional primary-care services that would be indicative of appropriately coordinated services, as suggested by the medical home model. Families with a child with an ASD experience significant difficulties accessing the care their child needs (Ruble et al., 2005). Many factors that lead to lack of access, such as race and education, could be mollified by systems and policies that provide a structure within which available services can be coordinated by personnel acquainted with ASDs and the network of agencies and programs needed. A medical home, discussed in more detail below, would meet this need. Kogan et al. (2008) reviewed data from the *2005–2006 National Survey of Children with Special Health Care Needs* and identified over 2,000 children with ASDs. They found that this population is more likely to have a variety of unmet needs, including specific health-care needs, difficulty receiving referrals, and delayed or foregone care. They concluded that receiving primary care through a medical home model could reduce financial impacts and the burden on employment and time spent coordinating care. Homer et al. (2008) have reviewed the literature on the effectiveness of the medical home and found it does indeed support improved health-related outcomes for children with special health-care needs.

The medical home is a primary-care practice—a pediatrician or family physician and support staff—that provides family-centered, comprehensive, community-based, coordinated care. The medical home communicates with specialty providers, service providers, and community agencies to coordinate the patient's care. The medical home also coordinates

coverage for services with the patient's health insurance provider, and provides ongoing monitoring and management of the patient's care with input from involved specialists and ancillary service providers. Patients receiving care through a medical home have reduced unnecessary duplication of services and fewer unmet medical needs.

Materials are available from a variety of sources on how primary-care providers can incorporate medical home services in their practices (American Academy of Pediatrics: www.medicalhomeinfo.org; Waisman Center: www.waisman.wisc.edu/nmhai/). These resources include guidelines for initiating discussion and promoting interaction and collaboration with service providers for ASD children and their families. The medical care for children and adolescents with ASDs will only increase with the advances in medical treatment under development. Promotion of the medical home philosophy on a broader scale is needed.

Conclusions

The diagnosis of an autism spectrum disorder is based purely on behavioral observations. Rapid advances in our understanding of the etiology of various "autisms" are increasingly calling for new laboratory tests to help identify medical conditions that may have a causative role. These advances will lead to a larger role for the medical component in the diagnosis and assessment of autism disorders. In addition, the potential for more and better medical treatments for core autism symptoms, as well as for associated conditions, will broaden the medical portion of autism management. The need for coordination of medical treatments with behavioral and other intervention approaches needed by the ASD population can be met through the further development of the medical home comprehensive care model, which promotes patient-centered, community-based, comprehensive care.

Challenges and Future Directions

- Further understanding of the relationship between medical symptoms such as gastrointestinal complaints and autism spectrum disorders can lead to healthier lives and better outcomes.
- Genetic testing techniques such as microarrays are rapidly evolving, and as their costs decrease and their usefulness increases they will become one of the most important parts of the medical evaluation.
- As the scope of medical treatments for autism increases, there will be challenges in keeping primary-care physicians up-to-date and competent in using these treatments. The medical home model provides a good framework for coordinating the care that persons with ASDs require.

Best Practice, Policy, and Future Directions: Behavioral and Psychosocial Interventions

Points of Interest

- Though individuals with ASDs have been receiving behavioral and psychosocial interventions for over 50 years, it has been difficult to clearly identify what practices are effective across age levels and skill domains.
- The National Professional Development Center on ASD, a federal initiative, has recently identified 24 evidence-based practices (EBP) for individuals with ASDs across domains and age levels.
- The National Standards Project, an initiative of the National Autism Center, identified 11 established practices for individuals with ASDs across domains and age levels and also conducted an evaluation of comprehensive treatment models serving individuals with ASDs.
- Once best practices are identified, implementation of the practices should be a systematic process that includes clear assessments of fidelity, as well as plans for sustainability.

Intervention for individuals with ASDs has a long and varied history—beginning primarily with psychodynamic therapy in the mid-1900s (Ruttenberg, 1971). Once deemed ineffective in treating ASDs, as the understanding of autism's cause began to shift, behavioral intervention emerged as an effective treatment in the early 1960s (Lovaas, 1971). Behavioral intervention refers to treatment derived from the field of applied behavior analysis, which includes a systematic application of behavioral principles and procedures. This type of intervention was first implemented under highly structured conditions (e.g., discrete trial training) and has more recently been applied in naturalistic settings and across skill domains. Psychosocial interventions, which are defined more broadly as any nonpharmacological treatment aimed at improving the functioning of individuals with ASDs, then followed (Seida et al., 2009). Psychosocial interventions include treatments in the fields of developmental and clinical psychology, cognitive-social learning theory, and

sensory integrative therapy (Mesibov et al., 2005; Schreibman & Ingersoll, 2005).

Despite the long history, the efficacy of and evidence base for a number of behavioral and psychosocial interventions for individuals with ASDs, remains inexact. Selecting and implementing evidence-based practices for individuals with ASDs pose a number of challenges for practitioners across disciplines, as well as families selecting interventions for their child. Though mandated through educational policy (e.g., No Child Left Behind), professional standards (e.g., National Association of School Psychologists), and ethics conduct codes (e.g., Association for Behavior Analysis), the identification and usage of scientifically proven practices in the field of ASD can be difficult. Factors contributing to this difficulty include the wide variety of interventions available, the difficulty in discerning "true" evidence from potentially biased information touted by intervention developers, and the sheer volume of information available to practitioners and families via mass media. In addition, universally agreed upon standards by which to identify a practice as evidence-based have not yet been developed and often little guidance is provided to practitioners and families in finding and selecting evidence-based practices. Finally, once EBPs are identified, support for implementation is limited and policies related to adoption and usage are scant. The purpose of this chapter is to identify behavioral and psychosocial interventions and comprehensive treatment models that have evidence of efficacy for learners with ASDs, describe the implications of implementation science for promoting the use of efficacious practices and models in programs, and highlight current challenges to the service provision based on EBPs.

Efforts to Identify Efficacious Practices

To address these challenges, national professional organizations, researchers, and practitioners have begun to identify

practices from the research literature that are evidence-based. In 2000, the National Academy of Sciences convened a committee to review research on educational practices for children with ASDs and their families, which subsequently generated general recommendations for practice (National Research Council, 2001). Some states, such as New York (www.health.state.ny.us/community/infants_children/early_intervention/autism/index.htm), have followed systematic processes for identifying intervention and educational practices for children with ASDs.

Scholarly reviews of the literature, reviews of reviews, and program evaluations have been conducted as well. For example, Iovannone, Dunlap, Huber, and Kincaid (2003) reviewed four studies (including the National Academy of Sciences report) and identified six core components of effective programs for individuals with ASDs. The identified components (e.g., individualized supports and services) were broad-based, however, and did not include recommendations for specific practices or treatment models. A number of additional reviews focus only on specific domains (e.g., problem behavior: Horner et al., 2002), research designs (e.g., single subject: Odom et al., 2003), and/or specific interventions (e.g., video modeling: Bellini & Akullian, 2007). Most recently, a systematic review of 30 research reviews related to behavioral and psychosocial interventions revealed a number of positive outcomes for many interventions (including behavioral and communication interventions) (Seida et al., 2009). However, the authors noted the difficulty in comparing and summarizing intervention effects across different outcomes with the use of different measures, and indicated that "uncertainty remains about best practices for the treatment of autism." (Seida et al., 2009, p. 103)

Classifying Interventions: A Note

When examining the evidence across behavioral and psychosocial interventions, an important distinction in intervention practices should be made. Two types of practices appear in the literature: focused intervention practices and comprehensive treatment models (Wolery & Garfinkle, 2002).

A *focused intervention* is a procedure designed to be utilized for a relatively brief period with the aim of producing specific behavioral and developmental changes related to targeted behaviors or skills (Odom, Collet-Klinenberg, et al., 2010). Focused interventions are utilized for a fairly brief period (e.g., several months) with the clear objective of changing targeted behaviors or skills (e.g., verbal language, attention to task). Ideally, focused interventions are based on explicit practitioner behavior that can be described and measured, such as prompting, reinforcement, discrete trial teaching, or use of visual schedules.

A *Comprehensive Treatment Model* (CTM) is a set of practices of relatively intense and lengthy duration designed to have a broad impact on a core deficit by using multiple components to target skills across multiple domains.

Comprehensive treatment models (CTMs) consist of a set of practices designed to achieve a broader learning or developmental impact on the core deficits of ASD, as described in previous chapters (National Research Council, 2001). They occur over an extended period of time (e.g., a year or years), are intense in their application (e.g., 25 hours per week), and usually have multiple components targeting skills across multiple domains. CTMs have been in existence for over 30 years and new models continue to be created. Examples of historic CTMs are the UCLA Young Autism Project (now the Lovaas Institute), Treatment and Education of Autistic and Communication Handicapped Children (TEACCH), the Denver Model, and the Princeton Child Development Institute (PCDI). When reviewing interventions, the National Professional Development Center on Autism Spectrum Disorders (NPDC) focused solely on focused interventions, while the National Standards Project (NSP) reviewed both focused interventions and CTMs.

Focused Intervention Practices

Two national centers have recently conducted independent and complementary reviews of focused intervention practices for individuals with ASDs. These national centers were charged with reviewing the intervention research literature, identifying standards for determining research quality evaluating research designs, categorizing evidence-based practices, and disseminating that information to practitioners and families. In 2007, the Office of Special Education Programs in the U.S. Department of Education funded the NPDC to promote the use of EBPs in programs for infants, children, and youth with ASDs and their families. An initial activity of this center has been to identify EBPs. In addition, the NSP, an initiative of the National Autism Center, has recently completed an exhaustive review of the strength of evidence for psychosocial and behavioral interventions for individuals with ASDs (NSP, 2009). These two efforts are the most current, comprehensive, evaluative reviews of the literature on focused intervention practices for learners with ASDs.

Criteria for Evidence

Several professional organizations have established criteria for determining whether an intervention is efficacious or evidence-based (Chambless & Hollon, 1998; Kratochwill & Stoiber, 2002; Odom et al., 2004). The criteria converge around several common indicators for the level of evidence provided by experimental/quasi-experimental group designs or single-case designs. The NPDC's criteria was drawn from the work of Nathan and Gorman (2007), Rogers and Vismara (2008), Odom and colleagues (2004), Horner and colleagues (2005), and Gersten and colleagues (2005).

In order for the NPDC to accept evidence about a practice from a particular study, the study had to: *(1)* have been conducted with participants diagnosed with ASDs who were

between birth and 22 years of age, *(2)* have outcomes for those participants as dependent measures, *(3)* clearly demonstrate that the use of the practice was followed by gains in the targeted teaching skills, and *(4)* have adequate experimental control so that one could rule out most threats to internal validity (Gersten et al., 2005; Horner et al., 2005). When a research study met these criteria, it could qualify as evidence for a specific practice. For a specific practice to meet NPDC criteria for an EBP, the practice had to have evidence from: *(a)* at least two experimental or quasi-experimental group design studies carried out by independent investigators, *(b)* at least five single-case design studies from at least three independent investigators, or *(c)* a combination of at least one experimental/quasi-experimental study and three single-case design studies from independent investigators.

The NSP developed a model for evaluating the research literature based on the work of health and psychology fields (Agency for Health Research and Quality, 2002; American Psychological Association Presidential Task Force on Evidence-based Practices, 2003). Similar to the NPDC, studies included in the NSP's review had to: *(1)* have been conducted with participants diagnosed with ASDs who were between birth and 22 years of age and *(2)* have outcomes for those participants as dependent measures. A Scientific Merit Rating Scale was developed and eligible studies were scored from 0 to 5 across five dimensions: *(1)* experimental rigor of the research design, *(2)* quality of the dependent variable, *(3)* evidence of treatment fidelity, *(4)* demonstration of participant ascertainment, and *(5)* generalization data collection. For example, when rating the design of the study, NSP reviewers scored items related to the number of participants, the number of groups, whether data were lost, and the overall study design. These scores were weighted and combined with a treatment effects rating (from beneficial to adverse) to produce a total strength of evidence classification system. Interventions were then assigned a classification of established, emerging, unestablished, or ineffective/harmful based on their scores.

Search Practices

Both the NPDC and the NSP conducted extensive and broad-based literature searches to locate peer-reviewed articles describing behavioral and psychosocial interventions and outcomes for individuals with ASDs. Detailed descriptions of the search processes can be found in work by Odom, Collet-Klinenberg, et al. (2010) and in the NSP's findings and conclusions (2009).

Identified Practices

NPDC

From their review of the literature, investigators with the NPDC have identified 24 EBPs, listed in Table 75-1. The practices are briefly defined in the table and further information about a number of the practices can be found in previous

chapters (e.g., Chapter 59). Two sets of practices are grouped within a larger descriptor. The first subgroup is *Behavioral Teaching Strategies*, which are fundamental intervention techniques (e.g., prompting, reinforcement) based on the principles of applied behavior analysis. These strategies appear as parts of other focused interventions (e.g., prompting and reinforcement is a part of *Discrete Trial Training*), but they also have sufficient evidence to be listed independently. Second, NPDC grouped a set of strategies used primarily to reduce or eliminate interfering behaviors (e.g., tantrums, disruptive behavior, aggression, self-injury, repetitive behavior) under a general classification of *Positive Behavior Support* (PBS). The general PBS approach consists of individual focused interventions, organized around the results of functional behavioral assessment and ordered in level of intensity (Horner et al., 2002). In this grouping, NPDC included *Differential Reinforcement of Other Behavior* (DRO/A/I) as a special application of the use of reinforcement to the reduction of interfering behavior. The additional practices are listed alphabetically.

In Table 75-2, each EBP is listed in a domain by age-level matrix. This matrix allows one to see what EBPs have evidence of efficacy for teaching skills in specific educational domains, and across what age level the intervention is deemed evidence-based. For example, for naturalistic intervention, the table indicates that this practice has demonstrated efficacy across the three age groupings for teaching communication and social skills.

NSP

The NSP has identified 11 behavioral and psychosocial interventions as established and they are listed in alphabetical order in Table 75-3. An established intervention is defined by the NSP as one that "has sufficient available evidence to confidently determine that it produces favorable outcomes for individuals with ASD." (NSP, 2009, p. 10.) These interventions have several published, peer-reviewed studies that received a Scientific Merit Rating Scale score of 3, 4, or 5 (described above) and produced beneficial treatment effects for specific targets. The NSP has also grouped interventions into packages, such as the Antecedent Package (e.g., priming, teacher presence, choice), Behavioral Package (e.g., differential reinforcement, discrete trial training, token economy), and a Peer Training Package (e.g., Integrated Play Groups, circle of friends). In Tables 75-4 and 75-5, the established practices are presented across domains and age levels. These are presented as separate tables, as the domain by age level by practice data are not yet available.

Similarities and Differences in Findings between NPDC and NSP

Table 75-6 outlines the similarities between the findings of the two projects. Nineteen of the 24 interventions (79%) recognized as evidence-based by the NPDC are also considered

Table 75–1.
NPDC Identified evidence-based practices with descriptors

Evidence-Based Practice	Descriptor
Behavioral Strategies	
Prompting	Behaviorally based antecedent teaching strategy.
Reinforcement	Behaviorally based consequence teaching strategy.
Task analysis and chaining	Behaviorally based antecedent teaching strategy that breaks down steps and links them for prompting.
Time delay	Behaviorally based antecedent teaching strategy that promotes errorless learning.
Computer-aided instruction	The use of computers for varied instruction.
Discrete trial training (DTT)	One-to-one instructional strategy that teaches skills in a planned, controlled, and systematic manner.
Naturalistic interventions	A variety of strategies that closely resemble typical interactions and occur in natural settings, routines, and activities.
Parent-implemented interventions	Strategies that recognize and utilize parents as the most effective teachers of their children.
Peer-mediated instruction/intervention (PMII)	Strategies designed to increase social engagement by teaching peers to initiate and maintain interactions.
Picture Exchange Communication System (PECS)™	A system for communicating that uses the physical handing over of pictures or symbols to initiate communicative functions.
Pivotal Response Training (PRT)	An approach that teaches the learner to seek out and respond to naturally occurring learning opportunities.
Positive Behavioral Support Strategies	
Functional Behavior Assessment (FBA)	A systematic approach for determining the underlying function or purpose of behavior.
Stimulus control/Environmental modification	The modification or manipulation of environmental aspects known to impact a learner's behavior.
Response interruption/redirection	The physical prevention or blocking of interfering behavior with redirection to more appropriate behavior.
Functional Communication Training (FCT)	A systematic practice of replacing inappropriate or ineffective behavior with more appropriate or effective behaviors that serve the same function.
Extinction	Behaviorally based strategy that withdraws or terminates the reinforcer of an interfering behavior to reduce or eliminate the behavior.
Differential Reinforcement (DRA/I/O/L)	Behaviorally based strategies that focus reinforcement on alternative, incompatible, other, or lower rates of the interfering behavior in order to replace it with more appropriate behavior.
Self-management	A method in which learners are taught to monitor, record data, report on, and reinforce their own behavior.
Social narratives	Written narratives that describe specific social situations in some detail and are aimed at helping individuals to adjust to the situation or adapt their behavior.
Social skills training groups	Small group instruction with a shared goal or outcome of learned social skills in which participants can learn, practice, and receive feedback.
Structured work systems	Visually and physically structured sequences that provide opportunities for learners to practice previously taught skills, concepts, or activities.
Video modeling	Utilizes assistive technology as the core component of instruction and allows for prerehearsal of the target behavior or skill via observation.
Visual Supports	Tools that enable a learner to independently track events and activities.
VOCA/Speech Generating Devices (SGD)	Electronic, portable devices used to teach learners communication skills and as a means of communication.

Table 75–3.
NSP-identified established practices with NSP descriptors

Established Practice	Descriptor
Antecedent package	Modification of situational events that precede challenging behavior.
Behavioral package	Interventions to reduce challenging behavior and teach functional alternatives.
Comprehensive behavioral treatment for young children	Comprehensive treatment programs that use a combination of behavioral analytic approaches.
Joint attention intervention	Interventions focused on teaching referencing/regulating others' behavior.
Modeling	Interventions using peers or adults to model appropriate target skill.
Naturalistic teaching strategies	Child-directed interactions occurring in natural settings.
Peer training package	Teaching children without disabilities how to elicit target behavior in children with ASDs.
Naturalistic interventions	A variety of strategies that closely resemble typical interactions and occur in natural settings, routines and activities.
Pivotal Response Treatment (PRT)	Teaching pivotal behaviors in natural environment producing naturalized behavioral improvements.
Schedules	Task list that communicates a series of activities.
Self-management	Teaching individuals to regulate their own behaviors.
Story-based intervention package	Written descriptions of a situation that assist in eliciting target behavior.

established practices by the NSP. Four of the NPDC's evidence-based practices (computer-aided instruction, Picture Exchange Communication System, social skills training groups, speech generating devices) are deemed "emerging" by the NSP report, while one of the NPDC's practices is not identified as "established" or "emerging" practices by the NSP (parent-implemented interventions). In addition, the NSP identified one focused intervention practice that was not identified by the NPDC (joint attention intervention and comprehensive behavioral treatment for young children, as the NPDC did not review comprehensive treatment models).

Comprehensive Treatment Models

As described previously, there remains a scarcity of evaluation or comparative evaluation information about CTMs. In their review of the literature, members of the National Academy of Sciences Committee on Educating Children with Autism (National Research Council, 2001) identified a set of widely acknowledged comprehensive treatment models and common features that exist across models, but they did not examine efficacy of the models. In a recent critical review of CTMs for young children with ASDs and their families, Rogers and Vismara (2008) evaluated the current research on comprehensive treatments for young children with ASDs, finding limited evidence of efficacy for all but the Lovaas model, with some limited support for Pivotal Response Treatment (PRT) (Koegel et al., 1999). Focusing only on a single model, Reichow and Wolery (2009) documented substantial support for the UCLA Young Autism Project Model (the Lovaas model), especially when the researchers were trained by model developers, hours of therapy were high, and the duration of the intervention was long. A second independent review by Howlin, Magiati, and Charman (2009) drew similar conclusions, but also found that documentation of the fidelity of implementation of the CTMs in the studies was often limited.

The previous summaries of the empirical evidence suggested that one may draw practical recommendations by examining features of CTMs that appear to be efficacious (National Research Council, 2001; Rogers & Vismara, 2008). Working with Autism Guidelines Project funded by the State of California Department of Development Services and with assistance from the National Standards Project, Odom, Boyd, Hall, and Hume (2010) conducted a multidimensional evaluation to examine features of CTMs. The purpose of the evaluation was to supply information to service providers so that they could make decisions about adopting a CTM, family members could make decisions about selecting a CTM for the individual with the ASD within their family, or a researcher could determine questions for future research. This process is summarized in the subsequent sections.

Criteria for Evidence

Odom, Boyd and colleagues (2010) defined CTMs by six criteria, which represent the inclusion/exclusion criteria. First, a description of the model and its components had to be published in a refereed journal article, book chapter, or book. Second, at least a single procedural guide, manual, curriculum, or description should exist to define the model. Third, the model must have a clear theoretical or conceptual framework. This framework must be published in one of the formats noted previously. Fourth, the model must address multiple developmental or behavioral domains that, at a minimum, represent the core features of autism spectrum disorder (i.e., social competence, communication, repetitive behaviors). Fifth, the model must be intensive. Intensity is defined by the number of hours the model is implemented per week (e.g., National Academy of Sciences Committee recommended 25 hours or more), longevity (e.g., model implementation extends across a period equal to or greater than a typical school year, which is usually 9 to 10 months), and/or engagement (i.e., a planned set of activities or procedures actively engage the child/person with autism in learning experiences consistent with the model). Finally, the sixth criterion was that the CTM must have been implemented in at least one site in the United States.

When a CTM was identified as having met the inclusion criteria, evaluators assembled a portfolio of evidence needed for evaluating the model, including published journal articles and/or chapters, web pages, books, curricula, and/or procedural manuals. Models were scored on a 0 to 5 rating scale on each of six domains: *(1)* operationalization, *(2)* implementation measures, *(3)* replication, *(4)* type of empirical evidence, *(5)* quality of the research methodology, and *(6)* complementary evidence from studies of focused interventions.

Search Practices

CTMs were located through several sources. First, a systematic and thorough review of the literature was conducted. A search in PsychINFO and EBSCO was initiated using the keywords *autism*, *comprehensive*, *treatment*, *program description*, and *intervention*. CTMs also tend to be described in book chapters and literature reviews, so the NSP surveyed well-known books that include chapter identifications of such models (e.g., Handleman & Harris, 2006, 2008), books that have reviewed the evidence from the field (e.g., National Research Council, 2001), and highly visible handbooks (e.g., Volkmar et al., 2005). Evaluators presented the information from this project in public forums and at conference presentations. Audience members were asked to review the list of CTMs identified, and to recommend models that were missed.

Identified Models

Evaluators identified a total of 30 CTMs using the inclusion criteria previously described. The ratings for each model are presented in Table 75-7. For more detailed descriptions of the models, please refer to Odom, Boyd, et al. (2010). As noted, the ratings range from 0 to 5, with 5 being the highest. Rather than generating a single summary score, this review established a profile across dimensions of the evaluation. This profile depicts the CTMs that have the stronger and weaker evidence for each dimension. Models that have ratings of 4 or 5 across dimensions of the evaluation have stronger evidence of what NSP calls "model development." That is, they are procedurally well-documented, they have been replicated, and there is some evidence of efficacy, even if limited. These models include: Denver, Learning Experiences: an Alternative Program for preschoolers and parents (LEAP), Lovaas Institute, May Institute, and Princeton Child Development Institute (PCDI). There are other models

Odom, S. L., Boyd, B. A., Hall, L. J., & Hume, K. (2010). Evaluation of comprehensive treatment models for individuals with Autism Spectrum Disorders. *Journal of Autism and Developmental Disorders. 40*, 425–436. Reproduced with permission.

Note: Errata information from Odom, Boyd, et al. (2010) has been incorporated in this table.

that have ratings of 4 or 5 on less than four domains, but there remain features of the model that could be strengthened. These include: Autism Partnerships, Center for Autism and Related Disorders, Inc (CARD), Children's Toddler Program, Developmental, Individual-Difference, Relationship-Based Model (DIR), Douglass, Responsive Teaching, Social Communication and Emotional Regulation, and implementing Transactional Supports (SCERTS), and Treatment and Education of Autistic and related Communication handicapped CHildren (TEACCH). Also, there are some models that received very low evaluation ratings across the board. These included Hanen, Higashi, Eden, Summit, Lancaster, and Son Rise. Again, potential consumers may use this as a general guide when determining the degree of model development and level of efficacy evidence that exists for individual CTMs.

As a group, CTMs were strongest in the operationalization of their models. Given the strength of the operationalization dimension, it was surprising that measurement of implementation was relatively weak in comparison. When CTMs are designed as models that may be adopted by service providers, the availability of implementation instruments would be a critical feature because they would allow: *(a)* the developer to observe and document the use of their model, and *(b)* the adopter to evaluate their own implementation. This is a much-needed direction for future developers of CTMs.

As a group, CTM projects reported frequent replications by individuals outside of the central project. Nearly half the CTM developers (14 out of 30) reported that two or more independent sites had replicated their model. Some sites reported replication by dozens of programs (e.g., TEACCH, Lovaas, DIR, LEAP). Across CTMs, the published evidence of efficacy was not strong. Over half (16 out of 30) of the CTMs had no publication of efficacy in peer-reviewed journals, although often they did report efficacy data in book chapters or from their program reports. Some models (Lovaas Institute, Responsive Teaching, Children's Toddler School, TEACCH) had at least two publications of efficacy in peer-reviewed journals, and among these the Lovaas Institute has the most extensive record of publications, which as noted earlier, had been found also by other authors (Howlin et al., 2009; Reichow & Wolery, 2009; Rogers & Vismara, 2008).

Promoting the Use of Evidence-Based Practices and Comprehensive Treatment Models: Implementation Science

The science of intervention has led to the identification of focused intervention practices and comprehensive treatment models having evidence that they produce positive developmental and learning outcomes for learners with ASDs and their families. A summary of these findings appears in previous sections. A common and naive assumption from some scientists is that if effective practices are identified, then service providers will employ them in their work with learners with ASDs. This logic fails in two ways. First, the professional development literature indicates that having a practitioner read about a practice or model of treatment or even learn about it in a workshop does not usually lead to use in classrooms, homes, or community (Joyce & Showers, 2002). Second, even if service providers use a practice or comprehensive treatment model, the key features of the practice or model have to be delivered in the way that they were delivered in the research documenting that documented their efficacy (Durlak & DuPre, 2008). Both of these issues, adoption of a practice to be used in a program and fidelity of implementation, are central constructs of an emerging field in human services called *implementation science*. In this section, we will describe implementation science, as it is employed in a range of disciplines for promoting wide-scale implementation.

Implementation Science

"Implementation research is the scientific study of methods to promote the systematic uptake of research findings and other EBP into routine practice, and, hence, to improve the quality and effectiveness of health services and care." (Eccles & Mittman, 2006, p. 1.) The definition of implementation and its measurement are factors associated with use in classrooms. Purveyors (i.e., EBP or CTM developers) have typically taken two approaches to assessing implementation at the program level. First, they may assess the amount of an intervention a learner with an ASD receives. O'Donnell (2008) referred to this as a structural approach to implementation. The metric may be number of lessons completed, number of trials delivered, or number of minutes in intervention. For example, the National Academy of Sciences' Committee on Educating Children with Autism proposed that children with autism receive at least 25 hours of an intensive intervention program each week (National Research Council, 2001).

Second, purveyors assess implementation by observing and rating the quality of implementation, which O'Donnell (2008) noted as a process approach to implementation measurement. For example, in their research on the relative treatment effects for preschool-age children with ASDs for two CTMs (i.e., TEACCH and LEAP), Hume and colleagues (2009) developed implementation measures describing the key features of each program model, and conducted 194 observations using the measures across 34 classrooms. Internal consistency reliability analyses and descriptive discriminant analyses were conducted and the measures were found to be reliable (total alphas ranged across measure from .93 to .94) and to clearly discriminate the models from one another and from a "business as usual" classroom not using either CTM.

Unfortunately, assessment of implementation occurs rarely in the ASD literature. In their review of the intervention literature from 1970 to the early 1990s, Wolery and Garfinkle (2002) found that only 13% of the studies reported procedural fidelity information. When reviewing only single-case design studies (SCDs) involving young children with ASD and published

from 1990 to 2003, Odom and colleagues (2003) found that 32% of the studies had fidelity measures. For CTMs, Odom, Boyd and colleagues (2010) found that 22 of the 30 models have some form of implementation assessment, but only nine could provide evidence of inter-rater agreement, and only one had documented the internal consistency form of reliability for their measures.

In addition to the importance of having fidelity of implementation measures for documenting the actual implementation of EBPs, such measures may prove to be useful tools for providing feedback to teachers (e.g., through coaching or consultation) on their use of specific EBPs or their implementation of the CTM. In addition, they may be used to assist service providers in self-monitoring their own use of practices. The NPDC has developed implementation checklists for each of the practices it has identified as having an evidence base (Odom, Colett-Klingenberg et al., 2010), and the checklists are currently placed in modules that will appear on the website of the Ohio Center for Autism and Low Incidence Disabilities (http://www.ocali.org/aim/).

From Implementation to Scaling up and Sustainability

To move science into practice on a broader-than-single-classroom scale, implementation scientists have elaborated on the ecological systems models of Bronfenbrenner (1979) and others to determine the factors in distal (from the learner and classroom) levels of an organization that may affect the "uptake" of EBPs and be sustainable across time (Durlak & DuPre, 2008). Fixsen, Naoom, Blase, Friedman, and Wallace (2005) proposed a multilevel model of implementation that has core implementation features (e.g., training, coaching) at the center, but is seated within a second system level of organizational components (e.g., site selection, administration), and a third even more distal level of influence factors (e.g., economic, political). They propose that implementation at a school district or system level is a six-phase process, beginning with exploration and adoption and ending with sustainability. For working with early childhood special education programs, Kahn and colleagues (2009) have articulated a model for achieving long-term systems change to support high-quality early-intervention practices for all children with disabilities, which involves establishing a multilevel plan that includes state infrastructure, professional development systems, local infrastructure, and local context (e.g., classroom or program).

To promote service providers' use of EBPs with learners having ASDs, the NPDC has developed a multisystem approach to promoting service providers' use of EBPs for children with ASDs. Basing their conceptual framework on the work by Fixsen and colleagues (2005), Kahn and colleagues (2009) and others, the process begins with states applying to work with the NPDC and completing a detailed plan of their involvement and the infrastructure support they would provide. Over a 2-year period, project staff work with state planning teams to share research information about the assessment of quality in

programs, EBPs, the process for linking learner goals and specific EBPs, and the process for documenting learner progress. NPDC staff and technical assistance support team collaborate in the first year to provide the coaching and consultation to classroom staff for promoting use of EPBs. The NPDC team systematically withdraws it support from the state's planning and technical assistance teams during the second year of their involvement. The efficacy of this type of support for producing changes at the state, classroom, and child levels is now being evaluated.

Future Trends and Directions

An active research literature on focused intervention practices and comprehensive treatment models now fuels the potential for increasing the quality of services provided to learners with ASDs and the prospect for more positive outcomes. This literature, and the glaring absences that exist in parts of the literature, provide insights into possible future directions in intervention research and service provision. In this concluding section, we will examine the types of models that are currently being developed or will need to be developed in the future, the changing demographics of the populations of the United States and its implications for ASDs, and the necessary economic and professional infrastructure needed for providing high-quality services.

EBPs and CTM Development

Identification of EBPs from the research literature is like shooting at a moving target. There are many journals that publish intervention research on ASDs, so even when a thorough review is conducted, its currency is limited and ongoing updates are necessary. For example, the newest literature in the reviews conducted by the NSP and the NPDC will be 3 years old by the time this chapter reaches publication. Documented practices will not necessarily go out of date, but literature will begin to support new practices. For example, when Odom and colleagues (2003) conducted their review, the social stories intervention was identified as an emerging practice but there had not yet been a sufficient number of studies demonstrating its efficacy, but when the NPDC conducted their review in 2007, a sufficient number of studies had been published to support it as an EBP (Odom, Colett-Klingenberg, et al., 2010). For the field, ongoing surveillance of the literature will be necessary to benefit from the most current science.

As illustrated in Table 75-2, which showed the ages of children for which there was efficacy evidence for focused intervention practices, most evidence was grouped around the preschool and elementary age ranges. Similarly, for CTMs identified by Odom, Boyd, and colleagues (2010), the majority focused on preschool-age and elementary-age children. Focused intervention research and model development in the

future will clearly need to be designed for participants younger than or older than the preschool and elementary age range. Already there is much activity at the infant/toddler level. Drawing from the summary by Odom, Boyd, and colleagues (2010) of CTMs, Boyd, Odom, Humphreys, and Sam (2010) identified five CTMs that have been developed specifically for infants and toddlers. In the future, major contributions to the infant/toddler intervention area will be publication of efficacy studies from projects within the Toddler Treatment Network, which has been funded by Autism Speaks (www.autismspeaks. org/science/research/initiatives/toddler_treatment_network. php). Along with a concerted focus on early screening and identification (Boyd et al., 2010), the possibility of efficacious services being available for infants and toddlers with autism is bright, although the caveat will come with funding, which will be described subsequently.

A glaring weakness in the field is evidence-based focused intervention practices and CTMs for middle-school and high-school students with ASDs (Odom, Colett-Klingenberg, et al., 2010). Practices identified for younger children can be effective with older learners with ASDs, but they must be adapted for developmental differences, a broad range of expectations, and a variety of contexts. Models that support students with ASDs attending inclusive middle- and high-school classes and school-to-work models that prepare students for the future in the community are largely underresearched. The National Institutes of Health Interagency Autism Coordinating Committee (2008) has identified as a priority the development and evaluation of practices and models for adolescents with ASDs, so this may well be a direction for research and development in the future.

Population Demographics and Provision of Services

The population demographics of the United States is changing, with our citizenry becoming more racially, ethnically, and linguistically diverse. Although it appears that ASDs are not associated with racial, cultural, and socioeconomic status (Fombonne, 2003), that does not mean that racial and cultural issues do not have an effect on the development and skills acquisition for children of color with ASDs. In their demographic analysis of a surveillance study for ASDs, Mandell and colleagues (2009) significant disparities in the frequency of diagnoses of ASDs, with African-American and Latino children significantly underdiagnosed. In reviews of interventions for participants with ASDs and other developmental disabilities, often information about the ethnic or racial characteristics of participants is not provided at all. In reviews by Odom and colleagues (2003) and Karasu and Odom (2009), the authors found few studies reported racial or ethnic information. Although it is likely that the central features of EBPs and CTMs will be effective for learners from diverse ethnic, racial, and linguistic backgrounds, ways in which interventions are delivered, information is shared, and families are involved may be different for children and families from some racially, ethnically, and linguistically different groups. The challenge for the field will be to build procedural systems that will allow implementation of key features of intervention in different cultural contexts.

Necessary Infrastructure with States to Support Use of Evidence-Based Practices

As noted previously, a large-scale movement to support the use of EBPs requires an infrastructure that will support professional development and implementation within states. The National Academy of Science Committee report (National Research Council, 2001) described previously noted that building such an infrastructure was a feature to promoting the quality of services for learners with ASDs. Such an infrastructure would ideally provide training to service providers, but importantly, also establish a system of ongoing coaching and consultation at the local level (Hall, 2009). It may also incorporate the rapidly advancing use of technology (e.g., web-based training modules, telemedicine), communities of practice, and peer coaching (Odom, 2009). Some states have invested in such an infrastructure (e.g., Indiana, Pennsylvania), while others are in the process of building such supports (e.g., states now working with the NPDC). However, without such support from this distal-system level, substantial change at the local district and classroom level is likely to be limited.

