Gross motor deficits observed in individuals with ASD suggest that both corticostriatal and corticocerebellar circuits are affected. Kanner (1943) originally reported that some children with autism walk late, walk clumsily, and/or never crawl prior to walking. Similarly, Asperger (1944, as translated by Frith, 1991) noted consistent clumsiness among the patients that he studied, suggesting that a broad range of motor abilities are impacted and that these disturbances persist throughout development. Disentangling the role of frontostriatal and corticocerebellar systems in the gross motor disturbances characteristic of autism and Asperger's disorder has been difficult. Some researchers have suggested that the "autistic gait" is similar to that of individuals with Parkinson's disease, characterized by bradykinesia, longer movement duration and deceleration, and lower peak velocity (Damasio et al., 1978; Mari et al., 2003; Vernazza-Martin et al., 2005; Vilensky et al., 1981), indicating that patterns of impaired motor preparation and inhibition evidenced in ASD may reflect frontostriatal pathology. Still, findings from several studies of early gait characteristics have been more consistent with patterns of cerebellar, rather than basal ganglia dysfunction. Rinehart and colleagues (Rinehart et al., 2006b) reported that, subsequent to learning to walk, children with ASD show persistent atypical gait with increased variation in overall stride length similar to patients with cerebellar ataxia. Their qualitative ratings of gait parameters revealed that both individuals with autism and individuals with Asperger's disorder were less coordinated, smooth, and consistent. Individuals with autism showed abnormal arm postures likely reflecting poor balance, and individuals with Asperger's disorder evidenced head and trunk postural atypicalities that may reflect interference of the frontostriatal motor preparation network. Esposito and Venuti (Esposito et al., 2008) found that, relative to developmentally delayed children without ASD and typically developing children, children diagnosed with ASD who were within their first six months of walking had problems performing typical heel-to-toe transfers of weight while walking, showed asymmetric postures of their arms while walking, and exhibited increased rates of a "waddling" walking style, again similar to patterns evidenced by some patients with cerebellar abnormalities. The picture is not entirely clear, however, as these same individuals further showed stereotyped movements while walking, implicating frontostriatal systems. Gait disturbances thus are

documented in both individuals with autism and individuals with Asperger's disorder, and each subgroup demonstrates early emerging atypicalities that include poor balance and postural stability. While these behavioral disturbances reflect, at least in part, basal ganglia dysfunction, they are not identical to the pronounced bradykinesia and motor initiation/inhibition deficits characteristic of Parkinson's disease patients. Similarly, overlap with patients experiencing cerebellar ataxia is considerable but not complete.

> **Bradykinesia:** Slowness of movement due to dysfunction of the basal ganglia and related structures.

Disturbances in these circuits emerge early and thus may be useful as screening indices early in development. In a study of parents' first concerns regarding their developing children with ASD, Chawarska and colleagues (2007) indicated that, next to reduced rates of sharing enjoyment, the primary indicator was delay in walking. Teitelbaum and colleagues also observed gross motor and sequential motor movement abnormalities by age 3 to 6 months in infants later diagnosed with autism (1998) and those later diagnosed with Asperger's disorder (2004). The most consistent abnormalities observed were lateralized asymmetries in crawling and walking as well as poor sequencing of component behaviors implicating corticostriatal circuitry and cerebellar feedback loops. Gross motor disturbances have been reported for children with ASD beyond the first years of life as well. Ahsgren and colleagues (2005) reported that 31/32 children and adolescents with ASD demonstrated some form of ataxia consistent with cerebellar pathology. Williams and colleagues (2006a) indicated that 8-year-old children with ASD without cognitive impairments show deficits in manual motor strength relative to age- and IQ- matched healthy controls. Hallett and colleagues (1993) reported that 4/5 adults with autism showed mild clumsiness and upper limb posturing during gait. Finally, Vernazza-Martin and colleagues (2005) reported that children with ASD walk with smaller steps and more irregular oscillation of upper limbs, head, and trunk than age-matched non-ASD children. Taken together, these findings indicate that the sequential processing of complex motor movements involving corticostriatal circuitry as well as the calibration of these movements modulated by corticocerebellar circuits are disrupted in ASD, and that these deficits present as delays within the first year of life and continue to manifest throughout childhood and later years as subtle deviations in gross motor coordination.

Neuroimaging studies aiming to define the neural pathways associated with motor disturbances in ASD have yielded inconsistent results likely due to limitations in early MRI capabilities (e.g., reduced resolution), small sample sizes in the context of biological and behavioral heterogeneity, and failures to assess widely distributed networks involving long-distance connective white matter fiber tracts and their terminal fields. The ability to investigate grey and white matter volumes with standard MR sequences, white matter tracts

through diffusion tensor imaging (DTI) and functional activation and connectivity with fMRI, ERP, and PET, now make it possible to simultaneously study the anatomic and neurophysiological substrates of motor dysfunction.

MRI studies of the basal ganglia in ASD have suggested that the caudate nucleus is enlarged (Haznedar et al., 2006; Hollander et al., 2005; Langen, Durston, Staal, Palmen, & van Engeland, 2007; Langen et al., 2009; Rojas et al., 2006; Sears et al., 1999; Stanfield et al., 2008, but see Hardan, Kilpatrick, Keshavan, & Minshew, 2003; McAlonan et al., 2008, for discrepant results), although it is unclear whether this enlargement is disproportionate to overall brain enlargement (Herbert et al., 2003), consistent across affected individuals (Hardan et al., 2003; McAlonan et al., 2008), and/or specific to the caudate nuclei as opposed to other striatal gray matter (McAlonan et al., 2008). Still, an association between caudate volume and repetitive motor behaviors in ASD has been reported (Hazlett, Poe, Smith, Gerig, & Piven, 2005; Hollander et al., 2005; Rojas et al., 2006; Sears et al., 1999) suggesting that the caudate nucleus is involved in some motor abnormalities in ASD.

Studies of the cerebellum in ASD also have yielded inconsistent findings. Studies of selective hypoplasia of vermal lobules VI–VII (Courchesne, Yeung-Courchesne, Press, Hesselink, & Jernigan, 1988; Hashimoto et al., 1995; Kaufmann et al., 2003; Schaefer et al., 1996) have not always been replicated (Holttum, Minshew, Sanders, & Phillips, 1992; Kleiman, Neff, & Rosman, 1992; Manes et al., 1999; Piven, Saliba, Bailey, & Arndt, 1997), owing perhaps to the fact that confounding factors (i.e., comparability of IQ in cases and controls) are not consistently taken into account. In contrast, histopathological studies provide strong and consistent evidence for cerebellar pathology in ASD. Reduced density of GABAergic Purkinje cells of the cerebellar vermis (50% to 60% cell loss) and hemispheres (42% cell loss) along with reduced granule cell number are the most consistent and frequently reported neuropathological findings in ASD (Bailey et al., 1998; Bauman, 1991; Bauman & Kemper, 1985, 2005; Ritvo et al., 1986). In one study, reduced Purkinje cell number and size in vermian lobules VI–VII and VIII–X was noted in all ASD cases examined (Arin, Bauman, & Kemper, 1991). This pathology may be related to comorbid seizure disorders (Crooks, Mitchell, & Thom, 2000) as subsequent analyses have indicated that only about half of postmortem cases show reduced Purkinje cell density (Whitney, Kemper, Bauman, Rosene, & Blatt, 2008). Further evidence for cerebellar pathology is found in studies of glutamate decarboxylase (GAD) 65 and 67, isoform tracers that catalyze glutamate to GABA within the cerebellum. Studies of GAD 65 and 67 reveal reduced isoforms in Purkinje cells (Yip, Soghomonian, & Blatt, 2007, 2009), and increased GAD67 production within basket and stellate cells (Yip, Soghomonian, & Blatt, 2008). More recent investigations of white matter integrity within the cerebellum indicate that intrahemispheric and efferent white matter tracts show decreased fractional anisotropy (an index of white matter integrity) in individuals with Asperger's disorder (Catani et al., 2008). Although the precise

mechanisms contributing to reduced fractional anisotropy within the cerebellum are not known, these findings suggest that connective pathways within the cerebellum and pathways projecting from the cerebellum to brain stem and thalamus are abnormal in ASD. The functional significance of cerebellar pathology remains unclear, and likely is diverse. However, the consistency of cerebellar pathology findings in ASD, the central role for the cerebellum in motor control, and the consistency of findings of disrupted motor control in ASD together highlight the importance of corticocerebellar circuitry in motor control dysfunction in patients with ASD.

Hypoplasia: Underdevelopment of an organ reflecting a decreased number of cells.

Granule cells: Tiny cells found within the innermost granular layer of the cerebellum and other brain regions, including the hippocampus and olfactory bulbs.

Basket and stellate cells: GABAergic interneurons that synapse with Purkinje cells within the molecular layer of the cerebellum.

Fractional anisotropy: A scalar value between 0 and 1 used to describe the degree of anisotropy of a diffusion process. This value is often extracted from diffusion tensor images (DTI) to index the integrity of white matter within the brain because water typically diffuses parallel to white matter tracts.

Fine Motor Impairments in Individuals with ASD

The neural control of fine motor manipulations involves neural systems that overlap considerably with those underlying gross motor movements, but these systems also require greater precision and rely on axons to more distal limbs. Premotor areas of the frontal lobe play a major role in the planning and control of complex and sequential voluntary movements (Kornhuber, 1978; Petrides, 2005). Distal and local motor pathways are dissociated at their origin, within the somatotopically organized motor cortex, and again diverge within the spinal cord (Dawnay & Glees, 1986).

Somatotopy: The correspondence of receptors in regions of the body via respective nerve fibers to specific functional areas of the cerebral cortex.

Although some early findings suggested that individuals with ASD show relatively superior (Jones & Prior, 1985) or intact (Ozonoff, Pennington, & Rogers, 1991; Rumsey & Hamburger, 1988) dexterity, subsequent studies utilizing

increasingly sensitive assessment tools have documented consistent patterns of deficit in children and adolescents with ASD (Freitag et al., 2007; Ghaziuddin, 2008; Green et al., 2002; Mostofsky, Burgess, & Gidley Larson, 2007; Vanvuchelen, Roeyers, & De Weerdt, 2007). Comprehensive neuropsychological studies of large samples of children (N = 56, Williams et al., 2006a) and adults (N = 33, Minshew et al., 1997) have indicated that performance on measures of motor strength, fine motor planning and motor speed is impaired in patients with ASD. These results suggest that both simple and complex motor behaviors are impacted, and that deficits are detectable with standardized neuropsychological measures across a large proportion of affected children and adults.

Consistent with large-scale neuropsychological studies, assessments of smaller samples of individuals with ASD have revealed fine motor abnormalities. Green and colleagues (2002) reported that 9 of 11 children with Asperger's syndrome ages 6.5 to 11.5 showed fine motor dexterity scores within the 5th percentile or lower relative to other children their age. Fourteen of 16 adolescent males with high-functioning autism or Asperger's syndrome studied by Freitag and colleagues (2007) demonstrated slowed alternation between prone and supine hand positions, as well as poor dynamic balance (i.e., jumping forward or side-to-side), each of which were associated with level of autistic symptomatology. Studies of graphomotor skills also suggest fine motor abnormalities, including demonstrations of macrographia (Beversdorf et al., 2001) and poor fine motor control (Mayes & Calhoun, 2003) in large samples of average-IQ and cognitively impaired children with ASD.

Impaired performance across gross and fine motor skills suggests that disturbances likely involve abnormalities of the upper motor neuron systems above the brain stem. Tracts involved in gross and fine motor skills diverge below the brain stem (Dawnay et al., 1986), so evidence that each set of abilities is affected in ASD to a relatively similar degree suggests a common supratentorial origin of motor impairments. Freitag and colleagues' (2007) finding that both gross and fine motor impairments are associated with the severity of autistic symptoms suggests that motor disturbances may contribute to the core traits of the disorder, or have pathophysiological mechanisms that relate to the causes of those traits.

Functional MRI studies of fine motor behavior in individuals with ASD directly implicate the basal ganglia and cerebellum. Mostofsky and colleagues (2009) reported that children with ASD ages 8 to 12 years demonstrated reduced ipsilateral anterior cerebellar activation and increased supplementary motor area activation relative to age- and IQ-matched controls during a finger tapping task. The authors also documented reduced coherence of activation between cortical and cerebellar regions of interest in ASD. Allen and Courchesne (2003) observed more diffuse cerebellar activation across lobules VI–VII among average-IQ patients with ASD performing a finger tapping task in which they received verbal cues to press a button as many times as possible within a fixed duration. Using an identical paradigm, Muller and colleagues (Muller,

Pierce, Ambrose, Allen, & Courchesne, 2001) identified decreased frontostriatal activation within eight participants with ASD suggesting that, despite the relative simplicity of these motor tasks and individuals' ability to perform the motor behaviors comparable to age-matched controls, robust alterations in frontostriatal and frontocerebellar networks in individuals with ASD are evident. Interestingly, Muller et al.'s results also highlighted increased activation in patients with ASD within areas typically not recruited for simple motor behaviors. These areas included precuneus, inferior parietal lobule, superior temporal gyrus, and PFC. Allen, Muller, and Courchesne (2004) suggest that disturbances of motor systems in ASD may show characteristics consistent with the "crowding effect" in which spared tissue performs the function of typically specialized brain regions that are dysfunctional (Teuber, 1974). It has been proposed that the functions normally subserved by more primitive systems, such as motor skills mediated by the paleocerebellum, are disrupted by aberrant Purkinje cell development, and that functions are subsequently carried out by more recently evolved systems within the neocerebellum and neocortex (Allen et al., 2004). The higher level neural system's ongoing need to compensate for disturbances in lower level systems in ASD may result in their being limited in their capacity to support the ontogenesis of higher-order cognitive operations such as executive functions and language. Evidence that areas not typically involved in fine motor manipulations are recruited for simple finger tapping tasks in ASD suggest that motor impairments could contribute to a cascade of effects disrupting developments in higher level systems that typically support complex cognitive operations.

Paleocerebellum: The anterior lobe of the cerebellum, which was one of the phylogenetically earliest parts of the hindbrain to develop in mammals.

Neocerebellum: The phylogenetically youngest part of the cerebellum comprising most of the cerebellar cortex and vermis.

Oculomotor Impairments in ASD

Oculomotor paradigms, which typically require sensory analysis, sensorimotor transformation, and motor control with varying levels of cognitive planning, are heavily dependent on effective integration of multiple neural systems. Brain regions that are involved in the control of eye movements include the PFC; frontal, parietal, and supplementary eye fields; basal ganglia; thalamus; superior colliculus; cerebellum; and brain stem. Structural magnetic resonance imaging and histological studies have documented that many of these brain areas are affected in ASD (Carper & Courchesne, 2005; Cody, Pelphrey, & Piven, 2002; Courchesne et al., 1988; Courchesne, Press, & Yeung-Courchesne, 1993; Sears et al., 1999; Tsatsanis et al., 2003). Consistent with these findings, several studies

suggest that conjugate eye movements are abnormal in ASD (see below), including both saccades and smooth pursuit, and that these deficits may be familial (Koczat et al., 2002; Mosconi et al., 2010).

Saccade Impairments in Individuals with ASD

Saccades are rapid ballistic eye movements that are typically made to focus gaze on objects of interest. Studies of saccadic eye movements provide opportunities to examine relevant motor circuitry as well as higher-level cognitive processes that modulate the use of saccades in a context appropriate manner. Peak velocity of saccades is determined primarily by the brain stem, while accuracy of saccades heavily depends on the cerebellum, especially the cerebellar vermis. Latency of saccades is primarily determined by a balance between input from cortical eye fields and basal ganglia to the superior colliculus. The PFC provides top-down modulation of saccade planning and execution using context-relevant information and behavioral plans that continue over time (see Figure 22-1).

Exogenous Saccades

Findings from early studies suggested that brain circuitry supporting the planning and execution of saccades is intact in individuals with ASD when saccades are guided by exogenous
Figure 22–1. Lateral view of human cerebral cortex and projections to superior colliculus (SC) involved in saccade generation. Cortical and subcortical areas involved in oculomotor control, with excitatory and inhibitory pathways depicted in solid and broken lines, respectively. Direct excitatory pathways to the SC shown are from the dorsolateral prefrontal cortex (DLPFC), frontal eye fields (FEF), parietal eye fields (PEF), and supplementary eye fields (SEF). Indirect cortical input from the DLPFC and FEF are through the caudate nucleus (CN), which inhibits the SC. Cerebellar connections (vermis and fastigial nuclei [FN]) and pontine connections to the SC are also shown.

sensory information, such as the sudden appearance of visual targets (these saccades are often called prosaccades or visually guided saccades). Minshew, Luna, and Sweeney (1999) observed no abnormalities in average peak velocity, duration, latency, or accuracy of exogenous saccades in 26 adolescents and adults with ASD when they were compared to age-and IQ-matched typically developing subjects, suggesting brain circuitry supporting basic saccade planning and execution is intact. A more recent study that used higher resolution measures (Takarae et al., 2004b), however, reported greater trial-to-trial variability in saccade accuracy in a larger sample (n = 46) of individuals with ASD compared to age- and IQ-matched typically developing individuals. Increased trial-to-trial variations in saccade accuracy with lack of consistent alteration in average saccade accuracy in subjects with ASD is a pattern similar to effects seen after chronic lesions in lobules VI and VII in the cerebellar vermis, which are critical for achieving saccade accuracy (Thier, Dicke, Haas, & Barash, 2000). A potential link to the cerebellar vermis is also suggested by histological and MRI studies documenting abnormalities of the cerebellar vermis in ASD (Bailey et al., 1998; Cody et al., 2002; Courchesne et al., 1988; Kemper & Bauman, 1998; Ritvo et al., 1986).

Takarae and colleagues (2004b) compared the accuracy of exogenous saccades of subjects with ASD who had delays in early language acquisition with those who did not. While both ASD groups had increased trial-to-trial variability in saccade accuracy, the group who did not have early language delays also had saccadic hypometria (tendency to undershoot saccades relative to target locations). Thus, it is possible that some individuals with ASD without language delays have a different pattern of neural system dysfunction that involves more severe cerebellar impairments. Perhaps more importantly, these findings suggest that development of basic motor circuitry supporting exogenous saccades may be associated with a specific pattern of early cognitive development. A cross-sectional study by Luna and colleagues (2007) has shown that reduced average saccade accuracy is present in children with ASD, but not in adolescents or adults. Thus, reductions in saccade accuracy might be resolved by adolescence, possibly by compensatory mechanisms or delayed brain maturation.

A functional MRI study by Takarae and colleagues (2007) reported altered patterns of brain activation in individuals with ASD during execution of exogenous or visually guided saccades. They examined brain activation in 13 individuals with ASD and 14 age- and IQ-matched typically developing controls during performance of a visually guided saccade task. The ASD group had reduced activation relative to the control group in brain areas that are typically involved in executing exogenous saccades, including the frontal, supplementary, and parietal eye fields, and cerebellar hemispheres. This is consistent with the observed behavioral deficits, since these regions receive and utilize experience related to error in previous saccades from the cerebellum to reduce error in future saccades. More strikingly, the ASD group also demonstrated increased activation in the dorsolateral PFC, caudate, thalamus, and dentate nucleus, all of which are more typically involved in endogenous or cognitive control of saccadic eye movements and much less so during exogenous saccades in typically developing individuals. These observations parallel findings of compensatory neurocircuitry alterations in manual motor control studies discussed above (Mostofsky et al., 2009; Muller et al., 2001), and indicate that frontostriatal systems might be providing compensatory input to the sensorimotor circuitry during exogenous saccadic eye movements in individuals with ASD. This would suggest that PFC is called on to perform computational functions other than those for which it is specialized, which over the course of development might reduce its ability to perform its typical functions.

Some studies of exogenous saccades in ASD have used a temporal gap or an overlap between offset of central cue and presentation of peripheral targets to vary the level of attentional investment in the central cue location at the time a new peripheral target elicits a saccade. There have been reports, though inconsistent, of abnormal saccade latencies using exogenous saccade tasks with this type of manipulation. Van der Geest and colleagues (2001) reported no abnormalities of saccade latency in gap and overlap trials in 16 children with ASD and 15 age- and IQ-matched typically developing subjects. However, they did report a reduced difference between latencies in gap and overlap conditions that primarily resulted from shorter latencies among individuals with ASD in the overlap condition. Kawakubo and colleagues (2007) examined saccade latencies using a gap-overlap paradigm in 7 adults with PDD with mental retardation and 9 typically developing control subjects. They found shorter saccade latencies and increased rates of express saccades in overlap trials in subjects with ASD compared to controls. In contrast, Goldberg and colleagues (2002) reported longer saccade latencies in gap and overlap trials as well as trials with synchronous central cue offset and peripheral target onset in a sample of 11 adolescents with ASD compared to 11 age- and IQ-matched control subjects. Kawakubo and colleagues (2007) showed significantly longer saccade latencies during overlap trials in 17 adults with ASD and cognitive impairment when they were compared to chronological age–matched typically developing adults.

These studies, though not all using IQ- and age-matched comparison groups, demonstrated abnormalities in saccade latency in individuals with ASD when the task had higher demand for attention disengagement, suggesting dysregulation of visual spatial attention in ASD. Kawakubo and colleagues (2007) examined presaccadic event related potentials during a gap-overlap task in 17 adults with ASD and cognitive impairment. They found that presaccadic positive potentials that are related to disengagement of attention (Csibra, Johnson, & Tucker, 1997) were greater in participants with ASD compared to the IQ-matched control group with mental retardation or chronological age–matched control groups. These results suggest that deficits in attentional disengagement in ASD and underlying physiological abnormalities are specific

to ASD and are not exclusively a generalized manifestation of cognitive impairment.

Endogenous Saccades

In contrast to findings regarding exogenous saccades, deficits during tasks that evaluate the intentional or endogenous control of saccades have been consistently reported in individuals with ASD. Endogenous control of saccades involves making saccades based on a cognitive plan rather than as a relatively automatic response to sensory input. These have been examined to evaluate capacities for voluntary response inhibition and working memory that are primarily supported by PFC, anterior cingulate cortex (ACC), and striatal systems. The ability to execute endogenous goal-directed saccades develops throughout adolescence into early adulthood, and thus has a prolonged period for neural plasticity (Luna, Garver, Urban, Lazar, & Sweeney, 2004). Endogenous saccades have been examined using antisaccade paradigms where subjects are required to voluntarily inhibit a saccade toward a target and instead make a saccade away from the new target, and using oculomotor delayed response (or memory-guided saccade) tasks, where subjects are required to make saccades to remembered target locations. In both paradigms, subjects are required to make saccades based on an internal plan rather than to the locations of unpredictably appearing sensory stimuli.

Increased rates of saccade inhibition errors during antisaccade tasks have been reported in ASD when compared to age- and IQ-matched typically developing control subjects, reflecting a reduced ability to voluntarily suppress the natural response tendency to look toward suddenly appearing targets (Luna et al., 2007; Goldberg et al., 2002; Minshew, Luna, & Sweeney, 1999). A cross-sectional study by Luna and colleagues (2007) examined developmental changes in endogenous saccades in 19 children (8–12 years of age), 21 adolescents (13–17 years), and 21 adults (18–33 years) with ASD and age- and IQ-matched typically developing control groups. They reported that saccade inhibition errors during an antisaccade task decreased with age in both ASD and control groups, but error rates in the ASD group were higher overall and did not reach the error rates observed in the control group even in adulthood. Latencies of antisaccades, the time needed to initiate a volitional saccade away from a target, gradually reduced with age in the control group but not in the ASD group. Mosconi, Kay, D'Cruz, Seidenfeld, et al. (2009) also found increased antisaccade error rates, and reported that error rates were associated with higher-order repetitive behaviors in ASD. The implications of these findings point to frontostriatal system disturbances as a cause of repetitive behaviors in ASD.

Studies of oculomotor delayed-response tasks have also documented poor performance in subjects with ASD. Minshew and colleagues (1999) demonstrated that adolescents and young adults with ASD had difficulty shifting their eyes accurately to remembered locations. This finding was not replicated by Goldberg and colleagues (2002), who reported no abnormalities in the accuracy of memory-guided saccades in subjects with ASD, although they did report a prolonged latency of saccades to remembered targets. In the previously mentioned developmental study, Luna and colleagues (2007) also reported that latencies of memory-guided saccades were longer in subjects with ASD than typically developing controls. Further, the ASD group's age-related improvements were limited to childhood and adolescence, while no improvement was observed from adolescence to adulthood. In contrast, the control group showed progressive reductions in response latency through childhood to adulthood. As with antisaccades, the accuracy of memory-guided saccades improved with age only in the control group, and no age-related improvement was observed in the ASD group. This suggests an alteration in maturational processes that leads to a persistent reduction in the ability to quickly make and initiate behavioral plans.

Goldberg and colleagues (2002) examined a different type of endogenous saccades, predictive saccades, using a task where targets alternated between two positions at a fixed time interval. Because of the predictability of the target sequence, subjects typically begin to make anticipatory saccades to the expected target appearance after only a few target presentations. Switching to use learned target timing to execute saccades depends on function of the frontostriato-thalamocortical loop (Simo, Krisky, & Sweeney, 2005). High-functioning individuals with ASD had fewer anticipatory saccades and more variable response latencies than age- and IQ-matched control individuals, suggesting that individuals with ASD are less able to take advantage of the predictable timing and location of targets. Using a similar paradigm, D'Cruz and colleagues (2009) reported that individuals with ASD show abnormalities in the timing of predictive rightward, but not leftward saccades. These findings suggest abnormalities in response timing systems within the left basal ganglia.

To investigate neural substrates of impairments in endogenous saccades, Luna and colleagues (2002) conducted an fMRI study of individuals with ASD performing an oculomotor delayed-response task. Eleven individuals with ASD demonstrated reduced activation in the dorsolateral PFC and the posterior cingulate cortex when performing the task. Other circuitry involved in performing the task, including cortical eye fields, ACC, basal ganglia, thalamus, and lateral cerebellum, had similar levels of activation in ASD and age- and IQ-matched control groups. Thakkar and colleagues (Thakkar et al., 2008) used fMRI to investigate the neural substrates of antisaccade performance in 12 subjects with ASD. During the study, rostral ACC (rACC) activation during incorrect trials was greater than that for correct trials in healthy controls but not for subjects with ASD. Individuals with ASD showed increased rACC activation during correct trials compared to controls and reduced fractional anisotropy within white matter tracts underlying ACC. Both increased rACC activation on correct trials and decreased fractional anisotropy in rACC white matter were associated with more severe repetitive behavior. Taken together, these fMRI findings of endogenous saccade performance in ASD are consistent with the idea that dysfunction in the PFC and ACC may not only contribute to

deficits in the generation of endogenous saccades, but be a marker for alterations in prefrontal systems that cause higher-order cognitive deficits that are widely observed in individuals with ASD (Hill, 2004).

Smooth Pursuit

Whereas saccades are used to acquire target objects that are located in the visual periphery, smooth pursuit is used to follow an object in motion that is already foveated. Neural systems that support smooth pursuit largely overlap with those that support saccades, though there are dissociable subdivisions in each relevant brain area for saccades and smooth pursuit and, thus, each type of eye movement could be selectively impaired (Rosano et al., 2002). Relevant brain circuitry includes extrastriate areas of visual cortex such as Area MT (also called V5), which is devoted to the processing of visual motion information; cortical eye fields and cerebellum, which are involved in translating sensory information to motor commands; and the basal ganglia, which are involved in initiating motor commands and perhaps predictive aspects of pursuit (Lencer & Trillenberg, 2008; Sharpe, 2008). Visual pursuit requires rapid, temporally precise integration of activity within these brain areas in order to visually track moving targets through space. Visual pursuit is typically described using a two-stage model. During the initiation or "open-loop" stage (first 100 ms after pursuit onset), control of pursuit is almost exclusively dependent on sensory analysis of visual motion that is performed primarily by contralateral area MT (Carl & Gellman, 1987; Lisberger & Movshon, 1999; Newsome, Wurtz, Dursteler, & Mikami, 1985). Analysis of visual motion information is passed from MT to the parietal and frontal eye fields, each of which project through the pons and the cerebellum to deep brainstem oculomotor areas to generate smooth pursuit eye movements (Yamada, Suzuki, & Yee, 1996). After the initial open-loop period of pursuit, the subsequent "closed-loop" stage of sustained pursuit relies primarily on memory for target velocity, predictions about target movement, and feedback about performance rather than an analysis of actual visual motion. The cortical eye fields, prefrontal cortex, striatum, and cerebellum play a crucial role during closed-loop pursuit to drive predictive pursuit using extraretinal information (Lencer et al., 2008; O'Driscoll et al., 2000).

Several studies have reported visual pursuit impairments in ASD. Scharre and Creedon (1992) and Rosenhall, Johansson, and Gillberg (1988) each noted difficulty eliciting pursuit responses in ASD. However, the latter study reported that pursuit accuracy was in the normal range in a small subset of participants with ASD who were able to initiate pursuit. It is important to note, however, that the time that these studies were conducted did not allow for the use of current criteria for diagnosing ASD. Perhaps more importantly, age- and IQ-matched control groups were not included in either study. A more recent report by Kemner, van der Geest, Verbaten, and van Engeland (2004) compared visual pursuit in subjects with PDD and age- and IQ-matched control

subjects and reported an approximate 10% reduction in pursuit accuracy.

A study with a large sample performed by Takarae and colleagues (2004a) used three different pursuit tasks to characterize both open- and closed-loop pursuit in 60 high-functioning subjects with ASD and 94 age- and IQ-matched typically developing control subjects. They reported reduced pursuit accuracy in 3 different tasks during the closed-loop stage. This group difference in closed-loop pursuit was specific to older subjects with ASD, suggesting age-related improvement in visual pursuit performance in controls that was reduced in ASD. Closed-loop pursuit depends on internal representations of target movement and feedback about performance, and this pattern of developmental curtailment of closed-loop pursuit is similar to maturational failures for endogenous saccades that also depend on memory about targets and internally set goals. Takarae and colleagues also found lateralized reduction in accuracy of smooth pursuit and primary catch-up saccades in the ASD group during rightward open-loop pursuit. This hemifield-specific impairment could be related to disturbances in the left extrastriate areas that extract visual motion information, or in the feedforward projections from the left extrastriate areas to oculomotor areas that transform visual information into appropriate motor commands. In a follow-up study with an independent sample, Takarae, Luna, Minshew, and Sweeney (2008) observed significant associations between visual motion perception in psychophysical studies with pursuit latency in individuals with ASD, suggesting contributions of visual motion processing disturbances to problems in pursuit initiation in this population. Of note, slower pursuit initiation was only observed in participants with ASD who did not have early language delays. In contrast, pursuit latency and open-loop pursuit gain were correlated with manual motor skills only in the ASD group with language delays. Thus, the observed impairment of open-loop pursuit is likely part of more general sensorimotor alterations in individuals with language delays as well as being related to alteration in visual input or functional connectivity between extrastriate and sensorimotor areas.

In order to examine the neural substrates of pursuit impairments in ASD, Takarae and colleagues (2007) examined brain activation during visual pursuit of predictable target movement in 13 participants with ASD and 14 age- and IQ-matched typically developing control participants. They reported reduced activation in brain areas that mediate sensorimotor transformations, including cortical eye fields, and areas that are involved in acquisition of skilled motor responses, such as dorsolateral PFC, cingulate motor areas, and the presupplementary motor area. These findings suggest that abnormalities in brain circuitry that are involved in motor learning might be a contributing factor for pursuit impairments in ASD.

Visual Fixation and Vestibulo-Ocular Reflexes

Several studies have demonstrated, albeit inconsistently, that individuals with ASD have unusual visual scanning patterns when they examine human faces and social scenes (Klin, Jones,

Schultz, Volkmar, & Cohen, 2002; Pelphrey et al., 2002; van der Geest, Kemner, Verbaten, & van Engeland, 2002; van der Geest, Kemner, Camfferman, Verbaten, & van Engeland, 2002) and make fewer visual fixations during visual search (Kemner, van Ewijk, van Engeland, & Hooge, 2008). While these studies are designed to evaluate how individuals with ASD extract visual information from their social environments, few studies have investigated brain systems supporting sustained visual fixation. Stability of visual fixation depends on the integrity of cerebellar–brain stem systems, more specifically a balance between activity of burst neurons in the paramedian pontine reticular formation that drive eye movements and omnipause neurons in the raphe interpositus nucleus that inhibit burst neurons and receive input from the cerebellar vermis (Fuchs, Kaneko, & Scudder, 1985).

Nowinski, Minshew, Luna, Takarae, and Sweeney (2005) examined rates of square-wave jerks during central and eccentric fixation and ocular drift during eccentric fixation in 52 individuals with ASD and 52 age- and IQ-matched typically developing control subjects. Square-wave jerks are intrusive eye movements that consist of two saccades: the first saccade, which results from reduced inhibitory input to the brain stem, takes the eyes off the target object and is followed by a second saccade that corrects eye position to return to the target. Rates and size of square-wave jerks increase when inhibitory input is disrupted (Dell'Osso, Abel, & Daroff, 1977; Zee, Yee, Cogan, Robinson, & Engel, 1976). Speed of ocular drift during eccentric gaze increases after lesions in the flocculus and paraflocculus of the cerebellum (Zee, Leigh, & Mathieu-Millaire, 1980), and thus depends on cerebellar integrity. Nowinski and colleagues (2005) found no alterations in rates of square wave jerks and speed of ocular drift in ASD suggesting that this system is largely preserved in ASD. They did find that the amplitude of square-wave jerks was larger in individuals with ASD while fixating peripheral targets and when the participant was asked to maintain central fixation without a visual target. Further, the second corrective saccade to refoveate the target (the second saccade of square wave jerks) was executed more quickly in individuals with ASD when they were asked to maintain central fixation without visual stimuli. These findings suggest a subtle imbalance between excitatory and inhibitory processes in the brain stem, which was sufficient to alter amplitude and timing of square-wave jerks. The cerebellar vermis is considered critical in using proprioceptive information about extraocular muscles to maintain fixation with the absence of visual stimuli and sends input to the brain stem (Zee et al., 1980). Because the metrics of square-wave jerks were most affected in the condition without visual stimuli, it is possible that disturbances in vermal input are the source of reduced inhibitory control of relevant brain stem neurons. This is consistent with the previously described observation of saccadic dysmetria in ASD (Takarae et al., 2004b) that also suggests abnormalities of the cerebellar vermis.

While the study of visual fixation indicates subtle abnormalities in the cerebellar–brain stem system, studies of the vestibulo-ocular reflex (VOR) have not indicated reduced cerebellar oculomotor system integrity in ASD. VOR stabilizes visual images of stationary objects on the retina during transient head rotation by compensating for the movement of orbits with eye rotation. The VOR system is particularly sensitive to effects of cerebellar nodulus and uvula lesions (Waespe, Cohen, & Raphan, 1985; Wiest, Deecke, Trattnig, & Mueller, 1999). Early studies comparing children with ASD and typically developing children reported similar duration (Ritvo et al., 1969) but a statistically longer time constant for VOR in darkness (Ornitz, 1985; Ornitz, Atwell, Kaplan, & Westlake, 1985) and shorter duration in lighted conditions for children with ASD (Ornitz, 1985; Ornitz et al., 1985; Ornitz, Brown, Mason, & Putnam, 1974; Ritvo et al., 1969). These studies, however, did not match patient and control groups by IQ, and examinations of individual data suggest that the group differences might have been driven by a few subjects with extreme performance abnormalities while the majority of children with ASD performed at levels similar to the control group. A more recent study by Goldberg and colleagues (2000) examined VOR in darkness in 13 children with ASD and 10 age- and IQ-matched typically developing children and found no differences in time constant of VOR between groups. Findings from studies of VOR thus suggest that cerebellar–brain stem systems supporting these oculomotor processes are largely preserved in ASD.