Conclusion

In recent years, considerable effort has been placed on identifying practices having scientific evidence of efficacy in producing positive outcomes for learners with ASDs. Reviews of the literature have found focused intervention practices and comprehensive treatment model programs that are evidence-based. Yet, a challenge for the field will be to support the use of efficacious practices in programs for learners with ASDs. Models for scaling up the use of practices have emerged from the field of implementation science and may well provide a basis for supporting the use of evidence-based practices in services for learners with ASDs. Yet, there are continued challenges for the field. These include the following:

- Ongoing surveillance of the literature to identify new practices that supported are by future research (especially for infant/toddler and middle-school/high-school programs) and further substantiation of EBPs and CTMs already identified;
- Development of EBPs and CTMs for adolescents and young adults with ASDs will be important;
- Creation of focused intervention and CTM procedures appropriate for and effective with learners with ASDs and their families who are racially, ethnically, and/or linguistically different from the majority culture in the United States;

- Establishment of infrastructure within states to promote the high-quality services and use of evidence-based practices at the local level.

Pharmacotherapy for Autism Spectrum Disorders

Points of Interest

- Studies of dopamine, serotonin, glutamate, and acetylcholine in ASDs suggest drug targets.
- Effective treatments have been demonstrated for two targets of severe irritability and hyperactive-impulsive behaviors.
- Clinical monitoring tools have emerged from the methods of clinical trials.
- Core ASD domains are largely untouched by current drug treatments.

Introduction

Children, adolescents, and adults with the full range of the ASDs are frequently referred for possible pharmacologic treatment for an array of associated difficult-to-manage behaviors, and to support adaptation and progress from other forms of interventions. Indeed, recent surveys of individuals with ASDs have documented an increasing acceptance of psychotropic medications as an often-reached-for component of treatment, with as many as 3/4 of individuals with ASDs reportly receiving a psychotropic medication within the past year (Esbensen et al., 2009). Furthermore, the use of multiple psychotropic medications, and other complementary and alternative treatments, is commonplace. These survey data observe that the frequency of use of psychotropic medications in the context of ASDs may be continuing to increase substantially (Esbensen et al., 2009; Martin et al., 1999). Such widespread use of pharmacotherapy for individuals with ASDs demands a careful appreciation of the evidence base for these treatments. In this chapter, we review the available evidence for each of the major drug classes, as well as

information regarding their safety and optimal use. In addition, we discuss current recommendations based on the best evidence available for the largest and most commonly presented targets for treatment in individuals with ASDs. Lastly we describe future directions for drug development in ASDs based on emerging models of etio-pathophysiology of ASDs and related conditions.

Neurobiology of ASDs and Co-Occurring Maladaptive Behaviors: Relevant Studies

Although the fundamental pathophysiology remains unknown for "idiopathic" ASDs, a variety of investigations have attempted to uncover changes in relevant neurochemical systems that also represent sites of action of many commonly prescribed psychotropics. Many of these ASD-related neurobiologic differences may be more germane to understanding specific dimensions of behavior or associated behaviors rather than core features of ASDs; nevertheless they form the basis for some arguments for consideration of particular drug classes. The bulk of these studies of the neurobiology of autism has been directed toward investigating changes in the serotonin (5-hydroxytryptamine; 5-HT), dopamine (DA), cholinergic, and glutamatergic systems.

Research demonstrating changes in the functioning of the serotonin system in individuals with ASDs has a long history dating back to the observation of elevated levels of whole blood 5HT in the periphery of children with autism (Schain & Freedman, 1961). This finding, observed in approximately 30 to 50% of individuals with ASDs, has been frequently replicated (Anderson et al., 1987), although the confounding of this relationship with degrees of intellectual disability complicates its interpretation. A variety of other research approaches have probed changes in the 5HT system in

individuals with ASDs; observations of blunted prolactin release following acute administration of the 5HT indirect agonist fenfluramine have been noted in ASD versus controls (Hoshino et al., 1984; McBride et al., 1989); decreased 5HT2A receptor subtype binding in leukocytes has been reported in hyperserotonemic individuals with ASDs (Cook et al., 1993), and acute dietary tryptophan depletion was found to exacerbate autistic symptoms in a controlled study of three adults with ASDs (McDougle, Naylor, Cohen, Aghajanian, et al., 1996). More refined dimensional analyses of the core domain of repetitive behavior in ASDs provided support for a relationship with gene variants in SLC6A4 (serotonin transporter protein) (Brune et al., 2006), which is intriguing given that SLC6A4 is the principal site of action of serotonin reuptake inhibiting (SRI) antidepressants, which are standard treatments for Obsessive-Compulsive Disorder (OCD). However, these data have often been critiqued as too indirect to glean conclusions regarding central nervous system (CNS) 5HT functioning. Yet bolstering the validity of these reports, studies utilizing positron emission tomography (PET) scanning have uncovered more direct evidence for altered serotonin synthesis patterns in children with ASDs (Chugani et al., 1999). The interpretation of these data is complex too; individuals with autism showed changes in the lateralization of 5HT synthesis and differences in the developmental trajectories of increases in early childhood followed by subsequent decreases in synthesis capacity comparable to adult levels, in some analyses correlating with language skill acquisition. Given the widespread regulatory influence of 5HT on a broad range of systems and behaviors including mood, activity, sleep, and repetitive behavior, such data cited above have been used as an argument for consideration of the use of many psychotropics thought to interact with 5HT function. Overall, 5HT function may differ in ASDs compared to typically developing children, but such changes in 5HT may be related more to dimensions of ASDs, rather than serving as a marker for ASD diagnostic status.

The dopamine (DA) system has also been the subject of some investigation in individuals with ASDs. The elevation of mean levels of cerebrospinal fluid (CSF) homovanillic acid (HVA) (Gillberg et al., 1983) suggested a possible relationship between increased DA function and hyperkinetic movements in ASDs including stereotypic behaviors, however most studies contrasting subject groups of autism versus controls have not found differences (Anderson & Hoshino, 1997). Again, negative studies have focused on small case-control comparisons; DA function may hold more importance in its possible association with motor activity and other specific domains of the ASD phenotype.

More direct information has been obtained from postmortem analyses of brain tissue from individuals with ASDs. *The cholinergic system*, a widespread and key component of learning and memory functions, has been investigated in studies assaying receptor expression in various areas of the cerebral cortex. Cholinergic muscarinic receptor-1

(M1 subtype) binding was found to be reduced by up to 30% in samples from subjects with ASDs. Nicotinic receptor binding was even more prominently reduced (65 to 73%) in the frontal and parietal cortical regions (Perry et al., 2001), in the cerebellum (Lee et al., 2002), but not in the basal forebrain (Perry et al., 2001). Such data on cholinergic changes are in need of replication, but have been interpreted to suggest cholinergic agonists as a possible suggested treatment path.

Overlapping problems in social communication and autistic features are common to females with Rett Syndrome, where evidence for abnormalities in glutamatergic transmission is known, so glutamatergic changes have been suggested to be possibly relevant to other individuals on the autism spectrum. Such data from studies of Rett Syndrome include the findings of increased CSF glutamate, and alterations in metabotropic glutamate receptors (mGluRs), depending on age (Armstrong, 2005). The role of glutamate also arises in the detailed molecular pathway analyses of Fragile X Syndrome (FXS), where the reduction in expression of the Fragile X Mental Retardation Protein (FMRP) releases inhibitory control on protein synthesis, and where mGluR5 antagonist agents have been shown to reverse effects and "rescue" the organism from preclinical FXS phenotypes in vivo (Dolen & Bear, 2008).

The possible role of alterations in neuropeptide hormone systems such as oxytocin and vasopressin in ASDs has been raised by extensive literature uncovering the influences of these hormones on social behaviors in both animals and humans. Oxytocin receptor knockout mice show disruptions of their usual social behavior, and acute administration of oxytocin to normal control adults has been shown to modulate behaviors such as trust, affect toward others, and social perception in experimental paradigms. Although other molecular signaling pathways such as ERK and PI3K are under consideration for their possible role in aspects of the physiology of ASDs (Levitt & Campbell, 2009), the above form the crux of observations of neurochemical systems that have formed the indirect arguments for the use of a number of common psychotropic agents as described below.

Prior to considering the common uses of psychotropic agents for individuals with ASDs, it is crucial to emphasize that currently drug therapy takes on an adjunctive role, mainly targeting associated maladaptive and specific impairing ASD symptoms. With few exceptions (noted below), little change has been noted in broader core symptoms of ASDs (e.g., social ability) from psychotropic drug treatment. However, the negative impact of common maladaptive behaviors and symptoms such as aggression, hyperactivity, self-injury, and disordered mood can be marked, interfering with educational and other therapeutic efforts, necessitating more restrictive schooling or living environments, and posing real threats to the safety of some individuals with ASDs and their family members. Therefore, drug therapy can play an important role, but needs to be considered in the context of a multimodal therapeutic approach, complementing educational, behavioral, and social habilitative efforts.

Review of Drug Classes for the Treatment of ASDs

Antidepressants

The antidepressants continue to be the most widely prescribed category of psychotropic agents for individuals with ASDs for more than the past decade. Among the antidepressants, the selective serotonin reuptake inhibiting agents (SSRIs) are the most frequently utilized. Although a relatively large number of reports are found in the literature for this class, including fluvoxamine (Luvox), fluoxetine (Prozac), citalopram (Celexa), escitalopram (Lexapro), sertraline (Zoloft), and paroxetine (Paxil), overall the number of rigorous controlled studies (those obtaining ratings of change from individuals "blinded" to treatment and comparisons to placebo groups) is small. One of the initial studies of the SSRIs, which generated much enthusiasm for these agents, examined the effects of fluvoxamine in 30 adults with autism. In a randomized placebo-controlled, double-blind design, substantial global clinical improvement was seen in 53% of adults randomized to fluvoxamine vs. 0% assigned to placebo group over 12 weeks of observation, with average fluvoxamine doses between 200 to 300 milligrams (mg) per day. Improvements included reduced repetitive behaviors by 36% from baseline, decreased aggression, improved language use, overall reduced maladaptive behavior ratings, and with good tolerability (McDougle, Naylor, Cohen, Volkmar, et al., 1996). These results generated the clinical hypothesis that many of the repetitive behaviors seen in individuals with ASDs could be considered analogs of OCD symptoms. However, an attempt to replicate these findings in a controlled trial with fluvoxamine in a group of children and adolescents with autism was unsuccessful; moreover, adverse events were pronounced and raised significant concerns about poor tolerability and safety of the agent in the majority of children who received the active drug. At present, these contradictory findings are unexplained but may relate to prominent developmental effects on treatment response in ASDs possibly specific to the 5HT system, given the alterations in developmental trajectories of 5HT synthesis cited above.

Fluoxetine has also been examined in a number of open-label reports and two controlled trials. Utilizing a low dose (less than 10 mg/day) designed to avoid adverse effects in children and adolescents with ASD, fluoxetine was demonstrated to be associated with an improvement in measures of repetitive behavior versus placebo and clinical global impression of severity (Hollander et al., 2005). However, closer inspection of the magnitude of change observed showed the extent of the improvement to be modest on the primary outcome of repetitive behaviors, and global improvement was not observed, leaving the clinical significance of the results uncertain. Also, even in this low dose range, 19% of subjects required a dose reduction because of side effects, mainly activation. A naturalistic study from clinic experience of open-label treatment with fluoxetine in 129 young children with autism suggested benefit in over 66% (DeLong et al., 2002), but the study is limited by the absence of controls and little descriptive information. In another open-label study of fluoxetine using doses of 10 to 80 mg/day, 65% of subjects were defined as responders using a global measure of severity (Cook et al., 1992). Similarly, additional pilot studies and clinical observations with fluoxetine have suggested possible benefits in symptoms such as irritability, depressed mood, and repetitive behaviors (Fatemi et al., 1998), however such reports lack the comparison to a placebo or inactive control, leaving them vulnerable to the likely effects of expectancy bias. Side effects of activation have been commonly noted in studies of fluoxetine, including hyperactivity, agitation, insomnia, and aggression. Lastly, a recent large, industry-sponsored, multisite, double-blind, placebo-controlled trial of fluoxetine for the treatment of ASDs associated with high levels of repetitive behavior was reported to show no benefit of fluoxetine over placebo. (personal communication from L. Scahill, 2009).

Citalopram has been suggested to be beneficial on several outcome domains in association with ASDs. However, in one of the largest controlled treatment trials in children and adolescents with ASDs for any agent, citalopram was found to have no benefit versus placebo in a total sample of 149 children (mean age of 9 years old) given average daily doses of 10 to 20 mg/day, on measures of repetitive behavior and global improvement (King et al., 2009). Secondary analyses suggest that caregiver strain may serve as a moderator of placebo response in the sample. Plasma citalopram levels were comparable to concentrations observed in efficacious adult antidepressant studies. The trial included sensitive and systematic examination of adverse events and results revealed increased rates of gastrointestinal symptoms and insomnia in citalopram-treated subjects versus those assigned to placebo. Moreover, nearly 1/3 of children randomized to citalopram displayed signs and symptoms of "activation," including increased activity, irritability, and dysregulated behavior, frequently leading to dose reductions and in some instances discontinuation of treatment. Analyses of secondary measures revealed little, if any, evidence for beneficial effects of citalopram across a wide range of symptom domains. One report has examined the benefits of escitalopram in a 10-week study for children and adolescents (mean age of 10 years) with ASDs and moderate levels of irritability (tantrums, aggression, mood lability), examining benefits on irritability as a target. In this report, 61% of subjects were noted to be good responders to doses of 20 mg or less per day. Adverse events were common, including extensive irritability and hyperactivity, and many subjects required dose reductions because of the emergence of side effects. Nearly 20% of the sample dropped out because of adverse effects or worsening behaviors; overall however, completing subjects showed solid improvement, with a 50% reduction in ratings of irritability from baseline for the entire sample (Owley et al., 2005). A follow-up report on an expanded sample of 58 subjects with ASDs noted similar improvements; analyses suggest gene

variants in the 5HT transporter gene (SLA6A4) may relate to initial improvement but there is no clear-cut association with ultimate response (Owley et al., 2009).

Sertraline has been reported in open-label studies to possibly have benefit for ASD-associated behaviors of aggression, repetitive behavior, anxiety, and irritability. Open-label treatment (average dose of 122 mg/day) observations in 42 adults with ASDs with varying profiles of maladaptive behaviors over 12 weeks reported improvement in 57% of subjects (McDougle, Brodkin, et al., 1998) though changes in symptoms assessed such as repetitive behaviors were modest (20 to 30% decrease from baseline); interestingly the smaller number of subjects with Asperger's Syndrome showed little improvement. A smaller case series described the experience of sertraline treatment in nine children with ASDs and anxiety/agitation, with the majority described as improved (Steingard et al., 1997). Overall, these uncontrolled reports have suggested good tolerability for sertraline in individuals with ASDs, though agitation, insomnia, and gastrointestinal (GI) symptoms are common. However, no controlled trials are available.

Tricyclic Antidepressants

Three tricyclic antidepressants—clomipramine, nortriptyline, and despiramine—have been studied in autism spectrum disorders. Observations of effects of clomipramine and despiramine were obtained in two small, well-controlled crossover comparisons of 12 children and adolescents with ASDs (Gordon et al., 1993). Clomipramine was superior to placebo and to desipramine with respect to ratings on the Children's Psychiatric Rating Scale (CPRS) autism subscale; capturing withdrawal, odd relating, and limited communication, and measures of repetitive behaviors were also noted to improve. Desipramine was equivalent to clomipramine on a measure of hyperactivity with a large reductions from 25 to 50% versus placebo ratings, but clomipramine was noted to produce a greater side-effect burden. Nevertheless, a remarkable 80% of subjects chose to continue clomipramine post-study. Improvements in hyperactivity were also noted in an open-label study of nortiptyline in 16 children with autism. However, the adverse event data from the above studies, as well as subsequent open-label reports, have documented the challenges to tolerability because of the tricyclic anticholinergic and antiadrenergic properties, which are associated with problems of urinary retention, irritability, cardiovascular effects, and fatigue in some individuals. Clomipramine may also lower the seizure threshold at doses above 3 mg/kg/day. Such adverse events coupled with concerns of cardiac effects of the tricyclics have undercut interest in further investigations of these agents, and the use of these drugs remains very limited.

Mirtazapine has been reported to have possible benefits for children and adults with ASDs from open-label clinical experience. Mean daily doses of 7.5 to 45 mg/day were noted to yield positive responses in 35% of 26 individuals receiving at least 4 weeks of treatment, based on improvement in a range of symptoms such as aggression, self-injury, hyperactivity, anxiety, and insomnia (Posey et al., 2001). Venlafaxine, a mixed reuptake inhibitor, was also noted in two case series of patients to yield apparent improvement in symptoms like those of attention deficit hyperactivity disorder (ADHD) (Carminati et al., 2006; Hollander et al., 2000), but the use of venlafaxine for ADHD symptom management is limited in typically developing children as well because of lack of evidence.

Taken together, rigorous studies of the effects of antidepressants in children and adolescents with ASDs do not confirm benefits suggested by wide community use, or by smaller scale, open-label treatment reports, regardless of the targeted symptoms or endpoints. Side effects are common including GI, weight gain, sleep, agitation, and activation, which can range from mild to severe, and must be considered against the limited benefits in the literature. Some adult data appear to suggest better efficacy in adults than in children, but data are sparse. Unfortunately, methodologic limitations in the measurement of mood and anxiety symptoms in ASDs have impeded more thorough study of these agents for these symptom targets. However, the common observations of dysphoric mood, anxiety symptoms, and in some instances diagnoses of depression and anxiety in individuals with ASDs continue to appear to prompt their consideration; the field awaits a large-scale controlled trial which specifically targets anxiety and mood in individuals with ASDs. Careful and slower titration of low doses of these agents is advised if they are to be prescribed at all. The use of side-effect rating scales may indicate early warning signs of activation and other potentially severe adverse effects. The risk of significant side effects of these agents added to the current limited evidence of benefit should lead to more restricted use of these medications.

Antipsychotics

As a drug class, the antipsychotics have emerged as the second most commonly prescribed class of agents in community surveys, with substantial increases in recent use despite cautions relating to adverse effects of long-term exposure. The apparent broad short-term benefits of the antipsychotics, particularly members of the second-generation antipsychotic drugs (SGAs), have led to several large-scale controlled trials and resulting approval from the FDA for two members of this class for the specific target of severe irritability and aggression associated with autistic disorder. Table 76-1 lists available rigorous controlled trials for these agents in ASDs.

The SGAs represent a diverse group of compounds (McGough, 2005). Most of these agents share prominent effects on both the 5HT and DA systems. In addition however, the majority of this class displays high affinity for a wide range of other neurotransmitter receptor targets, including histaminic, adrenergic, cholinergic, and other receptors (Nasrallah, 2008). These broad neuropharmacologic profiles are likely associated with the wide range and varying mix of commonly associated side effects of these agents.

Table 76–1.
Randomized, controlled trials of antipsychotics in autism disorders

Agent	Sample	Design	Average Dose	Outcomes
Risperidone, (McDougle 1998)	n = 31, autism 55%; PDD 45% 28 years.	12-week placebo vs. risperidone parallel groups.	2.9 mg	57% response to risperidone, 0% to placebo, 9/15 responders continued drug.
Risperidone (McCracken [RUPP], 2002)	n = 101, autism and severe irritability, 9 years (5 to 16).	8-week placebo vs. risperidone parallel groups.	1.8 mg	75% response to risperidone, 12% response to placebo.
Risperidone (Shea 2004)	n = 79, autistic d/o 68%, PDD, NOS, 7.5 years.	8-week placebo vs. risperidone.	1.2 mg	87% response to risperidone vs. 40% placebo.
Risperidone (Aman, 2009)	n = 124, ASD, (4 to 13).	16-week med-only vs. med + behavior therapy.	2.0 to 2.25 mg	Significant decreases in ABC-Irritability: No difference CGI-Improvement ratings.
Risperidone (Troost, 2005)	n = 24, ASD.	9-week open-label, 8-week double-blind placebo discontinued.	1.7 mg	No group effects on symptoms; risperidone group better on vigilance tasks.
Olanzapine (Hollander, 2006)	n = 11.	8-week placebo vs. olanzapine.	10 mg	Responders: 50% olanzapine vs. 20% placebo.
Aripiprazole (Owen, 2009)	n = 98, 9 years (6 to 17).	8-week placebo vs. aripiprazole.		Responders: 52% aripiprazole vs. 14% placebo.
Aripiprazole (Marcus, 2009)	n = 218, autistic disorder and irritability 9 years (6 to 17).	8-week placebo vs. aripiprazole fixed dose.	5 mg, 10 mg, 15 mg	Responders (CGI-I much or very much improved): Placebo: 35% ; 5mg: 56% (significant vs placebo); 10mg: 49% (non-significant); 15mg: 53% (non-significant).

Risperidone is the most widely investigated member of the SGAs in ASDs. Following a number of case reports and open-label trials suggesting possible beneficial effects of risperidone, risperidone has been studied in four large-scale controlled trials in ASDs. The National Institute of Mental Health (NIMH) Research Units in Pediatric Psychopharmacology (RUPP) Autism Network (2002) reported on the first major controlled trial of risperidone in children with autism. Risperidone demonstrated significant benefits versus placebo during a double-blind 8-week acute treatment phase involving 101 children and adolescents with autistic disorder with moderate to severe levels of irritability, aggression, and self-injurious behavior. Blind ratings of global improvement showed 75% of those treated with risperidone to show a clinically significant response versus 15% in the placebo group, with a mean daily dose of 1.8 mg/day. In a 4-month open-label extension phase, benefits observed in the acute phase were maintained in over 85% of subjects, with no requirement of increasing risperidone daily doses. A unique feature of this study was the final phase of a placebo-controlled discontinuation study of a subsample of 32 individuals completing 6

months of risperidone treatment. Placebo substitution was associated with a significant return of symptoms of irritability and aggression in 62.5% of subjects versus 12.5% of individuals maintained on their prior dose of risperidone for an additional 2 months, supporting durability of treatment for up to 6 months of treatment; this also suggests that some individuals can successfully interrupt treatment without relapse after short-term treatment. Subsequent studies have confirmed these observations using similar designs. Two additional large-scale studies have provided similar evidence of benefit for the target symptoms of agitation, aggression, and severe irritability (Aman et al., 2009; Shea et al., 2004). A study of 79 children from 5 to 12 years of age with any ASD diagnosis reported over 80% showing clinical improvement with a mean daily dose of 1.2 mg/day (Shea et al., 2004). Further studies involving risperidone administration have provided additional support for therapeutic effects on endpoints of aggression, irritability, and agitation. A large NIMH-supported controlled trial compared the benefits of risperidone monotherapy to risperidone plus weekly parent behavioral management treatment (Aman et al., 2009). Overall, risperidone led to marked decreases in ratings

of irritability from baseline, and the addition of behavior management training was associated with further decreases in ratings of irritability, reduced ratings of noncompliant behavior, and a modest decrease in average daily dose of risperidone from 2.25 to 2.0 mg/day (Aman et al., 2009). Relative to community dosing practices, the robust effects of low doses in the above studies represent an important statement to clinicians to question the clinical need for daily doses of greater than 2 to 3 mg per day in most children and adolescents treated with risperidone. The research model of this study, which evaluated the effects of combined treatments, both pharmacologic and behavioral, represents the possible beginning of a needed, new generation of research. Many questions remain about whether the benefits of accepted but lengthy and time-intensive behavioral, social, and educational interventions can be accelerated or enhanced by combined drug therapies; these are crucial questions for the field of ASD intervention research.

Interestingly, examination of secondary endpoints from the placebo-controlled trials suggest that other ASD symptom domains show significant improvements as well, as also reflected in a smaller controlled trial in adults with ASDs showing broad improvements (McDougle, Holmes, et al., 1998). Hyperactivity ratings and measures of repetitive behaviors have been found to display significantly greater improvements versus placebo, at times achieving reductions of 35 to 50% from baseline ratings, depending on the endpoints; however no trial has prospectively specifically tested the effects of any of the SGAs on the core ASD domain of repetitive behaviors.

Risperidone exposure is linked to a number of common side effects—increased appetite and weight gain (nearly 3 kg in 8 weeks), drowsiness and sedation, drooling, tremor, and dizziness. Longer-term metabolic effects of concern include the development of metabolic syndrome and diabetes, and unknown effects of prolonged hyperprolactinemia. Although data are sorely limited, smaller-scale investigations do not observe negative effects on cognitive functioning (Aman et al., 2005). Clinical recommendations based on the literature support initiating treatment at low doses (0.5 mg/day) and if needed by continued symptomatology, gradually titrating in no greater than 0.5 mg increments over 4 to 8 weeks, up to a recommended maximum dose range of 3 to 4 mg per day, with most individuals responding to doses as low as 1 to 2 mg per day.

Aripiprazole has been studied in two large-scale placebo-controlled trials as a treatment for aggression, severe tantrums, and self-injurious behavior associated with autistic disorder. Overall, those subjects assigned to aripiprazole treatment showed decreases in ratings of irritability between 43 and 50% with approximately 50% subjects treated with aripiprazole rated as "much" or "very much" improved versus 35% for those in the placebo group during the 8-week acute trial. Fixed-dose assignments of 5, 10, and 15 mg per day in one trial did not strongly point to a recommended or superior daily dose; open label and case series reports suggest improvements as well, with doses varying considerably between 2.5 to 15 mg per day over periods of treatment up to 15 months of

exposure, and with improvements most evident observed in aggression, severe tantrums, and agitation. Limited published information is available for longer-term treatment with aripiprazole. Side effects include fatigue, gastrointestinal symptoms, somnolence, weight gain, and extrapyramidal symptoms (EPS) such as akathisia. Weight gain of nearly 1.5 to 2.0 kg over an 8-week exposure have been noted in studies of aripiprazole, and not were strongly correlated to overall daily dose. Based on the above data, aripriprazole has also received FDA approval for the treatment of severe irritability associated with autism in children and adolescents. Effective doses appear to vary widely, and careful titration over the wide ranges tested in clinical trials is often needed. Clinicians should be aware of the possibility of clinical confusion between akathisia versus worsening clinical symptoms. Other mild symptoms of EPS such as drooling, slowed gait, increased motor tone, agitation, or cogwheeling should trigger consideration of dose reduction or addition of treatments for EPS.

Other than risperidone and aripiprazole, few controlled trial and systematic studies are available for other SGAs. Olanzapine was contrasted using random assignment to open-label treatment with olanzapine or haloperidol in one report involving 11 children and adolescents with ASDs. Overall, global response was found to be superior with those treated with olanzapine versus those receiving haloperidol. Improvements were noted across several outcomes including global ratings, agitation, hyperactivity, and language usage. However, weight gain was significantly greater in subjects treated with olanzapine even during the 6-week study period. Two open-label studies of olanzapine, both describing 12-week response to moderate mean doses of 7.5 to 10 mg/day found varying rates of improvement. Benefits were suggested to be observed in hyperactivity, irritability, anxiety, and mood symptoms, although the number of responders ranged from 12 to 86% (Potenza et al., 1999). One small double-blind placebo-controlled study of 11 children with ASDs suggested superior global response rates for those assigned to olanzapine (50%) versus those receiving placebo (20%), although symptom severity ratings did not differ between groups (Hollander et al., 2006). Quetiapine has been noted in open-label reports to be associated with limited benefit and tolerability. No controlled trial studies have been reported with quetiapine. A range of side effects has been noted including increased appetite, weight gain, sedation, possible sedation, drooling, and possible reduction in seizure threshold. Ziprasidone has been described in two open-label reports to have possible benefit on symptoms of aggression, agitation, and irritability; limited safety and tolerability observations are available. Target doses for ziprasidone are not well-defined; wide doses ranges from 20 to 160 mg per day are associated with improvement in 50 to 75% of individuals in the reports. Improvement has been most notably observed in relationship to maladaptive behavior, disruptive behavior, aggression, and hyperactivity. In contrast to most of the members of the SGAs, ziprasidone has shown little evidence for associated weight gain, even in individuals followed for up to 6 months of

exposure. Extrapyramidal symptoms have been noted to occur in association with ziprasidone. Although no symptoms suggesting common adverse effects on cardiac function have been described in individuals with ASDs, one open-label report documented an increase of 15 milliseconds in the Q-T wave interval, corrected for heart rate (QTC).

The oldest second-generation antipsychotic clozapine, has been subjected to little investigation for use in individuals with ASDs, mainly because of concerns about the risk of agranulocytosis requiring frequent blood monitoring and longer-term tolerability challenges. Case reports have noted possible improvement in aggression, hyperactivity, and stereotypic behavior with doses of 200 to 450 mg/day (Zuddas et al., 1996), with sedation, weight gain, enuresis, and drooling appearing frequently in these uncontrolled reports.

Typical Antipsychotics

Although less commonly utilized in clinical practice, haloperidol has a history of controlled study for the treatment of children with autism, with work dating back several decades. In double-blind placebo-controlled trials with low doses of haloperidol (less than 2 mg/day) in children from 2 to 8 years of age with a mixture of diagnoses (including what would fall into ASDs today), improvements were noted across a range of domains including reduced social withdrawal, stereotypy, and hyperactivity. Longer-term observations of continued haloperidol treatment suggested that benefits were maintained over time, however systematic studies examining outcomes in children where haloperidol was periodically withdrawn at 6-month intervals suggested that the frequency of dyskinesias observed was surprisingly high. Up to 1/3 of all subjects enrolled in these studies demonstrated withdrawal dyskinesias, which were more common in those subjects receiving higher daily doses of haloperidol. Although the reports documented the eventual resolution of dyskinesias in all cases, the high frequency of this adverse event has raised serious concerns about long-term exposure to potent dopamine antagonists such as haloperidol (Anderson et al., 1984; Campbell et al., 1978; Campbell et al., 1997; Perry et al., 1989). Low-potency typical antipsychotics, such as chlorpromazine, in individual doses from 12.5 to 50 mg are sometimes utilized for the short-term management of severe aggressive rage outbursts, but sedation, anticholinergic effects, EPS, dyskinesia risk, and potential cardiovascular effects such as orthostatic hypotension lower the benefit/risk ratio of this group of drugs as a maintenance treatment.

Overall, research on the clinical effects of the antipsychotics in children with ASDs possesses areas of substantial depth, though many agents have not yet been carefully studied. The methodology for investigating the clinical utility of these drugs for their common targets of agitation, aggression, irritability, and self-injury is sound and now widely accepted, and many of the measures used in the clinical trials of the FDA-approved agents have utility in the clinical monitoring of these agents (Aberrant Behavior Checklist, Community Version; Abnormal Involuntary Movement Scale; Parent Side Effect Rating Scale;

Parent Target Symptom Ratings). Clinicians faced with individuals with ASDs with moderate to severe aggressive behaviors, rage outbursts, agitation, and self-injury have two approved choices for treatment with a supporting evidence base. Along with tools for systematic monitoring of drug effects on behaviors comes recommendations for safety monitoring for these agents, including baseline and periodic fasting glucose, lipids, weight, and cardiovascular parameters (Correll, 2008).

Stimulants

The category of psychostimulants has been noted in community surveys to be frequently prescribed in as many as 15% of individuals with ASDs, usually for treatment of associated behaviors of hyperactive, inattentive, impulsive behaviors common to individuals with ASDs. Indeed, it has been less well-appreciated until recently that the disruptive behaviors may represent the most common impairing associated constellation of symptoms in individuals with ASDs, arguably conceived of as one aspect of an "expanded phenotype." (McCracken, in press) However, despite the frequent overlap of disruptive behaviors with ASDs, little information has been available until recently as to whether standard treatments for ADHD (in typically developing individuals) possess efficacy and safety in individuals with ASDs.

Small-scale studies, most with brief treatment periods and few with placebo controls, suggested modest benefit on ADHD symptoms but raised concerns about tolerability because of common side effects of social withdrawal, mood lability, motor tics, and even cases of apparent psychotic symptoms associated with stimulant exposure.

The largest controlled study of psychostimulants in children and adolescents with ASDs was conducted by the NIMH RUPP Autism Network, which enrolled 72 subjects (mean age of 9 years) with a range of ASD diagnoses (74% with DSM-IV autistic disorder). Subjects were entered into a double-blind placebo-controlled 4-week crossover trial, following a brief open-label period to establish tolerability. Average daily doses of methylphenidate were conservative (0.125, 0.25, 0.5 mg per kg tid; afternoon doses were halved). Overall results suggested solid benefit in 49% of the subjects enrolled in the trial as defined by substantial reductions in hyperactivity of greater than 25 to 30% from teacher and/or parent ratings, and study clinician ratings of clinical global improvement. However, nearly one of five subjects was unable to complete the brief trial because of intolerance of methylphenidate, with prominent adverse events of mood lability, social withdrawal, and decreased appetite frequently observed. Interestingly, secondary analyses of structured observational data obtained from a substudy of younger subjects in the trial suggested methylphenidate at best dose was associated with increases in some measures of joint attention behaviors and self-regulation (Jahromi et al., 2009). The observation represents one of the few suggestions of improvements in a core deficit of ASD associated with medication exposure, but requires replication.

Atomoxetine

Several small-sized open-label reports and one proof-of-concept controlled study suggest the possible benefit of atomoxetine on ADHD symptoms in individuals with ASDs, most prominently on hyperactive and impulsive symptoms. Open-label treatment with atomoxetine for an average of 20 weeks was associated with reductions from baseline in overall parent ratings of ADHD symptoms, with average reductions in the range of 25%; 60% of subjects were described as "much improved" or "very much improved" by clinician ratings, though no comparison treatments exist to balance expectancy bias (Jou et al., 2005). Two other open-label pilot studies also provided some evidence for possible benefit for atomoxetine. One report of 12 children with ASDs suggested improvements of parent ratings of ADHD symptoms, however 42% of these subjects discontinued because of adverse events, and some measures did not evidence statistically significant decreases in ADHD symptoms (Troost et al., 2006). An additional 8-week open-label study of 16 children with ASDs recorded more substantial decreases in ADHD symptom ratings; a drop of nearly 50% in parent and teacher ratings of inattentive and hyperactive behaviors from baseline during the 8-week trial were present, with mean doses reached of 1.2 mg per kg per day (Posey et al., 2006). However, no change in repeated testing with a computerized performance task of sustained attention was observed (Posey et al., 2006). One small study reported on results of a double-blind placebo comparison trial of atomoxetine of children with ASDs (Arnold et al., 2006). Although those subjects assigned to atomoxetine achieved nearly double the responder rate vs. placebo (56% vs. 25%) the improvement in symptoms appeared to be limited to decreases observed in hyperactive-impulsive symptoms. Taken together these data suggest possible modest benefit of atomoxetine for the treatment of ADHD-like behaviors in ASDs, but with questions about tolerability and disappointing impact on problems of inattention and concentration, clearly important because of the cognitive deficits common to individuals with ASDs (Ventola & Tsatsanis, in press). Dosing also remains uncertain, as most of the extant reports in samples with ASDs use relatively lower average daily doses than those found most efficacious in typically developing children with ADHD.

Alpha-2 Adrenergic Agonists/ Antihypertensives

Clonidine and guanfacine have been explored in small studies in mixed groups of subjects of autism spectrum disorders. Both exert effects through CNS cortical and subcortical alpha-2 receptors, which in a variety of experimental models have been noted to have beneficial effects on measures of cognitive performance. Two small but well-controlled studies have reported on clonidine's possible benefit on disruptive behavior symptoms on individuals with autism spectrum disorders. Using the clonidine transdermal patch in a crossover design, Clinical Global Impression (CGI) improvement ratings suggested superior benefit for the clonidine treatment

phase in subjects including children and adults, despite no significant difference in disruptive behavior symptoms as rated by parents (King et al., 2001), leaving estimation of overall benefit uncertain. Another study of clonidine also used a double-blind placebo-controlled crossover design with eight subjects with ASDs (Jaselskis et al., 1992). Although ADHD symptoms were rated by parents to be significantly lower during the clonidine phase, teacher ratings documented more modest improvements with estimated effect sizes in the moderate range (mean daily doses of 0.15 to 0.2 mg/day).

Guanfacine has been described as possibly beneficial in individuals with ASDs with prospective and open-label studies. A review of treatment experience of 80 subjects, primarily children, suggested improvement in global severity ratings by treating clinicians. A multisite 8-week course of guanfacine with average daily doses in the range of 1.5 to 2.5 mg per day in 25 children with ASDs and high levels of hyperactive-impulsive behavior suggested large improvements by both parent and teacher ratings of hyperactive-impulsive behavior (Scahill et al., 2006). Fifty-eight percent of subjects were rated "much improved" or "very much improved" by study clinicians. Overall, guanfacine has been well-tolerated, but adverse events are common and include sedation and fatigue, mood lability, headache, hypotension, bradycardia, and sleep changes. Too little data exists to rigorously assess the utility of the alpha agonists in ASDs at this time, and the level of indication is rated at best as "possibly indicated."

Mood Stabilizers and Anticonvulsants

The frequent co-occurrence of seizure disorders in 10 to 20% of individuals with ASDs often provides a clear indication for the use of antiepileptic drugs (AEDs). Additional associations of mood lability, mood swings, nonspecific EEG abnormalities, and rage outbursts have fueled interest in examining the benefits of mood stabilizers and AEDs in ASD. Unfortunately, little evidence from rigorous experimental studies is available, however an open-label report of the effects of divalproex sodium suggested benefits in five of 14 individuals across a wide age span (Hollander et al., 2001). A controlled trial of lamotrigine in 28 children with ASDs, found no significant benefits versus placebo-assigned subjects in an 8-week study, although the subjects entered the trial with only mild to moderate ratings of disruptive and maladaptive behaviors, perhaps limiting the potential of observing an effect of lamotrigine versus placebo. An additional report described treatment experience in a mixed sample of 50 children, in whom 13 children with autism were noted; global improvements were noted in several areas in terms of benefits for attention and maladaptive behaviors.

A chart review of treatment experience in 15 children with ASDs noted the possible benefit of topiramate in eight of 15 (53%) based on treating clinician ratings (Hardan et al., 2004). Benefits were found in symptom ratings of inattention and hyperactivity, where decreases from 30 to 38% were noted compared to pretreatment ratings. Another case series of topiramate use in doses in 2.5 mg per kg per day was noted to

be beneficial in two of 5 children with autism and maladaptive behaviors (Mazzone & Ruta, 2006).

Levetiracetam has been described anecdotally as a treatment for maladaptive behaviors in 10 children with ASDs. Benefits were described as widespread, particularly for problems of aggression, hyperactivity, irritability, and impulsive behavior. However, a 10-week double-blind placebo-controlled study of levetiracetam in 20 children and adolescents with autism found no drug versus placebo differences that achieved significance, and adverse events were common at a mean daily dose of 862.5 mg per day (Rugino & Samsock, 2002; Wasserman et al., 2006). Overall, the benefits of several diverse AEDs have not conclusively emerged from systematic studies, despite the promise suggested by anectodal reports and the association of seizures and abnormal EEG activity in many individuals with ASDs. Taken together, the disappointing results for AEDs in placebo-controlled trials provide another sobering example of the possible overestimation of drug effects in the absence of stringently controlled research designs.

Naltrexone

Naltrexone has been investigated in a number of reports, most commonly as a potential treatment targeting self-injurious behavior. Outcome measures of self-injurious behavior, language use, and social behavior have not documented significant effects of naltrexone especially versus placebo, but interestingly, ratings of hyperactivity have been noted to be reduced compared to baseline measures or placebo controls in most reports. Side effects have been confined to mild sedation. Naltrexone and related compounds may deserve additional examination as alternatives to stimulants and atomoxetine for the treatment of ADHD-like behaviors associated with ASDs.

Amantadine

Amantadine is a compound with multiple neurochemical effects from inhibition of the dopamine transporter and from N-methyl-D-aspartic acid (NMDA) receptor antagonist properties. Prior case series suggested benefits for treatment of individuals with ASDs. A well-controlled double-blind placebo-controlled study of amantadine hydrochloride in children and adolescents with ASDs, found few differences for amantadine versus placebo during the 4-week study period. However, blind investigator ratings of hyperactivity symptoms revealed significant improvement versus placebo in the amantadine-treated subjects (King et al., 2001). Benefits for younger children and higher-dose treatment are suggested by these results, given the maturation of the glutamate system and the low rate of adverse events described in the study.

Memantine

Memantine shares with amantadine antagonist effects at NMDA receptors; given the evidence of glutamatergic excess in Rett Syndrome and Fragile X Syndrome, some anecdotal

experience with memantine in ASD has been described in two open-label studies. One report of experience in 14 children and adolescents with ASDs found no prominent benefits on cognition but behavioral improvements were noted on scales on hyperactive behavior and social behavior (Owley et al., 2005). In a chart review of clinical experience with 18 subjects with ASDs, 61% were described by treating clinicians as responders based on global improvement with possible decreases noted in ratings of hyperactivity (Erickson et al., 2007) . However, increases in activity and behavioral worsening have also been noted in conjunction with memantine exposure even at low doses, leaving considerable uncertainty about whether safety and efficacy can be established for memantine in children with ASDs.

Cholinesterase Inhibitors

Because of reports cited above of postmortem tissue analysis suggesting reduced nicotinic receptors and reductions of other components of the cholinergic system, preliminary studies of acetylcholinesterase inhibitors have been completed. Retrospective reports of donepezil have suggested improvements in disruptive behaviors in one clinical report. Galantamine, another acetylcholinesterase inhibitor with more prominent effects on nicotinic receptors was tested in a randomized placebo-controlled crossover study of 20 children with ASDs. Modest benefits favoring galantamine were observed on outcomes of mood lability, aggression, hyperactivity, and inappropriate speech. An open-label study of 12 weeks of galantamine in 13 children with ASDs was noted to show improvement as measured by ratings of irritability and social withdrawal symptom scales, however these improvements were small; 23% could not complete the 12 weeks because of adverse effects, and disruptive behavior symptoms were not noted to decrease from baseline. Rivastigmine is another acetylcholinesterase inhibitor. Open-label clinical treatment experience for rivastigmine over 12 weeks was described in one report for 32 children with ASDs. Comparisons to baseline ratings suggested improvement in overall ratings of autism symptoms and on ratings of hyperactive and impulsive behavior. Although these similar agents have been associated with modest behavioral gains in children with ASDs, the extent of the symptom changes appear to fall short from providing pronounced global improvements; the utility of increasing tonic cholinergic tone in ASD remains to be determined.

Targeted Treatment Using Psychotropics in ASDs: Potential Guidelines

How to incorporate the observations reviewed above into individual patient recommendations is a definite challenge for clinicians who seek to reduce pronounced maladaptive behaviors not manageable by behavioral interventions alone. In the following section, we attempt to synthesize the available evidence, as it may be applied to specific and commonly

identified targets for treatment in individuals with ASDs. Each suggested pathway, with few exceptions, would at the present time be considered off-label treatment based on varying levels of evidence as summarized above. However, as demonstrated by two FDA approvals of agents for children and adolescents with autistic disorder and severe irritability, data are accumulating. A few general clinical recommendations are warranted. First and foremost, the use of psychotropic medication should always be considered as only one component of a multimodal plan incorporating psychosocial treatments, educational and rehabilitative interventions, and environmental manipulations. Efforts should always be made to reduce medication exposure to the least amount possible and for the shortest duration. Overall, the goals of treatment need to be clearly specified in advance, with suitable monitors of treatment impact on the designated targets acquired both pretreatment and at key intervals during the course of ongoing drug therapy. Goals for treatment should be behaviorally based and should be specified in advance, preferably utilizing observations obtained from multiple sources. Depending on the class of medication and the specific agent prescribed, pretreatment monitoring, including physical examination as well as possible lab studies, may be indicated. Overall, consideration of the possible benefits of any drug therapy should be weighed against the identified risks of such treatment, and particularly for longer-term exposure. As noted below, with the exception of treatments targeting repetitive behaviors, the benefits of pharmacological treatment appear to be limited to associated features, leaving most core features of the ASD, such as social and language impairments, untouched. It is of note that few moderators of drug therapy have been identified despite many efforts to reveal them. Neither IQ, sex, ASD subtype, nor pubertal status has been found to influence treatment response.

However, one exception to the above is the identification in studies of risperidone of the moderating effect of 5' nucleotidase, a marker of zinc status (Farmer et al., in press). However, additional efforts to identify moderators have been limited by the relatively small number of treatment samples available; in that regard it may be of interest that some studies of adults with ASDs note apparently greater improvement than that observed in parallel studies of children and adolescents. Such age differences are unexplained; treatment samples in adult studies may differ from child studies with the inclusion of higher-functioning individuals; other unknown influences on treatment outcome may be active.

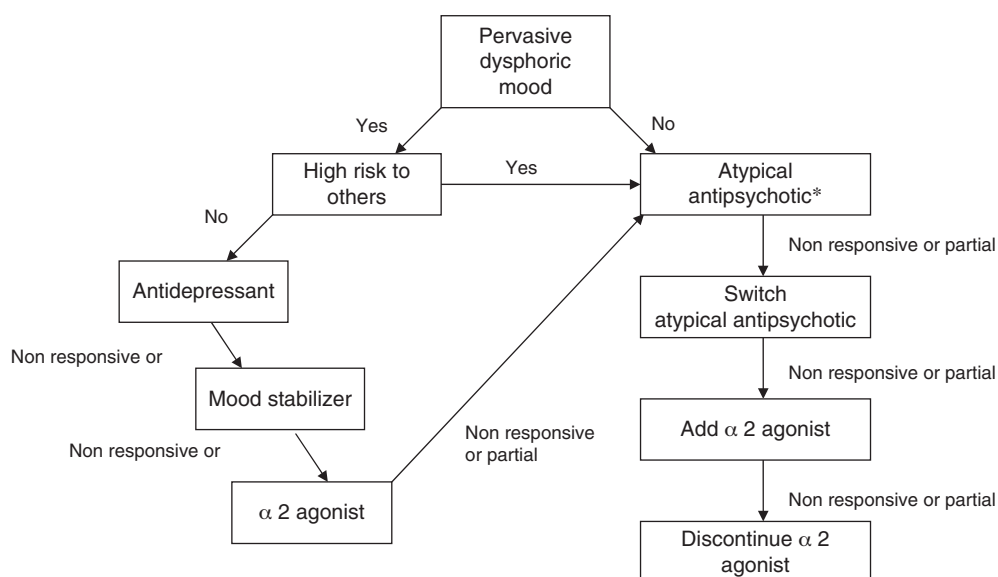
Presented in graphical form are two suggested clinical pathways for treatment selection: one for ASD associated with frequent, moderate to severe aggression, mood lability, and agitation (Figure 76-1), and one for ASD accompanied by high levels of ADHD symptoms (Figure 76-2). Treatment selection for these two sets of target behaviors can be argued to be solidly informed by research evidence, as synthesized in the pathways shown. What about other common targets of repetitive behaviors, anxiety, and insomnia? Unfortunately, data available fall short of clear and usual standards for even "probable indications." The failure of SSRIs to reduce repetitive behaviors in multiple trials raises questions about their application; the clinician is encouraged to assess carefully for other indicators which may be drug-responsive such as rage outbursts or hyperactivity. Anxiety is often invoked as an explanation for maladaptive behaviors in ASD, but is challenging to assess in the population; possible treatments may include antidepressants, AEDs, and even low-dose SGAs (*see Chapter 69, this volume*). Interventions for insomnia to be considered might include behavioral therapy, melatonin, atypical antidepressants, and alpha agonists (*see Chapter 69, this volume*).


Figure 76–1. Targeted pharmacotherapy for ASD rage outbursts, severe irritability, aggression. * Risperidone, aripiprazole FDA-approved.
Figure 76–2. Targeted pharmacotherapy for ASDs, hyperactive-impulsive, inattentive.

Conclusion

As can been gleaned from the review above, there is much work to do in developing and testing new possible pharmacotherapies for both associated and core features of ASDs. Significant progress has been made delineating reliable and relatively sensitive measures for most of the common associated maladaptive behaviors, and efforts are underway to improve on measures of core domains of the ASDs, which would be suitable for use in a clinical trial context. Given the hoped-for progress in identifying the molecular pathophysiology of autism, there is reason for continued optimism in the search for treatments that may have even more significant impact on functioning, overall outcome, and in reducing the morbidity of these disorders.

A major unmet need is to identify drugs that may have significant benefit in ameliorating the wide range of cognitive impairments seen in individuals with ASDs. Although ASDs are notable for their wide variability in cognitive functioning, even individuals in the "high-functioning" range are frequently noted to demonstrate impairments in a variety of basic cognitive skills, including judgment and planning, working memory, cognitive flexibility, organization, and social cognition. Besides cognition, the major gap in identified treatments to date has been the lack of obvious benefit of available drug therapies on social and communicative functioning of individuals with ASDs. Despite a robust preclinical science effort, to date no treatments explored in individuals with ASDs have been found to reliably improve global measure of social functioning. However, two recent examples suggest continued optimism. Acute administration of intranasal oxytocin in small but well-controlled experimental studies has identified improvements in measures of social perception and cognition, in normal volunteers and in a small number of adults with ASDs. Given the possible role of neuropeptides in regulating aspects of social functioning, such findings have generated strong interest, but clinical applicability of such a treatment approach is far from certain. In addition, the improvements in measures in social communication, in particular joint attention-initiating behaviors and emotion regulation ratings, observed in the small controlled trial of methylphenidate versus placebo in children with ASDs also suggests that these core deficits within the ASD may be both tractable and malleable targets for treatment.

Lastly, the greatest optimism is based upon the promise of an ultimate revealing of the underlying molecular pathophysiology in ASD, which is expected to be quite varied across large numbers of individuals with these conditions, likely reflecting the impact of multiple pathways, multiple genetic risk variants, as well as multiple possible environmental influences. However, once individual molecular pathways can be identified, targeted treatments become possible. Although such efforts to extrapolate from gene pathways to clinical treatment have not always proven to be foolproof in principle (witness Fragile X and neurofibromatous 1 treatment failures despite preclinical models), a molecular-based intervention science for ASD is just beginning.

Challenges and Future Directions

- Inadequate knowledge of important molecular pathways disrupted in ASDs.
- Need for identified drug treatments for core domains.
- Need for improved outcome measures and biomarkers of treatment response.

Best Practices: Pediatrics

⊞ Points of Interest

- Current recommendations call for developmental surveillance at every well-child check and the use of autism-specific screening tools at 18 months and 24 months of age, as well as when there is any developmental concern.
- Many resources regarding early detection and management of autism spectrum disorders have been developed in recent years including easy-access internet websites such as www.cdc.gov/autism, www.firstsigns.org, www.aap.org, and www.autismspeaks.org.
- The primary-care evaluation of a child with an ASD should include a comprehensive history including birth, developmental, medical, and detailed family histories, and a complete physical exam including observations of the child's interactions, communication, and behaviors.
- The primary-care physician (PCP) should consider the following medical issues when caring for a child with an ASD: seizures, sleep disturbance, gastrointestinal dysfunction, feeding and nutritional issues, immune problems, tics and Tourette Syndrome, and genetic abnormalities. Children with ASDs are also at increased risk for intellectual disabilities, a history of regression, sensory-motor abnormalities, behavioral problems, and other psychiatric disorders.
- Research suggests that intensive early intervention can substantially improve outcomes in children with ASDs.
- Although behavioral and educational therapies are the mainstay of treatments, there is a vast array of therapeutic options currently in practice. Unfortunately, there is very little evidence regarding what therapeutic technique is best for a given child.

⊞ Introduction

With the rise in the prevalence of ASDs in the last 20 years to approximately 1 in a 110 children (CDC, 2007; Fombonne, 2009), primary-care pediatricians must rise to meet the challenge of recognizing, screening, evaluating, and managing children with ASDs in their practice. Media concern, parental awareness, and an expanding research agenda have pushed this group of diagnoses to the forefront of child development. Most primary-care providers are aware that autism involves the core deficits of an autism spectrum disorder, which include qualitative impairments in social interaction and communication, and restricted, repetitive, and stereotyped patterns of behavior, interests, and activities (Association, 2000). Because it has been shown that children with ASDs can make significant developmental gains with intense early intervention, parents and pediatric providers must recognize children at risk for ASDs as early as possible, be knowledgeable about intervention, and be able to make proper referrals for further workup and management if necessary.

This chapter is dedicated to the description of what would be considered "best practices" for pediatricians and PCPs. Unfortunately, the state of research into most medical issues in ASD is not well enough developed to have established truly evidence-based practice parameters. Here we summarize much of what has been presented in detail in previous chapters in this volume and synthesize the elements into a guide for caring for a patient on the autism spectrum. We describe the importance of developmental surveillance, the usage and timing of specific ASD screening tools, and the gold standards for diagnosis and thorough assessments. A synopsis of the latest research and best practices for evaluation and management of common medical conditions, psychiatric and

cognitive comorbidities, and their workups will also be presented all in the context of providing a medical home for children with ASDs. Finally, we provide brief descriptions of the available interventions so the PCP can be familiar with the family's options and help them navigate the system.

⠿

Developmental Surveillance and Screening

For over 10 years, professional groups have published consensus guidelines, practice parameters, and clinical reports to help PCPs recognize, evaluate, and manage children with suspected ASDs. Although each group has a slightly different focus, there is a clear consensus regarding the role of the PCPs in surveillance and screening. The PCP has a unique role as the point of first contact for most children. The practice of developmental surveillance at every well-child visit and the further use of general and autism-specific screening tools at specific time points is clearly important, but is not in widespread use (Myers & Johnson, 2007). Unfortunately, it is still common to see delays in screening and diagnosis that result in slower referrals to intervention and may adversely affect developmental outcome. Some of these practice recommendations and tools designed to help the PCPs recognize early signs of ASDs are reviewed below.

The first publication regarding guidelines for screening and diagnostic referral came from a meeting of leaders in the research and clinical community sponsored by the Cure Autism Now (CAN) foundation (Geschwind et al., 1998). Shortly thereafter, practice parameters were released by the American Academy of Child and Adolescent Psychiatry (Volkmar et al., 1999), the Child Neurology Society and the American Academy of Neurology (Filipek et al., 2000; Filipek et al., 1999) and the American Academy of Pediatrics (AAP) (AAP, 2001). Most recently the AAP has put out detailed clinical reports regarding identification and evaluation (Johnson & Myers, 2007) and management of children with ASDs (Johnson & Myers, 2007). Each of these publications reviews the current evidence and makes recommendations that can be used in the primary-care setting.

There have been mixed results regarding the accuracy of clinical judgment alone in estimating the developmental progress of a child (Sices et al., 2003; Smith, 1978). In one study, 80% of the children who were eventually diagnosed with ASDs were not initially flagged for concern by their physicians (Robins, 2008). Thus, as the rate of identification of children with ASDs increases, so has the evidence for the importance of screening. Evidence has shown that general screening tools may not be sensitive enough to pick up all ASDs hence the need for ASD-specific screening at specific intervals (Pinto-Martin et al., 2008).

Current recommendations from the AAP call for developmental surveillance to be done at every well-child visit and suggest the use of validated developmental screening tests at specific visits: 9 months, 18 months, and either 24 or 30 months of age (AAP, 2006). Crucial elements of surveillance include careful attention to parental concerns, knowing relevant risk factors, following developmental milestones, and close observation of the child. Risk factors for ASDs include family history of ASD, certain genetic syndromes, or any loss of skills. The AAP report recommends ASD-specific screening testing at the 18-month and 24-month visits, the latter of which is required to identify the child who experienced developmental regression between 18 and 24 months of age (Johnson & Myers, 2007).

There are a number of standardized screening tests available for use in the primary-care setting (*see Chapter 5*). Some are general developmental screening tests, including: the Ages and Stages Questionnaire (ASQ), the BRIGANCE Screens, the Child Development Inventories (CDI), and the Parents' Evaluation of Developmental Status (PEDS). Others are ASD-specific, including: the Modified Checklist for Autism in Toddlers (M-CHAT), the Pervasive Developmental Disorders Screening Test 11 (PDDST-11), and the Social Communication Questionnaire (SCQ).

⠿

Increasing Awareness and Knowledge of ASDs

In response to poor consistency in screening for ASDs, several organizations have worked diligently to increase and enhance knowledge for professionals and for parents. These organizations provide valuable tools for use in the primary-care practice.

The Centers for Disease Control and Prevention (CDC) (www.cdc.gov/autism) has been closely tracking the prevalence of ASDs since 1996. A public awareness campaign called "Learn the Signs. Act Early" (www.cdc.gov/actearly) launched in 2004 has reached tens of millions of health-care providers, parents, child-care providers, and community supports. First Signs, an organization begun by a parent of a child with autism, is dedicated to guiding parents and practitioners through developmental monitoring, red flags for ASDs, screening, diagnosis and treatment. In 2007, First Signs and Autism Speaks teamed up to make a very useful ASD video glossary, which has video clips of typically developing children as well as children on the autism spectrum (www.firstsigns.org).

The AAP has released several publications and developed a resource toolkit to educate practitioners in recognizing the early signs of ASDs. They also help practitioners educate parents on both typical and atypical child development by giving them examples of when to be concerned (red flags). The "Autism A.L.A.R.M." flyer informs primary-care physicians that *Autism is prevalent, Listen to parents, Act early, Refer, and Monitor*, and includes the AAP surveillance and screening algorithm for ASDs[1]. With this algorithm, pediatric primary-care providers implement a risk assessment point system to guide proper follow-up and evaluation of children

who may have characteristics of an ASD. An AAP introductory booklet, "Understanding Autism Spectrum Disorders," is also available for parents and primary-care providers. The AAP Autism toolkit (2007)[2] is another valuable resource for physicians containing the surveillance and screening algorithm, ASD-specific screening tests, ASD evaluation checklists, physician information sheets, and parent handouts on autism-specific topics such as vaccines, therapies, and complementary therapies.

Autism Speaks (www.autismspeaks.org) is a private foundation dedicated to raising awareness and funding a global biomedical research agenda on the genetics, causes, early detection, diagnosis, and treatment of autism spectrum disorders. Their website is another resource for PCPs with general information about ASDs, reviews of various treatments and therapies, and research updates. They created the "100-Day Kit" for parents, a booklet published in both English and Spanish, which helps families organize and set priorities immediately after an autism diagnosis.

All of these tools are valuable to the PCP for their own use and to share with families.

Diagnosis and Assessment

Following the screening guidelines and employing these tools will allow the PCP to identify children suspected to have an ASD, but what then? Diagnostic criteria delineated in the Diagnostic and Statistical Manual of Mental Disorders from the American Psychiatric Association (DSM-IV or DSM IV-tr) (American Psychiatric Association, 1994 & 2000) can be used to confirm the suspicion or at least to narrow the diagnostic possibilities. In cases where the diagnosis is clear, the child can be immediately referred for early intervention services specific to autism. In other cases, practitioners may feel a referral for further ASD diagnostic testing is necessary but should be simultaneously recommending early intervention services. But PCPs need to understand that because of the heterogeneity of the disorder a diagnosis alone is insufficient. A thorough assessment of each child that can evaluate potential genetic causes, identify comorbid medical conditions, and delineate an individual's strengths and challenges is often the most important piece for families, and is essential for treatment planning.

The "gold standard" ASD assessments are usually performed at clinical centers that employ a multidisciplinary team of experts in the field. Teams are often comprised of some combination of child psychologists, child psychiatrists, child neurologists, pediatric developmentalists, speech-language pathologists, and occupational therapists. Ideally, in addition to specific ASD diagnostic testing, the assessment should include thorough evaluation of behavior, cognition, speech and language, and sensorimotor function. A medical assessment should also be performed and appropriate referrals to specialists such as in neurology, genetics or gastroenterology can be made. Unfortunately the access to these centers is often limited.

Primary-Care Evaluation for Children with ASDs

The primary-care evaluation of a child with an ASD is based on routine primary-care practice guidelines with special attention to specific issues characteristic of ASDs (*see Table 77-1*). Ideally, office visits should take into account the child's core deficits (e.g., poor social communication skills and resistance to change/need for routine) and PCPs should be aware that exams will often be limited by behavioral difficulties and visits may take longer (Myers & Johnson, 2007).

A comprehensive history includes a developmental history and three-generation pedigree. A complete medical history should include the typical review of systems but with special focus on problems that appear to be increased in children with ASDs: neurological issues (i.e., seizures), sleep difficulties, and GI problems. Birth history is also important because babies with prematurity, low birth weight, and perinatal difficulties appear to be at increased risk (Limperopoulos et al., 2008). Developmental history needs to query more than the simple language and motor milestones and should focus on social communication skills (e.g., back and forth sharing of sounds, eye contact, responding to name, imitating others, pointing) as well as any maladaptive behaviors (e.g., rocking, hand or finger mannerisms, spinning). Any sensory difficulties (e.g., sensitivity to loud noises, certain textures, certain tastes) should be elicited from the parent. A history of any loss of any

TABLE 77–1.

Keys to history and physical exam in a child with an ASD

- Thorough history
  - Query medical and behavioral issues past and present
  - Query developmental history
  - Query family history to include a three-generation pedigree
- Complete physical exam
  - Observe child in exam room
  - Measure growth parameters, especially head circumference
  - Conduct dysmorphology evaluation
  - Evaluate skin with Wood's lamp
  - Conduct neurological exam
- Studies for all children with developmental delays
  - Conduct audiologic evaluation
  - Screen for lead
- Studies to consider in ASD
  - Genetic testing
  - Metabolic testing
  - EEG
  - MRI

skills or regression should be documented. Given the strong genetic component of autism, the child's family history should be queried for any ASD diagnosis, genetic disorder, neurological disorders (seizures), psychiatric history (obsessive-compulsive disorder, anxiety or mood disorders), language delay or disability, and other learning difficulties.

Beyond its importance for routine health care, a physical exam is an opportunity for direct observation of a child's behavior allowing a preliminary assessment of eye contact, joint attention, and the child's main form of communication and expressive language skills. Any repetitive or stereotyped behaviors in the exam room should also be recorded. Noting the presence or absence of certain physical findings is essential. Although macrocephaly is not specific to autism, providers should be aware that this is overrepresented in this disorder with 20% showing head circumferences above the 98% (Fombonne et al., 1999). Examining the child for any dysmorphic features (face, limbs, stature, genitalia) can also yield clues to various genetic syndromes and diagnoses associated with ASDs. Because there is a higher incidence of autism in children with tuberous sclerosis, a careful evaluation of a child's skin for neurocutaneous lesions such as hypopigmented macules or ash-leaf spots (using a *Wood's lamp* or ultraviolet light source) is important. A neurological exam focusing on reflexes, abnormal movements, strength, tone, and coordination will assist the physician in ruling out neurological and muscle disorders that may be contributing to the core deficits of an ASD.

There are certain studies and labs that should be done in every child with developmental delay including an ASD. A formal audiologic hearing evaluation is recommended for all children with developmental delays (ASHA, 2004) to rule out hearing problems that could contribute to communication deficits. Lead screening is also recommended for all child showing signs of developmental delay, even if the child does not have pica or an oral fixation (CDC, 1997). Although not implicated in causing autism, lead poisoning can lead to learning disabilities, cognitive deficits, and behavioral problems. Many children on the autism spectrum, especially children with intellectual disabilities, remain in the oral-motor phase of development, placing them at a higher risk for lead poisoning (Cohen et al., 1976; Shannon & Graef, 1996).

Recommendations regarding additional medical testing are inconsistent (Johnson & Myers, 2007) and often based on clinical practice experience and expertise. PCPs need to recognize that further workup may have two different functions: diagnostic testing warranted by current health-related issues and testing for possible etiologies. This latter issue is often the most important to parents.

Tests to consider include EEG, MRI, and genetic testing. Some neurologists will use EEG for routine screening although the practice standards only call for it if there is a clinical suspicion of seizures or developmental regression. Brain MRIs are currently only recommended in the case of an abnormal neurological exam (Filipek et al., 2000). Many of the existing practice guidelines call for basic genetic testing in ASDs including high-resolution chromosome analysis and DNA for Fragile X. Many will also do fluorescence in situ hybridization (FISH)

for the 15q region looking for duplication. The newer microarray technology is more sensitive in identifying abnormalities in individuals with ASDs (Shen et al., 2010) and is likely to replace karyotypes in the very near future. The presence of moderate to severe intellectual disability and syndromic features greatly increases the yield of genetic testing. Discovery of a genetic abnormality is especially important because of genetic counseling implications.

Although any additional testing may not be done in a primary-care setting, it is important for practitioners to be aware of the possible comorbidities in this disorder and to have a low threshold for making subspecialty referrals appropriate for each child. All too often, issues are ignored because they are simply attributed to "the autism."

Establishment of a Medical Home

Despite the fact that a child may receive the diagnosis of an ASD outside of his primary care, a child's medical home will usually continue to remain with his PCP. For this reason, patients and families will be greatly benefited by a provider who is knowledgeable about ASDs. Navigating the world of autism can be extremely difficult for parents and children. They deserve to have a primary-care physician who will recognize and manage common medical problems seen with ASDs, facilitate early intervention and school issues, help sort through various therapies and treatments, and ultimately aid in planning for various transitions such as entering school, beginning adolescence, and venturing into adulthood.

It is especially important to remember that these children need the same standard of care as children with typical development. They need to be treated for the same childhood illnesses, receive appropriate anticipatory guidance, and have their immunizations kept up-to-date.

Medical Issues to Consider

Seizures

One of the most frequent medical comorbidities is epilepsy. It is commonly stated that 1/3 of individuals with ASDs will have seizures, although reported rates are variable, probably resulting from sample ascertainment differences. Large population-based samples show rates ranging from 5 to 26% (Fombonne, 1999). Risk factors for epilepsy include moderate to severe intellectual disability, comorbid neurological and neurogenetic conditions (e.g., cerebral palsy, Tuberous Sclerosis Complex, 15q duplication syndrome), and female gender (Spence & Schneider, 2009). Age of seizure onset is bimodal (early childhood vs. adolescence or early adulthood) (Volkmar & Nelson, 1990), and there is variability in the type and severity of seizures.

The diagnosis of epilepsy is made more challenging because the behavior exhibited during a seizure can be confused with typical ASD behaviors. For instance, absence (petit mal) and complex partial seizures are characterized by periods of

unresponsiveness. However, failing to answer to your name is one of the hallmarks of ASD behavior. Complex partial seizures can also demonstrate behavioral automatisms that could be confused with autistic stereotypical behaviors.

Any suspicion of seizures should prompt a neurology referral for further workup including EEG. Although a prolonged or overnight EEG (including natural sleep) is more sensitive to abnormalities than a routine office study, these are often more difficult to obtain in children with behavioral difficulties. Seizure treatment in ASD has the same goals as for all pediatric epilepsy: the best efficacy with the lowest side-effect profile; but with special consideration of behavioral side effects of anticonvulsants, both negative (behavioral dysregulation) and positive (mood stabilization).

Finally, there is growing awareness and interest in the occurrence of background EEG abnormalities—especially epileptiform discharges—in ASDs, even in the absence of clinical seizures. Some studies have shown epileptiform discharges in up to 60% of individuals (Chez et al., 2006; Kim et al., 2006). What to do about these abnormalities is not yet known but there are practitioners prescribing anticonvulsant medication based on the idea that discharges could negatively affect cognition or behavior. Although there are some small studies from other childhood epilepsy syndromes that suggest that these treatments could be beneficial (Spence & Schneider, 2009), more empiric data are needed to determine if these will eventually be considered among best practices in ASD.

Sleep Issues

Parents report significant sleep disorders as one of the most common comorbidities in ASDs. Sleep problems include insomnia, delayed sleep onset, sleep fragmentation, and early-morning awakening (Johnson & Malow, 2008) and appear to occur more frequently in children with ASDs than typical children (DeVincent et al., 2007; Polimeni et al., 2005). Although problems may be even more common in ASD children with comorbid intellectual disability, they are also prevalent for those with normal intelligence (Malow et al., 2006). PCPs must consider the multitude of causes for sleep difficulty including comorbid medical issues (seizures, gastrointestinal disturbance) or psychiatric issues (anxiety), medications (stimulants, asthma treatments) and/or behavioral/environmental issues. Finding the cause(s) and offering appropriate treatment may significantly improve daytime functioning (Johnson & Malow, 2008).

Gastrointestinal Dysfunction

Results from studies investigating the relationship between gastrointestinal (GI) symptoms and ASDs have been conflicting, leading to much discussion and debate. Initial reports of significant GI symptoms in children with ASDs (e.g., frequent constipation, loose stools or diarrhea, reflux, abdominal pain and bloating) suffered from selection bias and lack of control populations, calling into question whether this is an issue unique to autism. But a more recent study demonstrated significantly higher symptom rates in the ASD children

compared to those with typical development and other developmental disabilities (70% versus 28% and 42%, respectively) (Valicenti-McDermott et al., 2006), supporting the idea that GI dysfunction is an associated condition of ASDs.

There have also been reports of abnormalities on endoscopy. In a now infamous study[3] published in the *Lancet* in 1998, a group of GI specialists performed endoscopy in a small number of patients with ASDs and reported ileal lymphoid hyperplasia in these children (Wakefield et al., 1998b). Another group found esophagitis, gastritis, and duodenitis (Horvath et al., 1999). Further studies from the Wakefield group have postulated an immune-mediated pathology (Furlano et al., 2001; Torrente et al., 2002). However, interpretation of the findings is limited by lack of proper controls and biased recruitment of children with known GI symptoms, which may not be representative of the general population of children with ASDs. There is further disagreement regarding whether these histological changes are specific to ASDs or even pathological (MacDonald & Domizio, 2007).

At this time, there are no specific recommendations regarding GI workup or treatment in children with an ASD diagnosis. However, the Autism Speaks' Autism Treatment Network, a group of clinicians from 15 hospitals serving children with autism, is currently developing guidelines for GI assessment in autism. For ASD patients with GI symptoms, a closer evaluation of the GI system is certainly warranted. Dependent on the severity of the condition, a GI referral may be necessary. Anecdotal evidence suggests that GI discomfort can contribute to aberrant behavior and that behavioral improvement can be seen with proper medical treatment.

Feeding and Nutritional Issues

Food selectivity is frequently described in children with ASDs. Sensory as well as behavioral issues and rigid mealtime routines have been implicated. However, data on nutrient intake of these children is both limited and conflicting. One study demonstrated no differences in nutrient intake between children with and without ASDs (Lockner et al., 2008). Another showed inadequate vitamin intake in children with ASDs (Cornish, 1998). Anecdotally the authors have seen patients where strict food preferences have actually contributed to malnutrition and required intervention via tube feeding.

Many children with ASDs will be placed on modified diets and/or given supplements (Hanson et al., 2007; Levy & Hyman, 2003). Concern for food allergies may drive special diet choices but there has been limited research proving any overlap of non-IgE-mediated food allergies and autism (Jyonouchi, Geng, Ruby, Reddy, et al., 2005; Jyonouchi, Geng, Ruby, & Zimmerman-Bier, 2005). Families may confuse what they see as adverse behavioral reactions to a given food with a true allergy. This is not to say that children with ASDs never have food allergies, but these may not be related to the autism diagnosis (Murch, 2005). The pediatrician should be aware of the child's diet and should help supervise any exclusion diet or vitamin supplementation to ensure there are no significant nutritional deficiencies or significant side effects from high

doses of vitamins. If close monitoring of diet and supplements is beyond the scope of practice for the practitioner, a referral to a nutritionist might be beneficial.

Immune Problems

Involvement of the immune system in autism is currently a very active research area (*see Chapter 24*), but most of the work has been done in the basic science arena investigating etiology. From a clinical perspective the data are limited. Counter to anecdotal reports, there is no evidence for increased rates of infection in the early lives of children with autism (Rosen et al., 2007). Some studies have suggested higher rates of autoimmune disorders in family members of children with autism (Sweeten et al., 2003). Immunological profiling of children with ASDs has yielded inconsistent evidence of immune dysregulation (Ashwood & Van de Water, 2004) and the clinical significance of this remains unknown. Because auto-immunity has been implicated (Wills et al., 2007), some practitioners are advocating immune-mediated treatments (steroids or intravenous immunoglobulins). Although this may eventually prove to be an important treatment mechanism in ASDs, at this time there is scant evidence to support efficacy.