In summary, eye movement studies indicate that subcortical circuitry supporting visual fixation, VOR, and exogenous saccades are largely preserved in ASD, although modest disturbances in sensorimotor transformations implicating cerebellar dysfunction are present when subjects make visually guided saccades to sensory targets and when they fixate remembered target locations in darkness. When tasks place greater demands on higher cognitive processes of behavioral inhibition, planning, working memory, and motor learning, deficits in individuals with ASD are more consistently observed. This pattern of findings has been observed in impairments in antisaccade and oculomotor delayed response tasks, closed-loop pursuit, and predictive saccade tasks. Developmental trajectories that are observed in these tasks suggest that maturation in brain systems that support endogenous eye movements may reach a developmental plateau earlier in ASD and not reach the same level of ability/performance as typically developing individuals.

Eye Movement Abnormalities in Unaffected Family Members of Individuals with ASD

Recent data indicate that unaffected parents and siblings of individuals with ASD show saccade and smooth pursuit abnormalities that are similar to those observed in individuals with ASD (Mosconi et al., 2010). Studying 57 first-degree relatives (42 parents and 15 siblings) of individuals with autistic disorder, Mosconi and colleagues found that family members demonstrated saccade hypometria, reduced closed-loop pursuit gain, reduced rightward open-loop pursuit gain, impaired response timing mechanisms for rightward predictive saccades,

and increased rates of response suppression errors on an antisaccade task. These findings indicate that pontocerebellar circuitry alterations implicated in ASD by studies of saccade inaccuracy, increased trial-wise saccade amplitude variability, and reduced closed-loop pursuit gain may be familial. Similarly, rightward lateralized deficits in open-loop smooth pursuit and predictive saccade timing suggest left-hemisphere dysfunction affecting temporoparietal and basal ganglia systems, respectively. Last, impaired antisaccade performance is consistent with PFC abnormalities that also were implicated in the one previous study of eye movements in unaffected family members that identified inhibitory control deficits on a memory guided saccade task (Koczat et al., 2002). This profile of impairments has direct implications for shared neurocircuitry dysfunction in individuals with ASD and their first-degree relatives. Future studies are needed to examine relationships between eye movement performance in probands and family members (these studies did not examine family trios), identify whether these impairments are heritable, and investigate gene variants in ASD that are associated with neurophysiological developments underlying saccade and smooth pursuit abnormalities. Still, these recent data indicating parallel eye movement alterations in independent sets of probands and family members support the viability of eye movement alterations as intermediate phenotypes for future genetic and neurobiological studies of ASD.

Coordination of Complex Motor Sequences: Evidence of Dsypraxia in ASD

The neurophysiology of planning and executing motor sequences is less well understood than that regulating the initiation and precision of motor acts. Single-cell recording studies of behaving primates and human functional neuroimaging studies indicate that performing response sequences engages premotor cortex and basal ganglia to a significantly greater degree than the performance of single responses (Chan, Rao, Chen, Ye, & Zhang, 2006; Lecas, Requin, Anger, & Vitton, 1986; Requin, Riehle, & Seal, 1988; Rosenbaum, 1980; Tanji & Kurata, 1985; Wise, 1985), while also integrating unique connections with PFC, presupplementary motor area and parietal cortex (Grafton & Hamilton, 2007; Hamilton & Grafton, 2008; Seal & Commenges, 1985). Sequence learning and voluntary execution of motor sequences are organized at the neocortical level within the supplementary (SMA) and presupplementary motor areas and the inferior parietal lobule (Bapi, Miyapuram, Graydon, & Doya, 2006; Bischoff-Grethe, Goedert, Willingham, & Grafton, 2004; Grafton et al., 2002). Premotor and posterior parietal cortex are engaged during the planning phase of complex action sequences (Johnson-Frey, Newman-Norlund, & Grafton, 2005; Kawashima et al., 1996; Tunik, Rice, Hamilton, & Grafton, 2007) while the SMA is a vital node for the final assembly of action elements into a sequential motor plan (Gentilucci et al., 2000). Grafton and

Hamilton (2007) noted that the anterior intraparietal sulcus also is involved in goal representation for motor actions, while activity in the inferior frontal gyrus is sensitive to the local kinematic features of how an object is acted upon. In addition, these frontoparietal systems engage dorsolateral PFC that is known to store previously learned information in short-term or working memory and to organize complex behavioral plans. Utilizing this widely distributed neural system, frontoparietal motor planning and execution systems rely on previously learned motor behaviors to initiate sequences of actions that together allow rapid and adaptive management of complex environmental demands.

Numerous neurobiological and behavioral studies suggest that at least a portion of individuals with ASD are dyspraxic, demonstrating a reduced ability to organize or initiate motor sequences despite intact performance of constituent movements (Hughes, 1996; Jones et al., 1985; Leary & Hill, 1996; Minshew et al., 1997; Rogers et al., 1996). Dyspraxia is typically considered as a deficit that occurs in the context of spared basic motor skills, so that considering behavioral manifestations of dyspraxia in ASD is complicated, requiring demonstration that the dyspraxia is either more severe than can be accounted for by basic motor system deficits or occurs in contexts where basic motor deficits do not influence behavioral performance. Available evidence indicates that a subset of individuals with ASD show impairments in complex purposeful behavior that are disproportionate to their deficits in basic motor skills. Dziuk and colleagues (2007) reported that, although basic motor skills predicted a significant proportion of variance in overall praxis scores, differences in praxis performance exceeded deficits expected based on impairment in basic motor abilities. Additional research is needed to clarify the extent to which deficits in complex motor sequences are attributable to more fundamental motor impairments, but current evidence indicates that individuals with ASD show impairments in planning and implementing sequential motor responses that can not be explained fully by deficits in basic motor abilities.

Evidence of dyspraxia in ASD suggests that alterations in frontoparietal circuitry involving premotor cortex, SMA, pre-SMA, posterior parietal cortices, and the inferior parietal lobule negatively impact motor behavior in ASD. Frontoparietal connections have not been adequately investigated with functional neuroimaging during tasks evaluating motor praxis, but enlargement of inter-cortical white matter (indexed by MRI segmentation of cerebral white matter; Herbert et al., 2003; Herbert et al., 2004) and minicolumnar abnormalities in ASD (including increased minicolumnar width and number, smaller neurons and nucleolar cross sections, and increased neuron density; Casanova, 2004; Casanova, Buxhoeveden, Switala, & Roy, 2002; Casanova, van Kooten, Switala, van Engeland, Heinsen, et al., 2006) suggest that corticocortical pathways necessary for complex cognitive processing (e.g., coordinated motor movements) are altered during development. Mostofsky, Burgess, and Gidley Larson (2007) indicated that increased left motor and premotor cortical white matter volume was related to soft neurological signs (including incoordination, immature

reflexes, and poor perceptual or sensorimotor integration) in patients with ASD. Schmitz, Daly, and Murphy (2007) reported reduced prefrontal parenchymal volumes associated with increased motor reaction time in patients with ASD. Examining neural circuits involved in praxis in individuals with ASD with functional neuroimaging is one critical next step for understanding neurophysiological mechanisms of dyspraxia in this population.

> **Minicolumn:** A vertical column through the cortex comprising 80–120 neurons (except in visual cortex) that is the most basic organizational structure of neocortex.

Considerable variability in praxis ability exists among individuals with ASD, both between individuals and within individuals over time. Rinehart and colleagues (Rinehart, Tonge, Bradshaw, Iansek, Enticott, & Johnson, 2006a) reported that individuals with autism show greater variability in reaction time on a motor planning task relative to both an Asperger's group and a group of age-matched typically developing controls. The authors further demonstrated that movement related potentials (MRP) thought to be associated with SMA and motor cortical activity were less robust for patients with autism relative to healthy controls during premovement phases. Individuals with Asperger's disorder showed less robust peak activity during movement planning, but none of the comparisons between the Asperger's group and controls reached statistical significance. In a related study, Rinehart and colleagues (Rinehart, Bradshaw, Brereton, & Tonge, 2002) observed protracted motor preparation times for individuals with autism as well as a failure to benefit from the predictability of stimulus sequences as reflected by an absence of differences between their reaction time to predictable versus unpredictable cues. These patterns of abnormality were not observed for individuals with Asperger's disorder (although it should be noted that the Asperger's disorder group did show increased movement times that did not reach statistical significance). These studies highlight two major insights: First, significant variability both among individuals with autism and between individuals with autism and Asperger's disorder can be large with some measures, and this may explain some of the inconsistencies in the literature on motor impairments in autism (e.g., Rogers et al., 2003 reported oromotor and action on object imitation impairments, but no differences between children with autism and typically developing controls on manual gesture imitation tasks). Also, if the variability reducing functions of corticocerebellar networks fail to effectively regulate motor output in ASD, it too may explain some differences within subjects in terms of the consistency of deficits observed on motor tasks. Second, evidence of dyspraxia in a subset of individuals with autism likely reflects motor planning dysfunction that typically relies on SMA connections with PFC and the striatum. Individuals with Asperger's disorder also showed reduced peak amplitude of movement related potentials during the motor preparation phase, but this difference is not as robust as found for individuals with autism.

Postmovement cortical activity was largely intact for both groups in this study. Hypotheses regarding a similarity between patients with Parkinson's disease (who show characteristic pre- and postmovement cortical abnormalities; Cunnington, Iansek, Bradshaw, & Phillips, 1995) and ASD (Damasio et al., 1978; Vilensky et al., 1981) are thus informative but also limiting in that the pattern of frontostriatal dysfunction has both similarities and differences in these disorders.

> **Movement related potentials:** Electrophysiological changes in cortex leading up to voluntary muscle movement that reflect the cortical contribution to the premotor planning of movement.

Studies of motor planning also indicate that dyspraxia is linked to core features of ASD. Dziuk and colleagues (2007) found that the level of dyspraxia in children with ASD was associated with their overall level of impairment in social, communication, and repetitive behavior domains measured with the Autism Diagnostic Observation Scale (ADOS; Lord et al., 2000). Similarly, Rogers and colleagues (2003) reported that children with ASD who were "weak imitators" (defined as those performing below the mean level for age- and IQ-matched developmentally delayed children on tasks of imitation of sequential motor actions) had greater overall symptomatology, poorer social responsiveness, and weaknesses in fine motor skill relative to "strong imitators" with ASD. These studies suggest that either the core features of ASD result from a shared neurological basis with dyspraxia (e.g., similar neural alterations across different brain systems), or that impaired coordination of motor actions may contribute to the social and communicative deficits observed in ASD as well as patterns of repetitive behavior. Clearly dyspraxia is not a stand-alone cause of core features of ASD, as the majority of children with dyspraxia do not develop an ASD. However, evidence that dyspraxia contributes to delayed development in oromotor and imitation skills integral to language and social development (Crary, Landess, & Towne, 1984; Dewey, Roy, Square-Storer, & Hayden, 1988; Stone, Ousley, & Littleford, 1997) and that motor impairments precede or at least coincide with the emergence of core social and communication impairments in ASD (Baranek, 1999; Bryson et al., 2007; Teitelbaum et al., 1998) together suggest that dyspraxia may be one contributing factor to impairments that are core to the disorder (DeMyer, Hingtgen, & Jackson, 1981). Considerable development of the neurobiological systems associated with motor coordination and complex motor behavior precede the development of social and communication systems (Lawrence & Hopkins, 1976; Simonds & Scheibel, 1989), consistent with the hypothesis that early motor system dysfunction may have downstream effects for developing social and communication systems in ASD. Nonmotor brain systems have been shown to take on motor functions during childhood and adolescence in individuals with ASD (Muller et al., 2001; Takarae et al., 2007), indicating that these regions may be developmentally compromised in part because they are called on to provide ongoing compensation for deficits in motor skill and sequencing.

This is a novel and exciting hypothesis that may be important for understanding the sequential pattern of brain development in individuals with ASD.

Recent data on motor learning suggest that alternative mechanisms may be used to adapt motor behavior to consistent changes in external demands. Assessment of motor adaptation provides a useful clinical approach for evaluating the functional integrity of the cerebellum (Werner, Bock, Gizewski, Schoch, & Timmann, 2009; Xu-Wilson et al., 2009) and thus has been investigated in several studies of ASD. Gidley-Larson and colleagues (2008) and Mostofsky and colleagues (2004) each reported intact motor adaptation in ASD when either visual (Gidley-Larson study only) or proprioceptive feedback (both studies) was altered. In contrast, D'Cruz and colleagues (2008) administered an intrasaccadic target displacement task known to elicit saccade adaptation and found that individuals with ASD demonstrated reduced adaptation relative to controls for rightward saccades, and increased adaptation for leftward saccades compared to controls. Haswell and colleagues (2009) also reported disrupted motor generalization when subjects with ASD were required to rely on visual, as opposed to proprioceptive feedback. The authors examined the trajectories of reaching movements while children with ASD and age-matched healthy controls moved a robotic arm toward a visual target. During task trials, a perpendicular force was applied to the robotic arm causing subjects to modify the trajectories of their responses. Working in the left workspace, both groups of subjects learned to make more direct paths toward the visual target over trials. Two generalization conditions then were administered in the right workspace: (1) subjects made identical joint rotations as compared to the learning trials; and (2) subjects made identical hand motions as the learning trials. Therefore, condition 1 examined the generalization of learned proprioceptive feedback in a different workspace, and condition 2 examined the generalization of learned visual feedback in a different workspace. Children with ASD generalized learning to the proprioceptive feedback condition, but not to the visual feedback condition. Children with ASD therefore may show intact abilities to apply proprioceptive feedback during motor learning, but they appear to be impaired when having to rely on visual feedback to guide learned motor responses. Interestingly, performance during the generalization of visual feedback was associated with social dysfunction in ASD, suggesting that reduced skill in integrating visual feedback regarding motor performance may impact social development in ASD.

Are Mirror Neurons Involved in Dyspraxia in ASD?

Additional insights into complex motor learning and planning can be gained by examining "mirror neuron systems," the consideration of which recently has been popular in the ASD literature. Mirror neurons—neurons responsive during the observation as well as the performance of motor acts—were first identified in studies of nonhuman primates (Di Pellegrino, Fadiga, Fogassi, Gallese, & Rizzolatti, 1992; Gallese, Fadiga, Fogassi, & Rizzolatti, 1996; Rizzolatti et al., 1988). Subsequent human functional neuroimaging studies have indicated that rostroventral motor cortex (Area F5) activation increases both during the execution as well as the observation of hand and mouth movements (Arbib, Billard, Iacoboni, & Oztop, 2000; Fogassi et al., 2005; Grezes, Armony, Rowe, & Passingham, 2003; Kaplan & Iacoboni, 2006; Molnar-Szakacs, Kaplan, Greenfield, & Iacoboni, 2006). Discrete clusters of mirror neurons within the dorsal convexity and adjacent posterior bank of the arcuate sulcus in the macaque monkey have been found to selectively respond during the voluntary production of meaningful hand gestures as well as when these gestures are observed while being performed by others (Fogassi et al., 2005). However, the mirror quality of these neurons was evident only for meaningful movements with objects and not for meaningful social or communicative gestures (Arbib et al., 2000; Buccino et al., 2004), suggesting that it is the observation of intentional action related to manipulating objects rather than the intentions or communicative meaning of the actor's movements that is tied to the engagement of these neurons.

Mirror neuron characteristics also are observed within cell clusters located in the lateral bank of the inferior parietal lobule and in the superior temporal sulcus (Fogassi et al., 2005; Sakata, Taira, Murata, & Mine, 1995). Visual systems within the inferior parietal lobule and superior temporal sulcus show increased neuronal firing rates in the presence of an object even when an individual is instructed or cued not to act on the object (Grafton et al., 2007). This mirror neuron system activates in response to others' meaningful actions on objects, putatively reflecting the learning and storage of motor actions that guide response planning and execution regarding that class of objects (Jeannerod, Arbib, Rizzolatti, & Sakata, 1995; Jeannerod & Decety, 1995). This system allows an individual to understand that an action sequence is taking place, differentiate this action sequence from other actions, and use this information to guide subsequent motor behavior. Mirror neurons thus may contribute to complex motor learning, planning, and execution. Because of their social features, interest in this neuron population has been intense in the ASD community.

Deficits in the performance of overlearned motor sequences have been observed in ASD (Dziuk et al., 2007; Mostofsky et al., 2006; Rogers et al., 1996; Vernazza-Martin et al., 2005), and hypoactivation in brain regions believed to have some cells with mirror neuron properties has been documented in functional MRI studies of individuals with ASD (Dapretto et al., 2006; Martineau et al., 2008; Williams et al., 2006b). Findings from these studies suggest that imitation impairments in ASD may be related to alterations of mirror neuron systems, and that mirror neuron disturbances may contribute to social interaction deficits and dyspraxia in ASD (Williams et al., 2004). However, research on skilled motor gestures indicates that the errors made by individuals with ASD are not confined to social imitation but also are evident in response to

explicit instructions and with tool-use (Mostofsky et al., 2006). Thus, despite the intuitive appeal of the idea, there is significant risk of overinterpreting available evidence to infer a direct and pivotal role of mirror neuron disturbances in the social features of ASD.

Motor Development in Infants and Young Children with ASD

Examining the early development of motor systems in ASD may facilitate not only an earlier diagnosis, but also an understanding of behavioral and neurobiological phenotypes that will be useful in genetic research. Studies of the infant siblings of children with ASD are providing exciting new clues into the early development of these disorders. Results suggest that, overall, motor impairments are robust and prevalent across the majority of infants who go on to develop an ASD. Further, evidence indicates that not only do motor symptoms appear early, but they precede the onset of social and communication features of ASD.

Retrospective parent reports (Chawarska et al., 2007) and histological findings of pathology likely originating within the second trimester (Bauman et al., 1985) each have indicated that ASDs typically have a prenatal or early postnatal onset. Still, ASDs seldom are diagnosed prior to age three years (Mandell, Novak, & Zubritsky, 2005) suggesting that the emergence of symptoms often is not discernible until ages at which children typically achieve social and communication milestones and actively are engaged in peer interactions. The discrepancy between presumed onset and identification of ASD is likely related to multiple factors, not the least of which is an absence of knowledge regarding infantile developmental trajectories of affected individuals. There is an overarching assumption that symptoms of ASD are present early in ontogeny and that delays in obtaining formal diagnoses reflect a failure to recognize behavioral indicators or a failure to obtain adequate resources to aid in the detection of these indicators. However, this assumption has only inconsistently been supported by empirical evidence, and there may be variability in the onset of the pathophysiological and clinical presentation that will prove informative.