Tics and Tourette Syndrome

Studies have shown significantly higher rates of tics and Tourette Syndrome in individuals with ASDs than would be expected by chance co-occurrence alone. In samples of ASD patients tics have been reported in up to 22% and Tourette Syndrome in 8 to 20% (Baron-Cohen et al., 1999; Burd et al., 1987; Canitano & Vivanti, 2007).

One difficulty for practitioners is to differentiate tics (especially complex tics) from the motor and vocal stereotypies seen in ASDs. Tics tend to be brief and occur abruptly out of the context of typical or normal behavior. Stereotypies such as hand flapping, spinning, and hopping are repetitive or ritualistic movements that are typically more rhythmic and continuous than tics. Tics tend to have a waxing and waning course and can change in type and frequency while stereotypies will often remain constant for many years. Although children with autism will likely have stereotypies, it is important for pediatricians to be aware of the increased risk of tics and Tourette syndrome in ASDs because of the treatment implications. Children on the autism spectrum with comorbid tic disorders may have worsening tics when started on stimulant medications. Neuroleptic medications, often used in patients with a primary tic disorder, may be beneficial to the child on the spectrum with comorbid tics but will likely be less effective for the stereotypies.

Genetic Abnormalities

Although the etiology of autism remains largely unknown, it is clear that there is a strong genetic component, and recurrence risk within families is estimated at approximately 10%. Certain genetic syndromes or neurogenetic disorders are also known to be overrepresented in individuals with ASDs. Neurological or genetic disorders may account for up to 10 to 20% of autism cases (Barton & Volkmar, 1998; Kielinen et al., 2004; Oliveira et al., 2007) and chromosomal abnormalities are present in 3 to 9% using standard cytogenetic testing (karyotyping) (Fombonne et al., 1997; Wassink et al., 2001). Newer genetic testing methodologies using microarrays are now able to detect copy number variations (CNVs), which demonstrate microdeletion and duplications in the genome, postulated to be etiologically related to ASDs in a subset of patients (Sebat et al., 2007; Szatmari et al., 2007).

The most frequent associations are with Fragile X Syndrome, Tuberous Sclerosis Complex, and 15q duplication syndrome, each of which is thought to be present in 1 to 3% of individuals with autism. Rett Syndrome also shares phenotypic features with autism (at least at the early stages) and should especially be considered in girls with regression. A microdeletion and/or duplication syndrome involving a region on chromosome 16 (16p11) has also been reported (Kumar et al., 2008; Weiss et al., 2008). Autism has also been seen in patients with other neurogenetic syndromes, including: Neurofibromatosis, Hypomelanosis of Ito, Moebius Syndrome, Prader-Willi and Angelman, Joubert, Down Syndrome, Williams Syndrome, Sotos Syndrome; muscular dystrophy, Cowden Syndrome, Cohen Syndrome, Velocardiofacial Syndrome, ARX mutations, and Timothy syndrome (Spence, 2004). Obviously each of these syndromes must be considered in the context of its typical clinical presentation beyond autism symptoms.

There are also reports of an autism phenotype in some patients with metabolic disorders such as untreated Phenylketonuria (PKU) (Baieli et al., 2003), disorders of purine metabolism, biotinidase deficiency, disorders of cerebrospinal fluid (CSF) neurotransmitters including deficiency of folic acid (Moretti et al., 2008), and Smith-Lemli-Opitz syndrome (SLOS) (Tierney et al., 2001), and others (Manzi et al., 2008). Although these are rare conditions, detection is crucial because they may represent treatable entities.

There has also been interest in the overlap between mitochondrial disorders and ASDs, which is highlighted in a case report questioning the role of vaccines in the autistic regression of a child later found to have an underlying mitochondrial disorder (Poling et al., 2006). Published literature would suggest that these cases are rare, but clues to possible mitochondrial dysfunction include significant hypotonia, seizures, and severe delays (Filiano et al., 2002; Oliveira et al., 2005).

Other Associated Conditions

Intellectual Disabilities

Historically the literature has stated that approximately 70% of individuals with autism have comorbid intellectual disability

(Fombonne, 1999; Rapin, 1997). However, there have been more recent studies that have shown lower rates (Fombonne, 2009) and this may result from the inclusion of children on the milder end of the autism spectrum, availability of intervention, and improved testing of cognitive abilities in nonverbal children.

Cognitive abilities can be difficult to measure because of behavioral difficulties that interfere with testing and the fact that tests often rely heavily on language, a core deficit in this disorder. Therefore, low scores may not be completely reflective of true deficits. In tests that attempt to separate out nonverbal and verbal abilities, there is often a significant discrepancy between verbal and nonverbal scores. Although the trend has been either similar scores on these domains or higher scores on the nonverbal domains (Munson et al., 2008), higher verbal scores have been found in some studies of children with high-functioning autism or Asperger Disorder (Miller & Ozonoff, 2000).

Knowing the cognitive level of an individual with an ASD impacts several factors, including diagnostic clarity, treatment, and prognosis. Clinicians often have a difficult time differentiating autism core features in a child with severe intellectual disability. Because children with very low IQs will often be nonverbal and have limited social awareness, one might confuse this with autism. Therefore, clinicians must evaluate a child's social abilities in relation to their developmental age before diagnosing an ASD.

Individuals with ASDs and intellectual disability also have an increased risk of comorbid disorders such as epilepsy (Spence & Schneider, 2009), psychiatric disorders (attention-deficit/hyperactive disorder, mood disorders, catatonia) (McCarthy, 2007) and genetic syndromes (especially in dysmorphic individuals) (Battaglia & Carey, 2006; Miles & Hillman, 2000; Shevell et al., 2001). Furthermore, correct assessments of cognitive abilities are crucial for educational planning. Overall intelligence and particularly nonverbal cognitive ability tends be one of the strongest predictors of outcomes in general (Helt et al., 2008), in studies investigating pretreatment variables in predicting the success of behavioral treatments (Howlin et al., 2009), and in studies extending to adulthood (Howlin et al., 2004).

There are children on the autism spectrum with extraordinary splinter skills in areas such as math or art who may be considered savants, but these situations are rare and poorly understood.

Regression

Approximately 1/5 to 1/3 of children with ASDs will experience some type of regression of previously acquired skills. This typically occurs between 15 and 24 months of age (Turner et al., 2006; Werner & Dawson, 2005). Severe regression occurring after a 2-year period of typical development is diagnostic of Childhood Disintegrative Disorder, a rare pervasive developmental disorder (Association, 1994; Mouridsen, 2003).

Regression can be in the form of loss of verbal skills, loss of social skills (eye contact, play behaviors) or loss of gestural communication (waving bye-bye, pointing) (Lord et al., 2004; Meilleur & Fombonne, 2009; Stefanatos et al., 2002) and can occur in children with typical development or even more often, in the setting of already delayed milestones (Meilleur & Fombonne, 2009). Some studies have suggested a poorer cognitive outcome for children with ASDs and regression, with these children having more intellectual disability (Hoshino et al., 1987; Kobayashi & Murata, 1998).

The astute clinician should not automatically attribute signs of regression to psychosocial stressors (such as a family move or a new sibling), but rather further investigate the nature and severity of the regression. Epileptic disorders such as infantile spasms or Landau-Kleffner Syndrome or rare metabolic disorders need to be considered in the differential diagnosis.

Sensory-Motor Abnormalities

Although not part of the core features of autism, sensory and motor dysfunction is common in children with ASDs. Odd behaviors appear to indicate either decreased or increased interest or sensitivity to the sensory world (Rogers et al., 2003). These occur in all senses, including visual (close visual inspection, peering out of the corners of the eyes), auditory (intolerance to noises, holding hands over the ears), somatosensory (repetitive feeling of surfaces, intolerance to certain sensations) or olfactory systems (needing to sniff objects).

More interest is also being paid to subtle motor deficits in these children. There have been reports of motor delays (Mayes & Calhoun, 2003), hypotonia (Ming et al., 2007), gait and balance issues (Kielinen et al., 2004; Minshew et al., 2004), clumsiness (Ghaziuddin & Butler, 1998), and dyspraxia (Dziuk et al., 2007; Mandelbaum et al., 2006) in individuals with ASDs (*see Chapter 22*).

Behavior Problems

Many children with ASDs have challenging behaviors such as significant tantrums, aggression toward others, and self-injury, which often interfere with educational programs, community involvement, and family life. These may be more prevalent in individuals with comorbid intellectual disability (Bodfish et al., 2000; Schroeder et al., 2001).

A role for the PCP is to evaluate the child for medical reasons that may be contributing to these behaviors (Bosch et al., 1997), as a number of medical problems may negatively influence behavior. A careful history and examination is essential for their identification, especially because individuals with autism may not be able to communicate specific symptoms. The following medical issues should be considered: infections (otitis media, pharyngitis, dental abscess, UTI, URI); GI problems (constipation, reflux); sleep disturbances; undetected injuries (even fractures); hormonal fluctuations during puberty. Those medical issues that are amenable to treatment should be treated accordingly. In addition to common medical issues, medications or supplements that the child may be taking may produce behavioral side effects. Finally, possible

environmental or situational causes of the behaviors should be explored with the family. As with typically developing children, transitions, family events, certain places, and new siblings can be possible reasons for exacerbation of problem behaviors.

PCPs can also help families with behavioral intervention by requesting a functional behavioral analysis to be accomplished by a child psychologist or qualified professional in the school system. This analysis should not only assist in discovering the antecedents and triggers for the behaviors, but should also facilitate a behavioral plan to decrease and/or manage behaviors. In severe cases, physicians should consider referral to a specialist for medication management (a developmental-behavioral pediatrician, child psychiatrist, or child neurologist).

Other Psychiatric Disorders

It is important for the PCP to be aware that children with autism can and do present with comorbid psychiatric disorders. Although current DSM criteria preclude a diagnosis of Attention Deficit Hyperactivity Disorder (ADHD) in the setting of ASD, it is clear that many children on the spectrum have significant difficulty with attention and hyperactivity. Similarly, mood disorders and anxiety can be common. Given the complexities of teasing out behaviors that result from the autism vs. these other disorders, most PCPs will want to consider referral to a child psychiatrist for further evaluation and treatment. (*See Chapters 15–18, 20, 22, 69, and 76 for more detail.*)

Interventions

As soon as a child is suspected of having an ASD, early intervention services should be initiated as research suggests that intensive early intervention substantially improves outcomes (Sallows & Graupner, 2005). A panel convened by the National Research Council defined intensive early intervention as at least 25 hours per week of instruction with year-round services (Lord & McGee, 2001). Although a PCP may not be responsible for setting up therapy, understanding the options and educating families on their rights is important. A brief overview is presented below.

Navigating the Educational System

Federal regulations ensure that all children with disabilities be offered funded educational programming either through an Individualized Family Service Plan (IFSP) or an Individualized Education Plan (IEP). A state-funded IFSP will document and guide the early-intervention process for the family with a child under 3 years old with a suspected or diagnosed ASD. When the child turns 3 years old, the local school system takes over the child's educational services. IEPs outline the education services to include needed therapies (behavioral, speech,

occupational, physical) for learning purposes as well as specific short-term and long-term goals for the child with an ASD. However, these programs are not mandated to offer the 25 hours per week of instruction or year-round services, so the child's pediatrician should be aware of other community services and therapies to supplement the child's early-intervention experience. Local programs vary tremendously and many families will choose to go beyond the funded programs to obtain more intensive or different services.

Available Behavioral Interventions

Behavioral and educational therapies are the mainstay of treatments. Unfortunately, the literature regarding the efficacy of various therapies lags behind the growing number of children needing services. Although there are certainly differences between treatment programs in technique and even underlying theory (e.g., strict behaviorist vs. more developmental or naturalistic), there is some agreement on some common elements including the need for: immediate access, intensive therapy, low student–teacher ratios, parent training, exposure to typically developing peers, frequent evaluation, structure and predictability, and opportunities for generalization (Myers & Johnson, 2007). (*For more detail on these therapies, see Chapter 58–66, and 75 in this volume.*)

Applied Behavior Analysis (ABA) techniques have been the best-studied and have demonstrated efficacy for creating significant developmental and cognitive gains (Lovaas, 1987; McEachin et al., 1993; Sallows & Graupner, 2005). ABA therapy strives to increase and enhance social communication as well as teach cognitive skills and decrease problem behaviors through a variety of behavioral analytic methods to include, but not limited to: repetition, positive reinforcement, shaping, prompting, and fading.

The Treatment and Education of Autistic and Related Communication-Handicapped Children (TEACCH) program is a special education model tailored to the individual's needs, similar to ABA. The focus of TEACCH is a structured physical, social, and communicating environment, especially helpful for the visual learner (www.teacch.com). Another team-based educational model is Social Communication, Emotional Regulation and Implementing Transactional Supports (SCERTS). This model uses a variety of behavioral interventions including ABA, visual supports, and augmentative communication (www.scerts.com).

The Developmental, Individual-difference, Relationship-based (DIR) model contains "Floor-time" therapy. The Floor-time model involves the parent engaging the child at his or her current developmental level and allowing the child to lead the interaction (www.floortime.org). The Relationship Development Intervention (RDI) method is another parent-based therapy (Gutstein et al., 2007) with a goal of having the child make social improvements in everyday functioning and relationships through a variety of social activities (www.rdiconnect.com). These interventions, although popular, have not yet been empirically validated to be efficacious.

Responsive teaching (RT) (Mahoney & Perales, 2005) and Pivotal Response Training (PRT) (Koegel et al., 2001) are intervention models that encourage parents to be the primary interventionists and are applied in the child's natural environment, such as home and school.

Other approaches to augment behavioral therapies are also frequently employed. Speech and language therapy works on verbal and nonverbal skills as well as teaching other modalities of communication such as sign language or use of augmentative communication devices or systems. For children with fine motor delays, delayed self-help skills, or significant sensory issues, occupational therapy may be beneficial. Therapists often use sensory integration therapy for children with ASDs and sensory issues, although efficacy data are lacking. Another commonly used technique (especially for higher-functioning children) is social skills training, which may help with joint attention, social communication, and understanding of nonverbal cues.

The bulk of published evidence supports the efficacy of early intervention based on applied behavior analysis. Unfortunately, there is very little evidence regarding what therapeutic technique is best for a given child. This leaves many families struggling with which model to choose or being forced to go with what is available in their community.

Psychopharmacological Treatment

Although pediatricians may not be prescribing medications, they should be aware of those agents in most common usage for individuals with ASDs. Treatments are currently targeted on specific symptoms and medication choices are based on usage in other childhood psychiatric disorders. But as reviewed in this volume (*see Chapter 69 and 76*) there is limited empiric evidence for efficacy specifically in autism. At the same time, psychoactive medication usage is very common and increasing over time in this population with reported rates over 50% (Aman et al., 2003; Mandell et al., 2008; Oswald & Sonenklar, 2007).

Stimulants and alpha-adrenergic blockers target hyperactivity and attentional problems. Antidepressants (especially serotonergic) are commonly used for mood, anxiety, and the obsessive-compulsive type behaviors (restricted interests, repetitive behaviors). Various mood stabilizers (including anticonvulsants) are used for mood lability and outbursts. Antipsychotic or neuroleptic agents are most often employed for aggression and irritability. In fact, risperidone is currently the only agent with specific FDA approval for use in ASDs. Melatonin and a variety of sedative agents have been used for sleep problems.

Complementary and Alternative Medicine (CAM)

It is imperative for the pediatrician to appreciate the high rate of CAM use in individuals with ASDs. Studies estimate that up to 75 to 95% of ASD families may be using some form of CAM (Harrington et al., 2006; Levy & Hyman, 2003; Wong &

Smith, 2006). So in order to provide optimal care, physicians need to be asking families about CAM use. One role for the PCP is to encourage families to carefully evaluate the scientific evidence (or lack thereof) for these treatments and to point out those with "red flags" that would make us question their validity, such as claims of immediate benefit, cure, and total lack of side effects (Myers & Johnson, 2007). Parents also need to know that so-called "natural" treatments may produce adverse effects and affect other medications that the child is taking. Although a full review of the available CAM therapies is beyond the scope of this chapter (*see Chapter 71 for a complete review*), awareness of the most common treatments is important.

The gluten-free casein-free diet is one of the most commonly used special diets. Anecdotally parents report not only improved GI symptoms, but also improved behavior and communication skills. Unfortunately, this diet has not yet been rigorously tested for efficacy and small studies show conflicting results (Elder et al., 2006; Knivsberg et al., 1995; Knivsberg et al., 2002). Parents need to know that this diet is still unproven in children with ASDs.

Supplements are another common CAM therapy. There are a multitude of products marketed for children with autism, including vitamins, minerals, fatty acids and amino acids, and even enzyme preparations. Some are recommended in homeopathic doses, others in supratherapeutic amounts. Again, there are very few studies to support their use, but the PCP must be aware of what patients are taking and educate families on possible side effects such as those seen with high doses of certain vitamins (e.g., A, D, E, B-3, B-6, and C) (Rosenbloom, 2007).

Practitioners and families may find the National Center for Complementary and Alternative Medicine (NCCAM, www.nccam.nih.gov) to be a helpful resource for investigating various alternative therapies for ASDs.

Conclusions

Given the prevalence of autism, PCPs will inevitably be taking care of patients on the autism spectrum. Best practices would dictate that the child with an ASD is cared for in the context of a medical home where the practitioner is knowledgeable about everything from screening and diagnosis, to workup and management, to interventions and family support. This is obviously a lofty goal for many primary-care providers in the current practice setting but we hope the information provided in this chapter can get them closer to a realization of this goal.

Unfortunately, the state of the scientific literature is not at the point where truly evidence-based practice parameters can be devised for most of the problems encountered by individuals with ASDs in the primary-care setting, but we should be heartened by the fact that there are groups working on this issue. As mentioned above, the Autism Treatment Network[4] is a collection of autism centers around the country and in Canada that is dedicated to collecting the data necessary to

create practice parameters for medical workup and treatment of children with ASDs. As data are collected, practice standards and, later, true evidence-based practice parameters will be created and shared with the primary-care community. Until that time, PCPs are left with the enormous challenge of keeping up-to-date with a fast-moving and complex field.

Challenges and Future Directions

- Creation of a medical home in the primary-care setting for all individuals with autism that would greatly improve care practices for children and their families.
- Improved access to autism diagnosis and evaluation centers and subspecialty referrals for all families to reduce burden on primary-care providers.
- Improved data on prevalence of various medical and other comorbidities in ASDs that would allow for better education for families on the risks of these entities.
- Establishment of practice standards and eventually evidence-based practice parameters for management of medical issues in ASDs.

3 The real controversy came with the comment that these children had experienced a behavioral regression after their MMR vaccine, implying that the vaccination may have been causally related to autism (Kawashima et al., 2000; Wakefield et al., 1998a), a controversy that played out in the media. However, in 2004 allegations of scientific misconduct were brought to the Lancet editors (Horton, 2004) and a partial retraction was printed by 10 of 13 authors (S. H. Murch et al., 2004). Many further studies have failed to demonstrate a causal relationship between MMR and ASD (Chen, Landau, Sham, & Fombonne, 2004; Dales, Hammer, & Smith, 2001; DeStefano, Bhasin, Thompson, Yeargin-Allsopp, & Boyle, 2004; Hornig et al., 2008; Richler et al., 2006; Taylor et al., 1999). Unfortunately, because of the media frenzy, there are still concerns about the possible link between the MMR and autism in the lay community.

Bioethical Considerations in Autism Research and Translation: Present and Future

⊞

What Does Bioethics Have to Do with Autism?

Bioethics is a field of study focused on ethical controversies in science and medicine. Bioethics is often classified into clinical ethics, or ethical decision-making in a clinical setting, and research ethics, or ethical decision-making in the context of biomedical research. Both areas involve consideration of the four principles of bioethics, as described by Tom Beauchamp and James Childress in their book *Principles of Biomedical Ethics*: (1) autonomy, or respect for individual decision-making; (2) beneficence, or doing good and providing benefit; (3) nonmaleficence, or avoiding harm; and (4) justice, or treating individuals and groups equitably and fairly (Beauchamp & Childress, 2008).

Bioethics is more colloquially understood to be figuring out what is the "right thing" or "moral thing" to do in medicine and biomedical research. In this context, bioethicists are sometimes perceived to be the "ethics police" who look for wrongdoing and try to correct it, thereby slowing down the progress of science. This view of bioethics is distorted in several ways. First, most bioethicists act in advisory and commentary roles, and do not have enforcement authorities. Second, the role of bioethics is to work together with researchers, clinicians, institutions, and other stakeholders to think critically about emerging challenges in biomedicine, and to help develop tools and strategies to meet them and innovate when necessary. Bioethics as a discipline can help frame ethical challenges related to new technological advances in both research and therapeutic contexts. Bioethics can also help frame the debate when there exist conflicting societal values surrounding controversial issues in biomedicine.

One important context for bioethics is the area of research ethics, or advocating for the four principles of bioethics in the conduct of research. This means using the lens of bioethics to protect the individual rights of research participants (autonomy); balance benefit, or doing good (beneficence), with avoiding doing harm (nonmaleficence); and advocate for treating individuals and groups fairly, particularly groups whose perspectives are not always voiced or represented (justice).

In this commentary, I argue that autism, as a diagnosis and a field of study, has several features that may make it more susceptible to research ethics challenges than many other areas of study. Autism research is primarily conducted in children, adolescents, and adults who have challenges with communication and comprehension. There are many existing challenges to conducting research in children, and particularly research on new approaches with possible risks. As autism research proliferates, more individuals with autism and their typical siblings are being enrolled in studies, and therefore some of these challenges will be magnified. Additionally, the increasing prevalence of autism and the absence of firm etiological explanations of its causes, effective treatments, or preventions lead researchers and families to place extraordinarily high expectations on research as providing immediate and future benefit.

It is beyond the scope of this article to examine all of the bioethical challenges in autism, or even in autism research. Some of these challenges have been discussed elsewhere (Chen, Miller, & Rosenstein, 2003; McMahon, Batym, & Botkin, 2006). Bioethical challenges in autism would likely be framed and prioritized somewhat differently by different stakeholders and are likely to change over time. In this chapter will highlight several key and emerging challenges in research and in the shifting boundaries between research and clinical translation, which are likely to influence the practice of clinicians and researchers, as well as the experiences of families, in the near future. The first area examined is the challenge of obtaining meaningful assent for children with autism. While I examine this issue in a research context for children under the age of 18 years, many of the same issues will be applicable for adults with autism because of the communication difficulties

associated with the disorder, and will also be relevant for informed consent in a clinical context.

The second area examined is the research ethics involved with the enrollment of typically developing siblings of children with autism in research. The third area examined is the risk of therapeutic misconception in autism research. The fourth area examined is the potential for challenges associated with accelerated translation of research findings into clinical practice, using the example of array comparative genomic hybridization (array CGH) testing for autism.

Rethinking Meaningful Assent for Children with Autism

A fundamental principle of bioethics is the respect for autonomy, or the right of an individual to make decisions for oneself about medical care and about participation in research. One of the key tools for respecting autonomy in research is the process of informed consent. In research involving children, it is required that parents participate in informed consent and be told all of the possible benefits and risks to the child of participating in the research, ranging from possible physical harms to psychological harms. In addition, federal regulations from the Office for Human Research Protections (OHRP) require that researchers make every attempt to obtain assent from children. Assent is defined as "a child's affirmative agreement to participate in research" (US Code of Federal Regulations TITLE 45—Public Welfare, Department of Health and Human Services Part 46, Protection of Human Subjects, 46.402).

The concept of autonomy is challenging in autism because of the features of the condition. Children and adults with autism often have significant communication challenges both in terms of what they can communicate and what they can understand. Yet, a fundamental principle of autonomy is the right to know what is involved in a research protocol or clinical procedure, and being able to decide whether to participate.

Given the communication and comprehension challenges in autism, how should we assess what children with autism can understand or decide? Federal regulations suggest that IRBs and researchers should take into consideration the decision-making capacity of the target research population of children, including factors such as age, maturity, and psychological state. According to the regulations, the assessment of capacity for decision-making can be made for all the children to be enrolled in a particular study, or for each individual child. The guidelines recognize that not all children can be involved in the assent process. They state that the IRB may determine that assent is not a necessary condition for proceeding with research if "the capability of some or all of the children is so limited that they cannot be reasonably consulted" (US Code of Federal Regulations TITLE 45—Public Welfare, Department of Health and Human Services Part 46, Protection of Human Subjects, 46.408(a)).

Can children with autism, perhaps even severely affected children, be reasonably consulted about research participation? How can or should we assess their capacity for assent? There are no published accounts of assessment protocols, and anecdotal accounts of current practices seem to vary. When data already exist about the anticipated cognitive abilities of the children to be recruited (e.g., mental age levels), sometimes a rule, such as a mental age cutoff, can be used to determine which children can or cannot assent. However, it is likely that mental age measures, which are derived from IQ tests, will not be available for many children, and may not always accurately reflect the ability to understand simple explanations of procedures.

Alternatively, a verbal approach is sometimes used, where a consent form is explained in its most basic outline verbally to a child with autism. Pictures and photographs that explain the study can also be used. However, given the communication and attention challenges of some autistic children, this may not be the most effective method of delivering information. Still another approach that may be applied is to not require assent from children with autism, due to their limited capabilities. This solution, however, seems imperfect and not in keeping with the ethical principle of respect for autonomy behind the requirement for pediatric assent.

While some children with autism may not be able to understand the details of the goals of the research or the consent form, respecting the autonomy of children with autism requires that at least an effort be made to explain what the child will be required to do, and the possible risks and benefits of those procedures. The same commitment to autonomy requires that some effort be made to use data about best practices for communicating with children across the autism spectrum in order to develop, validate, and disseminate tools and protocols for assent that are more likely to be successful with this research population.

Increasing numbers of children with autism are being recruited to participate in research studies, often through a person or institution with whom they also have a clinical relationship. It is possible that the current and future scope of autism research will involve more children with communicative and intellectual disabilities than any other kind of disease research to date. True respect for autonomy in autism research requires new and creative approaches to assent for children and adolescents with autism.

There are some data from other studies suggesting that investment in this kind work might be successful. First, we need to develop autism-specific tools for measuring decisional capacity. Several papers have described such tools for clinical research in individuals with impairments such as schizophrenia (Jeste et al., 2007; Dunn et al., 2007; Andre-Barron, Strydom, & Hassiotis, A, 2008). There are also data indicating that the capacity to consent to research may vary across patients with different neuropsychiatric disorders, suggesting that some disease- and impairment-specific tools may need to be developed, as well as tools that may address different impairments on the autism spectrum (Palmer et al., 2005).

Second, there is also a need to develop tools for communicating with children and adolescents with autism about what is involved in research as part of the assent process. A recent study demonstrated that use of multimedia consent tools improved the capacity to consent among adult patients with schizophrenia (Jeste et al., 2009). This suggests that the development of autism-specific multimedia consent tools might also improve assent among pediatric autism research participants.

Autism researchers, policymakers, and families have the opportunity to help biomedical research more broadly by developing and incorporating new tools for respecting autonomy of people with disabilities and challenges like those seen in autism. The fact that communication and understanding are challenging for many children and adults with autism, and may be impossible for some, should not be seen as implying that meaningful assent in children, or consent in adults, is not possible or not worthwhile for all individuals with autism. New assessment tools will need to incorporate evolving strategies from research and from educational strategies about communicating with children with autism, ranging from graphics and pictures to the use of adaptive technologies. Such an effort would require commitment and funding from government and from advocacy organizations. It would also require creative and dedicated researchers who are willing to take the time and energy to implement and disseminate the tools developed, and families who are willing to participate in research to validate and test the tools.

What About the Siblings? Research Ethics Involving Siblings of Children with Autism

Another significant ethical challenge in autism relates to the involvement of typically developing siblings in many autism research projects. Many autism studies specifically recruit siblings for research. These range from family-based genetic studies to studies of infant siblings that are designed to assess early signs and developmental trajectories of young siblings who are at increased risk for autism due to genetic liability (Rogers, 2009). Siblings may be asked to participate in research in a variety of ways, ranging from providing a DNA sample, to more complex psychological, developmental, and medical assessments. The time commitment for involvement may range from a single visit to visits spanning much of their childhood.

Dr. Douglas Diekema has written an excellent article about the specific federal requirements regarding the level of risk allowed in research in children. In this article, he describes how federal regulations require that research in children "can only be justified if the level of risk entailed in the research is very low, or if there is the potential for direct benefit to the child by participating in the research project" (Diekema, 2006, p. S7). Research that does not fit these criteria can be approved for patients who have a specific condition or disorder "if the

research is likely to yield generalizable knowledge about the subject's disorder or condition… *and* the risk of research represents no more than a minor increase over minimal risk" for that group of patients (Diekema, 2006, S7).

Given this framework, it is unclear how to evaluate the risk to siblings of children with autism who are recruited to participate in studies. Unaffected siblings of children with autism are not in the same category of receiving direct benefit or benefiting *themselves* from generalizable knowledge coming from the study, although their siblings and family members may receive such benefits. It can be argued that siblings may receive some indirect benefits, including access to early screening for ASD-related phenotypes. They also may, in the present or in the future, experience positive feelings from participating in research on a disease that affects their sibling or their whole family. However, these benefits are likely smaller, less direct, and possibly more variable, than those for children with autism who are enrolled in research.

Another important ethical question is whether siblings of children with autism are exposed to risks, and possibly unique risks, when they are recruited to participate in research studies. On the one hand, giving a blood sample or having one's parents fill out a questionnaire reasonably might be described as posing minimal risk. On the other hand, having one's DNA sequence shared in a publically available database, or having one's behavioral assessment disclosed to others might be characterized as a greater than minimal risk.

Studies on siblings suggest that there may be other more complicated risks that are specific to unaffected family members of children with autism who participate in research (Dawson et al., 2002; Dawson et al, 2007; Toth, Dawson, Meltzoff, Greenson, & Fein, 2008). A Pubmed search using the terms "autism" and "siblings" revealed three articles examining nonautism phenotypes in siblings, including complex immune dysfunction (Sarasella et al., 2009), dysfunctions in the prefrontal cortex (Kawakubo et al., 2009), and emotional problems (Petalas, Hastings, Nash, Lloyd, & Downey, 2009). In each of these articles, results were described as evidence of autism endophenotypes, or genetic components of traits related to autism. An additional article examined the phenotypic features of siblings of individuals with autism with the rare CNV on chromosome 16p11.2, which were described as ranging from "apparently healthy" to "meeting criteria for ASD" (Fernandez et al., 2009). This kind of article represents a new kind of "genotype-driven" research, where previously undiagnosed family members who share genetic variants are examined more closely to see if they have any features that might be related to autism.

This sampling of recent articles represents a trend in autism research toward examining the phenotypic traits of unaffected siblings as a primary outcome in a way that may not be described in the original informed consent documents and process. There may be a risk to siblings of being identified as having traits both related and unrelated to autism when they and their parents were not aware that this activity was part of the scope of research. These risks may be psychosocial, for

example, being categorized by the researchers as having "emotional problems" or impaired cognition. They may experience stigma by having the research be interpreted broadly by society to mean that siblings of children with autism have emotional problems or brain dysfunctions, or perhaps undiagnosed autism. Alternatively, they may experience risks related to confidentiality. Siblings may not wish information about whether they carry a rare CNV to be published and possibly linked to them through the publication of detailed information about their family.

These concerns may not be unique to autism research, but they are becoming increasingly prevalent in autism studies. There are certainly compelling scientific reasons to study the siblings of children with autism. I would argue, however, that researchers, funding agencies, and IRBs need to carefully weigh the risks and benefits of this kind of research, not just to children and families with autism, but also to healthy siblings. Researchers need to tailor consent forms and perhaps pursue reconsent as the research objectives change to specifically address the unique risks to "healthy" siblings. It also seems critical to reconsent healthy siblings when they reach 18 and allow them the possibility to withdraw from the research. This may be particularly important for genetic research using samples in biobanks or repositories collected from children (Burke & Diekema, 2006), as a recent study suggests that 46% of participants would want to be recontacted as adults for consent for continued research use of samples collected when they were children (Goldenberg, Hull, Botkin, & Wilfond, 2009). As genetic research evolves, it may be more likely that siblings of children with autism are recruited for additional research specifically because of their genotypic information (McGuire & McGuire, 2009). This kind of genotype-driven recruitment may increase potential burden, both practical and psychological, on siblings, in a way that was not anticipated at the time of initial study recruitment and enrollment.

There is also evidence that siblings of children who participate themselves in genetic research may experience risks of psychosocial harms from participating in some kinds of research. In one study, siblings of children with ataxia telangiectasia (A-T) who were enrolled in genetic linkage studies before the age of 18 were interviewed retrospectively about their feelings about the research. The siblings described fear of the procedure involved in the blood draw, apprehension around reporting of carrier results, and confusion about the possibility of having A-T. The visit with the researcher represented "a highly charged event in the lives of these individuals" that increased anxiety, but also offered an opportunity to relay concerns or discuss information (Fanos, 1999, 276). While A-T is a very different disease in presentation and inheritance patterns than autism, this study suggests that siblings of children with autism who are asked to enroll in research may also feel anxiety and confusion, and that the psychosocial impact of their participation may be long-lasting.

There are also emerging data about how parents and children decide to participate in research that may impact assent in autism research. A recent study by Varma, Jenkins, and Wendler surveyed 117 parent-child pairs where the child was enrolled in clinical research or receiving clinical care for asthma or cancer. Among the respondents, 90.5% of pediatric patients believed they should be involved in making research enrollment decisions. Only 61.5% of the parents believed that children should be involved in making research enrollment decisions. The authors suggest that these findings highlight how parents and children can disagree about research participation, and suggest that researchers need to be aware of and address these possible disagreements when they enroll and obtain assent (Varma, Jenkins, & Wendler, 2008).

More research is needed about the experience of siblings in autism research, both at the time of the research and after they have reached adulthood, to characterize the possible risks involved. Researchers, bioethicists, and IRBs may need to develop tools to minimize these kinds of harms to siblings if they exist. In the meantime, researchers and funding agencies should consider the possible risks to unaffected siblings enrolled in research. Increasingly, academic medical centers are establishing research ethics consult services to support researchers in addressing ethical challenges such as these as they arise in the course of research planning and implementation (Cho et al., 2008; Pilcher, 2006).

How Can This Research Study Help My Child? Risk of Therapeutic Misconception in Autism Research

A third significant ethical challenge in autism research is the potential for therapeutic misconception, fundamental confusion among researchers and/or research participants between the goals of research, or generalizable knowledge, and the goals of clinical care, or improving the health of an individual person (Cho & Magnus, 2007; Applebaum, Roth, & Lidz, 1982). Essentially, research participants believe that the goal of research is to provide clinical care that will benefit them personally, rather than to produce generalizable knowledge that may help them and others. While therapeutic misconception is a challenge in many diseases and areas of research, I argue that families with autism may be more likely to have therapeutic misconception about research than families with other diseases.

The potential for therapeutic misconception in autism needs to be framed in the current context of the treatment and diagnosis of autism. A great deal of autism research is conducted at academic medical centers with "autism centers" or autism researchers who are considered experts in their field. Very often, these researchers are also clinicians and wear both "hats," with a range of overlapping clinical and research responsibilities and relationships. Frequently, parents bring their children to these centers to obtain access to expertise, advice, and treatment from experts that will help their child.

This occurs against a backdrop of a medical system that provides very little in the way of treatment for families with autism. Parents are often desperate to find medical guidance that they cannot find through their regular pediatrician or through any services that they get from government and school agencies. They may also find it challenging to get the services that they believe their child may need, like applied behavior analysis (ABA) interventions, because their medical insurance will not pay for it and their school district will not provide it.

Parents may be invited to have their children participate in research studies about autism, as patients at autism academic medical centers. These studies may be peripheral to their care. However, they may actually provide certain services or evaluations for free as part of the research, or on a faster timeline than might be available by remaining on a clinic waitlist. These kinds of services may range from diagnostic reports that can be shared with schools in order to access services, to access to experimental pharmaceutical therapies that might not be available elsewhere, to the provision of free behavioral interventions. In some situations, families may actually first come to the autism academic medical centers not as patients but as willing research participants, specifically in order to get access to these kinds of services and expertise which they cannot get access to elsewhere or as quickly.

This may not seem to be a serious problem. In fact, giving back information and expertise to research participants is an important aspect of respect for research participants and upholding the value of reciprocity. It also may be ethically incumbent on researchers to return research results that may have clinical utility outside the research context.

The challenge lies in the potential for therapeutic misconception: families may misunderstand the procedures, risks, and benefits of research, and may choose to participate based on this misunderstanding, believing that research fulfills the same goals as medical care. In autism, families may be more likely agree to participate in research specifically because they believe it will provide a direct clinical benefit to their child. When the standard recommendation for intervention is not available to them, they may be more likely to seek research studies as a means to obtain clinical interventions for their child. This may increase the likelihood of confusion about the goals of the research and the role of the clinician researcher.

Therapeutic misconception may influence how parents perceive the balance of risks and benefits in a particular research study. For example, if they will receive a diagnostic report from an autism "expert" at an academic medical center for free in exchange for their participation, they may be more willing to allow their child with autism, or their unaffected children, to participate in research protocols that they might not otherwise have considered beneficial, or that they might even consider potentially harmful. There are some data supporting this hypothesis specifically in autism. One recent study by Vitiello and colleagues assessed the understanding of parents whose children were enrolled in a randomized placebo controlled trial for risperidone. While parents showed accurate understandings of the main research components of the study, approximately one fourth seemed unaware that treatment was randomly assigned and not personalized, suggesting that parents believe that even in a research context, one of the goals is to optimize the treatment of their child, rather than to produce generalizable knowledge (Vitiello et al., 2003).

We need more empirical research about whether parents of children with autism who enroll in research experience therapeutic misconception, how, and what to do about it. One recent study used a qualitative interview guide to measure therapeutic misconception in research by focusing on research participants' understandings of the purpose of research in juxtaposition to their motivation for participating (Kim et al., 2009). This approach may be particularly useful in the context of autism. In the meantime, researchers and IRBs need to be very cautious about the significant potential for therapeutic misconception in autism research, specifically when individuals act both as researchers and as clinicians. This may require more careful consideration of recruitment strategies, informed consent processes, and clear delineation of clinical and research roles and decisions by providers.

Research Payoffs? Accelerated Translation of Research Results into Clinical Practice

The goal of autism research is to develop generalizable knowledge that can be then applied to screening, treatment, or prevention protocols and benefit the lives of individuals with autism. The pace of research often seems very slow, and it can take many years, even decades, for findings to be translated into the clinical setting. This is frustrating to researchers and clinicians, but is especially frustrating to families.

In the last few years, there have been efforts across biomedical research to more rapidly translate research findings into effective clinical therapies. Autism has been no exception to this trend. Rapid translation has the potential for great benefits. However, the rush to accelerate translation also has potential risks and harms that merit caution.

One recent example of accelerated translation is the adoption of array CGH testing for copy number variants as part of the evaluation for autism. In array CGH, the DNA from a patient sample and a normal reference sample are each labeled with different fluorescent dyes. The two samples are then hybridized to a glass slide containing several thousand probes that include most of the coding and noncoding regions of the genome. The ratio of the fluorescence intensity of the patient sample to that of the reference samples is measured and calculated for each probe to measure the number of copies present in that part of the genome. This method allows for smaller sizes of DNA sequences and structural variants to be detected than using older techniques, and therefore is much higher resolution and able to detect many more duplications and deletions.

Despite over two decades of genetic research in autism, very few genetic factors have been identified that are significantly associated with autism. This has been a great source of frustration to researchers, clinicians, and families. In 2007, using array CGH, CNVs were identified as structural variants in the genome that existed commonly among individuals, but varied in their location, size, and the genes involved. Researchers quickly developed projects to examine the possible role of CNVs in autism, by applying array CGH and analyzing genotyping results from existing studies.

Articles were published in 2007 and 2008 by several groups using different samples and techniques. Cook and Scherer described these CNV findings in their review in *Nature* in October 2008. Generally, the studies found that CNVs were rare, but that there were more CNVs in autism cases than in controls. They found that up to 40% of family-specific CNVs were found to be inherited from a parent without autism spectrum disorder. They also found that in several cases, unrelated individuals carried de novo or inherited CNVs at the same locus (Cook & Scherer, 2008).

One of the affected loci identified was a microdeletion or microduplication at chromosome 16p11.2. A CNV at this location was replicated across 3 studies. In these studies, a CNV was found in 1% of autism cases. Individuals with the CNV at 16p11.2 also had facial dysmorphology. The CNV at 16p11.2 was also found in non-ASD cases with developmental delay or mental retardation and in some controls (Cook & Scherer, 2008). The deletion was also found in individuals with language or psychiatric disorders, although at lower frequency (0.1%), as well as in the general population (0.01%) (Weiss et al., 2008). An additional recent study found a deletion in 16p11.2 in seven individuals with intellectual disability (Mefford et al., 2009). Other studies have found that the deletion is not specific to autism but is also enriched in patients with mental retardation, developmental delay, or schizophrenia without autistic features (Mefford et al., 2009; Itsara et al., 2009; Biljsma et al., 2009). These papers suggest substantial phenotypic heterogeneity and diversity among individuals with CNVs at 16p11.2.

One of the key steps in the translational pathway for genomics is careful consideration of each potential clinical application of scientific findings. In translating genetic research findings into the clinical setting, stakeholders, including researchers, clinicians, companies, families, and policymakers, must decide whether or not there is sufficient evidence to justify the broad application of a genetic test. From an ethics perspective, this requires weighing the possible risks and benefits to families from using the test. Translation requires consideration of who should get the test and when, who should give the test, and perhaps most importantly, how positive and negative results should be interpreted.

The story of the translation of testing of CNVs for autism in the last two years is a story of a kind of "accelerated translation" that is becoming more common in genetics and genomics, but that may also be becoming more prevalent in autism. Specifically, new genomic technologies, like array CGH, are being translated into broad clinical practice on a much more accelerated timeline than research results, or genetic results, have been in the past. Translation seems to be accelerated in situations like autism when there is a large possible target population for the test. Less than a year after the published findings on CNVs and autism, several companies came out with specific array CGH testing for autism. For example, Baylor College of Medicine advertised their "Genetic Testing for Autism" in the abstract book for the 2008 meeting of the American Society of Human Genetics, with the statement that "Through [*sic*] genetic evaluation of patients with Autism Spectrum Disorders (ASD) is critical for appropriate medical management and family counseling" (Baylor College of Medicine).

The advertisement referred to the 2008 Practice Guidelines from the American College of Medical Genetics (ACMG) on "Clinical genetics evaluation in identifying the etiology of autism spectrum disorders." The guidelines state that, "Defining the etiology of an ASD can be of great benefit to the parent and family. Information gained from an identified etiology can help with family counseling, medical management, preventive health strategies, and empowerment of the family" (Schaefer, Mendelsohn, & the ACMG Professional Practice and Guidelines Committee, 2008). The guidelines state that, "A genetic consultation should be offered to all persons and families with ASDs. Evaluations should be considered for any individual along the full autism spectrum" (304).

This is a dramatic recommendation. While autism has long been thought to have a substantial genetic component, genetic evaluation had been previously limited to ruling out known syndromes with autistic-like features, such as Fragile X, and was not considered part of standard practice (Abdul-Rahman & Hudgins, 2006). In this Practice Guideline, the ACMG suggests that array CGH testing will provide significant benefits to enough families that it is worthwhile to recommend it as part of standard practice.

It is unclear, however, whether the promise of these benefits is supported by the existing research evidence (Tabor & Cho, 2007). Given the very small proportion of autism that may be explained by CNVs, it is important to examine the claims of the ACMG Practice Guidelines and advertisements for testing services like the one from Baylor. The guidelines suggest that family counseling around CNVs is important, yet, given the phenotypic heterogeneity of autism, as well as the incomplete penetrance and heterogeneity of cases with specific CNVs, it is unclear what kind of counseling can really be given to families about how specific CNVs will manifest in phenotypic traits or what the recurrence risks are for future siblings. It is also unclear, at least until there is further research, how knowledge of the presence of a CNV in a child would affect medical management or preventive health strategies, such as targeting of early interventions. Finally, the ACMG guidelines suggest that this kind of genetic testing can provide "empowerment of the family" (Schaefer, Mendelsohn, & the ACMG Professional Practice and Guidelines Committee, 2008, 164). However, it is unclear what kind of empowerment

they refer to, and toward what end. Furthermore, if the information linking CNVs to autism is determined in the future to be incorrect or incomplete, it is unclear what potential harms might occur.

It is possible that future research will provide enough evidence to support integration of CNV testing into evaluation of all cases of autism. However, I would argue that the ACMG Practice Guidelines and their adoption may be premature in their optimism and enthusiasm. In an effort to translate the possible benefits of testing as quickly as possible, there may in fact be some unanticipated harms created. Genetic testing is very expensive, and may not be covered by insurance in all situations or even available for some families. By recommending testing for all families, clinicians, researchers, and organizations might be placing a significant financial burden on some of those families. Given the limited state of research data, it is not clear how families should be counseled about either positive or negative results. There is a chance that parents might interpret positive results to mean that they should not have more children, when the pattern of inheritance and penetrance of CNVs for autism is very ambiguous. If they receive negative results, families may decide that they do not have a genetic predisposition to autism, which may also be inaccurate.

What can the example of CNV testing for autism tell us about translation of autism research more generally? Certainly every effort should continue to be made to rapidly translate research findings to achieve the maximum benefit for patients and families. Yet, even as these efforts proceed, it is important to be cautious about the potential risks of accelerated translation, and not assume that rapid widespread translation of tests, services, and information is always an unmitigated good. It is critical for stakeholders, ranging from researchers, to clinicians, institutions, and professional organizations, to carefully consider the possible harms created by accelerated or premature translation. These harms, if anticipated, can be planned for and minimized, and procedures can be developed to monitor the translation process, its successes and challenges or failures, and modify practices and guidelines as needed.

Conclusion

In conclusion, there are specific features of autism and autism research that may make it more susceptible to certain research ethics challenges. The current expansion of autism research presents an opportunity for the field to take initiative and leadership in meeting these challenges and developing standard tools and practices to improve the respect for autonomy of children with autism and their typically developing siblings who participate in research. It also presents an opportunity for the community of stakeholders to evaluate the promises of research, and make sure that safeguards are in place to minimize therapeutic misconception, while still enhancing access to care and research participation. Finally, as autism research

identifies potential leads in understanding etiology, all stakeholders must temper their exuberance and eagerness to facilitate rapid translation by developing processes to ensure a thoughtful and deliberative process that will provide maximum benefit while minimizing potential harms of this translation.

78 · The Economic Costs of Autism: A Review

Djesika Amendah, Scott D. Grosse, Georgina Peacock, David S. Mandell

Points of Interest

- This chapter takes a lifespan approach and construes costs broadly to incorporate those of individuals with ASDs and their families. We consider cost in four domains: medical, nonmedical, productivity, and caregiver time.
- Estimates of incremental mean medical expenditures range from $2,100 to $11,200 per person per year.
- Annual estimates of nonmedical costs include $40,000 to $60,000 for intensive behavioral interventions for children prior to school age, $13,000 for special education services from ages 6 to 21 years, and $60,000 to $128,000 for residential services, although the proportion of persons using this last service is unknown.
- Estimates of the loss of productivity among adults with ASDs are less robust, and rely on convenience samples. Among adults with high-functioning autism, at least half are employed, but little is known about their skills level and earnings. The real productivity losses of adults with ASDs are unknown.
- The only recent U.S. population-based estimate suggests an annual loss of parental productivity of $6,000 per child, or $7,400 from the societal perspective.
- Most cost data on children and adults with ASDs is decades old. A full, contemporary understanding of the economic costs of autism and the cost-effectiveness of interventions is missing.

In the United States, the estimated prevalence of autism spectrum disorders in 2006 ranged from 4.2 to 12.1 per 1000, with an average prevalence of 9.0 per 1,000 (95% confidence interval 8.6–9.3) (ADDM 2009). This high prevalence provides a sense of urgency regarding the cost of care for persons with ASDs. There is much debate as to how public and private systems will bear the costs associated with the intensive interventions recommended for children with ASDs and the long-term supports needed by many adults with ASDs. Accurate assessment of the cost of care for individuals with ASDs allows for appropriate system planning and provides a baseline against which to measure the effectiveness of interventions designed to improve outcomes and community integration.

Most U.S.-based studies of ASD-related costs estimate medical expenditures, which represent only a small percentage of total costs, between 3% and 5% of the total (Ganz, 2007; Järbrink et al., 2003; Järbrink, 2007). Few studies have evaluated nonmedical costs, including productivity costs incurred by persons with ASDs or their parents. Most estimates of nonmedical costs have relied on data from European countries, which are not necessarily representative of the United States. Published estimates of total lifetime costs for a child with an ASD, including an often-cited estimate of $3.2 million (Ganz, 2007) rely on speculative assumptions. In this chapter, we critically assess these assumptions in the light of available data. We review both the peer-reviewed literature and additional sources for information on the costs of care for individuals with ASDs, with a focus on the United States. We take a lifespan approach, and construe costs broadly to incorporate those of individuals with ASDs and their families. We also make recommendations regarding the next steps in assessing costs of care for individuals with these complex lifelong disorders.

Methods

We conducted a literature search though the following databases: PubMed, EconLit, ERIC, and Google™. We used the keyword *autism*, paired with the following keywords: *cost, service utilization,* and *employment*. We also examined references of articles identified using these searches to identify additional documents addressing autism costs. Although we did not limit the search by language or date of publication,

we did not identify relevant publications in languages other than English.

We identified seven studies that estimate per capita medical costs or expenditures for individuals with ASDs in the United States (Table 78-1). For nonmedical expenditures, we included studies regardless of country of origin, owing to a scarcity of U.S.-based studies. We included studies that compared health care or educational service utilization between persons with and without ASDs (Tables 78-2–78-3). We also included studies with data on behavioral therapies, residential care, supported employment, and employment of individuals with ASDs or their caregivers, few of which reported expenditures or costs (Tables 78-4–78-9). Finally, we included studies on total annual and lifetime costs (Tables 78-10–78-11). Documents included in this review represent 40 studies.

In this review, we focused on the incremental cost of ASDs, defined as the difference between average (mean) costs incurred by persons with ASDs and the mean costs incurred by persons of the same age without ASDs. In other words, all cost estimates in this chapter are expressed as the net cost per person with ASD. When we refer to the "total" cost of ASD we refer to the sum of all types of cost, expressed on a per capita basis. The aggregate cost of ASD in a population can be calculated as the per capita cost multiplied by the number of people with an ASD.

We consider four cost components: medical, nonmedical, productivity, and caregiver time costs. Medical costs refer to the value of medical care provided by physicians, physician extenders (physician assistants, nurse practitioners), nurses, pharmacists, allied health professionals, and staff working under their supervision, as well as prescription medications and laboratory tests. We exclude studies of complementary or alternative medicines. Nonmedical expenditures include educational and early-intervention services, behavioral, occupational, and speech and language therapies, residential care and other items such as home modifications, travel to medical appointments, or supported employment.[1] Note that many therapies can be offered through either the educational or health-care systems. The distinction between medical and nonmedical costs largely reflects how services are typically paid for in the United States.

Studies of medical costs typically report expenditures, the amounts for which providers are reimbursed for a service. In the United States, reimbursements are negotiated between the payer, which usually is an insurance company, and the provider, and they vary in the extent to which they take into account all of the costs associated with providing a service or good. Few studies (e.g., Croen et al., 2006) have analyzed medical costs from the provider perspective, which is the value of resources (e.g., labor, supplies, facility costs) used to produce a service.

Productivity costs represent the lost value of gross earnings of an affected individual resulting from unemployment or underemployment. These might be caused by the inability of persons with ASDs to acquire skills needed for a higher-paying job or to work full-time and in a typical environment when they have those skills. The productivity losses include also the value of fringe benefits and taxes. Caregiver time costs typically refer to the income lost by parents and other familial caregivers because of competing caregiving demands.

In this review, all monetary estimates were converted to 2003 U.S. dollars,[2] adjusting for differences in currencies and inflation. Estimates in other currencies were first converted to U.S. dollars using Purchasing Power Parity values for the year in which the study reported monetary estimates. These values are calculated as the relative prices of a bundle of goods and services purchased in different countries in a given year[3] and are more stable than foreign exchange rates. U.S. dollar estimates for medical expenditures from different years were adjusted to 2003 values using the Medical Care Consumer Price Index. The Employment Cost Index of total compensation for state and local government workers[4] was used to adjust other nonmedical costs. All expenditure figures in the text were rounded to the nearest $100.

Results

Medical Expenditures

Five recent U.S. studies used either insurance claims or administrative data to calculate either medical expenditures or costs for persons with ASDs age 21 years or less. Two of these studies used the International Classification of Diseases, Clinical Modification (ICD-9-CM) codes 299.0 and 299.8 to characterize ASDs (Croen et al., 2006; Shimabukuro et al., 2008). Three others used all 299 three-digit codes, which encompass small numbers of children with disintegrative disorders and psychoses (Flanders et al., 2006, 2007; Leslie & Martin, 2007; Mandell et al., 2006). These latter three studies calculated mean expenditures for children with ASDs but only Mandell et al. reported expenditures for children without ASDs. The latter is required to calculate the incremental expenditures for children with ASDs relative to typically developing children.

Shimabukuro et al. (2008) used the MarketScan® Commercial Claims and Encounters database on Americans with private employer-sponsored insurance for the year 2003. They calculated incremental mean and median expenditures associated with ASDs in individuals 1 to 21 years of age of $4,700 and $2,600, respectively. The composition of expenditures in those data varied by age, with prescription medications comprising a larger proportion for adolescents and young adults (Oswald & Sonenklar, 2007). Croen et al. (2006) analyzed administrative data from one California health-management organization from July 2003 to June 2004. They calculated incremental mean and median expenditures per person with an ASD to the organization of $1,800 and $700, respectively. Mandell et al. (2006) used Medicaid claims to compute ASD expenditures in a metropolitan county in Pennsylvania for the years 1994 through 1999. The incremental mean expenditure was $10,500 per person with an ASD.

Other studies used information from household surveys to calculate medical expenditures. Liptak et al. (2006) examined parent-reported expenditures and health-care utilization from the Medical Expenditure Panel Survey for the years 1997 to 2000. The authors calculated the incremental mean and median expenditures per child with an ASD to be $2,100 and $1,400, respectively. In 1985 to 1986, Birenbaum et al. (1990) conducted the only U.S. national survey of individuals with ASDs or intellectual disabilities under the age of 25 years. Their sample relied on the national census of children receiving

Table 78–1.

Summary of studies on annual total medical expenditures for children with ASDs in the United States

Authors, Year, Data Source	Sample Composition		Included Expenditures	Annual Expenditures in 2003 (U.S. $ per Child)
	ASD	Comparison group		
Shimabukuro et al. (2008). MarketScan claim data, multistates, ICD-9 code 299.0 and 299.8.	Age 1 to 21 years in 2003; ASD size = 3,481.	Similar children without ASD, size = 1,199,380.	Sum (inpatient, outpatient, and pharmacy).	ASD: Mean $5,930, Median $2,870; Comparison: Mean $1,230, Median $320; Incremental: Mean $4,700, Median $2,550.
Croen et al. (2006). Private insurance capitated claim data in California, ICD-9 code 299.0 and 299.8.	Age 2 to 18 years between July 2003 and June 2004; ASD size = 3,053.	Similar children without ASD, size = 30,529.	Sum (hospital laboratory, radiology, outpatient home health utilization).	ASD: Mean $2,715, Median $1,058; Comparison: Mean $896, Median $335; Incremental: Mean $1,819, Median $723.
Mandell et al. (2006). Public insurance Medicaid claim data in metro county in Pennsylvania, ICD-9 code 299.	Age 0 to 21 years; 1994 to 1999 ASD size = 334.	Similar children without ASD and without Intellectual Disability, frequency = 183,488.	Sum (ambulatory care, emergency care, hospitalization, psychiatric hospitalization and psychiatric outpatient care).	ASD: Mean $11,832; Comparison: Mean $1,306; Incremental: Mean $10,525.
Liptak et al. (2006) Medical Expenditure Panel Survey (MEPS) parental reports.	MEPS 1997 to 2000, age ≤19 years with ASD size = 31; weighted size = 340,158.	Similar children without ASD, depression, and without mental retardation. size = 14,413, weighted = 152,293,614.	Sum (inpatient, outpatient, emergency room, physician, nonphysician, home health care, pharmacy, other).	ASD: Mean $2,423, Median $1,463; Comparison: Mean $340, Median $86; Incremental: Mean $2,083, Median $1,377.
Birenbaum et al. (1990). Nationally representative survey based on school and special education districts and 1980 censuses.	Survey period June 1985 to June 1986. Sample under age 18 years, size = 235; age 18 to 24 years, size = 58.	National Medical Care Utilization and Expenditures Survey [NMCUES] 1980. Age 0 to 16 years and 17 to 44 years. Excludes individuals with disabilities.	Annual health-care expenditures.	Under 18 years of age. ASD:Mean $2,435, Median< $1,218; Comparison: Mean $974; Incremental: Mean $1,461.
Flanders et al. (2006). 20% of 2.08 million on Medicaid California, PDD:ICD-9 299 and 330.8.	Age 3 to 17 years at the time of diagnosis. Period: from January 1, 1996 to June 30, 2002 (365 days after diagnosis); Size = 731 children with Pervasive Development Disorders (PDDs).	Similar children without Pervasive Development Disorders; size=731 with asthma and 731 with diabetes.	Sum (inpatient, outpatient, prescription); Special costs = sum (emergency department, home visit, outpatient, laboratory, speech therapy, radiology, surgery).	In the first 12 months after diagnosis; PDD: Mean $6,235, Median $1,177.
Leslie et al. (2006). MarketScan, Privately insured in U.S, ICD-9 code 299	Year: 2003 Age ≤ 17 years, ASD size = 2,411.	Persons with other mental health disorders.	Sum (inpatient, outpatient, and prescription).	ASD: Mean $6,073, Median $3,416.

ICD-9: International classification of diseases 9th edition.

special education, including those in private schools. The estimated prevalence of ASD at the time was 5 per 10,000 children. The comparison group consisted of individuals in the 1987 Medical Care Utilization and Expenditures Survey. They estimated incremental mean costs of $1,500 for children under the age 18 years and $1,700 for persons ages 19 to 24 years.

Summary. The incremental mean medical expenditures estimated in the five recent U.S. studies range from $2,100 to $11,200 per person per year. Differences in health-care expenditures across studies can result from a variety of factors. These include differences in who makes diagnoses or how they are reported, for example, medical vs. educational records, and administrative records vs. parental survey. Differences can also be associated with the type of insurance plan and methodological differences. Population-based surveys are likely to report lower average expenditures of ASD per person than health insurance administrative data for at least two reasons. First, children with medical diagnoses are likely to incur higher medical expenditures than children who were identified outside the medical system and did not have an ASD diagnosis confirmed by a physician. Second, surveys rely on parental reports, which are subject to inaccurate recall of expenditures. Järbrink et al. (2003) found that when parents were asked to recall expenditures, they underestimated them by 34% compared to diaries kept by parents in which costs were recorded as they occurred.

The type of insurance plan affects estimates of expenditures or costs. Children enrolled in a staff model managed-care organization incurred lower average costs (Croen et al., 2006) than privately-insured children enrolled in fee-for-service plans (Shimabukuro et al., 2008). In general, public insurance

programs reimburse at a lower rate than private insurance programs (Reinhardt, 2006). Moreover, covered services can differ between various payers. A few state Medicaid programs, including Pennsylvania, reimburse for behavioral therapy delivered in schools, and this might account for the particularly high expenditures reported by Mandell et al. (2006).

Another methodological issue relates to the composition of the comparison group involved in the calculation of incremental costs. For instance, Shimabukuro et al. (2008) and Croen et al. (2006) consider all children without ASDs as the comparison group while Liptak et al. (2006) and Mandell et al. (2006) used children without ASDs and without intellectual disabilities as the comparison group. Excluding other costly conditions from the comparison group could increase the incremental costs of ASDs.

Utilization of Health-Care Services

Not all studies have collected data on medical costs associated with ASDs; some surveys of parents only collected information about service utilization (Ganz, 2006; Gurney et al., 2006). Estimates of ratios of health-service utilization between persons with and without ASDs can also be used to approximate relative medical costs. Two recent U.S. studies found that children with ASDs had about twice as many nonemergency outpatient clinic visits on average, and to a lesser extent, a greater number of emergency department (ED) visits as their typically developing counterparts (Croen et al., 2006; Gurney et al., 2006). A third study estimated that children with ASDs had almost 13 times as many nonemergency outpatient visits as typically developing children and twice as many ED visits

Table 78–2.

Summary of studies on utilization of health-care services by children with ASDs in the United States

Authors, Year, Data Source	Sample Composition		Inclusion	Comparison
	ASD	Comparison Group		
Gurney et al. (2006). National Survey for Children's Health (NSCH).	483 children with autism; age range: 3 to 17 years; period: January 2003 to July 2004.	Similar children without ASD, frequency = 84,789 others.		Parents of children with autism reported more conditions: depression, anxiety, behavioral, and ADHD. Also more allergies.
Ruble et al. (2005). Medicaid managed care from Tennessee.	1,474 children with ASD. Age range: 0 to 17 years; period: July 1994 to June 2000.	None.	Family, individual, and group therapy, residential and inpatient services, medication management, day treatment, case management.	Number of children receiving service with ASD diagnosis increased by 171% but number of service days increased only by 74%. Mean number of service days decreased by 40%.
Leslie & Martin (2007). MarketScan, Privately insured in U.S, ICD-9 code 299.	Year: 2002 to 2004 Age ≤ 17 years, ASD size = 2,411.	Persons with other mental health disorders.	Inpatient, outpatient, and prescription care.	20% increase between 2000 and 2004.

(Liptak et al., (2006). The reason for the discrepancy in numbers of nonemergency outpatient visits is unclear and parallels the variation in reported medical expenditures or costs.

Data on trends in health-care utilization by children with ASDs are also inconsistent across studies. For example, the mean number of service days per child with an ASD enrolled in Medicaid in Tennessee decreased by 40% between 1994 and 2000 (Ruble et al., 2005). In contrast, a time-trend analysis of MarketScan data reported an increase of 20% in average health-care utilization among privately insured individuals with ASDs between 2000 and 2004, based on expenditures adjusted for inflation (Leslie & Martin, 2007). This finding suggests variability in the policy and practice of different payers regarding health-care delivery to children with ASDs.

Nonmedical Expenditures

As described earlier in this chapter, nonmedical expenditures include educational services, behavioral, occupational, and speech and language therapies, residential care, etc. Educational costs associated with ASDs depend on how services are delivered. Residential schools, which are much more costly, appear to be commonly used in Sweden (Järbrink, 2007) but not in the United States. In the United States, more children with ASDs receive behavioral therapy services in schools than in medical settings (Ruble et al., 2005; Yeargin-Allsopp et al., 2003). The Special Education Expenditures Project, commissioned by the U.S. Department of Education for the 1999-to-2000 school year, calculated mean expenditures for pupils receiving publicly funded special education services for

different disabilities. They found the mean incremental expenditures for ASDs as a qualifying condition were $12,900 per student receiving services for an ASD, the second-highest cost for any condition (Chambers et al., 2004, 2003). Children with multiple disabilities educated outside the public school system and reimbursed by special education services incurred a mean incremental expenditure of $20,000 (Chambers et al., 2003). Many children with ASDs receive special education services under a different qualifying condition, such as a specific learning disability or emotional disturbance, which is associated with lower costs. On the other hand, some children with ASDs receive services through the multiple disabilities qualification, which is associated with higher costs (Chambers et al., 2003).

In Sweden, the mean incremental cost of educating children with ASDs was reported to be $25,100. This estimate was based on a survey in four municipalities involving 33 families with children with ASDs and using unit costs reported by the school authorities (Järbrink, 2007). The strength of this Swedish study lies in the fact that it is a population survey. However, most of the higher cost estimate was associated with the use of separate schools for seven of the 33 children with ASDs, which is not characteristic of U.S. children with ASDs.

Behavioral interventions are generally recommended for children with ASDs and are more effective if started early, ideally before age 3 years (Butter et al., 2003). Early intensive behavioral intervention based on applied behavior analysis is one commonly used form of behavioral intervention. In this approach, the standard of care is for children with ASDs to receive about 35 to 40 hours per week of one-on-one teaching for 2 to 4 years. As originally conceptualized (Lovaas, 1987),

Table 78–3.
Summary of studies on nonmedical expenditures for children with ASD: Education

Authors, Year, Country	Sample Composition		Inclusion	Annual Expenditures in 2003 (U.S. $ per Child)
	ASD	Comparison Group		
Chambers et al. (2003, 2004). United States	Survey of U.S. approximately 5000 special education providers, 1000 schools, and 300 local education authorities; year: 1999 to 2000; children with disabilities.	Children without any disabilities.	School-related expenses for children by disability category, regular and special education classes, resources, specialists, related services, other special education services.	Mean ASDs: $18,790; Mean Comparison: $6,556; Mean Incremental: $12,854. Mean, Speech and language Disorders: $11,513; Mean comparison $6,888; Mean Incremental: $4,625. Education outside public school system, Mean ASDs: $26,876; Mean Comparison: $6,888; Mean Incremental: $19,989.
Järbrink (2007). Sweden	Population-based survey in four municipalities; 33 children in 2005. Average age: 11.6 years, range 4 to 18 years.	Other children without ASD.	All school-related expenditures. Unit cost obtained from schools. No more detail provided.	Mean $25,099.

this intervention costs on average $40,000 per year per child but can exceed $60,000 depending on family participation, economy of scale, and other factors (Butter et al., 2003; Chasson et al., 2007; Jacobson et al., 1998; Sallows & Graupner, 2005). We could find no cost estimates associated with other common behavioral intervention methods in the peer-reviewed literature, such as Treatment and Education of Autistic and related Communication-handicapped Children (TEACCH), floor time (Thomas et al., 2007a, b), or other applied behavioral analysis methods.

The costs of residential care for adults with ASDs are difficult to estimate, partly because of the lack of information on residential arrangements for representative samples. Residential options for persons with ASDs range from independent living with supports to institutional care for those with severe disabilities. Between these two extremes exists a range of options, such as group homes, supported living, semi-independent living services, and living with a family member or in a foster-care setting. In order to estimate average residential costs for persons with ASDs, the first requirement is to estimate the distribution of adults with ASDs in these different settings. Krauss et al. (2005) found that 67 of 133 (50%) U.S. adults with ASDs (mean age of 32 years), 96.5% of whom had autistic disorder, lived in a staffed residential setting and an additional 11% were in semi-independent living. An additional 51 (38%) lived with family members,

and one lived in foster care. Similarly, Eaves and Ho (2008) found that 23 of 47 (47%) young adults (mean age of 24 years) with ASDs in Canada lived in residential facilities. In a Swedish survey of young adults with ASDs, most with Asperger's Syndrome, two of 19 (11%) individuals lived in a group home (Järbrink et al., 2007).

An older study from North Carolina (Wall, 1990) reported the costs of residential care for persons with ASDs living in 11 group homes affiliated with TEACCH, one home for children, two for adolescents and eight for adults. These homes served 52 clients at any given time. The cost per person with an ASD was $56,600 and $34,000 for federally or state-funded homes, respectively.[5] A recent analysis (Lakin et al., 2008) reported average Medicaid expenditure for U.S. adults with intellectual disabilities, including persons with ASDs, of $128,300 for those living in residential facilities and $61,800 for those receiving home- and community-based services, mostly residing in group homes. Residential costs for adults with high-functioning autism (HFA) are presumably much lower as they may require less supervision. The Swedish study cited above reported mean expenditures of only $2,200 per person per year for all HFA adults, most of whom did not require residential care (Järbrink et al., 2007).

Children with ASDs and their families often require services such as respite care, home modification, or socialization services. Two studies calculated that mean annual expenditures for these types of nonmedical services ranged from $5,500 in a pilot study of 17 children in the United Kingdom (Järbrink et al., 2003) to $15,400 in Sweden (Järbrink, 2007).

Adults with ASDs may benefit from supported employment services "such as assessment and diagnosis, counseling, job search assistance, assistive technology, and on-the-job training" as they may increase job retention (Hagner & Cooney, 2005; Lawer et al., 2008) and decrease loss of productivity. In Sweden, Järbrink et al. (2007) evaluated the cost of community support and employment service for adults with ASDs, mostly Asperger's Syndrome,[6] at $9,800 per year. The annual mean cost of supported employment in a 2-year U.K. program was $20,400 per person (Mawhood & Howlin, 1999). The largest supported employment program in the United States is operated by the Rehabilitative Services Administration. In 2005, approximately 2,000 adults with ASDs received vocational rehabilitation services through it, less than 1% of the total served, at an average cost of $3,300 per person (Lawer et al., 2008).

Table 78–4.
Summary of studies on nonmedical expenditures for children with ASD: Behavioral therapy

Authors, Year, Country	Sample: Children with ASD	Annual Expenditures in 2003 (U.S. $ per Child)
Jacobson et al. (1998). United States	Children receiving Early Intensive Behavioral Intervention in Pennsylvania in 1996.	Mean $33,000.
Butter et al. (2003). United States	Children receiving Lovaas therapy.	Mean exceeds $60,000.
Chasson et al. (2007). United States	Cost of Applied Behavioral Analysis based on Sallows and Graupner (2005).	Mean: $40,000 to $60,000.
Sallows & Graupner (2005). United States	Lovaas therapy, 24 children, Age 2 to 3½ years at start.	Mean Exceeds $50,000.
Järbrink (2007). Sweden	Population-based survey in four municipalities; 33 children in 2005. Average age: 11.6 years, range 4 to 18 years.	Mean $25,099.

Loss of Productivity among Individuals with ASDs

Persons with ASDs often incur loss of productivity resulting from unemployment or underemployment; the latter occurs if they either work less than full-time or earn less than the average wage because they lack appropriate work or social skills. Lawer et al. (2008) found that 42% of U.S. adults with ASDs who received vocational rehabilitative services were competitively employed and 2.1% were in a sheltered employment. One of the few empirical estimates of average productivity

Summary of studies on other nonmedical expenditures specific to person with ASD

Authors, Year, Country	Sample: Children with ASD	Inclusion	Annual Expenditures in 2003 (U.S. $ per Child)
Birenbaum et al. (1990). United States	Nationally representative survey based on school and special education districts and 1980 censuses. Survey period June 1985 to June 1986. Sample under age 18 years, size = 235; age 18 to 24 years, size = 58.	Child care, special programs, after school, day care, weekend program, summer school, overnight respite, travel to medical appointments, home and car modification, damage replacements.	Mean $362.
Järbrink (2007). Sweden	Population-based survey in four municipalities; 33 children in 2005. Average age: 11.6 years, range 4 to 18 years.	Home placement, respite care, camp, domestic support worker, day outings, personal assistant, befriending service.	Mean $15,390.
Järbrink & Knapp (2003). United Kingdom	17 children, convenience sample for pilot study.	Damages, extra help, transport, special activities, extra cost for siblings, court cases, other.	ASD mean range: $5,505 to $8,366; median range: $4,678 to $6,106.

costs comes from Sweden and included 19 adults with HFA (average age of 29.6 years) who could work and were enrolled in a project that offered support for employment. Järbrink et al. (2007) found that about 50% of the sample had a paid job and the average loss of potential income was $16,400 per person per year, accounting for almost half of the annual cost of ASD in that study. A published review of six studies of adults with HFA by Howlin (2000) found that the percentage of individuals in paid employment ranged from 5% to 55%, depending on the survey sample, the geographic location,

Table 78–7.
Summary of studies on supported employment

| Authors, Year, Country | Sample Composition | | Inclusion | Annual Expenditures in 2003 (U.S. $ per Child) |
	ASD	Comparison Group		
Järbrink et al. (2007). Sweden	Adults mostly with ASD, mean age 29.6 years, data collection in 2000 and 2003.		Community support, employment service.	Mean $9,768.
Mawhood & Howlin (1999). United Kingdom	30 adults with ASD, average age 31.1 years, collection in 1994 to 1996.	20 adults without ASD, average age 28 years.	Supported employment.	Mean: $20,445.
Rogers et al. (1995). United States		19 adults with severe psychiatric disabilities, average age 36 years, range 18 to 55 years; collection in 1990.	Supported employment.	Mean: $7,731.
Cones (2008). United States		Adults with intellectual and developmental disabilities.	Supported employment.	Mean: $4,334.

the type of support available to persons with ASDs, and how employment was defined. A survey of 117 adults (no age information provided) with HFA who were clients of a U.K. job placement service found that 54% to 100% of clients were in paid employment (Howlin et al., 2005), but that was not a representative survey of the population of adults with HFA. Two Canadian studies based on convenience samples reported that the majority of adults with ASDs who were interviewed were employed for pay, but with variable earnings. Eaves and Ho (2007) studied 47 young adults in Canada (mean age of 24 years) with ASDs and found that 4% were independent and held a job, 49% were "generally in work" and 47% held a low-paying, part-time, or a volunteer work position (personal communication from Linda Eaves, October 17, 2007).[7] Among a sample of nine young adults in Canada with Asperger's syndrome (average age of 20.3 years) who were not students, three had never held a paid job, three had part-time employment, and the other three held full-time jobs (Jennes-Coussens et al., 2006). An international review of the labor market participation of low-functioning individuals with ASDs indicated that 2% to 18% of adults were employed (Synergies Economic Consulting, 2007).