Recent studies of infant siblings later identified with ASD challenge the assumption that behavioral indicators are present within the first 6 months of life. Studies of ASD infants' development within the first year of life have failed to detect behavioral features of ASD prior to age 9–12 months (Landa, Holman, & Garrett-Mayer, 2007; Osterling & Dawson, 1994; Zwaigenbaum et al., 2005) suggesting that: (1) the core symptoms are not present early in ontogeny, (2) current methodology is not sensitive enough to reliably measure core features, or (3) the early behavioral development of infants with ASD does not map cleanly onto the behavioral phenotype evident after the first year of life. In contrast to the absence of consistent evidence for social and nonverbal communication deficits

prior to age 12 months in children later diagnosed with ASD, an emerging and consistent literature regarding motor abnormalities within the first year of life suggests that this domain of impairment may be detectable earlier. In two independent studies of early development of infants later diagnosed with ASD, Teitelbaum and colleagues (1998) and Bryson and colleagues (2007) collectively identified motor dysfunction prior to age 12 months in 24/26 infants studied. Teitelbaum and colleagues (2004) reported similar findings for a sample of infants later diagnosed with Asperger's syndrome. While Teitelbaum's studies did not examine social or communication behaviors, Bryson and colleagues (2007) reported that hallmark characteristics of ASD, including deficits in social reciprocity, eye contact, and social referencing, were largely absent at age 6 months despite motor impairment in 7 out of 9 infants studied. Motor impairments included poor visual tracking, limited motor control when grasping or reaching for objects, and difficulty sitting independently. Additional motor disturbances were observed at 12 and 18 months, including abnormal, repetitive motor behaviors and odd posturing. Interestingly, the two infants identified with ASD at age 3 years who did not show motor abnormalities by age 6 months did, in fact, demonstrate motor impairments by age 12 months. These infants also were the only two observed that were identified as having ASD but who did not meet criteria on both the Autism Diagnostic Inventory (Lord, Rutter, & Le Couteur, 1994) and ADOS. Although these studies collectively examined only a small sample of children with ASD, results do suggest that motor impairments are associated with ASD and may precede aberrant development in more complex cognitive functions, including executive impairment, deficits in socialization, and atypical communication development.

These reports have significant implications for the early identification of infants with ASD and for understanding pathophysiological mechanisms. In addition, this research points to the importance of future studies examining the relationship between early emerging motor impairments and the altered development of complex cognitive processes involving both social and communication skills in children with ASD. Elucidating the neurobiological basis of motor control deficits may help resolve several controversies about the timing of alteration and specific pathophysiological mechanisms associated with the earliest manifestations of ASD.

Factors Associated with Motor Deficits in ASD

Initial reports of motor abnormalities in ASD relied largely on retrospective accounts of major developmental milestones, and suggested that motor impairments in ASD were confined to early childhood gross motor abilities. Deviations in vestibular control, gross and fine motor skill, oculomotor processes, and complex motor learning and adaptation across development are not yet well understood. The severity of disturbances

among individuals with ASD in gross motor and fine motor systems may diminish over the lifespan, but oculomotor impairment and dyspraxia appear to persist throughout development (Freitag et al., 2007). Further, developmental failures may cause some abnormalities of motor control, such as the neocortical/cognitive control of planned actions, to deviate from normative trajectories so that greater differences can be seen later rather than earlier in life. These observations have critical implications for understanding the developmental pathophysiology of ASD.

Currently available evidence suggests that dysfunction in basic motor and sensorimotor circuits may be compensated for by the recruitment of alternative neural networks as demonstrated in functional imaging studies of manual (Muller et al., 2001) and oculomotor (Takarae et al., 2007) systems in patients with ASD. These compensations may mitigate basic motor impairments, but consequently adversely affect developments in more complex processes that rely on the "borrowed" higher-order systems. Elucidating the developmental neurobiology of ASD thus will require a mechanistic approach in which the neural system characteristics of component motor processes are investigated with longitudinal functional and anatomical imaging studies.

While there appear to be high rates of motor system dysfunction in ASD, alterations of motor systems are of course not specific to ASD and therefore are not specific diagnostic indicators. Thus, many of the motor problems in ASD may be sensitive but not specific markers for ASD—similar to other domains of deficit associated with the disorder when considered in isolation. For example, Provost, Lopez, and Heimerl (2007) reported gross and fine motor delays in children with ASD ages 21–41 months but also indicated that these deficits were not disproportionate in children with ASD relative to children with specific motor delays. Studies of oculomotor and praxis performance comparing individuals with ASD and cognitive impairment with age- and IQ-matched individuals have not been performed, but are necessary for clarifying the specificity of motor impairments to ASD phenotypes relative to the cognitive delays often associated with these disorders. Impairments that are specific to the disorder are of especial interest, especially those that have not been reported for other developmental or neuropsychiatric disorders studied. In this regard, the observation of left-lateralized abnormalities on eye movement testing, for example reduced rightward open-loop pursuit gain (Takarae et al., 2004a), has not been identified in other neuropsychiatric disorders with smooth pursuit impairments, and this is a potentially important observation. Overreliance on proprioceptive relative to visual feedback during motor adaptation also may be specific to ASD (Haswell et al., 2009). Further, most neuroimaging studies of motor functions performed to date have not typically included cognitively impaired individuals with ASD, making it difficult to generalize findings regarding the integrity of motor systems to a broader population of affected individuals. While the requirements of functional imaging studies often preclude the inclusion of severely cognitively impaired individuals, novel strategies for acquiring anatomical data, including morphometric and diffusion weighted imaging, may provide a basis for useful studies of brain-behavior linkages across the autism spectrum and spectrum of cognitive ability. Additionally, studies of familial motor phenotypes may provide insights into pathophysiological mechanisms relevant to severely impaired and less impaired individuals.

Demarcation of ASD subgroups has been attempted with analysis of motor performance patterns. Initial reports provided inconsistent evidence for disproportionate motor impairments in individuals with Asperger's syndrome relative to individuals with autism (Gillberg, 1989; Manjiviona & Prior, 1995; Szatmari, Tuff, Finlayson, & Bartolucci, 1990). Motor impairments in individuals with Asperger's syndrome have been documented for a range of motor skills (Lopata, Hamm, Volker, & Sowinski, 2007; Sahlander, Mattsson, & Bejerot, 2008), but few studies have found evidence for a dissociation between Asperger's syndrome and autism on the basis of motor functioning. Rinehart and colleagues (2002) reported that individuals with autism show lateralized delays in performing motor responses to visual-spatial cues presented to the right visual field consistent with left hemisphere underdevelopment. In contrast, individuals with Asperger's syndrome did not show this pattern of motor delay but did show impaired motor preparation abilities as demonstrated by increased response latencies to predictable targets. Studies have rarely compared Asperger's syndrome and autism directly, but a few have found significant group differences (Ghaziuddin, Butler, Tsai, & Ghaziuddin, 1994; Manjiviona et al., 1995; Miller & Ozonoff, 2000) or disproportionate impairment in individuals with autism (Gepner et al., 2002; Ghaziuddin & Butler, 1998). Gepner and Mestre (2002) reported poor postural stability and postural adaptation to environmental motion in individuals with autism relative to individuals with Asperger's syndrome. Comparisons between these groups are difficult owing to the inconsistency of Asperger's syndrome diagnostic criteria applied across studies (Volkmar, 1999) and the tendency of many studies to include small samples of each diagnostic group and consequently combine these samples. Studies directly comparing these subpopulations will need to utilize consistent diagnostic classification criteria along with comprehensive and more sensitive motor measures to thoroughly parse neurobehavioral profiles.

Summary and Conclusions

The analysis of motor system deficits presents a unique opportunity to study alterations in brain systems that cause neurodevelopmental disorders such as ASD. Motor abnormalities in ASD have their onset early in ontogeny and involve multiple widely distributed neurophysiological systems. Several features unique to motor systems make them ideally suited for the translational studies needed to link genetic mechanisms to neurophysiological and cognitive substrates

of ASD. Motor systems can be more reliably assessed than many complex cognitive operations, and can be examined from the first moments of postnatal life. This aspect allows researchers to reliably detect early emerging motor impairments in infants with ASD and track these impairments over time using quantitative objective laboratory procedures. Studies of infants later diagnosed with ASD indicate that motor impairments may be among the earliest indicators of behavioral pathology, and thus they may be useful for identifying high risk individuals for early intervention. Motor disturbances also can be assessed across wide levels of cognitive ability enabling the examination both of higher-functioning individuals with ASD and individuals with ASD whose cognitive abilities are in the impaired range. Finally, recent evidence

Table 22–2.

Motor system deficits and brain regions most directly implicated in neuroimaging and neurobehavioral studies of ASD*

	Frontal Lobe	Temporoparietal Lobes	Basal Ganglia	Cerebellum	Brain Stem Nuclei
Vestibular functions Poor balance Poor postural control	—	**Somatosensory cortex**	—	**Spinocerebellum; interposed nuclei**	**Reticular formation**
Walking movements Bradykinesia Variable stride rates Poor balance	**Primary motor cortex**	—	**Substantia nigra; striatum**	**Spinocerebellum; interposed nuclei**	—
Writing and finger movements Dysgraphia Impaired grooved pegboard performance	**Dorsal premotor, supplementary motor and primary motor cortex**	**Superior temporal gyrus; precuneus; inferior parietal lobule**	**Striatum**	**Anterior cerebellum (lobules V–VI); lateral cerebellum; inferior vermis (lobule VIII); dentate nuclei**	—
Saccades Dysmetria Increased amplitude variability Increased latencies Increased response inhibition error rate Memory guided saccade inaccuracy	**Frontal eye field; supplementary eye field; DLPFC; anterior cingulate cortex**	**Parietal eye field; inferior parietal lobule**	**Caudate nucleus Substantia nigra pars reticulata**	**Vermis (lobules VI–VII); fastigial nuclei**	**PPRF; superior colliculus**
Smooth pursuit Reduced rightward open-loop gain Reduced closed-loop gain	**Frontal, supplementary and parietal eye fields**	**MT/V5**	—	**Vermis (lobules VI–VII); fastigial nuclei**	**PPRF**
Fixation Large amplitude square-wave jerks Reduced latency of corrective saccades	—	—	—	**Vestibulocerebellum; vestibular nuclei Vermis (lobules VI-VII)**	**Superior colliculus**
Motor sequences/learning Dyspraxia Impaired saccadic adaptation Impaired manual adaptation with visual feedback	**Inferior frontal gyrus; DLPFC; premotor, presupplementary motor, supplementary motor and primary motor cortices**	**Inferior parietal lobule; intraparietal sulcus; superior temporal sulcus**	**Striatum**	**Lateral hemispheres; dentate nuclei; vermis (lobules VI–VII); fastigial nuclei**	—

* This is not an exhaustive list of brain regions involved in each aspect of motor behavior. Brain regions were included if they were identified in previous neuroimaging studies of ASD or are directly implicated by neurobehavioral findings.

MT/V5: middle temporal area/visual cortical area 5; DLPFC: dorsolateral prefrontal cortex; PPRF: paramedian pontine reticular formation.

indicates that motor disturbances are evident in the majority of individuals with ASD and that these disturbances involve multiple neurophysiological systems. Impairments in gross motor, fine motor, oculomotor, and coordinated motor sequencing skills implicating corticocortical, frontostriatal, and corticocerebellar circuitry dysfunction in individuals with ASD all have been observed and they parallel findings of neuroanatomical and neurofunctional abnormalities. The extent to which these neural systems are affected in parallel, or differentially in different individuals, remains to be fully clarified (Table 22-2).

Higher level cognitive functioning impairments are often emphasized in the examination of ASD development, including language skills, executive functions, and social processes, but these are particularly difficult to characterize with the mechanistic, neurobiologically informed approaches that are provided by motor and sensorimotor studies. For example, although deficits in imitating observed gestures are robust and consistently noted in individuals with ASD (see Williams et al., 2004, for a review), the neural systems that enable individuals to implicitly learn, integrate, and execute the complex motor sequences inherent in motor praxis seldom have been systematically assessed in studies of ASD. However, by studying discrete motor processes and their underlying neurobiology, a clearer picture of the developmental neurophysiology of ASD may be drawn and insights into brain-behavior mechanisms that can be more closely linked to candidate genes are possible. A potential contributory role of motor system disturbances to the later emergence of social, language, and cognitive deficits also can be evaluated.

ASDs are characterized by complex and diverse sets of impairments. It is now recognized that single-factor models focusing on only one cognitive/behavioral process or brain region can not sufficiently account for the full constellation of clinical disturbances in ASD that involve pathology across multiple levels of the neuroaxis. Motor disturbances traditionally have not been included in these unitary frameworks because they are much less disabling features of the disorder than communication and social deficits. However, motor system research lends itself to translational studies, some of which have been initiated and offer preliminary evidence converging around gene-brain-behavior associations that provide a suitable model for investigating the neurobiology of motor impairments in ASD. Evidence also exists suggesting that motor profiles may distinguish individuals with Asperger's syndrome and individuals with autism, and individuals with autism with and without language delay, and thus may offer a focus for studies aimed at teasing apart subgroups of individuals with ASD in a neurobiologically informed manner that will be useful as quantitative phenotypes for genetic research. Motor disturbances in ASD, therefore, require increased behavioral, neurobiological, and genetic research attention, and should be included in models characterizing the pervasive and complex behavioral impairments that characterize ASD and related neurodevelopmental disorders.

Challenges and Future Directions

- Integrating converging findings on the profound and diverse motor deficits and dyspraxia in ASD into the definitions of the disorder(s) that currently are under revision will be important for fully elucidating these disorders and parsing heterogeneity.
- Longitudinal neurobehavioral and imaging studies of the development of motor skills are needed. Existing evidence suggests that motor impairments are among the earliest abnormalities to emerge in ASD development. Further, neuroimaging studies indicate that higher order neural systems may compensate for motor neurocircuitry dysfunction in a way that may alter the maturation of those systems and contribute to higher-level cognitive and social communication deficits.
- Motor profiles may distinguish individuals with Asperger's syndrome and individuals with autism, and individuals with autism with and without language delay, and thus may offer a focus for studies aimed at teasing apart subgroups of individuals with ASD in a neurobiologically informed manner.
- Identifying shared motor impairments in individuals with ASD and their unaffected first-degree relatives could offer clues to pathophysiological mechanisms, indicate disrupted neural systems that cosegregate within families, and provide direction for future genetic research.
- Cerebellar pathology has been consistently reported in ASD, but the functional impairments associated with these abnormalities are poorly understood. In addition, the extent to which this pathology is attributed to a history of seizures has been questioned (Crooks, Mitchell, & Thom, 2000; Whitney et al., 2008), suggesting that examination of motor skills in individuals with ASD with a history of seizures should be investigated relative to those without a history of seizures.

Epilepsy and Electroencephalography in Autism Spectrum Disorders

Points of Interest

- Epilepsy is approximately 10 to 30 times more prevalent in individuals with ASD than in the general population.
- The prevalence of seizures and epileptiform activity is highest in children with ASD with moderate to severe intellectual disability.
- Frequent seizures and epileptiform activity in the first 3 years of life are a risk factor for developing ASD with intellectual disability.
- Children with both ASD and epilepsy have poor developmental outcomes, and epilepsy is a risk factor for early mortality in ASD.
- ASD and epilepsy do not reflect singular entities with uniform etiologies; there is no one single treatment or treatment protocol for children with ASD and epilepsy; rational pharmacotherapy requires an understanding of the shared neuronal networks, genetic and molecular biological mechanisms that account for both ASD and the epilepsies.
- The best hope for improving developmental outcomes in children with ASD and epilepsy is early recognition and comprehensive treatment of both the ASD and epilepsy.

Autism Spectrum Disorders—Epilepsy: Definitions

Standardized classification systems for autism and epilepsy are essential, as both autism and epilepsy are heterogeneous disorders with multiple etiologies (Tuchman, Cuccaro, & Alessandri, 2010a). An understanding of the terminology for both autism and epilepsy is crucial in the interpretation of research studies on the relationship of what are now conceived

of as the autisms (Geschwind & Levitt, 2007) and the epilepsies (Reynolds & Rodin, 2009).

Throughout this chapter the term "autism spectrum disorders" (ASD) is used to include children with autistic disorder, Pervasive Developmental Disorders Not-Otherwise-Specified (PDD-NOS) and Asperger's syndrome. In this chapter children with disintegrative disorder (DD) or Rett syndrome (RS) are discussed separately from those with autism. In DD and RS rates of seizures are significantly higher than in autism, and both are associated with regression of skills.

Seizures are clinical events characterized by paroxysmal, stereotyped, relatively brief interruptions of ongoing behavior, associated with electrographic seizure patterns, and epilepsy is operationally defined as two unprovoked seizures of any type (ILAE, 1981). Seizures are the most dramatic aspect of epilepsy, although recent definitions of epilepsy have emphasized the neurologic, cognitive, psychological, and social consequences of this group of disorders (Fisher et al., 2005).

The term "subclinical" or "nonconvulsive" seizure is used to refer to electrographic patterns, without clinically recognizable cognitive, behavioral, or motor functions or apparent impairment of consciousness, and requires a concurrent EEG, with behavioral testing for identification; however there is significant controversy to what constitutes a seizure or an interictal event, and this differentiation becomes increasingly challenging in a child with complex behavioral manifestations as occurs in ASD (Besag, 1995). "Interictal epileptiform discharges" and "epileptiform activity" (both terms are used interchangeably) describe abnormal electroencephalogram (EEG) activity, specifically referring to spikes alone or accompanied by a slow wave, occurring either singly or in bursts, and lasting at most 1 or 2 seconds (Chatrian et al., 1974). This term is used to describe interictal paroxysmal activity, is not used to refer to seizure patterns, and the association of

epileptiform activity with an epileptic disorder is variable (Worrell, Lagerlund, & Buchhalter, 2002). The terminology and standards used to determine epileptic activity, seizures, or epileptiform activity, in children with ASD has varied widely among studies (Kelley & Moshe, 2006).