Generally, these studies suggest that at least 50% of adults with HFA are employed; however adults with a lower level of functioning are less likely to be employed. These results are based on convenience samples of adults. None of the studies cited in this section reported whether persons with ASDs worked in a capacity commensurate to their skills, except that one study noted that average earnings among those who had paid jobs were lower (Jennes-Coussens et al., 2006). Thus, their substantial losses of productivity are not well-measured. Also, it should be acknowledged that the availability of government benefits can deter people with disabilities from being employed for pay, although the Ticket to Work and Work Incentive Improvement Act of 1999 (Public Law 106–170)

attempts to reduce the disincentives to employment among individuals receiving Social Security disability benefits.

Loss of Productivity of Caregivers

Parenting children with ASDs requires extra time that could otherwise be spent in paid work or other activities. Parents in one U.K. survey[8] were reported to spend an average of 40 extra hours per week caring for their young child with an ASD (Järbrink et al., 2003); this is a very high estimate relative to those from other studies. A representative, national U.S. survey found that 27% of families of a child with an ASD (ages 3 to 17 years) reported spending 10 or more hours per week providing care or coordinating care for their child (Kogan et al., 2008). Family caregivers in Sweden during 2002 to 2003 reported spending about 2 hours per week caring for an adult child with an ASD (Järbrink et al., 2007).

Other researchers have estimated the loss of hours of paid work and earnings (Grosse, 2010). The majority (57%) of a sample of 2,088 U.S. families of children or youth ages 3 to 17 years with ASDs in the 2005–2006 National Survey of Children with Special Health Care Needs reported that a family member reduced or stopped employment because of their child's condition (Kogan et al., 2008). An analysis of data from the 2003–2004 National Survey of Children's Health found that 39% of 82 families of preschool-age children with ASDs reported that child-care considerations had led a family member to quit work, change jobs, or alter type of work in the last 12 months, compared with 9% of 14,079 families with typically developing children (Montes & Halterman, 2008b).

Estimates of the loss in earnings require the collection of detailed information for representative samples of families of children with and without ASDs. Using the 2005 National Household Education Survey of After School Programs and Activities, Montes and Halterman (2006) found that mothers

Table 78–8.
Summary of studies on loss of productivity of persons with ASD

Authors, Year, Country	Sample: Adults with ASD	Percentage of Individuals with ASD in Work	Mean Annual Productivity Loss
Järbrink et al. (2007). Sweden	Survey: 19 adults with functioning ASD in Sweden, Mean age 29.6; two waves of collection: 2000 to 2001 and 2002 to 2003.	50%.	$16,413.
Howlin (2000). Canada, Denmark, U.K., U.S.	Review of studies on high-functioning autism (HFA); mean age across studies ranges from 18 to 38 years.	5% to 100%.	
Howlin et al. (2005). United Kingdom	117 adults; No age provided .	54% to 100%.	
Eaves & Ho (2008). Canada	47 adults; mean age 24 years, range 19 to 31 years.	4% independent. 49% "generally in work." 47% low-pay, part-time, or volunteer.	
Jennes-Coussens et al. (2006). Canada	12 adults with HFA, mean age 20.3 years among the nonstudents.	33% full-time. 33% part-time.	
Synergie Consulting review (2007). Australia	Review of international studies. Low-functioning adults with ASD.	2% to 18%.	

of children with ASDs in grades kindergarten through eight were less likely to be employed than other mothers, (53% vs. 67%). Like mothers, fathers of children with ASDs were less likely to be employed (82% vs. 93%), and more likely to be working part-time. Montes and Halterman (2008a) calculated the mean loss of parental income in this sample to be $6,000 per year for each child with an ASD. To be equivalent to the total loss of productivity from a societal perspective, one should multiply this estimate by 1.31 to adjust for employer-paid fringe benefits and payroll taxes (Grosse et al., 2009), or approximately $7,900 per year in 2003 dollars.

In Sweden, Järbrink (2007) evaluated parental time loss for paid work to be $5,400 per child. For young adults with ASDs in Sweden, parental loss of earnings was much lower, averaging about $103 per person (Järbrink et al., 2007). In the United Kingdom, Järbrink et al. (2003) estimated the loss of income for caregivers of young children with an ASD to be $19,300 per year. The median parental income loss amounted to $16,700 per year.

Generally, these studies suggest that parents of children with ASDs spend more time caring for their children than parents of typically developing children, but the time required for care seems to decrease as children with ASDs age. In the United States, this extra parenting time translates into a loss of earned income of $6,000 according to Montes and Halterman (2008a), which is equivalent to 17% of median income of a married U.S. worker in 2003 (Bureau of Labor Statistics, 2004)[9].

Mean Annual Total Cost

Mean annual total costs provide a useful summary as the distribution of cost may vary depending on local policies and the

age of the persons with ASDs and whether they have an intellectual disability or not. In the United Kingdom, Knapp et al. (2009) calculated that the mean annual expenditures per child with an ASD without intellectual disability age 4 to 17 years was $33,100, and education and respite care account for 89% of it. For children with intellectual disability, the cost rose from $36,900 for those ages 4 through 11 years to $63,200 for those ages 12 to 17 years. Together, education and respite care account for 58% and 89% of those expenditures, respectively. In an earlier study in the U.K., the mean and median annual costs per child were respectively $57,600 and $54,200 in a small pilot survey of 17 children with ASDs (Järbrink et al., 2003). Medical costs accounted for 3%, nonmedical costs accounted for 63% (53% for education and behavioral therapy), and parental loss of income represented 34%. In Sweden, the annual per capita costs of ASD in a sample of 33 children were $54,500 (Järbrink, 2007). Medical-care costs represented 5% of the total, nonmedical care accounted for 80%, of which education alone accounted for 51% of total costs, and caregiver costs were 15% of total costs.

Annual expenditures for adults are generally higher than those of children. In the United Kingdom, Järbrink and Knapp (2001) found that annual expenditures per adult with an ASD and intellectual disability is $116,500 and the cost per adult without intellectual disability was about 58% of that at $67,900. In Sweden, the mean annual cost for 19 young adults with ASDs ages 19 to 39 years was calculated to be $35,600 per person (Järbrink et al., 2007). Medical-care costs constituted 16% of total costs, nonmedical care accounted for 30%, productivity losses accounted for 49%, and parental earnings losses were 5% of the total costs. In Australia, the mean total incremental costs for individuals of all ages with ASDs were

Table 78–9.
Summary of studies on parental loss of productivity

Authors, Year, Country	Sample Composition	Percentage of Parents Who Work		Incremental Time Spent on Care	Annual Productivity Loss
		ASD	Comparison		
Järbrink et al. (2003). United Kingdom	17 children, convenience sample for pilot study.			40 hours per week.	Mean: $19,297. Median: $16,707.
Järbrink et al. (2007). Sweden	Survey: 19 adults with functioning ASD in Sweden, Mean age 29.6; two waves of collection: 2000 to 2001 and 2002 to 2003.	N/A	N/A	48 hours per month.	Mean: $103.

estimated based on a compilation of literature and modeling to be $38,000 per person. Medical costs represented 3%, non-medical costs 25%, productivity losses represented 49%, and caregiver costs accounted for 23% of the total costs (Synergies Economic Consulting, 2007).

Lifetime Costs

Three published studies estimated the lifetime cost of ASDs using modeling techniques to address gaps in information. First, Ganz (2007, 2006) estimated a lifetime cost of $3.2 million for a typical child with an ASD, calculated using a 3% per year discount rate to discount costs incurred in the future to present values, as is standard practice in U.S. health economics analyses. He assumed that a child would be diagnosed at age 3 years and receive behavioral therapy for 4 years, special education and child care through age 22 years, and adult care from age 23 years to the end of life. Ganz assumed that 10% to 35% of adults with ASDs engage in supported employment in which they receive specific work-related help and coaching and earn 20% of average national income[10] but that no adult with an ASD works independently. Ganz assumed that 10% to 20% of fathers and 55% to 60% of mothers of children with ASDs were out of the workforce. Further, 50% of adults with ASDs were assumed to live in a specialized institution. On the basis of these assumptions, Ganz projected lifetime medical expenditures of approximately $100,000 (3%), non-medical expenditures of $1,185,100 (37%), loss of productivity of $971,100 (30%) and parental loss of productivity of $904,600 (28%).

Several of these cost components appear overstated. First, Ganz assumed that a "typical" child would receive intensive behavioral therapy at a cost of $40,000 per year for 4 years. However, few children with ASDs currently have access to these intensive therapies (Thomas, et al., 2007b). Second, Ganz made pessimistic assumptions about the employment of both individuals with ASDs and their parents. The author assumed that no adult with an ASD works independently, whereas as many as one-half of HFA adults are employed (Eaves & Ho, 2007; Howlin, 2000; Howlin et al., 2005; Järbrink et al., 2007; Jennes-Coussens et al., 2006). Ganz (2007) assumed an average parental loss of annual earnings of $43,000 per year, which is seven times higher than a subsequent empirical estimate of $6,000 per year (Montes & Halterman, 2008a). It should be noted that the median yearly earnings of a married U.S. worker in 2003 was just over $36,000 (Bureau of Labor Statistics, 2004).[11]

Earlier, Järbrink and Knapp (2001) evaluated lifetime costs in the United Kingdom. They assumed that 25% of persons with an ASD have HFA and 75% have an intellectual disability in addition to an ASD. During their lifetime, persons with HFA were projected to cost $1.3 million and those with lower-functioning autism about $4.7 million, without discounting costs in future years. "Living support" or residential care represented about 40% of the cost for persons with HFA and 73% of the total costs for low-functioning individuals. A maximum of 35% of adults with HFA were assumed to live independently and it was assumed that all others would need living support. Also, it was assumed that 60% of persons with ASDs and intellectual disability would be in residential care by 20 years

Table 78–10.

Summary of studies on annual total cost of ASD

Authors, Year, Country	Sample: Persons with ASD	Total per Person with ASD	Distribution			
			Medical	Nonmedical	Productivity Loss	Parental Productivity Loss
Järbrink et al. (2007), Sweden.	Population sample of 33 children.	Mean: $54,546.	5%	80%	0%	15%

Mean: $36,947; Mean: $63,245; Mean: $33,078; Mean: $116,481; Mean: $67,861, respectively.	33% 6% 10% 7% 34%	59% 89% 89% 59% 15%	0% 0% 0% 2% 45%	8% 5% 1% 32% 7%

ASD: Autism Spectrum Disorders; ID: Intellectual disability.

of age and the others by 55 years of age. It was assumed that the majority of adults with ASDs could not live independently during their adulthood, an assumption based on a sample of adults who received autism-specific services.

Third, Knapp et al. (2009) calculated lifetime cost estimates for the United Kingdom for individuals with ASDs with and without intellectual disability, assuming a 45:55 split. Using a 3.5% discount rate, as is now standard practice in U.K. health economic analyses, the lifetime cost was estimated to be $1,221,366 for those without intellectual disability and $1,893,400 for those with intellectual disability. Neither estimate included any loss of parental earnings resulting from informal caregiving. Knapp and colleagues assumed that 79% of adults with an ASD without intellectual disability live in private households, compared with 35% of adults with an ASD and intellectual disability. These estimates appear more in line with prior findings than the assumptions in the previous U.K. cost study by Järbrink and Knapp (2001).

Overall, the Ganz estimate of lifetime costs assumed optimal patterns of care for children with ASDs but the worst possible outcomes in terms of lost productivity. Access to early intensive therapy and appropriate education should improve long-term outcomes and reduce both productivity costs and residential costs (Jacobson et al., 1998; Motiwala et al., 2006). All of the studies cited appear likely to overstate service utilization and expenditures among adults, especially for residential care, because they did not account for adults who had an ASD diagnosis as children but did not continue to receive ASD-related services as adults.

Conclusion

In the United States, there are a number of fairly precise estimates of mean incremental medical expenditures for children with ASDs, although there is substantial variation among these different estimates. Recent estimates of annual medical expenditures per individual range from $2,100 to $11,200 and represent 3% to 5% of the estimated total annual cost for a child with an ASD. For nonmedical costs, the mean annual incremental cost of educating a child with an ASD as a qualifying condition for special education is about $13,000. Intensive behavioral interventions cost between $40,000 and $60,000 per child per year. Recent U.S. estimates of other nonmedical costs such as home transformation or respite services are not readily available.

There is a dearth of empirical data on costs for adults with ASDs, particularly residential-care costs, loss of productivity, and cost to parents or other caregivers, which most likely represent the bulk of ASD-related lifetime costs. The only one of these with a recent U.S. population-based estimate suggests an annual loss of parental productivity of $6,000 per child, or $7,400 from the societal perspective. This calculation needs to be replicated with other surveys. Estimates of residential costs per person with an ASD or learning disabilities range from $60,000 to $128,000 per year, but estimates of the proportion of persons who need these services do not exist. Our review indicates that estimates of the loss of productivity of adults with ASDs mostly rely on convenience samples. Among adults

Table 78–11.

Summary of studies on lifetime cost of ASD

Authors, Year, Country	Sample: Persons with ASD	Total Mean per Person	Distribution			
			Medical	Nonmedical	Productivity Loss	Parental Productivity Loss
Ganz (2007, 2006), United States.	Societal perspective: literature review, all children received appropriate care but with worst possible outcomes. Discount cost.	$3,200,000.	3%	37%	31%	29%
Järbrink & Knapp (2001), Sweden.	Societal perspective: literature review, no discounting.	Low-functioning: $4,700,000; HFA: $1,300,000.	Low-functioning: 3.4%; HFA: 9%.	Low-functioning: 95.3%; HFA: 71.7%.	Low-functioning: 0%; HFA: 17.5%.	Low-functioning: 1.3%; HFA: 1.8%.

HFA: high-functioning autism

with HFA, at least half are employed but we do not know much about their skills level and their earnings. The real productivity losses of adults with ASDs are unknown. Thus, we lack reliable estimates of total yearly or lifetime costs of ASDs in the United States.

Cost components are affected by the time period of the data, the services considered, sample size and representativeness, and the organization and financing of care, as well as how ASDs are diagnosed and ascertained. Most studies cited in this chapter were not based on population samples, and self-selection may bias the results. The only U.S. national survey to collect cost data on children and adults with ASDs (Birenbaum et al., 1990) was conducted more than two decades ago. New, population-based surveys are needed. The 2005–2006 National Survey of Children with Special Health Care Needs collected qualitative information on impacts of ASDs for a representative sample of more than 2,000 families with a child or youth with an ASD but did not collect cost data (Kogan et al., 2008) and did not address costs for adults with ASDs.

ASD describes a continuum in which some persons require a high level of lifelong support but others function independently or with little support. Consequently, it is necessary to collect cost and service utilization data for representative samples of individuals with ASDs. Such data could be used as a reliable baseline to measure the cost-effectiveness of

interventions and to guide policymakers in allocating resources for the care of persons with ASDs.

Challenges and Future Directions

- We do not have a reliable estimate of the overall lifetime costs associated with ASDs for an individual child or for a nation. Some cost estimates include implausible assessments of productivity losses.
- We lack standardized cost estimates for both ASDs and other developmental conditions or disabilities that would allow for comparability in estimates of the economic impacts of these disorders.
- The biggest gap in data is the lack of information from representative samples of parents of children with ASDs on out-of-pocket expenditures and use of therapies, particularly alternative therapies.
- We lack data on large, representative samples of adults with ASDs to document costs associated with productivity losses and personal care/housing.
- The greatest need for economic data on ASDs is to quantify the economic impact of early-intervention programs. However, this requires cost estimates that are sensitive to differences in functioning, which can be affected by such

intervention programs. We do not have such data at the present time.

ACKNOWLEDGMENTS

NOTES

1 Children in the United States with ASDs are entitled to services mandated under the special education law "Individual with Disabilities Education Act (IDEA)" from birth until the age 21 years.

2 We chose 2003 because it is the modal year of data in the U.S.-based papers reviewed.

3 Purchasing Power Parity are conversion rates from the Organisation for Economic Cooperation and Development that equalize the purchasing power of different currencies. http://www.oecd.org/department/0,3355,en_2649_34357_1_1_1_1_1,00.html accessed on 4/7/2008.

4 See www.bls.gov accessed on 9/20/2007.

5 The author did not provide the years covered by his study and attempts to contact him were unsuccessful. We therefore assume that those costs are effective in 1990, the year in which the paper was published.

6 The study is described in more detail below in the productivity section.

7 Linda Eaves reported that persons with ASDs in British Columbia were eligible for public support of C$800 per month and that public support could reduce their incentives for labor market participation.

8 Data collection dates not clear, but study offer prices of 1999 to 2000.

9 Median usual weekly earnings of full-time wage and salary workers by selected characteristics, 2003 annual averages. The weekly earning of a married worker with spouse present equals $697, or $36,244 per year.

10 Unpublished appendix obtained from Michael Ganz, personal communication, December 5, 2007.

Future Directions: Setting Priorities to Guide the Federal Research Effort

Points of Interest

- The Interagency Autism Coordinating Committee, a federal advisory committee composed of federal and public members, issued the first federal strategic plan for autism research in 2009 and an updated strategic plan in 2010.
- The strategic plan and its first update were developed through an extensive process involving input from federal agencies, scientific experts, advocacy and research organizations, people with ASD and their families, and the public.
- The 2010 IACC Strategic Plan for ASD Research is organized according to seven key consumer-based questions that are critically important to people with ASD and their families. The plan spans a broad range of topics in ASD biomedical and services-related research.
- The National Institutes of Health (NIH), the primary federal agency that conducts biomedical research on autism, has had a steadily rising autism research budget from 1997 to 2009.
- The NIH is currently conducting autism research through its extramural and intramural programs, and is providing critical research resources to the scientific community to foster autism research.
- With the framework provided by the IACC strategic plan and judicious use of funds such as those provided by the American Recovery and Reinvestment Act (ARRA) of 2009 to support a diverse portfolio of science, the federal autism research effort is poised to address critical needs of people with ASD and their families.

Several federal agencies have been involved in research or services for individuals affected by ASD for the past three

decades. The Children's Health Act of 2000 (P.L. 106-310) established the IACC to integrate the commitment of most of the involved agencies under the leadership of the Department of Health and Human Services (DHHS). As research and service budgets for ASD grew during the years following the enactment of the Children's Health Act, the IACC provided a forum not only for coordination of federal research efforts, but also for research planning, public input, and documentation of the increasing need for services. The national Autism Summit Conference, held in November 2003, focused on the federal government's role in biomedical autism research, and provided a public forum to disseminate, evaluate, and integrate the latest practice- and science-based autism information among federal, academic, and community participants. The conference, attended by the Secretary of Health and Human Services, the Secretary of Education, and several members of Congress, described the importance of increasing awareness about autism and launched a research matrix to guide the field toward specific short- and long-term goals for ASD research (Autism Summit Conference Summary, 2003). Progress on these goals was described in the report, "Evaluating Progress on the IACC Autism Research Matrix," published by the IACC in 2006. Among key findings from the report were that the science of autism had recently begun to converge on the concept of ASD as a group of brain disorders, that several prominent gaps remained in research to understand the causes and molecular bases of autism, that more randomized clinical trials of individual comprehensive intervention approaches were needed, and that more emphasis on research was needed to enhance services and supports for individuals with ASD and their families.

The Combating Autism Act (CAA) of 2006 (P.L. 109-416) reauthorized Title 1 of the Children's Health Act and expanded coordination of federal activities in autism. The CAA mandated the reestablishment of the IACC to coordinate all efforts concerning autism spectrum disorders across the DHHS and

required a more specific composition of the committee. Up to two-thirds of the committee was required to be composed of representatives of federal agencies, and at least one-third was to be composed of public members, including at least one individual with a diagnosis of an autism spectrum disorder, at least one parent or legal guardian of an individual with an autism spectrum disorder, and at least one member who is a representative of a leading research, advocacy, or service organization for individuals with autism spectrum disorder. This partnership between federal agencies and members of the public provides a meaningful way to include public input in government priority setting. Currently, IACC membership includes two individuals with ASD, several parents of children with ASD, and individuals who are leaders of national autism advocacy groups (Autistic Self Advocacy Network, Autism Society, Autism Speaks, and Coalition for SafeMinds), representatives of private national research organizations (Autism Science Foundation, Simons Foundation, the U.C. Davis M.I.N.D. Institute), as well as officials from the following federal agencies that deal with autism research or services: Centers for Disease Control and Prevention (CDC), the Department of Education, the Centers for Medicare and Medicaid Services (CMS), the HHS Office on Disability, Substance Abuse and Mental Health Services Administration (SAMHSA), the Administration for Children and Families (ACF), the Health Resources and Service Administration (HRSA), five Institutes of the National Institutes of Health and the NIH director. The federal partners cover different parts of the ASD landscape. For instance, scientists at the CDC focus on epidemiology and public awareness, different institutes of the NIH cover the biology of and interventions for ASD, and CMS provides support to states for ASD services. Similarly, the public members represent a variety of viewpoints and perspectives. The IACC serves as a forum for representatives of each agency and public members to inform each other, as well as the general public, about the challenges and opportunities for ASD research and services as seen from different corners of the community. The IACC also regularly invites speakers to discuss current findings in scientific and services research to present at its meetings, holds public workshops, and collects public input through events such as town hall meetings and formal Requests for Information (RFI). As the new IACC was established in accordance with the Federal Advisory Committee Act, all meetings are open to the public and all decisions are advisory to the federal government.

The responsibilities of the IACC under the CAA include development of a research strategic plan for autism spectrum disorders, annually updating the strategic plan to reflect advances in science and newly identified research opportunities and needs, monitoring of federal activities related to autism, preparation of a summary of biomedical and services research advances in autism spectrum for Congress, and making recommendations to the Secretary of HHS and the Director of NIH regarding the strategic plan for autism research and federal activities related to autism.

A Research Strategic Plan for ASD

Building on the experience of developing the matrix for autism research in 2003, the new IACC developed the first federal strategic plan for ASD research, which documents recent progress in autism research, identifies current research gaps and opportunities, and recommends a series of research objectives spanning biomedical science and services that can be supported through the activities of federal agencies, private foundations, or public–private partnerships.

The original 2009 plan was developed through an extensive process engaging a variety of federal agencies, scientific experts, and public stakeholders. In December 2007, the IACC issued a public RFI to solicit high-priority research questions within the areas of autism: risk factors, biology, diagnosis, and treatment (IACC Request for Information, 2007). The IACC used the input received to inform a series of scientific workshops that involved over 60 scientists, clinicians, and autism advocates, where a series of research objectives for the strategic plan were developed. A town hall meeting and other RFIs were used to gather additional public input as the draft plan continued to take shape (IACC Town Hall Meeting, 2008; IACC Request for Information, 2008). The language of the draft plan was meticulously reviewed and revised by the IACC in a series of public meetings that took place between November 2008 and January 2009 (IACC Meetings and Events, 2009). This first IACC strategic plan was finalized in January 2009 and submitted to the Congress, the Secretary of Health and Human Services and the Director of NIH, as required by the CAA (*IACC Strategic Plan for ASD Research*, 2009; IACC News Release, 2009).

In January 2010, the IACC completed an update of the strategic plan (*IACC Strategic Plan for ASD Research*, 2010; IACC News Update, 2010). This revised plan more fully addresses the needs of the people with ASD across the spectrum, from young children to adults, and places new emphasis on both nonverbal and cognitively impaired people with ASD. The committee also decided to create a new seventh chapter in the plan on surveillance and infrastructure in order to focus attention on the need for expanded and enhanced research infrastructure—from bio-repositories to better surveillance—to bolster ASD research. Input for the 2010 plan was gained through a variety of means, including a formal RFI soliciting public input on additional topics that could be addressed in the 2010 update of the plan, a town hall meeting on services for people with ASD, and a 2-day scientific workshop involving ASD researchers, clinicians, advocates, people with ASD and family members of people with ASD (IACC, Request for Information, 2009; IACC Services Town Hall Meeting, 2009; IACC Scientific Workshop, 2009).

An important part of the strategic planning effort leading to the first IACC strategic plan and the 2010 update of the plan was the consideration of the historical and current funding landscape for ASD research. The largest funder of ASD research worldwide is the U.S. National Institutes of Health.

Figure 79-1 illustrates the levels of NIH funding for autism research over the past two decades, showing a steady increase in funding starting in 1996. The American Recovery and Reinvestment Act, signed into law by President Obama on Feb. 17, 2009, provided funds to many federal agencies to stimulate the economy. NIH used a portion of the ARRA funds it received to support new initiatives to advance research on ASD. As shown in Figure 79-1, the NIH official funding commitment for ASD-related research reached an all-time high of approximately $196 million in 2009, encompassing $64 million in ARRA funds and $132 million in non-ARRA research funds (NIH RePORT website, 2010).

The IACC and NIMH Office of Autism Research Coordination (OARC), the office that provides logistical and policy support to the IACC, undertook the first ever comprehensive analysis of the research portfolios of government and private funders of ASD research in 2009, looking back into 2008 funding data. Table 79-1 shows the research funders who provided information for the portfolio analysis, their ASD research budgets, numbers of projects and average funding

per project. In 2008, these funders supported over $222 million in ASD research. The analysis of the autism research portfolio showed that approximately 65% of the overall funding was provided by government agencies, while private funders contributed approximately 35% (see Figure 79-2). When examining how these funds were distributed in relation to the 2009 IACC Strategic Plan for ASD Research, the greatest proportion of funding was found to have been allocated to research on risk factors for ASD (37%), followed by treatments and interventions (24%), the underlying biology of autism (18%) and diagnosis (13%) (see Figure 79-3). Services research and research on lifespan issues lagged behind at 1% and 5%, respectively, indicating a need for increased research efforts in these areas.

The mission of the IACC Strategic Plan is to "focus, coordinate, and accelerate high-quality research and scientific discovery in partnership with stakeholders to answer the urgent questions and needs of people on the autism spectrum and their families." In keeping with this mission, the research objectives recommended by the IACC in their 2010 update of

NIH Autism Funding 1987–2009

	1987	1988	1989	1990	1991	1992	1993	1994	1995	1996	1997	1998	1999	2000	2001	2002	2003	2004	2005	2006	2007	2008	2009
■ ARRA																							63,969
■ Actual	8,073	8,678	8,201	9,605	10,277	11,586	9,640	11,661	10,507	13,030	22,171	26,889	40,015	51,724	55,775	73,850	93,386	99,828	101,632	108,320	126,843	117,214	132,402

Fiscal year/total dollars in thousands
Figure 79–1. Autism funding at the NIH has greatly increased over a 22-year span. Over the past decade, general NIH funding for ASD research more than tripled from approximately $40 million in 1999 to over $132 million in 2009. With an addition of almost $64 million from the American Recovery and Reinvestment Act (ARRA) in 2009, NIH funding for autism research reached its highest level yet at $196 million. Please note that funding levels prior to 2008 were calculated using the former NIH coding system. Since 2008, the NIH has used the automated Research Condition and Disease Categorization (RCDC) system to standardize how NIH-funded projects are categorized as autism research. The change from the old NIH coding system to the new RCDC system results in what appears to be a decrease in funding in 2008 from 2007, but this dip actually only represents a change in how specific projects were counted toward the autism funding total and not an actual decrease in funding of projects. Source: NIH RePORT website.

Table 79–1.

2008 Autism spectrum disorder research funding by funding agency/organization

Funding Agency/Organization	Number of Projects Funded	Average Funding Per Project	Total Funding
National Institutes of Health	340	$346,970	$117,969,770
Simons Foundation	77	$558,256	$42,985,684
Autism Speaks	200	$154,141	$30,828,116
Centers for Disease Control and Prevention	27	$682,855	$15,022,812
Health Resources and Services Administration	3	$2,030,264	$6,090,792
Department of Education	7	$491,292	$3,439,047
Autism Consortium	22	$100,683	$2,215,017
Department of Defense	8	$147,223	$1,177,781
Center for Autism and Related Disorders	26	$31,369	$815,581
Organization for Autism Research	16	$45,625	$730,000
Autism Research Institute	13	$40,085	$521,099
Southwest Autism Research & Resource Center	5	$79,000	$395,000
Centers for Medicare and Medicaid Services	1	$24,643	$24,643
Grand Total	**745**	**$300,291**	**$222,215,342**

Notes: This table lists the total funding provided by the agencies and organizations included in the IACC/OARC 2008 portfolio analysis, as well as number of projects funded, and the average funding per project. Together the agencies and organizations funded over $222 million in research in 2008. The NIH project number shown reflects unique NIH projects. NIH projects cofunded by more than one NIH institute were combined and counted only as a single project. This approach differs from that used by the NIH RePORTER system, where each cofund is counted as a separate project.

Please note that research projects included are those identified by the agencies and organizations as funded in the most recent 12 months for which data were available. The NIH project number shown reflects unique NIH projects. Projects funded by more than one NIH institute ("cofunds") were combined and only counted as a single project. This approach differs from that used in the NIH RePORT Expenditures and Results (RePORTER) system, where each cofund is counted as a separate project.

Source: IACC Portfolio Analysis, 2008.

the ASD strategic plan are organized around seven general questions that are commonly asked by individuals and families when facing the challenges of ASD (see Table 79-2).

The plan includes not only research opportunities, but short- and long-term objectives with metrics for evaluating
Figure 79–2. Contributions of Federal and Private ASD Research Funders to ASD Research in 2008. Of the $222 million spent on ASD research in 2008, 65% came from federal sources, while 35% of funding came from private organizations. Source: IACC Portfolio Analysis, 2008.

progress, and proposed budgetary requirements. The proposed budgetary requirements are professional judgment estimates for how much each project or program associated with a specific objective would potentially cost. The budgets are provided as advisory figures to guide agencies and organizations that may be involved in implementing various objectives from the plan. Importantly, the IACC does not have its own budget for research. It can accelerate, focus, and coordinate research efforts, but funding to accomplish the research must be provided by the government agencies and private organizations represented on the Committee, as well as by other members of the community who wish to support these efforts.

Although most scientists recognize that many important scientific discoveries have been made through serendipity resulting from investigator-initiated projects, targeted research initiatives are another approach used by government agencies to fund science—particularly in cases where there are clear research gaps that need to be filled to move the science forward. The IACC Strategic Plan for ASD Research lays out a series of targeted research objectives that correspond to consumer-focused questions and that reflect the urgency of ASD as a public health issue. The plan's logically organized research objectives chart a course toward needed breakthroughs in autism research, while also providing a framework for accountability. The completion of the initial 2009 plan just before the passage of the American Recovery and Reinvestment Act of 2009 was fortuitous, as some of the new funds appropriated to
Figure 79–3. 2008 Autism Spectrum Disorder (ASD) Research Funding Categorized According to the 2009 IACC Strategic Plan for ASD Research. In 2008, the largest proportion of research funding (37%) from 13 U.S. funding agencies and organizations was devoted to risk factors for ASDs, reflected in the IACC strategic plan question, "What caused this to happen and can this be prevented?" Twenty-four percent of the research addressed interventions and treatments, 18% related to the underlying biology of ASDs and 13% related to diagnosis. Research on services and lifespan issues garnered the smallest proportion of funding. Source: IACC Portfolio Analysis, 2008.

Table 79–2.

The structure of the 2010 IACC strategic plan for ASD research

Question/Strategic Plan Chapter	Scientific Categories
1. When should I be concerned?	Diagnosis
2. How can I understand what is happening?	Biology of ASDs
3. What caused this to happen and can this be prevented?	Genetic and environmental risk factors
4. Which treatments and interventions will help?	Treatments and interventions
5. Where can I turn for services?	Comparative effectiveness and implementation research, access to services
6. What does the future hold, particularly for adults?	Services and supports that improve quality of life across the lifespan
7. What other infrastructure and surveillance needs must be met?	Infrastructure to support research, the research workforce and to conduct ASD surveillance

Notes: The 2010 IACC Strategic Plan for ASD Research is divided into seven chapters, each of which is named for a critical consumer-based question regarding autism research, indicated in the left-hand column. The plan's recommended research objectives correspond to these questions and fall into the scientific categories indicated in the right-hand column. Source: 2010 IACC Strategic Plan for Autism Spectrum Disorder Research.

NIH were able to be committed to implementing the plan in 2009 and 2010. Indeed, a series of autism-focused initiatives were successful in soliciting a large new pool of autism research projects, amounting to over $64 million in new research in 2009 to jumpstart implementation of the IACC Strategic Plan,

with an additional infusion of over $20 million anticipated in 2010. New projects include studies to develop new screening tools, identify biomarkers, conduct deep sequencing and epigenomic studies to identify genetic and environmental risk factors, conduct clinical studies to test behavioral therapies,

assess various service modalities such as telehealth, and characterize the impacts of autism in the second half of life. The new ARRA funds, as well as increases in non-ARRA spending on autism, resulted in more than a 50% increase in the NIH budget for autism in 2009 relative to 2007. While the ARRA funds are only a 2-year addition that will not continue in future years, it is expected that general/base (non-ARRA) NIH autism funding levels will keep pace with, and hopefully exceed, the trends of overall NIH funding levels over time. Future NIH funding for autism will, as always, be dependent on Congressional appropriations.

Intramural ASD Research

Roughly 90% of NIH research funds are awarded to institutions around the nation outside of NIH where scientists engage in what is called "extramural" research. The remaining 10% are invested in the "intramural" research program, where laboratory research is conducted by NIH scientists at the agency's main campus in Bethesda, Maryland. The NIH intramural program exists for high-risk research, for a rapid response to emerging public health problems (i.e., SARS, AIDS), and for the development of unique tools and resources to serve scientific investigators across the nation.

In the summer of 2006, the National Institute of Mental Health (NIMH) launched an intramural effort specifically focused on ASD. Early goals of this program included identifying subtypes of ASDs with a focus on regression (using cerebrospinal fluid [CSF] proteomics, magnetic resonance imaging [MRI], sleep electroencephalography [EEG], and testing of novel interventions [e.g., minocycline, riluzole, donepezil]). By January 2010, over 500 children had been screened and over 100 had been enrolled in one of the protocols. Studies in the intramural program can recruit patients from across the nation and provide extensive clinical and research testing without charge. Current protocols include a study of children who reportedly have recovered from ASD.

Services for ASD

Complex service systems present a challenge to people with ASD and their families. The emerging field of health-services research, sometimes called implementation science, is helping to meet this challenge. *Health-services research* plays a critical role in evaluating the effectiveness of interventions in community settings, identifying best practices for broad dissemination of research findings into clinical practice, and informing policy on ASD services and supports. Research in areas such as comparative effectiveness studies of evidence-based practices can inform health-care quality, health-care reimbursement, and educational policies. Participation by families and people affected by ASD is critical to the success of this research if it is

to optimize the quality and accessibility of needed services for the autism community.