Historical Perspective

Epilepsy has been associated with ASD since the initial description of the disorder by Leo Kanner in 1943 (Kanner, 1971). In the 1960s the first studies on the relationship of ASD to epilepsy and to EEG abnormalities emerged (Creak & Pampiglione, 1969; Hutt, Hutt, Lee, & Ounsted, 1965; Schain & Yannet, 1960; White, Demyer, & Demyer, 1964). These studies were among the first neurobiological studies to suggest that the behaviors of children with ASD were secondary to a disorder of brain function.

In the early1970s a relationship between infantile spasms, hypsarrhythmia, and ASD (Taft & Cohen, 1971) was first described. A Finnish study in 1981 (Riikonen & Amnell, 1981) confirmed the relationship between infantile spasms and ASD. Recent studies have found that up to 35% of children diagnosed with infantile spasms in the first year of life go on to develop the ASD phenotype with associated intellectual disability (ID) (Saemundsen, Ludvigsson, & Rafnsson, 2007). At the present time we are just beginning to appreciate the high number of children with epileptic encephalopathies who later go on to develop the ASD phenotype and how often ASD coexists in children with epilepsy (Clarke et al., 2005).

In the late 1970s and early 1980s there was an interest in specific aspects of the relationship of ASD to epilepsy and of epilepsy and EEG abnormalities to language disorders. During this period the increased risk of seizures in autism at puberty was highlighted (Deykin & MacMahon, 1979), the relationship of autism to tuberous sclerosis was recognized (Mansheim, 1979), and clinical researchers began to investigate the relationship of epilepsy and the EEG to language disorders (Deonna, Beaumanoir, Gaillard, & Assal, 1977; Holmes, McKeever, & Saunders, 1981). At the present time, the neurobiological basis of the secondary peak of seizures during adolescence in ASD is still not clear, tuberous sclerosis has become an important model to explore the neurobiological underpinnings of the association between ASD and epilepsy, and the relationship of language regression, epilepsy, and EEG abnormalities to ASD remains controversial.

In the 1980s studies on autism-epilepsy investigated the differences in rates of epilepsy in different groups of children with ASD (Olsson, Steffenburg, & Gillberg, 1988). During this time standardized criteria for ASD (Lord et al., 1989) and advances in the classification of the epilepsies (ILAE, 1981) emerged; both of these advances had a positive scientific impact on the study of ASD-epilepsy. By the 1990s the relationship between ASD and epilepsy had been established (Volkmar & Nelson, 1990). During the 1990s studies focused on the specific risk factors for development of epilepsy in children with ASD (Tuchman, Rapin, & Shinnar, 1991) and explored the relationship of epilepsy and EEG findings to autistic regression (Tuchman & Rapin, 1997).

Recently studies have found that individuals with ASD and epilepsy have poorer cognitive (lower IQ), adaptive, behavioral, and social outcomes than those with ASD without epilepsy (Hara, 2007; Turk et al., 2009). There is emerging evidence that the mortality in ASD may be twice as high as in the general population with a significant percentage of the deaths being associated or secondary to coexisting epilepsy (Billstedt & Gillberg, 2005; Gillberg, Billstedt, Sundh, & Gillberg, 2010; Mouridsen, Bronnum-Hansen, Rich, & Isager, 2008). There has also been recent interest in the effects of chronic seizure disorders such as mesial temporal lobe epilepsy on deficits in higher-order social cognitive tasks in adults (Schacher et al., 2006; Walpole, Isaac, & Reynders, 2008). One study suggested that epilepsy is not part of the broader autism phenotype (Mouridsen, Rich, & Isager, 2008), but how often ASD is part of the broader epilepsy phenotype is not known. There is a renewed interest in the relationship of ASD to epilepsy with a shift in focus to the molecular biology mechanisms common to both ASD (Bourgeron, 2009) and the epilepsies (Rakhade & Jensen, 2009).

Epidemiology

Neither ASD nor epilepsy is a singular entity with uniform etiologies (Guerrini, 2006; Happe, Ronald, & Plomin, 2006). In children with ASD, cognitive and motor impairments, age of epilepsy onset, severity of receptive language deficits, and genetic and molecular abnormalities are associated with an increased prevalence of epilepsy (Tuchman, Moshe, & Rapin, 2009). In children with epilepsy, younger age at seizure onset, cognitive impairment, temporal or frontal lobe onset of seizures, and intractable epilepsy are associated with an increased likelihood of coexisting social-communication and behavioral disorders (Hamiwka & Wirrell, 2009).

The recognition of clinical seizures and the classification of seizure type are difficult in the general population (Camfield & Camfield, 2003), and in children with ASD the challenge of diagnosing and classifying seizures is even greater, secondary to their diverse behavioral manifestations (Tuchman & Rapin, 2002). Studies on individuals with ASD have reported that all seizure types may be associated with autism (Tuchman & Rapin, 2002). In a group of 98 children with ASD, ages 6 to 13 years, all with intellectual disability, the predominant seizure types in order of frequency were generalized tonic-clonic, myoclonic, atypical absences, and partial complex seizures (Steffenburg, Hagberg, & Kyllerman, 1996). In addition this found that children who only had partial complex seizure types were less likely to have other evidence of brain damage such as severe intellectual disability, cerebral palsy, or visual impairments as contrasted to those with generalized epilepsies.

Epilepsy

The prevalence of epilepsy in ASD is highly variable and depends on the cohort studied, with rates ranging from 5% to 46% (Spence & Schneider, 2009). The reported rates of epilepsy in ASD are several-fold higher than the 0.5% to 1% prevalence of epilepsy in the general population (Hauser, Annegers, & Kurland, 1993). However, the prevalence of epilepsy in ASD is similar to prevalence of epilepsy in a population of children with intellectual disability, with the highest rates of seizures in those with severe cognitive impairments (Goulden, Shinnar, Koller, Katz, & Richardson, 1991; Murphy, Trevathan, & Yeargin-Allsopp, 1995; Steffenburg et al., 1996; Steffenburg, Hagberg, Viggedal, & Kyllerman, 1995). There is a paucity of information on how often ASD is found in children with epilepsy, although in a study conducted in a tertiary epilepsy clinic, approximately 30% of children with epilepsy screened positive for ASD (Clarke et al., 2005) and approximately 7% of children with seizures in the first year of life develop ASD (Saemundsen, Ludvigsson, Hilmarsdottir, & Rafnsson, 2007).

Studies suggest that there are two peaks of seizure onset in autism—one in early childhood and one in adolescence (Volkmar & Nelson, 1990). Studies that include younger children with autism, that is, prior to adolescence, have in general a prevalence rate of less than 10% (Fattal-Valevski et al., 1999; Hoshino et al., 1987; Voigt et al., 2000). In studies that include a high number of adolescents and adults with autism, the rates of seizures reported are higher than 30% (Giovanardi Rossi, Posar, & Parmeggiani, 2000; Kawasaki, Yokota, Shinomiya, Shimizu, & Niwa, 1997). In those that include a mixture of infants, children, adolescents, and adults the prevalence of epilepsy is 10% to 20% (Kobayashi & Murata, 1998; Tuchman & Rapin, 1997; Tuchman et al., 1991).

It is not uncommon for children who go on to develop ASD to have seizures in the first year of life, with one study of 246 children with ASD ages 4 to 15 years reporting that 80% had their seizure onset in the first year of life (Wong, 1993). Studies suggest that the prevalence of autism is highest among children whose seizures started around age 2 years or earlier and those with low cognitive level (Clarke et al., 2005) and that approximately 7% of children with epilepsy whose seizure onset is in the first year of life go on to develop ASD with intellectual disability (Saemundsen, Ludvigsson, Hilmarsdottir, et al., 2007). Children with autism who have a history of epilepsy at an early age likely reflect a subgroup that is associated with more significant insults to the developing brain. Seizures in the first year of life are a risk factor for ASD, and may reflect the role of early insults to the developing brain, genetic or environmental.

The secondary peak in seizure onset during adolescence and adulthood, although possibly unique to children with ASD as compared to other developmental disabilities, is not well understood. In a prospective population-based study of adolescents and adults with epilepsy and ASD ages 18 to 38 years, all with moderate to severe mental retardation, almost 50% of those with severe intellectual disability had epilepsy by early adult life as compared to 20% of those with moderate intellectual disability (Danielsson, Gillberg, Billstedt, Gillberg, & Olsson, 2005). This latter study did not find the secondary peak of epilepsy and found the highest risk of epilepsy in the first year of life. They did find that greater than 10% of individuals in their study developed epilepsy after age 18 years. They also pointed out that in their study they included individuals with ASD and epilepsy with congenital or acquired disorders, such as individuals with tuberous sclerosis and Rett syndrome. This would bias their study to finding a younger age of seizures, as this is a different population than that in other studies that have found a secondary peak (Giovanardi Rossi et al., 2000). The suggestion here is that the secondary peak is found among those with ASD and intellectual disability without a known etiology.

One intriguing study has found that during the decades of adulthood the prevalence of epilepsy in mental retardation and in cerebral palsy declines, while the prevalence of epilepsy in individuals with Down syndrome and ASD increases during this same period of time (McDermott et al., 2005). In contrast, in Rett syndrome the severity of epilepsy tends to decrease with age with lower seizure frequency and less severe seizures as these girls approach adulthood (Steffenburg, Hagberg, & Hagberg, 2001). These findings suggest that the observed second peak of seizure onset in adolescence and increasing prevalence of epilepsy into adulthood is secondary to an ongoing pathological process in individuals with ASD (Deykin & MacMahon, 1979; Hara, 2007), although clearly more research in this area is needed.

One of the most consistent findings on the coexistence of ASD and epilepsy is that intellectual disability is a significant risk factor for the development of epilepsy in ASD (Amiet et al., 2008) and that the highest rates of seizures are observed in those with the most severe intellectual disability (Pavone et al., 2004). The role of intellectual disability as a primary risk factor for the development of epilepsy in children with ASD was highlighted in the early 1990s in a study of a cohort of 314 children with ASD and 237 children with language disorder without ASD, evaluated over a 30-year period (Tuchman et al., 1991). The major risk factor for epilepsy identified in this study was severe intellectual disability, and this risk was heightened in the presence of severe intellectual disability with a motor deficit. In contrast, epilepsy occurred in 6% of children in the ASD group that was negative for severe intellectual disability, motor deficit, associated perinatal or medical disorder, or a positive family history of epilepsy. The prevalence of epilepsy in this group was similar to the 8% of language-impaired non-ASD children with the highest risk of epilepsy, regardless of whether they had ASD, or language impairment without ASD in those with the most severe receptive language disorder (Tuchman, et al., 1991). This study also found a statistically significant higher percentage of epilepsy in girls with ASD (24%) compared to boys with ASD (11%), which was attributed to the increased prevalence of cognitive and motor deficit in girls. In addition, this found a high risk for developing seizures in the first 5 years of life and that infantile spasms were overrepresented in ASD. A follow-up of this cohort of children

into adulthood confirmed previous finding of a secondary peak of seizure onset during adolescence (Ballaban-Gil, Rapin, Tuchman, Freeman, & Shinnar, 1991).

In summary, best estimate of the prevalence on epilepsy in ASD is 8% in ASD without intellectual disability and 20% in ASD with intellectual disability (Amiet et al., 2008). Sample ascertainment and associated medical disorders contribute to the wide range of prevalence rates found in studies on epilepsy in ASD (Spence & Schneider, 2009; Tuchman et al., 2009). Variables such as early brain pathology and degree of intellectual disability are strong contributors to the risk of developing epilepsy in ASD. There are two peaks of seizure onset one occurring prior to age 5 years and one occurring into adolescence and adulthood. Studies on the prevalence of epilepsy in ASD clearly indicate that the highest prevalence of epilepsy, regardless of age or gender, is in individuals with ASD and ID (Elia, Musumeci, Ferri, & Bergonzi, 1995; Mouridsen, Rich, & Isager, 2000; Rossi, Parmeggiani, Bach, Santucci, & Visconti, 1995).

EEG Abnormalities

Studies on the prevalence of epileptiform activity in individuals with ASD and no clinical history of seizures range from 6% to 31% (Kagan-Kushnir, Roberts, & Snead, 2005), although rates as high as 60% have been reported (Chez et al., 2006). Despite documentation of the higher prevalence of epileptiform activity in ASD compared to the 1.5 to 4% rate of epileptiform activity in the general population (Capdevila, Dayyat, Kheirandish-Gozal, & Gozal, 2008; Cavazzuti, Cappella, & Nalin, 1980), there is significant controversy regarding the specificity of these findings to the ASD phenotype. For example in ADHD without epilepsy, epileptiform activity occurs in 6% to 30% of children (Hughes, DeLeo, & Melyn, 2000; Kaufmann, Goldberg-Stern, & Shuper, 2009; Richer, Shevell, & Rosenblatt, 2002), which is remarkably similar to the prevalence of epileptiform activity in children with ASD without seizures. The suggestion is that the high prevalence of epileptiform activity is secondary to the neuropathological processes common to neurodevelopmental disorders. However, there is emerging evidence that epileptiform activity can, independently of seizures or the underlying brain pathology, contribute to specific cognitive dysfunction (Sengoku, Kanazawa, Kawai, & Yamaguchi, 1990; Shewmon & Erwin, 1988) and, when it occurs early in brain development, can cause acute and long-lasting impairment of brain function and neurodevelopment (Galanopoulou & Moshe, 2009; Holmes & Lenck-Santini, 2006).

The term "transient cognitive impairment" is used to describe individuals with epileptiform EEG discharges in association with a momentary disruption of adaptive cerebral function (Aarts, Binnie, Smit, & Wilkins, 1984; Binnie, 2003). The controversy is whether treating this group of children in the absence of seizures is justifiable (Binnie, 2003; Pressler, Robinson, Wilson, & Binnie, 2005). Despite the higher prevalence of epileptic activity in ASD, there is a lack of evidence that treatment of the interictal epileptiform discharges has a positive impact on language, social, cognitive, or behavioral outcomes (Tharp, 2004; Tuchman, 2004).

All of the reports on EEG findings in children with ASD are retrospective reviews of clinical populations and are flawed secondary to selection bias. The studies with the highest rates of epileptiform activity are those from child neurologists who are being referred children with ASD for the evaluation of seizures. In addition, the technology used, such as ambulatory EEG, may be prone to artifacts that may be falsely interpreted as epileptiform (Jayakar, Patrick, Sill, Shwedyk, & Seshia, 1985). Furthermore an overnight sleep EEG study of healthy adults found that 13% had epileptiform activity (Beun, van Emde Boas, & Dekker, 1998), and how often epileptiform activity is present in overnight sleep EEG of infants, children, and adolescents is not known. Therefore the practical impact and relative value of epileptiform activity in children with ASD both from a prognostic and treatment perspective is not known (Baird, Robinson, Boyd, & Charman, 2006).

In summary, the prevalence of epileptiform activity in ASD without seizures is dependent on the type of EEG study done, the length of the EEG recording, methodology specific to collecting and interpretation of EEGs, and the specific population of children with ASD being studied. The significance of epileptiform activity in children with ASD without epilepsy and with or without regression is not known. There is much to be learned regarding the relationship of epilepsy and epileptiform activity to ASD. There is emerging evidence that seizures and frequent epileptiform activity can negatively impact the developmental trajectory and life of individuals with ASD. In addition, in rare instances an epileptic process could be causally related to communication deficits or sociocognitive dysfunction manifesting as behaviors that overlap with the ASD phenotype (Deonna & Roulet, 2006).

Autistic Regression and Epileptic Encephalopathy

Autistic Regression

Regression associated with ASD is usually related to the loss of only a few words but is accompanied by the loss of nonverbal communication skills and occurs in approximately 30% of children with autism (Goldberg et al., 2003; Lord, Shulman, & DiLavore, 2004; Luyster et al., 2005; Werner & Dawson, 2005). The language and social regression that occurs in a subgroup of children with ASD has been termed "autistic regression." Autistic regression may be superimposed on prior abnormal development and occurs prior to age 3 years and in most instances prior to age 2 years (Baird et al., 2008).

Children with ASD and late-onset autistic and cognitive regression that can include motor regression and loss of bowel and bladder use, usually occurring after age 3, are classified under the subgroup of childhood disintegrative disorder (Burd, Fisher, & Kerbeshian, 1989; Mouridsen, Rich, & Isager, 1999; Rapin, 1995; Rogers, 2004; Volkmar, 1992). The prevalence of epilepsy in childhood disintegrative disorder has been reported to be as high as 77% (Mouridsen et al., 2000),

and EEG abnormalities are significantly more common in the histories of those with disintegrative disorder than those with infantile autism (Kurita, Kita, & Miyake, 1992). Children with childhood disintegrative disorder regress at a later age than children with ASD, have loss of more than just language and social skills, have significant cognitive impairment, and have a higher rate of seizures than children with ASD, including those with mental retardation and regression.

The other disorder under the ASD umbrella with a rate of seizures compatible with disintegrative disorder is Rett syndrome (Steffenburg et al., 2001). Rett and disintegrative disorder are both associated with regression and severe mental retardation. To what extent the high rate of seizures in this group is secondary to the severe degree of cognitive impairment present in both Rett and disintegrative disorder or what influence other specific variables such as metabolic or molecular factors, i.e., the role of MECP2, have in the development of seizures, remains unknown.

Since the early descriptions of regression in ASD, there has been a suggestion that the subgroup of children with autistic regression have a higher rate of epilepsy (Hoshino et al., 1987; Kurita, 1985). Some studies have found no differences in history of autistic regression in ASD children with epileptiform EEGs and epilepsy versus ASD children with a normal EEG and no epilepsy (Canitano, Luchetti, & Zappella, 2005; Hara, 2007). Contrary to results showing no relationship of regression to epilepsy in autism, one study found that autistic regression was more frequent in children with ASD and epilepsy versus those with ASD and no epilepsy (Hrdlicka et al., 2004). Giannotti et al. (2008) also found that epilepsy was more likely to occur in children with autistic regression. This latter study also found that children with autistic regression had more disrupted sleep than those with ASD without regression.