The 2009 IACC Strategic Plan for ASD Research identified the need for research related to autism services, and the 2010 edition of the plan added several new objectives to better address services needs across the full lifespan and including people of varying levels and types of disability. Because states differ in the services offered, the IACC called for an initial "state of the states" report, currently underway at the Centers for Medicare and Medicaid Services, to describe the variation in policies and resources across the states. This variation also provides an opportunity for naturalistic experiments to determine which policies and which resources are providing the most value in communities. NIH currently supports a portfolio of research on services for people with ASD, which was expanded using a portion of the funds received through ARRA, but there is a need to continue to increase this effort to ensure that the best science on autism informs the services offered to diverse populations.

The National Database for Autism Research

In addition to the IACC research strategic plan, the National Database for Autism Research (NDAR) will be a critical tool in fostering communication throughout the global ASD research community (National Database for Autism Research, 2010). NDAR is a secure biomedical informatics platform created by the NIH for scientific collaboration and data sharing for investigators who collect genotypic, phenotypic, imaging, pedigree, and other relevant ASD research data. Beyond providing investigators with significant technical capabilities for their data, NDAR has developed strategies to assure protection of research subjects, ensure data quality, and harmonize compatibility across other publicly and privately funded ASD research data sources.

NDAR uses a secure system of computer-generated codes called *Global Unique Identifiers* (GUIDs) to allow the association of a single research participant's genetic, imaging, clinical assessment, and other information even if the data were collected at different locations or through different studies. The use of GUIDs keeps direct personal identifiers from ever being transmitted or stored in the NIH NDAR records and thus minimizes risks to study participants. As many subjects have been enrolled in multiple studies (often from different funding sources), the GUID ensures that each individual can be tracked across multiple research projects. NDAR is scheduled to begin to provide data available for broad research access in 2010. NDAR agreements with 54 NIH-supported studies should ultimately yield data from 45,000 human subjects, and by federating with other federal and private databases, NDAR anticipates acquiring data from another 25,000 people with ASD. This wealth of data will serve to stimulate ASD research and research collaborations not only in the United States, but also around the world.

⣿
Research Gaps and Opportunities

What is missing in the current federal approach to ASD? As noted above, ASD research is supported by many groups, both federal and private. The increase in private funding for ASD research and the success of advocacy groups in educating families about ASD research and services attests to the importance of a combined public–private effort to: *(a)* provide synergy for areas of need, *(b)* reduce redundancy in funding, and *(c)* to identify gaps that may be served better by either private or public funding. For instance, the need for biobanks for ASD research can be fulfilled by a combined outreach effort from advocacy groups using federal funds to supply the needed infrastructure for storing and distributing tissue. In the future, the coordination that has developed via the IACC for federal partnerships needs to be extended to ensure close working relationships with private funding organizations.

In contrast to many other childhood-onset disorders, such as Type 1 diabetes or asthma, there is relatively little investment in autism research within either the biotechnology or the pharmaceutical sectors. This may reflect the state of the science—there are no molecular targets yet for drug development—or it may reflect a historical bias toward behavioral and rehabilitative approaches to ASDs. Increasing private interest in Fragile X syndrome and Rett syndrome suggests that the emergence of molecular targets for autism will instigate growing interest in ASD from biotechnology and pharmaceutical companies in the near future. This is particularly important given the absence of medications for the core symptoms of ASD. Although NIH research traditionally identifies potential new targets for medications, the private sector has usually taken the lead in product development efforts.

Finally, much of the surge in NIH funding of ASD research was made possible with ARRA money which arrived just after the release of the IACC strategic plan. ARRA funds are, however, limited to 2009 and 2010. Although there has been an increase in NIH funding of ASD research using non-ARRA funds, this increase will not substitute for the loss of ARRA in 2011. This means that a decrease in total funding for ASD research is expected at NIH just as new scientific opportunities and needs arise from updates of the strategic plan. Following the ARRA surge in funding, the IACC may need to set priorities for its objectives in order to advise funding agencies about the optimal use of funds.

⣿
Conclusions

Most discussions of the federal role in ASD research focus on funding. Although money is necessary for scientific breakthroughs, it is never sufficient. Some of the most important medical advances of the past century, such as the polio vaccine, have used little federal money (Oshinsky, 2005) and

others were serendipitous or resulted from small clinical studies, such as the discovery of the bacterial cause of peptic ulcers (Marshall & Warren, 1983, 1984). Base funding for ASD research at NIH has more than tripled in the past decade. If the the additional funds provided by ARRA are also taken into account, the overall increase in NIH funding for ASD was nearly fivefold between 1999 and 2009.

Enhanced funding has the potential to increase the number of scientists working on ASD and attract scientists from other fields into ASD research, but it cannot ensure breakthroughs. We have learned from other areas of biomedical science that basic science, often seemingly unrelated to a clinical problem, can reveal the critical opportunity. Translational science that builds on basic insights and uses new tools, such as induced pluripotent stem cells (Takahashi et al., 2007; Yu et al., 2007) can be the bridge between the laboratory and the clinic. And paradoxically, clinical research, which seems the most urgent and most likely to yield immediate benefit, may be the most frustrating in the search for breakthroughs. Nevertheless, clinical research will be the only way to discover biomarkers, to demonstrate the efficacy of a new treatment, or to understand which intervention will be best for any specific individual with an ASD. The federal ASD research enterprise, in partnership with private funders and with guidance from the IACC, aims to support a diverse portfolio of science, from basic to clinical, with a coordinated, strategic approach that ensures that the available funds are used for optimal public good.

⣿
Challenges and Future Directions

- Supporting a diverse portfolio of basic to clinical research to enable advances in: diagnosis, understanding the underlying biology of ASD, identifying risk factors and biomarkers, developing effective treatments and interventions, services research, and research on lifespan issues.
- Building new partnerships between federal agencies and private organizations to enable both research and the development of needed research infrastructure (i.e., database networks and biobanks).
- Identifying molecular targets for potential drug therapies, which would bring biotechnology and pharmaceutical companies in as partners.
- Judiciously using federal funds and partnering with private organizations to build on the discoveries made through ARRA-funded grants, whose funding was a special 2-year opportunity enabled by the American Recovery and Reinvestment Act of 2009.

80   Craig Snyder, Peter Bell

To Petition the Government for a Redress of Grievances

Two anecdotes, separated in time by a little more than a decade, illustrate just how far the autism community has come in advocating for the attention and assistance of the federal government.

October 1997—Just 2 years after it was founded, and with a total budget hovering around a million dollars, the autism advocacy organization, Cure Autism Now (CAN) had just hired a Washington lobbyist to try to get the government of the United States to do something, do anything, about the clearly growing number of children being diagnosed with autism.

CAN's cofounders—Jonathan Shestack and Portia Iversen—were seasoned Hollywood figures, whose world came crashing down in 1994 when their 2-year-old son, Dov, was diagnosed with autism. They had been shocked to find that very little was known about the causes of autism. To make things worse, the only effective treatment available, Applied Behavior Analysis (ABA), wasn't even covered by health insurance.

No group in America, not even 13-year-old girls swooning over the latest boy band, was more gaga over mixing with celebrities than the powerful lawmakers of Washington. Elected officials have a sort of fame themselves, but no glamour. And these people who actually run the world are drawn, as if by gravity, to the orbit of the stars residing on the Left Coast (a.k.a. Hollywood).

So a young lobbyist—1 month into private practice following a stint as chief of staff for a prominent U.S. senator—managed to get an audience with the new chairman of the Senate Health, Education, Labor and Pensions (HELP) Committee, Senator Bill Frist (R–TN). One year prior, Senator Frist had become the first medical doctor elected to the Senate in a century. The meeting took place in an uncommon venue. Not in the chairman's Capitol office, but rather he was invited to a VIP tour of the set of the NBC television series *ER*. He was a fan of the popular show, and the opportunity to hold our meeting in the fictitious doctor's lounge on the *ER* set, hosted by "Dr. Green" (played by actor Anthony Edwards), was irresistible.

Senator Frist didn't know much about autism. Being a doctor in an unrelated field (heart surgery in his case), in those days, barely gave one a leg up in background on the subject over any layman. The essential reference point on autism at that time was still Dustin Hoffman's character in the 1988 movie *Rain Man*.

But Senator Frist was a good listener and quick study. It was clear—much to the surprise of a liberal Democrat like Shestack (who expected nothing could really get done for autism while Republicans controlled Congress)—that this man, who went to Africa during Congressional recesses to operate by flashlight on the sickest of kids in the remotest of villages, wanted to walk the talk of his professed Christian Conservatism in his new role as America's most powerful legislator on health policy.

"Okay," he said, "I got it. There's a new epidemic of autism. No one knows why. The NIH is spending very little on research. The CDC isn't even trying to figure out accurate prevalence numbers. The federal government has a role, a responsibility."

"But what do you want specifically?" he asked.

"A law about autism," we told him. "A piece of legislation detailing and authorizing funds for a federal effort to combat autism."

"Impossible," he replied. "Congress doesn't, won't, just can't pass 'single-disease' bills. My Lord, if Congress started doing this, it would be all we ever did. And we shouldn't do it. Politicians shouldn't start telling scientists what to do based on which group of sufferers screams the loudest, hires the best lobbyists and—irony noted—gets the best celebrity meat to promote their cause."

"Still, this autism thing sounds bad," he added. "Work with my staff. We'll figure something out."

October 2008—It's the Thursday before the Tuesday of Election Day, the final weekend before America will choose its 44th president.

Barack Obama probably has the race won but his campaign is taking no chances. His disciplined, methodical staff will leave no votes on the table that may still be persuadable.

Polls show six states still too close to call. Theoretically, their electoral votes constitute enough uncertainty to determine the outcome by some models. One of these states is Nevada, where a prominent autism advocate is pressing the Obama team for more detail on the candidate's platform about autism than had hitherto been published. So Obama's staff releases to this parent activist a previously undisclosed draft bill.

In his capacity as a sitting senator, Obama (D–IL) has written a bill to expand and intensify the federal fight against autism. Most notably, the proposed legislation includes a provision to mandate that all health insurance policies in the nation must provide coverage for autism services, including the current, expensive, gold standard of care, Applied Behavior Analysis.

The internet lights up with the news. Short of a cure, the greatest single relief possible for the families grappling with autism is an insurance mandate. Providing coverage for evidence-based, medically necessary therapies would end the nearly universal discrimination against people with autism and help those suffering from the disorder to lead lives of the highest possible quality.

Within hours, supporters of Senator John McCain (R–AZ) within the autism community have the Obama bill in front of GOP vice presidential candidate, Alaska Governor Sarah Palin (R–AK), whose sister has a child with autism, and the McCain campaign is pondering a response.

At the highest levels of American politics, within the inner circles of both major party candidates for president of the United States, among the final tactical decisions being discussed during this historic race, are about autism—not about cancer, AIDS, Alzheimer's, not even solely about Iraq or the economy—but about autism.

The next day, which happens to be Halloween, the Obama campaign offers a final pre-election treat to America's kids with autism, and all of those who love them—the Obama platform statement on autism, published on www. ObamaForAmerica.com, is amended to promise that, as president, Obama will "mandate insurance coverage of autism treatment…."

So we've come quite a distance in just a decade, along the path of securing a public policy commitment to fight autism—from a bizarre meeting with a senator, caring, but largely naive about autism, to substantial attention from the new President of the United States.

How did it happen?

The most powerful source of the progress is nothing to celebrate. It is the autism epidemic itself. It is the fact that parents find themselves in every corner and at every level of American society—from West Nowhere to the West Wing of the White House—raising kids with autism, in such numbers

and with such social and economic impact, that the problem can simply no longer be ignored.

Prevalence produces awareness. But that alone is no guarantee of the kind of consciousness that ignites action. And on this score there is much for the autism community to be proud.

The United States Constitution guarantees to every American the right to petition the government for the redress of grievances, and many do so with passion and conviction. On most days, the Capitol complex in Washington, D.C. seems under siege with people wearing this or that hat, ribbon, or sash, lobbying for this or that cause. It's inspiring and infuriating at the same time.

But for more than a decade now, ever since that meeting on a Hollywood sound stage with Senator Frist, no group of ordinary Americans has more consistently and capably petitioned their government than the families affected by autism—whether their "kid" is 2 or 42 years old.

Of course, parents of this recent generation (children born in the 1990s and after)—with all of their fervor and refusal to accept defeat—have stood on the shoulders of the even more isolated and ignored generations of parents who raised their children with autism when it was considered rare and the result of bad parenting. These earlier advocates helped establish special education in our schools and saved many children from our society's shameful waste pail.

And, against that truly heroic backdrop, the present generation of parents—more numerous and more connected (by technology)—have worked, rallied, and sang. They have written, faxed, and emailed. They have testified with poignancy, argued with rigor, and dug deep to contribute to friends. They have been marvelous and utterly unflappable.

And with no disrespect to many other worthy and effective lobbying groups, heaven help the politician who gets in the way of a mom trying to help her child with autism.

In one instance, symbolizing countless others, Elizabeth Emken, a CAN volunteer from Northern California and mother to then 6-year-old Alex with autism (later vice president for government relations at Autism Speaks (AS) and a self-taught lobbyist, in the way Abe Lincoln was a self-taught country lawyer), went to meet with Senator Arlen Specter (R–PA). Specter then chaired the Appropriations Subcommittee, which funds all federal health agencies and, as such, is constantly lobbied by representatives of every disease that afflicts the human race.

Senator Specter has been a tireless and singularly effective champion for expanded funding for biomedical research, being largely responsible, along with Senator Tom Harkin (D–IA), for more than doubling the budget of the NIH from $12 billion to $30 billion per year.

He is, however, equally legendary on the Hill for his brilliance and for his temper, and Ms. Emken first met him on a bad day.

It turned out the inopportune moment for this meeting was just following an interview of the senator by ABC News in which he was ambushed and harshly criticized for supposedly dividing up medical research dollars based on which diseases

had the biggest celebrity spokespeople. When Ms. Emken tried to present her case, with actor/autism advocate Anthony Edwards at her side, the senator cut her off in mid-sentence and, red-faced, excoriated her for being before him with a request on autism funding levels.

Mama lion had no thought of herself, only of her cub. She got very close to the senator's face and said with as much grace as tenacity, "Are you telling me that the mother of a sick child has no right to ask for help from the people elected to serve our nation, no right to come here and educate you about the needs of these suffering families and, about the proper role of your office in overseeing what the bureaucrats are doing with my dollars?"

The senator, who was in truth already on Elizabeth's side, has been even more so ever since. Through the work of so many parents, in so many meetings, is how autism became a national public health priority, at least in Congress.

And the emergence of autism as such marks a good moment both to look back on accomplishments in autism advocacy to date and also to look forward to the continuing agenda.

Why Lobby?

Why has it been necessary for parents to march and mobilize and for lobbyists to be engaged and deployed on autism? Surely the federal government agencies charged with the public health of the nation—principally the CDC and the NIH—should have detected the coming tsunami, understood its social and economic costs, and set about to do their jobs. Well, maybe not.

At a minimum, it is the CDC's job to know about trends in morbidity, to count Americans who suffer from various maladies and track patterns as they take shape. A host of federal programs—from Medicaid to various programs relating to housing and vocational training—are responsible for assisting disabled Americans to live their lives with the highest quality possible, given their limitations. And, of course, it is the job of the NIH to find the causes and ultimately the treatments and cures for disease, so the other agencies will have fewer to count and rescue.

Before the late 1990s, when the autism community began to aggressively lobby for more research in Washington, virtually none of this was happening. The CDC had no plan to undertake epidemiological work on autism prevalence or patterns, the human service agencies had no focused efforts on autism and the NIH was spending, at best, about $5 million to $10 million per year on autism research. Although using very meager funds, scientists had made significant progress in developing reliable diagnostic instruments, defining the symptoms and characteristics of the disorders, documenting its association with certain biological features and a genetic etiology, and developing what remains to this day the most effective intervention for autism (Applied Behavioral Analysis), their efforts before the 1990s were greatly hampered by a lack of adequate funding and awareness of autism

as a major public health problem. Because of the lobbying efforts that began in the mid-1990s that led to enhanced funding, as well as the advent of a wide range of new technologies that allowed scientists for the first time to study brain function and explore the genome in detail, a new era of autism research has emerged that rests on the foundation built by earlier science. This research holds the promise to discover the causes, more effective treatments, and hopefully, a cure for autism.

Before the late 1990s, there simply was no federal recognition of the urgency of the growing autism epidemic and no plan to respond with appropriate resources. Almost everything that has been done recently to combat autism results from parents lobbying Congress and Congress therefore compelling the executive agencies to do what needs to be done—with those agencies, inexplicably continuing to this very day, fighting a rear-guard action against the mandate of Congress to take autism more seriously.

In this story lies a perfect case study of the failure of bureaucratic institutions to remain true to their missions. The federal public health apparatus has failed the autism community and the nation at large with every effort they have made to avoid or minimize work on autism, displaying a greater concern for maintaining their fiefdoms as independent centers of power than for doing the very things they are in business to do.

On autism, we should all be thankful for the American right to lobby. The ability of the autism community to persuade Congress to pass pieces of legislation dealing with autism, and to appropriate funds to carry out autism activities has been the locomotive of autism progress.

Foundational Accomplishments

Thus far, autism advocates have convinced the federal government to pass two landmark bills that have benefited their loved ones with autism—the Children's Health Act of 2000 and the Combating Autism Act of 2006. The community has also won the attention and action of the Pentagon by obtaining critical funds for autism research through the Congressionally Directed Medical Research Programs (CDMRP).

These acts of legislation and appropriations constitute a federal declaration of war on autism, the disorder and not those living with autism. They embody national recognition of the urgency of the autism epidemic and they begin the process of deploying a scale of resources appropriate to the problem.

The Children's Health Act of 2000

Senator Frist's brilliant (in the "through-the-looking-glass" world of Washington) solution to the problem of how to legislate on autism, when Congress can't and shouldn't legislate about a "single disease" (his view and the "rule" until then), was to put together a bill about many single diseases.

The Children's Health Act of 2000 (CHA) had more than 20 titles, each in essence a wholly distinct piece of legislation

about a separate disease. In addition to autism, which was given the honor of being Title I, the law cobbled together previously separate proposals on things ranging from infant hearing screening to asthma to head injuries.

The autism advocates, frankly, didn't care. Frankenstein might not be handsome, but he did come to life. Likewise, what they wanted—a law to kick-start federal efforts on biomedical research and epidemiology on autism—would get signed into law by the president.

The main features of the CHA title on autism included:

- Direction to the NIH to expand, intensify, and coordinate the activities of the NIH with respect to research on autism.
- Establishment of Autism Centers of Excellence to conduct basic and clinical research into autism and required communication and cooperation among centers.
- Requirement of NIH to provide for a program under which samples of tissues and genetic materials that are of use in research on autism are donated, collected, preserved, and made available for such research.
- Mandating a means through which the public can obtain information on the existing and planned programs and activities of NIH with respect to autism.
- Direction to the CDC to establish three regional centers of excellence in autism and pervasive developmental disabilities epidemiology for the purpose of collecting and analyzing information on the number, incidence, correlates, and causes of autism.
- Creation of a clearinghouse within the CDC for the collection and storage of data generated from the monitoring programs established by the act.
- Establishment of an Autism Coordinating Committee to coordinate all efforts within the Department of Health and Human Services concerning autism.

The path to the enactment of the CHA was the proverbial "long and winding road." There are no straight lines between a policy objective and a public law, but the course of the CHA was extraordinarily complicated because it involved so many distinct interests.

At first, the effort faced the usual obstacles that cause so many bills to languish. Most importantly, there is the conventional wisdom (and the cold reality on which that wisdom is based) that the vast majority of legislation introduced in each Congress simply dies. Added to that was the sense that the CHA was especially ambitious.

If there was any one area in which the Clinton White House and the Republican Congress had never seen eye-to-eye—and therefore in which little policy making actually got done—it was health care.

Therefore, the early phase of autism community lobbying for the CHA had to follow the motto of "slow and steady." Relationships had to be built and cosponsors were added one office visit at a time.

Although Senator Frist had come up with the concept of the CHA—putting together a number of previously

free-standing legislative proposals loosely related to one another around the concept of children's health—autism advocates thought it best for there to be a separate, free-standing autism bill for which they could seek cosponsors, in order to show a significant and always growing number of supporters in both the House and Senate.

The free-standing bill—which then became Title I of the CHA—was called the "Advancement in Pediatric Autism Research Act." It was first introduced in the Senate, by Senator Slade Gorton (R–WA), and next in the House, by Congressman Jim Greenwood (R–PA).

Interesting events accompanied both introductions.

What happened on the Senate side—the run-up to Senator Gorton's introduction of the country's first piece of legislation about autism—was both dramatic in real life and later dramatized (overly dramatized, actually) in an episode of the NBC television series *The West Wing*.

The choice to ask Senator Gorton to take the lead on autism issues in the Senate was made for sound but prosaic reasons. He was known as smart and hard-working and as a tough conservative. Sponsorship by someone on the right, we thought, would send a strong message that concern for autism was not simply another bleeding-heart federal-spending exuberance.

He was a member of the committee of jurisdiction, the HELP Committee. He was friends with the majority leader, Senator Trent Lott (R–MS) (and the leader would ultimately decide, as anyone in that position does for any bill, whether it would ever be brought to a vote on the floor of the Senate). Additionally, some members of CAN's lobbying team had experienced past friendly dealings with Senator Gorton's chief of staff, Tony Williams. This increased the probability of getting a fair hearing in trying to persuade the senator to become their champion.

The initial meeting with Mr. Williams produced the unexpected turn-of-events, which ultimately would lead to a portrayal on national television.

Mr. Williams listened, with less than his usual patience, to the presentation of the policy concepts behind the proposed autism legislation. He then asked the legislative assistant who handled health matters for Senator Gorton to leave the room. After the door closed, he asked "How did you find out?"

It seems that a grandchild of the senator's had recently been diagnosed with autism—a fact that had not yet been publicly reported and which the senator and his family were not at that moment ready to reveal.

The honest truth—still doubted by many more than a decade later—is that the advocates had no idea.

Call it luck, karma, or just coincidence, but the autism advocates had stumbled into asking a powerful member of the Senate to sponsor the first ever piece of legislation about autism just as he was coming to grips with life as the Senate's only grandfather of a child with autism.

They never learned all of the personal details—and never asked—but it was soon clear that the senator's wife and daughter would accept nothing less than that he enthusiastically support the proposed legislation. And he did just that.

On the House side, the drama to give birth to the first autism bill was much more commonplace, and yet more potentially harmful to the project.

Congressman Jim Greenwood was a highly regarded "moderate" Republican, a member of the Health Subcommittee of the House Commerce Committee, and someone with a long record of work on children's health issues. Prior to serving in Congress, he was a social worker who had close contact with children and adults on the autism spectrum. He was a natural target for the autism advocates as the leading House player on the bill.

However, Congressman Chris Smith (R–NJ) wanted in on the action. Representative Smith's district includes Brick Township in New Jersey, where in the late 1990s, alarms had gone off, heard around the nation, about an unusually high rate of autism–a so-called "cluster." Naturally, wanting to serve his constituents, Congressman Smith saw himself as leading any House efforts on autism. Indeed, he eventually created—along with Congressman Mike Doyle (D–PA)—a Congressional Autism Caucus known as Coalition for Autism Research and Education (C.A.R.E.), which members of Congress could join as an expression of their concern about autism as a public health issue.

Going to Greenwood was never meant to disrespect Smith. Nonetheless, a turf struggle emerged.

As in many such instances, the path of political compromise often does coincide with doing the right thing.

The initial version of Representative Greenwood's bill had only included provisions relating to biomedical research at the NIH. Representative Smith's separate bill, however, required action by the CDC—meaningful epidemiology on autism.

In committee, it was agreed to combine the two bills and to speak of the new product, as was correct, as having been jointly authored by Congressmen Greenwood and Smith.

This combined Greenwood/Smith bill became the one introduced by Senator Gorton in the Senate. And that, in turn, became Title I of the Children's Health Act, once Senator Frist had agreed to go forward in that fashion.

There is a curious thing in the life cycle of a legislative initiative in Washington. Often, the chances for enactment of a bill go from being impossible to inevitable with nothing apparent in between.

And so it was with the CHA.

Many of the disparate interests whose causes stood to benefit from passage of the bill formed a coalition to get it done. There was strength in numbers. As a result of this multi-pronged lobbying effort, many members of Congress became cosponsors—perhaps not agreeing with or even being fully aware of all of the provisions of the bill—but committed to the enactment of some particular piece within it.

Even though the CHA was now "real," with a perceived high chance of passage, another curious legislative phenomenon kicked in—people throwing unrelated baggage onto the moving train, some of which contained bombs that could have derailed the whole vehicle.

In the end game of the passage of the CHA, the fall of 2000 was of course an election year, and the CHA became, at times, a hostage, and a potential murder victim, of both the Right and the Left.

The strongly pro-life Chairman of the House Commerce Committee, Representative Tom Bliley (R–VA), insisted that the bill include a provision promoting adoption (but also involving very controversial requirements for counseling women seeking abortions regarding adoption). The liberal lion (and Dean of the House of Representatives) Representative John Dingell (D–MI) insisted that that bill include his favorite provisions aimed at stopping Americans from smoking and various forms of gun control.

With fights over abortion and guns—there were certainly moments when it seemed all too much weight for our program to improve and expand research on autism to bear.

But the momentum of the moving train proved quite strong. In the end, everyone compromised—Bliley and the pro-choice groups reached an accommodation on language (through spectacular negotiating by Jim Greenwood) and Congressman Dingell relented under a crushing pressure of public support for passing the CHA.

President Clinton signed the CHA into law during the transition after the election of President Bush. It was widely heralded as the only significant health-care legislation which the combination of the Clinton administration and the Republican Congress had been able to achieve.

In his signing message, President Clinton gave credit for the bill to his wife—who was then just about to become a candidate for Senate from New York.

In truth, Mrs. Clinton, as first lady, had limited involvement in the process. But the autism community welcomed her desire to become a champion of the cause—something she went on to embrace with enthusiasm and skill as a senator and a candidate for president in more recent years.

The Combating Autism Act of 2006

The CHA was a breakthrough, to be sure. Without question, additional funds were spent on autism research—both biomedical and epidemiological—than would have been absent the law and the continued advocacy throughout its 5-year term to appropriate the authorized amounts. The work of the Autism Centers of Excellence (ACE Centers), created by the act, helped build the cadre of scientists willing to work on autism and, in turn, basic medical knowledge about the disorder which those scientists generated. CHA funds also got the CDC into the autism surveillance business in a measurable way and led to the first standard data point for autism—that one in 150 children in America have an autism diagnosis.

By the end of the 5-year authorization of the CHA, autism awareness, both popular and political, had grown enough that the advocates were confident about seeking to reauthorize and expand the federal autism legislative commitment through the vehicle of a true "single-disease" bill.

By this time, a new powerhouse of an organization, Autism Speaks, had been created and brought great resources to the

table, both material and perceptual, than the prior organizations. CAN and Autism Speaks entered into a formal partnership, which would become a prelude to their ultimate merger, and the whole proved greater than the apparent sum of the parts.

At the beginning of the effort, it was still very much an uphill battle. The arguments we had heard from Senator Frist, back in 1997, about why Congress couldn't and shouldn't pass such bills were still the position of all the Congressional leaders and committee chairmen who would be relevant for this process. Still, life is easier when you have no choice, and we faced the apparent "catch 22" that although single-disease bills were still a taboo, we were also told there was no appetite for another multidisease Frankenstein like the CHA.

The lobbying effort took two years and, just like its predecessor, had many twists and turns. The bill died far more times than it passed.

Perhaps the two most notable obstacles that had to be overcome were Senator Tom Coburn (R–OK) and Congressman Joe Barton (R–TX).

Bills like this—which are wrongly perceived as special-interest favors—are almost never brought to the Senate floor for a full-fledged process of debate, potential amendment, and a vote on final passage. They are passed by *Unanimous Consent* (UC). That means that any single senator can kill a piece of legislation by withholding his or her consent.

In the fall of 2006, with a Congressional election upon us and Republicans justifiably nervous about substantial losses, owing to the rapidly declining popularity of President Bush and the war in Iraq, the business of the Senate had stalled, even more than usual.

The Combating Autism Act (CAA) had prime sponsorship by Senator Rick Santorum (R–PA), the third-highest ranking member of the Majority Republican Caucus, who was in deep trouble in his own re-election effort. Generally, someone in a position like that gets whatever he wants from other members of his party.

The CAA also had the support of HELP Committee Chairman, Senator Mike Enzi (R–WY), whose staff had labored diligently and brilliantly to produce a single-disease bill for which it was worth breaking "the rule." It also had the support of the majority leader—the position to which autism's old friend Senator Frist had risen.

On the Democratic side, Senate Minority Leader Harry Reid (D–NV), committee ranking member, Senator Edward Kennedy (D–MA), and original Democratic bill sponsor Senator Chris Dodd (D–CT) all wanted to get the bill passed—defying the conventional approach of wanting to deny the vulnerable Santorum anything good on which to campaign back in Pennsylvania.

With such a constellation of supporters, what could go wrong?

Tom Coburn.

Senator Coburn—a hard conservative and budget hawk, believed the rule against single-disease bills should remain unbroken. He also believed that the new spending authorized in the bill—slightly over $1 billion during the 5-year

term— was too much money. He was impervious to all arguments about the growing prevalence and public costs of autism. He was just against any new government spending, on pretty much anything.

Senator Coburn was approached by Majority Leader Frist and cajoled by Committee Chairman Enzi, to no avail. Finally, just before the Senate would recess for the 2006 elections, Senator Coburn was begged by Senator Santorum, and he traded something—we still don't know precisely what. Senators Santorum, Enzi, and Frist agreed to reduce the authorized spending levels in the bill by $100 million, bringing the total under $1 billion and Coburn agreed to release his hold.

The details of the dollar cut were executed between staff, on the floor of the Senate and with autism advocates on the telephone. There was no rational basis for the cuts. It was pure sausage-making.

But the bill passed the Senate unanimously.

When transmitted to the other side of the Capitol, it was dead on arrival. The Chairman of the House Commerce Committee, Representative Joe Barton, shared the same beliefs about single-disease bills as did Senator Coburn, and he had the gavel of the committee, which would have to act on the bill before it could ever get to the floor of the House.

The autism community was frankly merciless and relentless in its efforts to persuade Mr. Barton.

Protestors staged acts of civil disobedience in his district offices and used the then-new technology of YouTube to show the world images of their being arrested for trying to visit with their congressman on the subject of their sick kids.

A group of Texas moms protested the arrival of the Speaker of the House, Congressman Denny Hastert (R–IL), at a fundraiser on behalf of Barton's re-election campaign.

The constant deluge of phone calls to the Barton offices overwhelmed the switchboards and reduced receptionists to tears.

And last, but certainly not least, radio and television personality Don Imus practically burned Barton in effigy on his national airwaves every day for more than a month.

In the end, there was an accommodation. Congressman Barton was able to maintain the principle, as he saw it, that Congress should not authorize appropriations for the NIH to conduct research on a specific disease. Instead, the bill as passed by the Senate was modified in the House to authorize appropriations for the purposes of the act—including biomedical research by the NIH—with the appropriations authorized to be spent under the control of the secretary of Health and Human Services, rather than the director of the NIH.

Another "perfect 10" Washington gymnastics routine. Just as Senator Frist had been willing to pass a bill about a bunch of different diseases because he was unwilling to pass a bill about any single disease, Barton was willing to pass a bill that gave the Department of Health and Human Services (of which the NIH is an organic and subordinate part) authorization to spend money on autism because that money was not specifically identified to be spent by the NIH.

More sausage, but another historic victory.

The CAA is arguably the most comprehensive single-disease bill ever adopted into law. Its main features include:

- Elevation of ownership of the federal response to autism from the NIH director to the HHS secretary.
- Authorization of nearly $1 billion over 5 years to combat autism through research, screening, early detection, and early intervention—at least a 50% increase.
- Expansion and intensification of biomedical research on autism, including an essential focus on possible environmental causes.
- Broadening of training opportunities to increase the number of sites able to diagnose—under such program, trainees receive a balance of academic, clinical, and community opportunities.
- Promotion of research into best practices and to determine evidence-based interventions.
- Requirement of the CDC to support collection, analysis, and reporting of state data and award grants for regional centers of excellence.
- Direction to the Interagency Autism Coordinating Committee (IACC) to provide information and recommendations on programs, and to develop and annually update a strategic plan for autism research, including proposed budgetary requirements.
- Requirement of the IACC to have increased and mandatory public representation—at least 1/3 of the committee—including an individual with an autism spectrum disorder (ASD), a parent of an individual with an ASD, and a representative of leading research, advocacy, and service organizations for individuals with ASDs.

Department of Defense Funding

In the early 1990s, advocates for increased federal spending on breast cancer research came up with a brilliant—even if theoretically questionable—strategy. There is only so much money in the NIH and it is hand-to-hand combat among the disease groups for control of that money.

Despite the pretense that the NIH allocates funds based only on scientific promise, the process is intensely political—actually involving many kinds of politics, among which any alleged meddling by elected officials may well be the least intrusive and offensive.

The kinds of politics that determine disease funding include: which universities have more clout and better relationships, which individual scientists establish themselves as thought leaders in their fields, and which bureaucrats within the NIH are better at building their individual power bases.

Given all the limits—both in terms of aggregate dollars and in terms of the number and sharpness of knives slicing up the NIH pie—breast cancer advocates looked to the Department of Defense (which, of course, has historically spent significant sums on battlefield-related medical research and the actual provision of healthcare) as fertile ground for an end-run around the NIH.

These advocates got an astounding $150 million appropriated to be spent by the Pentagon on research for breast cancer. That sum has been reappropriated—and grown—every year now for the better part of almost two decades.

Thus was born the Congressionally Directed Medical Research Programs (CDMRP) in the Pentagon's budget—a mini-NIH for the diseases whose supporters can get Congress to pony up.

On the very general argument that the America that was once defended with a force of volunteers no longer primarily sends to war unattached 18-year-old men, but rather has an obligation to the needs of the families of servicemen and service-women who are, in effect, part of our current fighting forces, nearly any health-care research can be justified as potentially effecting the morale and readiness of the troops.

Led by the National Alliance for Autism Research (NAAR) (another major pre-Autism Speaks research and advocacy group, since also merged into AS) that was what the autism community repeated in order to finally be admitted to this club in fiscal year 2007.

Current best estimates are that there are approximately 8,000 minor children of active-duty military personnel afflicted with autism. The pressures on kids with autism participating in military life, with frequent moves from base to base, even country to country, are enormous. So the Pentagon budget now includes support for autism research.

One of the unique aspects of the CDMRP for autism research is that consumer advocates (consumers) are active participants in virtually all aspects of the program execution. The consumers represent the voice and vision of individuals affected by autism and they work collaboratively with leading scientists and clinicians in setting program priorities, reviewing proposals, and contributing their unique perspectives and a sense of urgency to program processes.

To date, about $30 million has been appropriated to the Department of Defense (DOD) Autism Research Program. The program mission is to "promote innovative research that advances the understanding of autism spectrum disorders and leads to improved treatment outcomes." Importantly, the research funded by this group is perceived by the autism community as being more innovative, cutting edge, and more likely to produce significant findings than research funded by the NIH. Autism advocates now have, by virtue of the demonstrated success of this program, nothing less than the Department of Defense at their backs to urge similar innovation in autism research at the NIH.

All That Remains

The platform promise by Presidential candidate Barack Obama to secure a federal guarantee of autism insurance coverage was, without doubt, a huge symbolic victory for the community. As already noted, ending the discrimination against those with autism by the health insurance industry— getting

coverage for ABA and other medically necessary, evidence-based treatments for autism—will be the single most important improvement in the quality of life of those facing autism, short of dramatic medical breakthroughs. As of this writing, and following three years of battles, 23 state laws have been enacted along these lines. Collectively, these states represent almost half of the US population. However, this is less than meets the eye, as the reach of each state's regulatory authority over health insurance is generally about 15% to 30% of its own population.