Epileptic Encephalopathy

The relationship of regression of language and epileptiform EEG abnormalities that occurs in a subgroup of children with ASD has been compared to children who have an epileptic encephalopathy.

> "Epileptic encephalopathy" is a conceptual term that captures the emerging evidence that epileptic activity, seizures, or interictal epileptiform discharges, can lead to cognitive and behavioral impairment above and beyond what might be expected from the underlying pathology (Berg et al., 2009).

Approximately 40% of all epilepsies that start in the first 3 years of life are characterized as epileptic encephalopathies (Guerrini, 2006), and the most common and recognized epilepsy syndromes associated with developmental stagnation or regression in cognitive and behavioral skills include: severe myoclonic epilepsy of infancy (Dravet syndrome, see Box 23-1), infantile spasms (West syndrome), Lennox-Gastaut

syndrome, and Landau-Kleffner syndrome–continuous spike-waves during slow-wave sleep (Engel, 2001).

As a group the epileptic encephalopathies are commonly associated with poor developmental outcomes and many of the children affected develop an ASD phenotype (Tuchman et al., 2009). A common epileptic encephalopathy that has been associated with ASD is infantile spasms, an age-specific epilepsy syndrome with a peak age of presentation between 4 to 8 months of age (Zupanc, 2009). The prevalence of autism spectrum disorders is as high as 35% depending on the severity of intellectual disability (Saemundsen, Ludvigsson, & Rafnsson, 2007), with a heightened risk of ASD in the presence of identifiable structural lesions of the brain (Saemundsen, Ludvigsson, & Rafnsson, 2008).

A controversial example of an epileptic encephalopathy that can overlap and sometimes be confused with other conditions, as in children with language regression and an epileptiform EEG, is Landau-Kleffner syndrome, an acquired aphasia in association with an epileptiform EEG with spikes, sharp waves, or spike and wave discharges that are usually bilateral and occur predominantly over the temporal regions (Landau & Kleffner, 1998). On a continuum with Landau-Kleffner syndrome is continuous spike-waves during slow-wave sleep, an epileptic encephalopathy associated with the EEG pattern of electrical status epileptics during slow-wave sleep, various seizure types, and with cognitive, motor, and behavioral disturbances (Tassinari, Cantalupo, Rios-Pohl, Giustina, & Rubboli, 2009). Continuous spike-waves during slow-wave sleep and Landau-Kleffner syndrome are sleep-related epileptic encephalopathies with common clinical features including seizures,

---

Box 23–1

Dravet syndrome is a genetically determined infantile epileptic encephalopathy mainly caused by de novo mutations in the SCN1A gene (Scheffer, Zhang, Jansen, & Dibbens, 2009). Progressive decline or plateau in development occurs by 1 to 4 years of age, with intellectual disability and an autism phenotype commonly present especially in those with greater than five seizures per month (Wolff, Casse-Perrot, & Dravet, 2006). There is emerging evidence that vaccine encephalopathy, characterized by the appearance of seizures and regression in infants following vaccination, may be secondary to SCNA1 gene mutations, suggesting that vaccine encephalopathy could in fact be a genetically determined epileptic encephalopathy (Berkovic et al., 2006). Whether these findings have relevance to the controversy of vaccine encephalopathy and ASD (Berg, 2007), especially in those children with autistic regression and seizures or an epileptiform EEG, is not known. A susceptibility locus for ASD has been reported on chromosome 2 in the vicinity of the epilepsy-involved genes SCN1A and SCN2A (Weiss et al., 2003); how often SCNA1 mutations are present in children with autistic regression and epilepsy may be an instructive research question with implications to the larger vaccine and ASD debate.

regression, and epileptiform abnormalities that are activated by sleep (Nickels & Wirrell, 2008). In continuous spike-waves during slow-wave sleep there is a regression in global skills, while in Landau-Kleffner syndrome the primary clinical manifestation is a regression of language.

Landau-Kleffner syndrome can be differentiated from children with autistic regression and an epileptiform EEG or seizures based on variables such as age of onset of regression (age less than 3 years for autistic regression versus greater that 3 years of age for Landau-Kleffner syndrome), type of regression (primarily language in Landau-Kleffner syndrome), and sleep-related EEG findings, with more frequent epileptiform activity on the EEG, activated in sleep in Landau-Kleffner (McVicar, Ballaban-Gil, Rapin, Moshe, & Shinnar, 2005; Shinnar et al., 2001; Tuchman, 2009). The clinical differences between Landau-Kleffner syndrome and autistic regression with epilepsy or an epileptiform EEG suggests that they are overlapping but distinct phenotypes with potentially different etiologies and pathophysiology, as well as developmental outcomes.

In summary, there are many unanswered questions regarding autistic regression and its relationship to epilepsy and epileptiform activity on the EEG. Clinical reports suggest that children with epileptic encephalopathies are at high risk for developing ASD (Tuchman, 2006). There are also reports of children with early-onset seizures and autistic regression (Deonna, Roulet-Perez, Chappuis, & Ziegler, 2007; Deonna, Ziegler, Moura-Serra, & Innocenti, 1993; Humphrey, Neville, Clarke, & Bolton, 2006; Neville et al., 1997), however the contribution that epileptiform activity has in the development of autistic regression is not presently understood. Nevertheless, the epileptic encephalopathy model suggests that in the absence of seizures, an EEG needs to be considered when there is clinically significant loss of social and communicative functions and there is a clinical suspicion that epilepsy or that epileptiform activity may be contributing to the regression (Filipek et al., 2000). If abnormal electrical activity is found in a child with ASD with or without seizures, the interpretation and potential treatment needs to be based on the type, location, and frequency of the epileptiform activity within the clinical context of that individual child (Trevathan, 2005). There will be rare children with ASD and markedly abnormal sleep EEG suggestive of a sleep-related epileptic encephalopathy (Scheffer, Parry-Fielder, Mullen, & Saunders, 2006). However there is a lack of clinical signs and biomarkers that can presently guide a clinician to provide evidence-based guidelines for performing an EEG in children with ASD with or without regression (Kagan-Kushnir, Roberts, & Snead, 2005). Finally, in the child with autistic regression with epilepsy or frequent epileptiform activity, a work-up for metabolic and mitochondrial disorders should be strongly considered (Shoffner et al., 2009).

Treatments of Epilepsy and the EEG in ASD

ASD and epilepsy do not reflect singular entities with uniform etiologies (Guerrini, 2006; Happe et al., 2006), and it follows that there is no one single treatment or treatment protocol for children with ASD or epilepsy. An understanding of the shared neuronal networks, genetic and molecular biological mechanisms that account for both ASD and the epilepsies is emerging and essential to rational pharmacotherapy, but our knowledge is far from complete (Tuchman et al., 2009). The heterogeneity of clinical symptoms in children with ASD highlights the importance of a comprehensive assessment that includes investigation of underlying biological etiologies as well assessment of cognitive, language, affective, social, and behavioral function prior to initiating treatment and throughout the intervention process.

Conditions common to both epilepsy and ASD as separate disorders challenge both diagnostic and therapeutic strategies, when both disorders co-occur in the same child. Of importance is not missing treatable causes such as metabolic disorders, which may account for both the epilepsy and ASD (Zecavati & Spence, 2009). In addition, disorders of mitochondrial function, which may be more common than appreciated among children with childhood epilepsies, including a number of the epileptic syndromes associated with ASD, should be considered as potential etiologies (Lee et al., 2008).

The view of pharmacotherapy in epilepsy has evolved from the treatment of seizures to include targeting improvement in cognitive symptoms, mood, and psychiatric disorders (Devinsky, 2003). The psychotropic mechanism of action of several antiepileptic drugs is now well established, and there are several reviews that attempt to place this within the context of treating children with ASD and epilepsy (Di Martino & Tuchman, 2001; Ettinger, 2006; Ettinger & Argoff, 2007). Nevertheless, at the present time there are no randomized controlled trials or large clinical studies that have looked closely at the effects of these anticonvulsants in well-defined populations of children with ASD and epilepsy to guide a clinician in the treatment of a child with ASD and epilepsy. As such, the standard of care in children with both ASD and epilepsy is no different from treatment of seizures in other children with epilepsy without autism (Gillberg, 1991; Tuchman & Rapin, 2002).

Antiepileptic drugs are administered widely to children with ASD with and without epilepsy (Aman, Lam, & Collier-Crespin, 2003), and one of the most commonly reported medications used in the treatment of ASD and epilepsy is valproic acid. Several clinical reports of the use of valproic acid in children with ASD with or without clinical seizures but with epileptiform abnormalities on the EEG report overall behavioral improvement (Childs & Blair, 1997; Nass & Petrucha, 1990; Plioplys, 1994). An open trial in 14 individuals using divalproex sodium found improvement in core symptoms of ASD and the associated affective instability, impulsivity, and aggression, only in those children with autism and an abnormal EEG or seizure history (Hollander, Dolgoff-Kaspar, Cartwright, Rawitt, & Novotny, 2001). Hollander and colleagues reported the use of valproic acid in repetitive behaviors in repetitive compulsive behaviors and found improvement (Hollander et al., 2006), suggesting that valproic acid has a wide effect on numerous behaviors, as do other anticonvulsants, and highlighting the limitations on our knowledge of the mechanisms and specificity of this group of medications.

A study of 50 children with intractable epilepsy measured the effects of lamotrigine, an antiepileptic drug with a beneficial psychotropic profile, on 13 children with autism. Eight of these children showed a decrease in "autism symptoms" without a concomitant decrease in seizures, suggesting a specific benefit of lamotrigine in ASD (Uvebrant & Bauziene, 1994). In a subsequent double-blind placebo control trial of lamotrigine in 28 children with autism without seizures, no significant benefit was found on the Autism Behavior Checklist, the Aberrant Behavior Checklist, the Vineland Adaptive Behavior scales, the PL-ADOS, or the CARS; nevertheless, parents reported a beneficial effect of lamotrigine (Belsito, Law, Kirk, Landa, & Zimmerman, 2001). Clinical experience suggests that picking anticonvulsants with favorable psychotropic effects in children with autism and epilepsy is important. The problem is that generally small numbers of children limit the power of the studies, and these samples cannot be considered representative of all children with ASD and epilepsy (Garcia-Penas, 2005; Pellock, 2004). The findings of whether antiepileptic drugs have positive psychotropic effects on children with ASD with or without epilepsy are equivocal. For example, in an open-label study of levetiracetam in 10 children with ASD without epilepsy, positive effects were noted on measures of hyperactivity, impulsivity, mood instability, and aggression (Rugino & Samsock, 2002). However, a second study of levetiracetam in 20 children with ASD and no seizures found no positive effects on behavior (Wasserman et al., 2006).

Some clinicians have used the strategies recommended for the management of children with Landau-Kleffner syndrome in children with autistic regression and an epileptiform EEG with or without clinical seizures. Therapy in Landau-Kleffner syndrome has been the subject of numerous case reports or short series that have reported poorly documented improvements in language in response to anticonvulsants, especially valproate, ethosuximide, and the benzodiazepines (Marescaux et al., 1990). There are other positive reports of improvement with ACTH, steroids, or immunoglobulins (Lagae, Silberstein, Gillis, & Casaer, 1998; Mikati, Lepejian, & Holmes, 2002; Prasad, Stafstrom, & Holmes, 1996, Tsuru, 2000). Despite these reports, and because of the limited data documenting the specifics of language improvement, the role that these therapies have in autistic regression with an epileptiform EEG but without frequent seizures is controversial. In addition, as emphasized earlier, the clinical phenotype of autistic regression is not the same as that of Landau-Kleffner syndrome, and recommendations for treatments in children with autistic regression and epileptiform EEGs without epilepsy should not be extrapolated from treatments used in an epileptic encephalopathy. Furthermore in children with ASD it is rare to find the same frequency of epileptiform activity or intractability of epilepsy as is found in children with an epileptic encephalopathy.

Other potential interventions that have been used in epilepsy, such as vagal nerve stimulation and the ketogenic diet, have been tried in children with both epilepsy and ASD with mixed results (Danielsson, Viggedal, Gillberg, & Olsson, 2008; Evangeliou et al., 2003; Mantis, Fritz, Marsh, Heinrichs, &

Seyfried, 2009; Park, 2003; Warwick, Griffith, Reyes, Legesse, & Evans, 2007). In children with ASD with and without intractable seizures that have undergone epilepsy surgery, there are reports of transient behavioral improvements; however core deficits in social communication functioning remain, as do other affective and social emotional issues, despite improvement in seizure control (Lewine et al., 1999; Nass, Gross, Wisoff, & Devinsky, 1999; Neville et al., 1997; Szabo et al., 1999; Taylor, Neville, & Cross, 1999). In addition, intellectual capacity influences response to intervention in children with ASD and epilepsy, and current medical and surgical interventions do not appear to dramatically alter intellectual ability (Danielsson et al., 2009).

At present we are just beginning to understand the mechanisms of epileptogenesis (Rakhade & Jensen, 2009) and the risks, risk processes, symptom emergence, and adaptation leading to impairments in the normal trajectory of sociocommunicative development and to ASD (Dawson, 2008). There is some emerging evidence that early and successful treatment of seizures and interictal epileptiform activity may be crucial to positive neurodevelopmental outcomes in children with epileptic encephalopathies (Arts & Geerts, 2009; Bombardieri, Pinci, Moavero, Cerminara, & Curatolo, 2010; Freitag & Tuxhorn, 2005; Jonas et al., 2005; Lux et al., 2005) and that early treatment of children at risk for ASD may prevent the full-blown syndrome from developing (Dawson, 2008). However there is still significant controversy and uncertainty regarding treatment approaches for children with ASD and epilepsy or those with autistic regression and an epileptiform EEG (Deonna & Roulet, 2006).

An emerging approach to the development of therapeutic agents specific to the ASD-epilepsy phenotype is based on our understanding of common mechanisms for ASD and epilepsy such as abnormalities of synaptic structure in ASD (Garber, 2007) and epilepsy (Caleo, 2009; Lado & Moshe, 2008). For example, in Rett syndrome abnormalities in synapse formation and modulation contribute to a higher rate of seizures, epileptiform activity, and to the ASD phenotype (Glaze, 2004; Zoghbi, 2003). Other mechanisms that can lead to both ASD and epilepsy are abnormalities in the genetic calcium channel signals, which are also involved in regulatory pathways and in energy metabolism (Gargus, 2009). In addition, genetic disorders such as Angelman's syndrome, where epilepsy and ASD commonly coexist (Dan, 2009), and animal models such as Pten mouse, where conditional deletion of Pten is associated with abnormalities in circadian rhythms, seizures, and social interaction deficits (Ogawa et al., 2007; Zhou et al., 2009), allow for the investigation of common mechanisms and potential targets for therapeutic drugs for individuals with ASD and epilepsy. A prototype clinical disorder that allows for investigation of the complex interrelationship between genetics, seizures, brain pathology, and the development of cognitive impairments and ASD is the tuberous sclerosis complex (Box 23-2).

In summary, the clinical heterogeneity, numerous coexisting conditions found in both ASD and epilepsy, and our limited understanding of the pathophysiology of the ASD-epilepsy

Tuberous sclerosis complex and ASD-epilepsy phenotypes: common mechanisms and treatment

---

Tuberous sclerosis complex is a neurological disorder commonly associated with ASD, epilepsy, and cognitive impairments (Napolioni, Moavero, & Curatolo, 2009). Tuberous sclerosis, which occurs in about 1 in 6000 live births, is an autosomal dominant disorder, although up to 60% of affected children carry spontaneous mutations of one of two different genes causing the disorder, TSC2 and TSC1 (Curatolo, 2003). In tuberous sclerosis temporal lobe epileptiform discharges, a history of infantile spasms, and onset of seizures in the first 3 years of life appear to be risk factors for development of ASD (Bolton, 2004). There is also a suggestion that the proportion of the total brain volume occupied by tubers and age at seizure onset are the best predictors of cognitive function in individuals with tuberous sclerosis (Jansen et al., 2008), and that prolonged duration of infantile spasms, longer delays prior to initiation of treatment of the infantile spasms, and poor seizure control after cessation of infantile spasms are risk factors for development of intellectual disability in tuberous sclerosis complex (Goh, Kwiatkowski, Dorer, & Thiele, 2005). In addition, seizures unresponsive to treatment and tuberous sclerosis complex 2 mutations are associated with poor cognitive outcomes (Winterkorn, Pulsifer, & Thiele, 2007). Tuberous sclerosis complex has become an informative model to investigate molecular mechanisms and potential treatments for the ASD-epilepsy phenotype (Crino, 2008). In the mouse model of tuberous sclerosis, treatment with the mTor inhibitor rapamycin has been reported to prevent epilepsy and reverse learning deficits (Ehninger et al., 2008; Meikle et al., 2008; Zeng, Xu, Gutmann, & Wong, 2008). A recent report of rapamycin reducing seizures in a child with tuberous sclerosis complex raises the intriguing question of the clinical use of rapamycin for epilepsy, especially in children with an epileptic encephalopathy that are at high risk of developing ASD (Muncy, Butler, & Koenig, 2009).

---

phenotypes have challenged our ability to find effective treatments for individuals with epilepsy and ASD. In addition, a lack of clear clinical and biological markers to measure effectiveness, particularly developmental outcomes, hinders study design. The few studies that have been conducted have included small numbers of children, are based on short periods of observation, rely on incomplete diagnostic measures of either ASD or epilepsy, and measure efficacy in a limited fashion.

The importance of a comprehensive approach to treatment, especially in the early-onset epilepsies, is that if the epileptic activity interfering with the normal trajectory of development is eliminated, then intensive, frequent, and structured intervention may allow for the plasticity of the brain, now unburdened of the epileptic activity, to overcome the language, social, and cognitive deficits associated with ASD. There are no studies in individuals with ASD and epilepsy that use a comprehensive approach to treatment, incorporating

behavioral, educational, medical, and surgical interventions (Tuchman, Cuccaro, & Alessandri, 2010b). Treatment of the seizures follows the standards of epilepsy management and is clearly indicated in all children with ASD with epilepsy, but when and how to treat epileptiform activity in the absence of seizures is not known.