Certainly, despite the great and continuing success of the autism community's state-based lobbying on this issue, the answer to the problem still must be found at the federal level.

In the context of the heated legislative process - the mother of all legislative battles - which led to the national health care reform bill passed in June 2010, the autism community secured language (through the championship of Senator Robert Menendez (R–NJ) and Congressman Mike Doyle) which includes a requirement for the coverage of "behavioral health treatments" in the "essential benefits" package which the law mandates for all those who will purchase their insurance through the newly created health insurance "state-based exchanges".

This is a far cry from a universal federal mandate - principally because the law does not cover the benefits which must be provided by companies which self-insure (and are regulated under the pre-existing ERISA federal statute). This omission occurred as the political popularity of the President's proposals plummeted between the time the House of Representatives passed its version of health reform and the time of the final passage of the bill which became law, through the Senate.

It is not that the appetite of Congress and the President for autism coverage shrank but politics being the art of the possible, the ultimate provision of coverage for autism treatments in the final bill simply shrunk with the downsizing of the overall scope of the legislation.

It therefore remains a principal objective of the autism community going forward to achieve in federal law a universal guarantee of autism insurance coverage. Clearly, those political winds have turned forcefully against any further expansion of federal intervention in the health insurance arena. But autism insurance discrimination remains wrong and the community will continue to seek redress for this grievance.

Beyond insurance, the time is already upon us - and work has already been in progress, as of this writing, for over a year, on the reauthorization of the CAA, with key provisions due to expire in September 2011.

Senator Christopher Dodd, retiring from the Senate as of January 2011, and long time autism champions in the House, Mike Doyle and Chris Smith, have once again signed on to initiate the legislative process for reauthorization.

The principle new facets being sought by the community in the second coming of the CAA include:

- Further reform and rationalization of the administration of federal autism research efforts. Although most lobbying in Washington can really be reduced to every group wanting more money, the autism community has come to understand that without a more thoughtful approach to how research dollars are spent, greater spending by itself might well produce almost nothing tangible for those living with autism.
- Expand (to a scale equal to the challenge) and coordinate federal service delivery efforts with respect to the lifelong needs of those with autism. From housing, to transportation and vocational training, people on the autism spectrum have needs that change throughout their lifespan that our society has an obligation to address. Providing appropriate services can also reduce overall social costs by maximizing not only the quality of life of adults with autism, but their ability to be productive members of their communities.

In addition to insurance and the CAA, the ambitious, but warranted, agenda of the autism community for continued expansion in the federal response to autism also includes the enactment of a tax-preferred savings vehicle for the long-term financial needs of those with autism. At present, the federal tax code provides preferential treatment to the most able and advantaged of America's children—those who will go on to 4-year colleges. Yet the code offers nothing to help with the long-term financial needs of America's disabled children, including those with autism. Again, this is an area where the equities and efficiencies of the policy position urged by the autism community are both clear.

Conclusion

By the relevant standards of comparison, the autism community's advocacy efforts in Washington have been fantastically successful over the last decade. The community now is perceived to have a degree of political clout that leads to the ability to get things done.

Still, as the autism epidemic has progressed, with no cure yet in sight, the work is just beginning.

As all sides in the titanic debate over health reform—perhaps the only thing on which they do—is that the greatest long-term threat to the economic health of the United States is unfunded liabilities for medical (and related social) needs in the middle of this century. Certainly, the aging of our population is one of the main factors in this looming crisis. But so is autism. With at least one in 110 Americans born today predicted to be diagnosed with autism (1 in 70 boys), there is a surging cadre of people with a lifetime of expensive necessities.

Public policy to respond to these threats—and all the other problems we face as a nation—tends to be made in ways that aren't pretty. But, so far, autism advocacy has achieved great things in notably honorable ways. And it needs to keep doing so.

Top Priorities for Autism/Asperger's Research: Perspectives from a Person with Autism

Points of Interest

- A top research priority is sensory oversensitivity.
- Research participants with autism or Asperger's Syndrome must be assigned to studies based on their specific sensory problems.
- The different type of sensory problems are visual, auditory, tactile, taste, and vestibular problems.
- Individuals on the autism/Asperger's spectrum need to be taught job skills such as being on time, doing things that other people want, and good manners.
- Factors that help individuals to be successful are using obsessions to motivate learning job skills and having mentors who provide instruction in career-relevant skills.
- The three kinds of specialized minds are: *(1)* Photo-realistic visual thinkers, *(2)* Pattern thinkers (music and math minds), and *(3)* Verbal specialists (facts minds).

I was born in 1947 before many doctors knew what autism was. Fortunately, when I was 2 ½ year old, I was taken to Boston Children's Hospital to see Dr. Bronson Cruthers, a well-known child neurologist. I had all the symptoms of autism—no speech, rocking, a lack of tolerance for being hugged, and no social relatedness. Instead of recommending institutionalization, she referred me to a small speech therapy school that had two dedicated teachers who ran it out of their modest home. Within a year, I was talking. At 3 years of age, my mother hired a nanny who played constant turn-taking games with me and my sister. My early educational program was as good as many programs used today. In this chapter, I offer my perspective, as a person affected by autism, on what I view as the three highest priorities for future autism research: sensory oversensitivity, employment, and cognitive styles.

Top Research Priority 1: Sensory Oversensitivity

Since the mid-1980s, I have been giving talks on my experiences with autism throughout the U.S. and other countries. From a research perspective, I believe a top priority is doing research on sensory oversensitivity problems. Sensitivity to noise, fluorescent lights, scratchy clothes, or strong smells is a serious problem for many individuals with autism and Asperger's Syndrome (Grandin, 1995/2006; Williams, 1994, 1996; Barron & Barron, 1992; Joliffe et al., 1992). Sensory problems are very variable from a minor nuisance to completely debilitating. For some individuals, a noisy restaurant, a sporting event, or a busy office cannot be tolerated. Socializing and employment are extremely difficult for an individual if they are not able to tolerate the environments in which these activities occur.

I have been talking about sensory oversensitivity problems for over 20 years. Why have many researchers overlooked sensory problems? They have done hundreds of research studies on theory of mind and only a handful of studies on sensory issues. The time has now come to change the ratio of the studies. There need to be hundreds of studies on sensory issues and only a handful of studies on theory of mind. Problems with sensory oversensitivity can completely wreck the lives of some individuals on the autism spectrum.

Why are Sensory Issues Neglected?

I think a major reason why sensory issues are neglected is that people who have a normal sensory system are not able to imagine an alternate reality, where a loud noise hurts like a dentist's drill or scratchy clothes cause a burning sensation. Normal people have a huge deficit in sensory theory of mind. They are not able to empathize with an overwhelming intense

sensory experience. First-person accounts published during the last 25 years have described the sensory issues. In my book *Thinking in Pictures*, I reviewed every first-person account I could find that was published before 1995 (Grandin, 1995/2006). There were a bunch of them. Sensory issues are not a new issue. Today on the internet, people on the spectrum describe their battles with sensory oversensitivity.

Oversensitivity vs. Scrambling

Sensory problems are very variable and can range from mild problems with overly sensitive touch to sensory scrambling. Recent studies show that the sensory systems in autism are very abnormal (Kern et al., 2007; Van der Smagt et al., 2007; Leekam et al., 2007 ; Boddart et al., 2004 ; Wiggens et al., 2009). Parents have reported many sensory symptoms (Rogers et al., 2003). In my own case, I have difficulty screening out background noise, and the school bell ringing was like a dentist's drill hitting a nerve. Another individual reported that when other kids spoke, his hearing would either fade out or their voices sounded like bullets (White & White, 1987). Many individuals report that they can see the flicker of fluorescent lights. They say it is like being at a disco and it makes paying attention in a class really difficult. One of my students was a severe dyslexic and fluorescent lights made many classrooms and office environments intolerable for her. She would get so spaced out that she could not think. Another friend of mine who has autism told me that certain rough fabric created a burning sensation on her skin. When I was little, I could not tolerate the feeling of being hugged. I wanted to feel the good feeling of being hugged but the stimulus was too overwhelming. It was like a tidal wave engulfing me (Grandin & Scariano, 1986).

Donna Williams, in her many books, describes becoming overcome with sensory overload and conversations would turn into "blah blah" meaningless noise (Williams, 1994, 1996). When she gets overstimulated she may see colored blobs instead of the objects in the room around her. Sinclair (1992) describes problems with his senses getting mixed up. Other people have described that their hearing fades in and out like a bad mobile telephone connection. Many nonverbal individuals can say only the vowel sounds. I have heard this myself and many parents have reported it. I think the reason why they say vowel sounds results from not being able to hear the consonants.

When I was little, one of my first words was "ba" for ball. My speech teacher helped me to hear consonant sounds by slowing down and enunciating hard consonants. She would say, "c…c… u… p…p," so I could hear the consonants stretched out, and she said each word more slowly. When grown-ups talked quickly to each other I could only hear the vowels. When I was little, I thought grown-ups had a special language that they used with each other. People who remain nonverbal often rely on touch and smell because seeing and hearing is so scrambled and does not provide accurate information. This is why they often smell and constantly touch

things. Tito, a nonverbal adult with autism, told me (via typing) that he saw colors and disjointed shapes. Both Tito (Iverson, 2006; Muckhopadhyay, 2004, 2008) and my dyslexic student are auditory learners. Their visual system often gives them scrambled information so they rely on hearing because there is less distortion. Ceasaron and Garber (1991) and Williams (1994, 1996) all describe a sensory system that is monochannel. Seeing and hearing at the same time is difficult. Sensory information coming to one sense may get mixed up with another sense and one of the sense systems partially shuts down.

Research Difficulties

The extreme variability of autism/Asperger's sensory issues makes research studies difficult. If you examined 20 children labeled with autism, maybe only five or six would have severe visual processing problems like Donna Williams. In my own case, vision is normal. To do meaningful research on sensory issues requires assignment of subjects to experiments by their *specific* sensory problems instead of broad labels such as autism or Asperger's Syndrome. When the general labels are used, a person with major visual processing problems is put into the same study with people like me who have mainly touch and sound sensitivity problems.

The variability of autism spectrum disorders has also made many brain studies difficult. Amaral et al. (2008) reviewed neuroanatomical studies and many studies have had conflicting results. For both sensory and brain studies, autism spectrum subgroups should be identified and assigned to separate studies. Mixing apples and oranges together in the same study introduces so much variability that getting consistent results becomes more difficult.

Occupational therapists have worked for years doing sensory therapies that use deep pressure, swinging, or balancing activities to help individuals with autism to function better. The pioneer in this field was Jean Ayres (1979). People who work directly with individuals with autism know that these therapies are effective but many professionals reject them because hard scientific data are lacking on their effectiveness. This probably results from the great variability in sensory problems. A particular sensory therapy may really help improve the functioning of one individual and have little effect on another. Below is an outline of my three recommendations for sensory research.

1. Participants with autism and Asperger's Syndrome must be assigned to all studies based on their *specific* sensory problem(s). This will reduce variability of the data and make a study more likely to show significant results. Assignment to studies with labels such as autism or Asperger's Syndrome will introduce excessive variability into the data.
2. Studies need to be done with brain scans and other brain function technologies to determine how the brain is malfunctioning compared to a normal child or adult.

A few good studies have already been done. More studies like these need to be funded.

3. Studies need to be done to test therapies for treating sensory problems. Subjects must be assigned to the study by the sensory modality that is abnormal. Individuals should be grouped in categories such as *visual processing problems* or *auditory processing problems*.

How to Identify Sensory Problems

Identifying sensory problems as a tool for assigning subjects to a study can be done with a simple questionnaire and observation of the subjects. Even if these assessment tools are crude, they will be more precise than assigning subjects strictly by autism or Asperger's Syndrome labels. My suggestions below are based on over 20 years of experience talking to individuals on the spectrum and reading first-person accounts.

Signs of Visual Processing Problems

1. Finger flicking near the eyes (nonverbal).
2. Tilts head when reading, looks out the corner of his eye.
3. Avoids fluorescent lights. If the child or adult is verbal, they will tell you that fluorescent lights flicker and bother them (Williams, 1994, 1996). Most likely to be a problem with fluorescents that operate at 50 to 60 cycles. Higher frequencies may have less effect. In the individual who is nonverbal, he will perform more poorly in rooms with fluorescent lights and may have more tantrums. Tantrums may occur more often in rooms or stores with fluorescents.
4. Fears escalators. Individuals with visual processing problems often get scared because they have difficulty figuring out how to get on and off the moving stairway.
5. Acts blind. –The individual may act like a blind person when she goes up or down a strange stairway they are *not* familiar with.
6. Print "wiggles." Verbal individual may report that black print on a white page wiggles or vibrates.
7. Poor night perception. If the individual drives, they often hate driving at night.
8. Dislikes rapid movement. Avoids automatic sliding doors and other things that move rapidly.
9. Dislikes high contrast of light and dark. Bright contrasting colors are avoided. Dislikes multicolored floor tiles and anything that forms a lattice or grid pattern.

From my many conversations with individuals on the autism spectrum, 50- to 60-cycle fluorescent lights are the number one visual sensitivity problem. Another common symptom is the print moving on the page.

Signs of Auditory Processing Problems

1. Auditory threshold for hearing sounds or tones is normal or close to normal but sometimes the individual appears deaf.

2. Cannot hear when there is a lot of background noise (Geder-Salejarvi et al., 2005).
3. Difficulty hearing hard consonants. Hears vowels more easily. Mixes up words that have vowel sound that are similar (e.g., cat, bat, and sat).
4. Verbal individuals have abnormal test results on tests of central auditory processing. The results of my auditory tests are covered in *Thinking in Pictures* (Grandin, 1995/2006). I was shocked at how abnormal they were.
5. Child or adult covers his ears when loud sounds occur. More sensitive auditory threshold (Tharpe et al., 2006).
6. Tantrums are frequent in noisy places such as a train station, sporting events, or very loud movies.
7. Verbal individuals will tell you that their ears hurt from certain sounds such as smoke alarms, firecrackers, balloons popping, or fire alarms (Grandin, 1995/2006).
8. Verbal individuals will tell you that sometimes their hearing will shut off or change volume, especially when they are in overstimulating environments (White and White, 1987). Their hearing may sometimes seem like a bad mobile phone connection.
9. Difficulty localizing the source of a sound (Teder-Salejarvi et al., 2005).

Signs of Touch Sensitivity and Abnormal Tactile Sensitivity

1. The child pulls away when hugged by a familiar adult.
2. Constantly takes off all his/her clothes or only certain articles of clothing. Wool and other scratchy materials cause the most problems.
3. A verbal individual will tell you certain fabrics cannot be tolerated against her skin. I could not tolerate wool clothes. More sensitive individuals may not be able to tolerate cotton socks that have a coarse texture.
4. The child or adult may seek deep-pressure stimulation and get under heavy pillows, carpets or roll herself up in blankets. The individual may wedge herself in a tight spot such as between the mattress and the box spring. Deep pressure is calming (Edelson et al., 1999; Grandin & Scariano, 1986).
5. The individual may lash out or tantrum when suddenly touched by another person.

Signs of Olfactory Sensitivity and Abnormal Smell

1. Smells of certain substances are avoided.
2. Attracted to certain strong smells.
3. Certain smells can trigger a tantrum.

Signs of Taste Sensitivity

1. Restricted diet; eats only certain foods.
2. May avoid foods with certain textures (Barron & Barron, 1992).

Signs of Balance, Vestibular and Motor Problems

1. Clumsy and/or poor gross motor skills.
2. Difficulty balancing. Tandem walking is difficult (like walking on a tightrope).
3. Does not get dizzy easily after doing activities that would normally cause dizziness.
4. Very sloppy handwriting.

Sensory problems are very variable. I think there is a tendency for the nonverbal individuals on the autism/Asperger's spectrum to have more severe sensory problems. However, I have met many very intelligent high-functioning individuals who have severe debilitating problems with sensory oversensitivity. People like me who think in pictures may have more sensory oversensitivity problems than the type of individual with Asperger's Syndrome who is a more verbal, nonvisual thinker. These verbal individuals know lots of facts about their favorite subjects and are poor at visual skills such as drawing. People like me who are good at visual skills such as drawing often have more sensory problems and higher levels of fear and anxiety.

Research on Sensory Therapies

Problems with visual and auditory oversensitivity need to be researched first because they cause the most problems and can make functioning in a normal work or social environment so painful that the individual withdraws. If a visual therapy such as Irlen colored lenses is studied, only subjects who have visual problems should be included. I should be left out of this study because my answers are all "No" on the visual processing problem symptoms. My dyslexic student really benefited from Irlen lenses and answered "Yes" to all nine of the vision questions. Irlen lenses are pale colored lenses. The person tries on many different colored lenses until he/she finds a color where the print no longer jiggles on the page he/she read. Each person has to pick out the color that works best for them. I have talked to many other people on the autism spectrum who said that they would answer "Yes" on all the questions. If a study is done on auditory problems, I should definitely be included. In my own case, my answers are "Yes" on all the auditory questions except question 8, which asks about hearing shutting off or the volume changing. This occurs in individuals that have more severe problems than I do. To conclude this section, individuals *must* be assigned to studies based on the sensory modality that has a problem. To be involved in a study, the subject should have a "Yes" answer on at least half of the questions. Sensory problems are highly variable. One individual may have severe visual processing problems and another does not.

Practical Tips for Sensory Problems that People Can Do Themselves

These tips have come mostly from my own experiences, as well as those of other individuals on the autism/Asperger's spectrum. The books by Biel and Peska (2004) and Kranowitz (1998) provide additional information.

Visual Processing Problems

1. Wear a hat with a brim when in rooms with florescent lights.
2. Use a lamp with an old-fashioned incandescent light bulb to block out florescent lights at your desk.
3. In a room with florescent lights, sit next to a window.
4. Get Irlen lenses or experiment with different pale-colored sunglasses (Lightson et al., 1999; Evans & Joseph, 2002).
5. Print reading materials on tan, light blue, gray, light green, or other pastel paper to reduce contrast or use transparent-colored overlays.
6. Get a laptop computer to reduce screen flicker. TV monitors and flat panels lit with florescent lights flicker like a strobe. All new computer screen technologies should be compared to a laptop when a person with visual processing problems buys a new computer screen.

Sound Sensitivity

1. Wear earplugs in noisy places. Take them off for at least half the day to prevent hearing from getting more sensitive.
2. Record sounds that hurt the ears on a recording device. The individual with the sound sensitivity problem should play them back at a reduced volume.
3. Loud sounds and noise will be more easily tolerated when the person is rested and not tired.
4. Loud sounds are better tolerated when the individual on the spectrum initiates them.

Touch Sensitivity

1. Deep pressure can help desensitize an individual to touch sensitivity. Most individuals with autism spectrum disorders (ASDs) can be desensitized and learn to tolerate being hugged.
2. Sensitivity to scratchy clothing is more difficult to desensitize. I cannot tolerate anything scratchy against my skin. Washing all new clothing that touches the skin several times before wearing it will make it more comfortable. Remove all tags and wear underwear inside out to get the seams away from the skin.
3. Sensitivity to medical examinations can sometimes be desensitized by applying deep pressure to the area that has to be examined.

Medication Research on Cognition

Some people on the spectrum really need medication. Medication saved me and stopped horrible anxiety and panic attacks (Grandin, 1995/2006). When medication is used,

doctors must be careful to choose medications that do not interfere with the ability of a person to use his brain. I have speculated that visual thinkers like me can often benefit from taking Prozac or Zoloft to stop panic attacks and anxiety. These medications are good because they do not affect the person's ability to work and design things. To avoid agitation and insomnia, people on the autism/Asperger's Syndrome spectrum often need much lower doses of antidepressants.

Some medications could wreck a person's career. I tried Buspar for anxiety and it made me so "spacey" that I would not think clearly. After 1 week, I stopped taking it. Several other people had memory problems when they took Paxil. There is a need for doing research on the effects of medication on cognitive functions. The right medications can work wonders, but the wrong medications could have the person walking around in a fog.

Behavior Problems and Sensory Oversensitivity

When a child or adult has a behavior problem, the question that should be asked is—is the problem caused by sensory problems or is it simply bad behavior? When I was growing up in the 1950s, autism was never used as an excuse for rude behavior or having no table manners. In the 1950s, all kids were taught to have manners and say "please" and "thank you". My strict 1950s upbringing was an important key to my success. My mother recognized my problems with sensory issues and that certain noises terrified me. She knew I could learn to behave myself at a formal Sunday dinner at Granny's because her apartment was quiet. At the circus, I had a big tantrum because of the noise. My mother was observant enough to determine when I misbehaved because of a sensory issue and when I misbehaved because of bad behavior. Sensory issues were never punished. Bad behavior had consequences and the consequence for such behavior was no TV for 1 night. This emphasizes the importance of structure in the upbringing of a normal child, which may even be more important in an autistic child.

Top Research Priority 2: Prepare for Successful Employment

One of my greatest concerns is many individuals with a diagnosis of Asperger's Syndrome may be held back by the label. I was shocked when some social service agency said that only 20% of the people with Asperger's Syndrome can get good stable employment. I do not believe that the prevalence of Asperger's Syndrome has increased. In the past, people with Asperger's Syndrome were called "geeks" and "nerds." Most of the older people with Asperger's Syndrome who were born before 1970 are in the workforce in good jobs they have kept for many years. I can remember kids I went to school with who may be labeled as having Asperger's Syndrome today.

One has a good job as a psychologist with a PhD and the other has kept good retail jobs with full health benefits. He is a valued member of the store's staff because he can talk to customers about every product in the store.

In the meat industry, I have worked with many successful individuals who are all undiagnosed Asperger's Syndrome. One of them is the head engineer at a large meat plant. He has kept his job even though his bosses have changed many times. He keeps the plant running and his social life is with the other persons with Asperger's Syndrome and "nerds" who work in the plant maintenance department.

Young Individuals with Asperger's Syndrome are Getting Fired from Jobs

I have talked to numerous young people with Asperger's Syndrome who have been fired from countless jobs that the older individuals with Asperger's Syndrome have managed to keep. I think that today's less structured methods of upbringing children are to blame. They are getting fired for doing stupid things that I learned not to do when I was 9 years old. All the table manners and polite social skills that I learned when I was little really helped me. Below are the skills I learned as a child that have helped me keep jobs.

1. *Being on time.* By the time I was 8 years old, I learned to be on time. When I entered first grade at age 6 years, mother taught me to use an alarm clock and to lay out my clothes the night before so I could get dressed quickly in the morning. Many individuals have Asperger's Syndrome lost good jobs they were good at because they were always late to work. Nobody had taught them to be on time when they were little.

2. *Learn to do things others want.* A major key for successful employment is learning to do tasks that will please other people. In the year 2010, I am hearing too many individuals with Asperger's Syndrome saying things like, "I have authority issues with the boss." They never learned that sometimes they have to obey other people. In the 1950s I was taught that sometimes you have to do things the grown-ups want, such as demonstrating good table manners. My mother motivated me by making sure I got real recognition when I did a really good job. I was thrilled when I was allowed to sing a solo at an adult concert. I knew this was a special privilege and the audience loved it. When I painted a really nice watercolor of the beach, mother framed it in a real frame with glass. I responded to this recognition, and later on it translated into doing work that other people appreciated and wanted. In high school, I painted signs for many different people. I learned that when I made a sign for a hair salon, I had to paint a design the client would like. John Robison, the Asperger's Syndrome author of *Look Me in the Eye*, has had good employment all his life. He started out in high school and college where he became an expert at fixing tape recorders

and record players. Other people appreciated his skill with electronics (Robison, 2007).

3. *Teach job skills young.* I am seeing too many individuals with Asperger's Syndrome graduating from college with no job skills. When I was 13 years old, my mother got me a seamstress job for two afternoons a week. I worked for a dressmaker out of her home. This was the first time I earned money at a job and I bought some crazy shirts with it. During high school I worked summers at my aunt's ranch. Even though I talked nonstop about things that bored people, everyone loved the horse bridles I made. In college, I had two summer intern jobs at a research lab and at a school for children with autism. These work experiences were extremely beneficial.

In Silicon Valley, there are young people with Asperger's Syndrome who get good jobs in computers or the tech industry. These kids are successful because their parents taught them career-relevant programming skills starting at 10 to 12 years of age. They were apprenticed into the industry.

1. *Use mentors.* When I was in high school I was an unmotivated student who seldom studied. I saw no point in studying until I had a goal of becoming a scientist. Many successful individuals with Asperger's Syndrome, both diagnosed and undiagnosed, became successful because they had either a parent or a teacher instruct them in career-relevant skills such as electronics, programming, scientific research, journalism, or auto mechanics. I have talked to many successful people with Asperger's Syndrome who have skilled jobs. In most cases, a mentor gave them formal instruction in computer programming, photography, or some other vocation. Young people will fool around with computers but they need a mentor to get them turned on to learning programming. Formal instruction is needed to get a teenager with Asperger's Syndrome focused about learning a career.

2. *Teach turn taking.* When I was a child, all the games and activities that were fun required participation and taking turns with another child. We played lots of board games and table hockey. Another big problem I observe today is that many young people with Asperger's Syndrome do not know how to take turns. This can cause many problems at work. Turn taking must be taught to all children on the spectrum. Board games and card games are good methods. Turn-taking skills learned in childhood will translate into being able to get along well with other people in the workplace.

3. *Avoid multitasking.* Many of the entry-level jobs such as waiter in a busy restaurant or working in a big grocery store require too much multitasking. Myself and many other people on the autism/Asperger's spectrum cannot multitask. All the good job experiences I had in high school and college did not require multitasking. My work on livestock equipment design has no multitasking.

4. *Sell your work, not yourself.* People thought I was weird, but they were impressed when they saw a portfolio of my drawings and photos of completed projects. People respect abilities (Grandin & Duffy, 2004). I used attractive brochures and portfolios to sell my design services.

5. *Develop areas of strength.* Many educators put too much emphasis on deficits and not enough emphasis on development of areas of strength. My ability in art and drawing was *always encouraged*. I think it is really unfortunate that many U.S. schools have stopped classes in art, wood shop, electronics, auto mechanics, and other hands-on jobs. A child that is bored taking elementary math should be allowed to take advanced math, but he may need special education in reading (Grandin & Duffy, 2004).

6. *Expose children and teenagers to interesting things.* I became interested in cattle when I went to my aunt's ranch. A high-school experimental psychology class that featured lots of fascinating optical illusions stimulated my initial interest in becoming a scientist. These experiences stimulated my interest in both psychology and cattle behavior. Kids are not going to get interested in things that they are not exposed to. Children and teenagers on the spectrum need to be exposed to many interesting things.

7. *Use obsessions to motivate learning and job skills.* Obsessions are great motivators. A creative teacher can channel them into career-relevant skills. If a child likes trains, read a book about trains and do math with trains. My obsessions with my squeeze machine were used to motivate scientific study. My science teacher told me that if I wanted to figure out why pressure was relaxing, I had to learn how to read scientific journal articles. He taught me to read real scientific papers when I was a teenager and I learned that scientists did not use the *Encyclopedia Britannica*. Today, I am really worried about kids who get so addicted to video games that it is difficult to get them interested in other things. Playing video games should be limited to 1 hour per day. However, career-relevant skills such as programming a game can be done for much longer periods. Take a video game obsession and broaden it. One parent encouraged development of artistic ability by having her son draw pictures of video-game characters.

8. *Do not make rude comments or discuss controversial subjects at work.* Many brilliant individuals with Asperger's Syndrome have been fired from jobs because they made rude comments about the appearance of coworkers and customers. When I was about 8 years old, I learned that calling somebody "Fatso" was not appropriate. People are losing good jobs because they made rude comments to customers. My old-fashioned 1950s upbringing stopped me from losing a job because of stupid rude comments.

I also was taught to avoid controversial subjects such as religion and politics at work. These subjects should only be discussed with intimate friends. I follow the advice that was on

an old stagecoach sign:"No discussion of politics or religion while riding in the coach."

Worried About a Handicapped Mentality

I am very concerned that some teenagers and adults with Asperger's Syndrome and high-functioning autism are getting into a "handicapped mentality." Asperger's Syndrome is sometimes used as an excuse to not be successful. Recently I talked to a college student with Asperger's Syndrome who asked for so many accommodations from the disability office that it had become ridiculous. People on spectrum do need some accommodations such as a quiet place for sleep and study and a little more time to take tests. The problems with florescent lights also need to be addressed. Asking for a room free from 50- to 60-cycle florescent lights may be required for some individuals for taking tests. One girl told me that it drove her crazy when another student was typing text messages on her phone in class. She wanted the disability office to do something about it. I told her to sit in another part of the classroom. The law says that *reasonable* accommodations should be made. Her requests were no longer reasonable.

I am seeing too many smart young people with Asperger's Syndrome on Social Security disability pay who would be perfectly capable of working. John Robison, author of *Look me in the Eye*, has made the same observation during many of his speaking tours. We are both concerned about young people with an Asperger's Syndrome label using it as an excuse to not succeed. Both John and I were called "retards" when we were little. This very negative label motivated me in my early 20s to prove to other people that I was not stupid. John now has a very successful car dealership and he has had good employment his whole life.

Top Research Priority 3: Research on Different Kinds of Minds

Another area that needs to be researched is the different specialized ways that different people on the autism spectrum think. Through reading other personal accounts and talking to many individuals on the spectrum, I have observed that there are three basic kinds of specialist cognitive types (Grandin, 2009). They all share the common trait of having a skill in one area and a huge deficit in another area.

1. *Photo-realistic visual thinkers:* This is my type and it is described in detail in *Thinking in Pictures* (Grandin, 1996/2006). When I wrote this book in 1995, I thought all people on the spectrum were visual thinkers. I have discovered that this is not true. All my thoughts are in photo-realistic pictures. I can search the database in my head like searching the internet with an internet search engine set for finding photos. My weak area is algebra and foreign language. Algebra made no sense because there was no way to convert it to pictures.

At conferences I have talked to several individuals who could not do algebra but could do geometry and trigonometry. I never got a chance to try geometry because I failed algebra. Another interesting thing I have found about visual thinkers is that they seldom have severe visual processing problems. I think this would interfere with putting clear pictures into memory.

2. *Pattern thinker with a (music and math mind):* This is a more abstract form of visual thinking. Instead of seeing photo-realistic pictures in their imaginations, they see patterns and relationships between numbers. The first-person accounts of Jerry Newport and Daniel Tammett are good examples of pattern thinking (Newport & Newport, 2007; Tammett, 2006).

Interestingly, some of these individuals also had difficulty with algebra, but they can do many higher forms of math. I have talked to many pattern thinkers. Some have severe visual processing problems. They have told me that they see or hear sound patterns. A woman with autism named Michelle Dawson has teamed up with researcher Laurent Mottron from the University of Montreal. A groundbreaking paper published in 2007 clearly shows that people with autism have intelligence skills that may be different than normal people (Dawson et al., 2007). When a normal child takes the WISC IQ test and the Raven's Progressive Matrices, they get similar scores on both tests. When children with autism took both tests, the Raven's scores were an average of 30 percentile points higher than the WISC scores. The Raven's is a test that measures pattern thinking. It tests the ability to see sameness and differences in a series of complex patterns. The WISC measures pattern thinking in the block design text, but many of the other subtexts require good language skills.

3. *Verbal specialist with a (facts mind):* There are the individuals who know all the verbal facts about their favorite subject. They are definitely not visual thinkers and often their math skills are only average. Many children and adults with this cognitive pattern love history. Some of these people make great journalists or legal researchers. They also may run fantastic fun websites about their favorite star or book.

Match Skills to Job Title

There needs to be more research on matching the individual's cognitive type to the right jobs. Visual thinkers can be really good at art, graphic design, photography, animal behavior, architecture, cartooning, industrial design, and other jobs that utilize visual skills. The pattern thinkers excel at engineering computer programming, math, statistics and other technical jobs. The verbal thinkers make excellent journalists, and researchers who are good at finding information in vast

archives of data. Any job that requires meticulous record keeping would also be a good occupation.

Is Mild Asperger's Syndrome Really a Disability?

Simon-Baron Cohen has asked this question many times (Baron-Cohen, 2000). None of our technology or computers would exist if Asperger's Syndrome and autism traits were eliminated. The really social people did not invent the first stone spear. They spent all their spare time talking to each other and socializing. In fact, many famous scientists such as Einstein or Tesla (who invented the power plant) would probably be diagnosed with autism today. Mozart, Carl Sagan, Thomas Jefferson, and many others probably had Asperger's Syndrome (Ledgin, 2002; Fitzgerald & O'Brien, 2007). Brain research is showing that maybe there is a wide range of brain types ranging from hyper-social to a brain better suited for solving scientific or technical problems, which requires more attention to detail.

How I Conceptualize the Neurobiology of Autism

The research of Manual Casanova at the University of Knoxville really got me thinking (Cassanova et al., 2007). His research showed that three famous neuroscientists and people with autism both have had more *mini-columns* per square inch of brain gray matter (Casanova et al., 2006). Mini-columns are analogous to the brain's microprocessor units. Maybe additional mini columns helps people with autism and scientists process detailed information. The work of Dr. Nancy Minshew and her colleagues at the University of Pittsburgh indicates that the normal mind may drop out the details (Minshew et al., 2007; Minshew et al., 2002). Another study showed that people with autism use the visual parts of the brain more for processing verbal language (Kana et al., 2006). Eric Courchesne has suggested that local circuits in the brain may be enhanced and long-distance circuits may be poor. The work of Bruce Miller and his colleagues also provides great insight into how the brain works. In the normal person, language and abstract reasoning may cover up visual, math, and music skills. Patients with frontal temporal lobe dementia, a form of presenile dementia, sometimes have art and music talents emerge when the frontal cortex areas are destroyed (Miller et al., 2000; Miller et al., 1998). The paintings done by several of these patients resemble autistic savant art.

From reading all of these research studies, I hypothesize that there is a continuum of brain types. At one end, the highly social emotional brain would have super-efficient, long-distance connections between different brain regions to process rapidly changing social cues. The disadvantage of this brain is that details would get left out. At the other end of the spectrum would be a brain that has poor long-distance connections, but local connections with extra wiring. This would provide the ability to pay attention to details, but the processing speed would be much slower. It is likely that in an earlier era, people with Asperger's Syndrome and high-functioning autism would have been highly valued as scribes, artisans, stone masons, and other highly specialized trades. I had an interesting conversation with a mother from India. She said, "In our culture we recognize that kids labeled with Asperger's Syndrome are smart and sometimes naughty, and we prepare them for engineering and computer jobs starting at an early age." Getting a good job is important. The happy people on the spectrum have interesting work they can do with other people similar to them. One computer programmer with Asperger's syndrome said to me, "I am with my own people."

Conclusions

Autism/Asperger's Syndrome research needs to branch out into new areas. These areas include sensory oversensitivity problems, employment, and cognitive types. As described above, sensory problems can be extremely debilitating and make normal socializing impossible because the person is not able to tolerate a noisy restaurant or sports stadium. Florescent lights that operate at 50 to 60 cycles, cause serious problems for some individuals because they can see the flicker. For some individuals, fluorescents really interfere with learning or work. Sensory problems need to be researched to find ways to treat them. Research projects will be more likely to have significant results if subjects are assigned to studies based on the type of sensory symptoms instead of just broad labels such as autism. Sensory problems are extremely variable. Some individuals have noise sensitivity and others may have visual problems.

A second top priority research area is how to promote successful employment for people with Asperger's Syndrome and high-functioning autism. Intervention programs that help develop vocational skills and assess the types of job a specific individual is likely to succeed in are needed. In addition, techniques that offer mentoring and role-modeling, such as job coaches, should be studied.

A third topic area that needs studied is cognitive subgroups. People on the autism spectrum have areas of strength and areas of deficits. The cognitive types are: *(1)* photo-realistic visual thinkers, *(2)* pattern thinkers (music and math minds), and *(3)* verbal specialists (facts minds). Steps must be taken to improve employment of individuals on the spectrum. My highly structured upbringing in the 1950s really helped me. I was taught manners, turn taking, and other social skills that really helped me in the workplace. It is also essential to develop the individual's area of strength into employment and a career.