Conclusion

The wide range of co-occurrence of seizures and epileptic activity is dependent on multiple variables that include age, presence of genetic syndrome or underlying brain pathology, and degree of intellectual disability. The best estimate of the prevalence on epilepsy in ASD is 8% in ASD without significant intellectual disability and 20% in ASD with intellectual disability. The prevalence of epileptiform activity in individuals with ASD and no clinical history of seizures is approximately 6% to 30% and is dependent on the type of EEG study done, the length of the EEG recording, methodology specific to collecting and interpretation of EEGs, and the specific population of children with ASD being studied. The prevalence of epilepsy and of epileptiform activity is significantly higher, greater than 50%, in those with severe intellectual disability, genetic syndromes, and other associated brain pathology.

An emerging consensus is that shared genetic and molecular mechanisms account for the common co-occurrence of ASD and epilepsy. In the overwhelming majority of children with ASD neither the epilepsy nor the epileptiform activity is frequent or intractable. ASD is a common developmental outcome of the early-onset epilepsies, such as the epileptic encephalopathies. The contribution of epileptic activity to brain development, and specifically to the language and socio-cognitive dysfunction characteristic of ASD, remains inadequately studied and poorly understood. In children with epileptic encephalopathies the contribution of the seizures and epileptiform activity to brain development may in and of itself account for lower intellectual ability, adaptive function, and an ASD phenotype. This has important implications for treatment, as early and successful treatment of seizures and epileptiform activity is more likely to be associated with good neurodevelopmental outcomes.

Challenges and Future Directions

- Defining the clinical and biological determinants that account for the phenotypic convergence of ASD and epilepsy with lowered cognitive profiles, motor impairments, attention difficulties, hyperactivity, and mood problems.
- Identification of ASD-epilepsy phenotypes, defined by common clinical and biological criteria, such as those

with early- versus late-onset seizures, facilitating the search for common developmental genes for epilepsy and ASD.

- Determining in a population of children with epilepsy those at high risk for development outcomes associated with the ASD phenotype by characterizing subgroups based on etiology and brain pathology, as well as by seizure type, frequency, and EEG characteristics.

- Investigating the biological significance of interictal epileptiform discharges, the effect they have on neural networks critical for development of early social and communicative skills, and their usefulness as biomarkers defining subgroups of children with ASD.

- Development of biologically informative animal models with shared clinical features of ASD-epilepsy phenotypes, allowing for identification of common molecular mechanisms for ASD and epilepsy and identification of therapeutic targets for pharmacological intervention.

The Immune System, Autoimmunity, Allergy, and Autism Spectrum Disorders

Points of Interest

- The immune system is complex and dynamic. It balances between defending the body from invaders and minimizing harmful overreactions to self-tissues and innocuous agents.
- Extensive reciprocal interactions exist between the immune and nervous systems. Activity in one system is capable of modifying the activity of the other.
- Several genes that have been linked to autism spectrum disorders have immunological significance.
- Individuals with autism and their family members have an increased incidence of immune system anomalies compared to the general population.
- Gestational exposure to brain-directed antibodies or various immune stimulants may be involved in some cases of autism.
- The exact mechanisms underlying the immunological observations in autism remain ambiguous, and are an active area of investigation.

Introduction

For three decades, immune anomalies have been described in subjects with autism spectrum disorders (ASD) and their family members. Examples include signs of inflammation in the brain and cerebrospinal fluid (Vargas, Nascimbene, et al., 2005) and gastrointestinal tract (Ashwood, Anthony, et al., 2004), as well as differences in both the humoral and cellular immune systems, (reviewed in Pardo, Vargas, et al., 2005; Ashwood, Wills, et al., 2006). In addition, autoimmune and allergy-associated disorders appear more frequently in ASD subjects and their families compared to "neurotypical" control populations (Ashwood & Van de Water, 2004; Silva, Correia, et al., 2004; Croen, Grether, et al., 2005; Ashwood, Wills, et al., 2006; Cabanlit, Wills, et al., 2007). The nature of the connection between behavior and the immune system in autism is the current focus of several exciting new studies. While the clinical significance of immune related findings in autism is unclear, it provides a valuable opportunity to understand the underlying biology of the disorder, and may lead to future therapies. The following is a discussion of the complex relationship between immune dysfunction and ASD. An overview of this relationship is depicted in Figure 24-1.

Immunity, Autoimmunity, and Allergy

Immune System 101

The immune system is intricately linked to every organ system in the body, where it demonstrates great versatility and specialization in different locations. For example, immune activity in the bacteria-filled gastrointestinal tract is very different from that found in the sterile blood stream. The lymphatic system is the major conduit for immune components. Reminiscent of the circulatory system, the lymphatics consist of a clear fluid called "lymph" mixed with an array of immune cells. Lymph and cells drain from tissues throughout the body, and filter through local lymph nodes, where more selective immune responses are initiated.

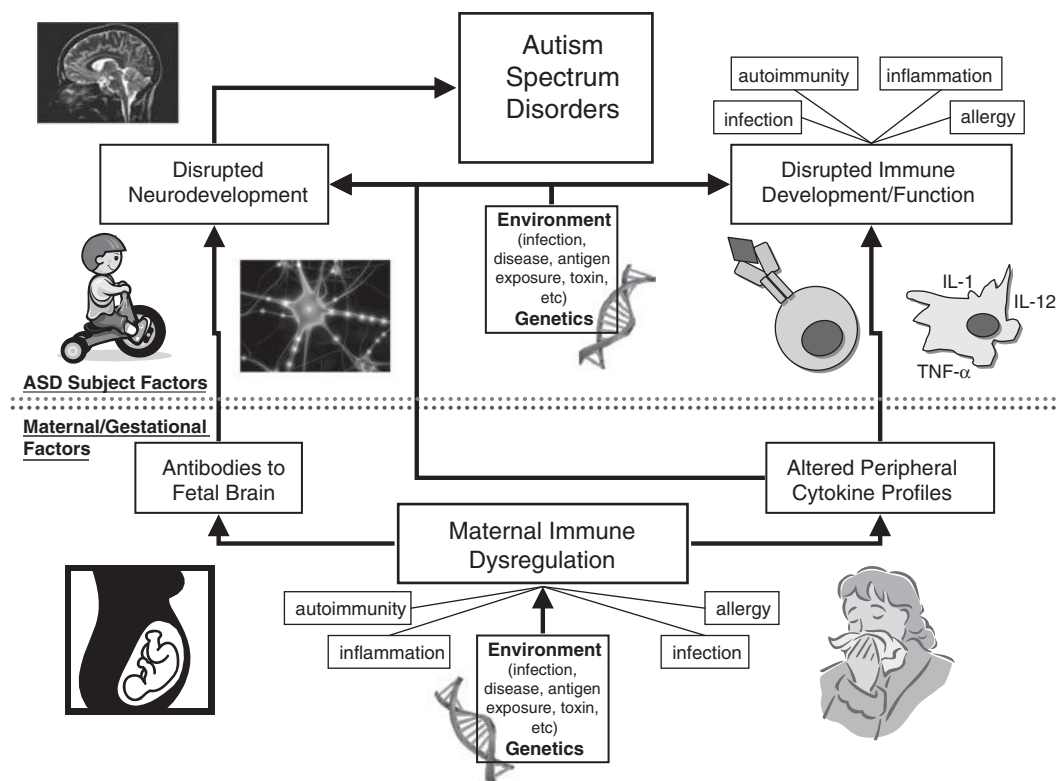
The immune system is made up of "innate" and "adaptive" branches. The innate branch is the first line of bodily defense. It responds rapidly and nonspecifically to injury or infection by recognizing the telltale signs of danger. Cells such as neutrophils and macrophages engulf pathogens, and secrete immune-stimulating species like cytokines, chemokines, and reactive oxygen species. Dendritic cells are antigen-presenting cells (APCs) that serve as the link between the innate and adaptive systems by


Figure 24–1. An overview of the relationship between immune dysfunction and autism spectrum disorders.

stimulating B and T cells under specific conditions. Natural killer (NK) cells are specialized members of the innate immune system that respond rapidly to viral infections and tumors by secreting cytokines and cytolytic molecules. These cells have additional importance in stimulating the adaptive immune system, maintaining pregnancy, and regulating autoimmune reactions (Perricone, Perricone, et al., 2008). Additional innate immune cells include mast cells, eosinophils, and basophils. Under normal conditions, such cells are important in defense against parasites, though they are more often associated with allergy/asthma in developed countries.

When the innate branch of the immune system cannot resolve the threat, the adaptive branch is called into action. The adaptive immune system is dominated by highly specialized B and T cells that focus the response on specific components of the invading agents, known as "antigens." When activated, B cells make targeted, antigen-specific antibodies, while T cells carry out antigen-specific helper and cytotoxic functions. With the continuing aid of the innate immune system, B and T cells orchestrate the elimination of the foreign antigens.

Autoimmunity and Allergy-Misfiring of Adaptive Immunity

A healthy immune system must be poised for attack against harmful pathogens. Simultaneously, it must be tolerant of harmless agents, since unnecessary immune responses can be destructive and energy depleting. Immune tolerance is

Autoimmunity

In order for the immune system to identify and destroy unwanted assailants, it must be able to distinguish between self-tissues and foreign invaders. The innate immune system achieves this by targeting features that are common among various pathogens, but are absent in host tissues. The adaptive immune system recognizes more specific features, and depends on a complex signaling network to discriminate between appropriate targets, self-tissues, and innocuous agents. Under normal circumstances, adaptive immune cells directed toward self-tissues are eliminated or regulated to prevent harmful immune reactions. However, if these cells persist and the identification or regulatory systems break down, the adaptive immune system may become activated to target the body's own tissues. This phenomenon is called "autoimmunity," and is observed in diseases like systemic lupus erythematosus, rheumatoid arthritis, and multiple sclerosis.

A major weapon used by the immune system to protect the body is a group of proteins called "antibodies." Produced by highly specialized "B cells," antibodies protect the body by flagging unwanted invaders for destruction and removal. In autoimmune disorders, antibodies are directed toward the body itself. Self-directed antibodies are called "autoantibodies." T cells are additional members of the adaptive immune system that become involved in autoimmunity. They help to facilitate immune reactions by activating B cells and directing various innate cells to carry out specific immune-related tasks. Autoreactive T cells encourage destructive immune reactions against self-tissues, and are key players in autoimmune processes.

Allergy

Each day the body is exposed to far more harmless agents than pathogens. The immune system is therefore poised to distinguish between innocuous and harmful environmental entities that are inhaled or ingested. Occasionally, the immune system mistakenly targets harmless environmental species, which are known as allergens. Some common allergens include dust mite antigen, pet dander, pollen, and peanuts. Adaptive immune cells can become activated to respond when the body encounters these allergens, and mount increasingly exuberant responses upon subsequent exposures. Symptoms of allergic reactions vary, ranging from mild irritation to severe anaphylactic shock and death.

Allergic responses usually include a specific subset of antibodies known as Immunoglobulin E, or IgE. Levels of IgE are often elevated among highly allergic individuals. IgE molecules target specific allergens, and help stimulate effector cells including mast cells, basophils, and eosinophils. Upon activation, these cells rapidly secrete immune stimulating factors, including histamine, which increase vasodilation and a rapid propagation of the immune response.

---

enabled by deletion and/or suppression of B and T cells that target self-tissues or innocuous environmental antigens. *Autoimmune disease* occurs when *self-antigen specific* B and T cells are activated to attack host tissues. For example, multiple sclerosis (MS) is an autoimmune condition where specific B and T cells destroy the myelin sheaths that insulate nerve axons. In contrast, *allergy* describes the activation of B and T cells that target *harmless environmental agents* like pollen, peanuts, or pet dander. The resulting hypersensitivity ranges from annoying, as is the case of allergic rhinitis, to potentially fatal in the case of severe asthma or anaphylaxis. Autoimmune and allergic diseases are each examples of a misdirected immune response with potentially severe pathological consequences for the host.

Immunity, Behavior, and the Central Nervous System

Central Nervous System (CNS) Immune Privilege

Historically, the central nervous system (CNS, brain and spinal cord) was thought to be sequestered from the body's peripheral immune system (Bailey, Carpentier, et al., 2006; Carson, Doose, et al., 2006). This was accepted for several reasons. First, the CNS lacks obvious lymphatic drainage. It was therefore thought that immune cells did not come into contact with components from the brain or spinal cord. Second, neurons have extremely low regenerative capacity, so damaging immune reactions within the CNS can destroy vital neural networks.

Third, the bony cranium limits space for expansion of the brain due to the edema (swelling) that accompanies inflammation. Finally, neurons (nerve cells) were thought to lack expression of major histocompatibility complex (MHC) molecules, which are required for recognition by T cells. Despite these issues, it has become clear that the immune system does in fact interface with the CNS in many ways (Carson, Doose, et al., 2006). Overly exuberant systemic immune responses are restricted from the CNS through a combination of limited access and local immune suppression. The former is accomplished through an intact "blood-brain barrier," which under normal circumstances prevents the passage of most immune components. Local immune suppression and activation are achieved through the actions of local CNS cells such as astrocytes and microglia. These cells have immune functions including phagocytosis, cytokine secretion, and T cell activating capacity (Nelson, Soma, et al., 2002; Raivich, 2005; Bailey, Carpentier, et al., 2006). They are additionally far more immunosuppressive than their counterparts in the body periphery (Nelson, Soma, et al., 2002).

Neuroimmune Networks

The old dogma of CNS immune privilege has faded further as growing evidence suggests that the immune and nervous systems are actually highly interconnected. Complex interactions between the CNS and immune system begin early in development and continue throughout life (Haddad, Saade, et al., 2002; Steinman, 2004; Wrona, 2006; Bauer, Kerr, et al., 2007). Immune system factors such as MHC I, cytokines, and chemokines are important during several stages of neurodevelopment. Additionally, they are involved in CNS plasticity, functioning, and maintenance. Likewise, several proteins associated with the nervous system, such as neuropeptides, have a broad range of suppressive and activating effects on the development and function of the immune system, including the innervation of immune organs such as the lymph nodes and spleen (Rothwell, Luheshi, et al., 1996; Mehler & Kessler, 1998; Huh, Boulanger, et al., 2000; Biber, Zuurman, et al., 2002; Mignini, Streccioni, et al., 2003; Marques-Deak, Cizza, et al., 2005). A carefully established equilibrium and timing of immune and neural parameters is vital for normal development and functioning of each system. An insult to either system during a critical developmental stage may have life-long effects, such as changes in receptor distribution and/or number, as well as modifications in neuropeptide, cytokine, hormone, and neurotransmitter release (Merlot, Couret, et al., 2008) (Figure 24-2).

The adaptive immune system also has an important role in several CNS processes. T cell trafficking into the CNS is well characterized (Engelhardt & Ransohoff, 2005). Once in the brain, T cells aid in the repair of CNS injuries, (Hammarberg, Lidman, et al., 2000; Kipnis, Yoles, et al., 2001; Kerschensteiner, Stadelmann, et al., 2003), and are required for neurogenesis in the adult brain (Kipnis, Cohen, et al., 2004; Ziv, Ron, et al., 2006). Studies using immunodeficient mice have demonstrated the importance of adaptive immunity in learning
Figure 24–2. Cross-talk between the immune and central nervous systems. Intercommunication between the cells of the immune and nervous systems is possible on several levels. Neurons, microglia, and astrocytes can produce various cytokines and express cytokine receptors. This enables them to direct immune cells as well as respond to various immunological stimuli. In turn, cells of the immune system are able to secrete various neurotransmitters, such as glutamate, and express receptors for many of these molecules. This allows immune cells to impact neural processes and respond to neural stimuli. These mechanisms permit extensive cross-talk between the immune system and neural systems. Illustration by Milo Careaga. (See Color Plate Section for a color version of this figure.)

(Kipnis, Cohen, et al., 2004; Brynskikh, Warren, et al., 2008). SCID mice (*severe combined immuno deficient*, having no B or T cells) have reduced cognitive function compared to immunocompetent controls. Immunodeficient mice have difficulties with learning a new task, and take longer than control mice to adjust to changes in previously acquired tasks. It is currently unclear whether T cells interact with neurons directly or indirectly through soluble immune mediators called cytokines, or whether similar phenomena occur in humans.

Autoimmunity, Allergy, and Behavior

There is evidence that certain autoimmune disorders can have behavioral and psychological consequences. This has been explored in recent studies of patients with systemic lupus erythematosus (SLE) accompanied by neuropsychiatric symptoms (Diamond, Kowal, et al., 2006). Antibodies toward double stranded DNA isolated from the serum of neuropsychiatric SLE patients were found to cross-react with the NMDA receptor for the neurotransmitter glutamate (Diamond, Kowal, et al., 2006; Huerta, Kowal, et al., 2006). The neuropathogenic significance of these autoantibodies was established in a murine model. Following lipopolysaccharide (LPS) administration (to breach the integrity of the blood-brain barrier) and passive transfer of serum from patients with

SLE, recipient mice demonstrated cognitive impairments. Further, brain histopathology revealed that the transferred human antibodies caused apoptotic neuronal death in the hippocampus (Kowal, DeGiorgio, et al., 2004). Elevated levels of circulating autoantibodies to nervous system components have been reported in a number of psychiatric disorders including ASD (discussed in detail below), schizophrenia, obsessive-compulsive disorder, pediatric autoimmune neuropsychiatric disorders associated with streptococcal infection (PANDAS), and Gilles de la Tourette's syndrome (TS) (Pandey, Gupta, et al., 1981; Kiessling, Marcotte, et al., 1994; Rothermundt, Arolt, et al., 2001; Perrin, Murphy, et al., 2004; Jones, Mowry, et al., 2005; Huerta, Kowal, et al., 2006; Yeh, Wu, et al., 2006). While brain-directed antibodies are clearly observed in many CNS disorders, their clinical relevance is uncertain because they are also found in some unaffected control subjects.

In addition to the capability of the immune system to affect brain function through autoimmune mechanisms, there is evidence that the CNS directly affects the inflammatory response. This has been observed in the autoimmune disorder rheumatoid arthritis. For example, Boyle et al. demonstrated that selective inhibition of spinal cord p38 MAP kinase in rats with adjuvant arthritis markedly decreased paw swelling, synovial inflammation, and joint destruction (Boyle, Jones, et al.,

2006). The data from this study suggest that peripheral inflammation is "sensed" by the CNS, which subsequently activates stress-induced kinases in the spinal cord via a mechanism involving the inflammatory cytokine TNFα. Intracellular p38 MAP kinase signaling processes this information and profoundly modulates the somatic inflammatory response.

While the pathophysiology of allergic and immune mediated–disorders such as asthma is fairly well understood, little is known about the influence of such disorders on brain activity and behavior. Costa-Pinto et al. (2005) described the neurobehavioral correlates of food allergy using an experimental murine model with high levels of IgE. They demonstrated that mice allergic to ovalbumin (OVA) have increased activity in the paraventricular nucleus of the hypothalamus (PVN) and the central nucleus of the amygdala (CeA). Both of these CNS areas are commonly associated with emotionality-related behavioral responses following a single intra-nasal challenge with OVA. Further, using a classical passive avoidance test, with OVA aerosol as the aversive stimulus, the authors noted that allergic mice avoided entering the dark compartment of the apparatus that had been previously associated with an aerosol spray of the allergen, in contrast to the nonallergic controls (Costa-Pinto, Basso, et al., 2005). These data suggest that through activation of specific brain regions, there is a modification of behavior after only one challenge with an allergen in a highly sensitized mouse model.

Autism Spectrum Disorders and Immunity

Immune Dysregulation in Subjects with ASD

Emerging evidence suggests that the immune system may play a role in the etiology of behavioral disorders like autism (reviewed in Ashwood, Wills, et al., 2006). Subjects with ASD demonstrate skewed immune activity compared to neurotypical populations. Some irregularities include decreased numbers of B and T cells, reduced lymphocyte responses to stimulation (Stubbs & Crawford, 1977; Warren, Cole, et al., 1990; Plioplys, Greaves, et al., 1994), increased numbers of monocytes (Sweeten, Posey, et al., 2003), skewed cytokine profiles (Sweeten, Posey, et al., 2003; Molloy, Morrow, et al., 2006), and abnormal immunoglobulin levels (Croonenberghs, Wauters, et al., 2002; Trajkovski, Ajdinski, et al., 2004; Heuer, 2008; Table 24-1; Figure 24-3).

Vargas et al. reported findings of an ongoing immune response in the postmortem brain of patients with ASD (Vargas, Nascimbene, et al., 2005). Brain regions especially affected included the cerebral cortex and cerebellum. Microglial and astroglial cells were found to be immunologically activated based on cell appearance and morphology. Additionally, altered glial fibrillary acidic protein (GFAP) staining and cytokine profiles were found in brain tissue and cerebrospinal fluid (CSF) from subjects with ASD.
Figure 24–3. Relationship between ASD diagnosis and immunoglobulin levels.

Lymphocytes and antibody (IgG) were absent from the brain tissue, and accumulation of perivascular macrophages and monocytes was noted, which may be indicative of innate (as opposed to adaptive) immune activation. The sample size (n = 11) in this study was limited by the availability of postmortem tissue and may not be representative of the entire ASD spectrum, but did include patients over a wide range of ages and clinical symptoms. The studies by Vargas et al. (2005) have not yet been replicated, and additional CNS immunopathologies may exist. Two animal models have demonstrated similar immune activation ("neuroinflammation") in brain, along with behavioral changes in the offspring, following: (1) administration of terbutaline (a beta-2 adrenergic agonist) to neonatal rat pups (Zerrate, Pletnikov, et al., 2007); and (2) gestational administration in mice of antibodies to fetal brain from mothers of children with ASD (Singer et al., 2008).

Cytokines and ASD

Recent evidence suggests a correlation between the pluripotent cytokine TGF-β and ASD (Okada, Hashimoto, et al., 2007; Ashwood, Enstrom, et al., 2008). TGF-β has diverse roles in development, cell migration, apoptosis, and immune regulation (Letterio & Roberts, 1998). Additionally, this cytokine may play a role in CNS development, protection, and function (Gomes, Sousa Vde, et al., 2005). Two independent studies demonstrated low serum levels of TGF-β in individuals with ASD. Okada et al. reported their findings using ELISA among a group of adults with ASD compared to age-matched controls (Okada, Hashimoto, et al., 2007). Similar data were reported by Ashwood et al. in an extensively characterized group of 143 2- to 4-year-old children with ASD. Decreased TGF-β was found in ASD subjects compared to both neurotypical and non-ASD developmentally delayed controls (Ashwood, Enstrom, et al., 2008). Further, TGF-β

Table 24–1.

Evidence of altered immune function in subjects with autism

		Study Description	Reference
Altered Immunoglobulin Levels in Autism Subjects		**Serum IgG, IgG2, and IgG4** levels were **higher in autism** subjects than in normal controls. There was a correlation found between behavioral problems, total serum protein, and serum gamma globulin.	(Croonenberghs, Wauters, et al., 2002)
		Increased plasma IgG1, IgG4, and IgM in 35 **autistic subjects** compared to their siblings. No unrelated healthy controls were included.	(Trajkovski, Ajdinski, et al., 2004)
		Decreased total **plasma IgG and IgM** in a large group of **ASD subjects** compared to age matched developmentally delayed and healthy controls. Ig levels correlated with behavior, such that subjects with the most severe behavioral scores had the lowest Ig levels.	(Heuer, 2008)
		Young children with **autism** were found to have **significantly higher levels of IgG4** compared with age-matched typically developing and developmentally delayed control subjects.	(Enstrom, Krakowiak, et al., 2008)
Altered Cytokine and Inflammatory Profiles in Autism Subjects	**Circulatory Cytokine Profiles**	Plasma levels of several cytokines were measured in small group of autistic patients and age-matched normal controls ranging in age. The levels **of IL-12 and IFN-gamma** were significantly higher in autism subjects.	(Singh, 1996)
		Increased neopterin in peripheral blood of autism subjects compared to age and gender matched controls.	(Sweeten, Posey, et al., 2003)
		Decreased serum TGF-B in small groups of ASD subjects compared to matched healthy controls.	(Okada, Hashimoto, et al., 2007)
		Decreased plasma TGF-B in large group of ASD children compared to matched typically developing controls.	(Ashwood, Enstrom, et al., 2008)
		Increased plasma **Macrophage Migration Inhibitory Factor** (MIF) in large group of ASD subjects compared to controls. Lower MIF correlated with worse behavior, MIF gene polymorphisms also associated with ASD.	(Grigorenko, Han, et al., 2008)
		Large group of ASD subjects, especially those with the regressive version of the disorder had **increased** levels of plasma **leptin** compared to age-matched typically developing, mentally retarded, and sibling controls	(Ashwood, Kwong, et al., 2008)
	Tissue/Cellular Cytokine Expression	**Intracellular cytokines w**ere measured by FACS in blood from ASD subjects compared to healthy controls. Proportions **Th1 and IFN-g$^+$ cytotoxic cells** were lower in autistic children, while **Th2 and IL-4$^+$ cytotoxic T cells** were increased in autism compared to healthy controls.	(Gupta, Aggarwal, et al., 1998)
		Mucosal lymphocyte cytokine phenotypes in ASD subjects and neurotypical controls with and without gastrointestinal symptoms. ASD subjects had more lymphocyte infiltration and pro-inflammatory T cells (**IFN-g$^+$ or TNF-a$^+$**), and fewer regulatory (**IL-10$^+$**) T cells than controls.	(Ashwood, Anthony, et al., 2004)
		Postmortem **brain inflammation** in ASD subjects demonstrated by increased **MCP-1, TGF-B**, and **activated microglia/astroglia**. Increased MCP-1 in cerebrospinal fluid from live ASD subjects compared to controls.	(Vargas, Nascimbene, et al., 2005)
	Cytokine Expression in Cell Culture	Peripheral blood mononuclear cells from a large group of ASD subjects produced **more TNF-a, IL-1B,** and **IL-6** in the absence of stimulation, and after stimulation with LPS, PHA, tetanus, IL-12, and IL-18 compared to cells from normal siblings and healthy controls.	(Jyonouchi, Sun, et al., 2001)
		Unstimulated whole blood cultures from a small group of ASD subjects showed increased production of **IFN-g** and **IL-1RA** compared to healthy controls. A trend towards higher **IL-6** and **TNF-a** was also observed.	(Croonenberghs, Bosmans, et al., 2002)
		Cytokine production by PBMCs stimulated with LPS or dietary proteins in a group of ASD subjects compared to siblings and healthy controls. ASD cells produced high levels of **IFN-g** and **TNF-a** compared to controls.	(Jyonouchi, Sun, et al., 2002)
		Cytokine production by PBMCs stimulated with dietary proteins was compared between a large group of ASD subjects with and without GI symptoms and healthy controls. ASD subjects with GI symptoms made more **TNF-a** and **IL-12** after stimulation with milk proteins.	(Jyonouchi, Geng, et al., 2005)
		Increased production **of both Th1 and Th2** cytokines by PBMCs from 20 ASD children compared to matched controls.	(Molloy, Morrow, et al., 2006)

Altered Cellular Immunity in Autism Subjects	Functional Differences	NK cell Activity	Peripheral blood mononuclear cells from 31 autism subjects and no controls were tested for **cytotoxic potential**. Cells from 12 subjects had reduced cytotoxicity, which was not due to lower NK cell numbers.	(Warren, Foster, et al., 1987)
			NK cells from a large group of ASD subjects and healthy controls were compared. **RNA expression** of NK cell receptors and effector molecules was increased in ASD, as was **production of perforin, granzyme B,** and **IFN-gamma** under resting conditions. Functional characterization showed **reduced** NK cell **cytotoxicity,** and **production of perforin, granzyme B,** and **IFN-gamma** after stimulation compared to controls.	(Enstrom, Lit, et al., 2008)
			NK cell activity in peripheral blood was compared between a large group of ASD subjects and healthy controls. ASD subjects demonstrated **reduced NK cell activity** compared to controls. Authors suggest that low intracellular glutathione levels may be in part responsible.	(Vojdani, Mumper, et al., 2008)
		PBMC Activity	Decreased **lymphocyte proliferation** with PHA stimulation in 12 ASD children compared to normal controls.	(Stubbs and Crawford, 1977)
			Cellular response to human myelin basic protein in blood from a small group of autistic subjects and mentally disabled controls was analyzed using a macrophage migration inhibition factor test. Several autism subjects and no controls had **a cell-mediated immune response to brain tissue**.	(Weizman, Weizman, et al., 1982)
	Phenotypic or Quantitative Differences	Monocytes	Increased numbers of **monocytes** in peripheral blood of ASD subjects compared to age- and sex-matched controls.	(Sweeten, Posey, et al., 2003)
		Peripheral Blood Lymphocytes	36 autism subjects were shown to have **reduced** numbers of peripheral blood lymphocytes, **CD2$^+$ T** cells, **CD4$^+$** T cells, and **CD4$^+$CD45RA$^+$** lymphocytes in circulation compared to healthy age-matched subjects.	(Warren, Yonk, et al., 1990)
			Peripheral blood lymphocytes from 25 autistic subjects were characterized by FACS. Autistic subjects had **fewer total lymphocytes, CD4$^+$, and CD20$^+$** cells compared to siblings and healthy control subjects.	(Yonk, Warren, et al., 1990)
			Characterization of peripheral blood lymphocytes from 17 autism subjects, 8 Rett syndrome subjects, and no healthy controls. All had normal B and T cell numbers. Some autism subjects had **abnormal CD4:CD8 ratios,** and more incompletely activated T cells (**IL-2R negative non-naïve cells**). Results were not seen in the Rett syndrome subjects.	(Plioplys, Greaves, et al., 1994)
			Peripheral blood lymphocytes were characterized in 10 autistic subjects and 10 age- and sex-matched healthy controls. Autism subjects had **a lower percentage of helper-inducer cells**, a **lower ratio of helper: suppressor cells**, and a **lower** percentage of **interleukin-2receptor$^+$ lymphocytes** following stimulation. All findings correlated with behavioral severity.	(Denney, Frei, et al., 1996)
		Mucosal Immune Populations	Mucosal biopsies were compared using immunohistochemistry and histology between autism subjects and developmentally normal subjects with inflammatory bowel diseases (IBD). Autism subjects had **inflammation** that was less severe than IBD controls, though **basement membrane thickness, gamma-delta T cell, CD8$^+$ cell,** and **intraepithelial lymphocyte density** was **increased in autism** compared to IBD controls.	(Furlano, Anthony, et al., 2001)
			FACS and histological analysis of cell infiltrate in mucosal biopsies from a large group of autism children and normal controls with and without gut inflammation. ASD subjects had more **intraepithelial and lamina propria lymphocytes** compared to healthy noninflamed controls, which neared levels in inflamed healthy controls. **Eosinophil infiltration** was seen in ASD subjects, and was less severe in those on elimination diets.	(Ashwood, Anthony, et al., 2003)

levels correlated with behavioral measures, such that lower levels predicted worse behavior. In contrast, increased levels of TGF-β were found in brain tissue from postmortem brain, and CSF from living ASD subjects (Vargas, Nascimbene, et al., 2005). In addition, these authors described increased levels of the inflammatory chemokine MCP-1. It is unclear how these findings within the CNS relate to peripheral cytokine levels, specifically TGF-β. Collectively, these studies suggest that aberrant levels of TGF-β and other cytokines may have a lifelong role in various aspects of ASD. It is unknown whether the immune activation present is harmful or beneficial, or if immune treatments will be indicated for patients with ASD. Another point of view is that this immune activation may reflect persistence or reactivation of a fetal pattern, since similar phenomena occur normally in brain development with the appearance of MHC II on microglia during midgestation (Wierzba-Bobrowicz, Kosno-Kruszewska, et al., 2000).

The innate immune regulator macrophage inhibitory factor (MIF) has also been linked to ASD (Grigorenko, Han, et al., 2008). MIF is a unique proinflammatory regulator of many acute and chronic inflammatory diseases through activation of the innate immune system (Calandra & Roger, 2003). Furthermore, certain genetic polymorphisms in the MIF locus have been associated with autoimmune and inflammatory conditions (Gregersen & Bucala, 2003). Genotyping of two large populations found 2 polymorphisms in the promoter region of MIF that were associated with ASD. Additionally, plasma levels of MIF were higher in subjects with ASD, suggesting the possibility that the polymorphisms have functional significance (Grigorenko, Han, et al., 2008). Finally, it was found that higher levels of MIF correlated with more severe behavior (Grigorenko, Han, et al., 2008). The neurological significance of MIF is currently unknown, though this correlative evidence may represent another link between genetics and the immune system in neurologic disorders such as ASD.

An additional cytokine/hormone that has recently been linked to ASD is leptin (Ashwood, Kwong, et al., 2008), which is produced primarily by adipocytes, though it is also produced by lymphocytes (Sanna, Di Giacomo, et al., 2003). Leptin shares functional similarities with inflammatory cytokines such as IL-6 and IL-12 (Zhang, Proenca, et al., 1994) and has been implicated in various autoimmune diseases (Sanna, Di Giacomo, et al., 2003). Leptin is also capable of crossing the blood-brain barrier (Banks, 2001) to regulate food intake, and promotes the formation of CNS lesions in an animal model of multiple sclerosis (Matarese, Procaccini, et al., 2008). Ashwood et al. recently demonstrated that plasma leptin levels were elevated in a population of children with ASD compared to typically developing controls (Ashwood, Kwong, et al., 2008). This was especially dramatic among children with early-onset autism as opposed to those with clinical regression. Increased levels of leptin were also noted by Vargas et al to be present in postmortem brain tissue of persons with autism (Vargas, Nascimbene, et al., 2005).

Immunogenetics of ASD

Interestingly, several genes associated with autism are relevant to both the nervous and immune systems. Immunogenetic associations include PTEN (a negative regulator of the PI3K/AKT pathway) (Goffin, Hoefsloot, et al., 2001; Butler, Dasouki, et al., 2005; Boccone, Dessi, et al., 2006; Kwon, Luikart, et al., 2006), MET (a receptor tyrosine kinase; Campbell, Sutcliffe, et al., 2006; Campbell, D'Oronzio, et al., 2007), and Ca(V)1.2 (an L-type calcium channel; Splawski, Timothy, et al., 2004). Each of these genes is involved in regulation of the innate immune system, and alterations in these genes have the potential to affect development and function in both the immune and neural systems. Thus, it is highly possible that the genetic associations of these genes to ASD also contribute to both neural and immune dysfunction in ASD subjects.

In addition to genetic polymorphisms and protein levels, differential gene expression may also play a role in ASD. Local expression levels of several immunologically relevant genes have been characterized in ASD. There are increased transcript levels of many immune system–related genes in neocortical regions of ASD postmortem brain tissue (Garbett, Ebert, et al., 2008). Using microarray analysis, Garbett et al. demonstrated differential gene expression in the superior temporal gyrus between ASD and control tissues (Garbett, Ebert, et al., 2008). Several of the differentially expressed genes were immunologically relevant, and included heat shock proteins, chemokines, costimulatory molecules, and leptin receptors. Differences were also detected within immune pathways including NF-κB, TOLL, TNFR, P38MAPK, 4-1BB, IL-6, MET, and IL-2R, among others. Altered expression of many of the aforementioned genes can result in a susceptibility toward the development of autoimmune and immune-mediated sequelae.

In addition to cortical brain tissue, several other tissues have been used for gene expression analysis relating to ASD. This includes analysis of NK cells (Enstrom, Lit, et al., 2008; Gregg, Lit, et al., 2008), peripheral blood (Nishimura, Martin, et al., 2007), and cerebellar tissue (Fatemi, Halt, et al., 2001; Fatemi, Stary, et al., 2001; Yip, Soghomonian, et al., 2007). Many of these studies reported differences in genes associated with immune activity. In a recent study, gene expression profiles of peripheral blood were compared between well-characterized groups of ASD children and typically developing controls. This study revealed differential expression of several genes related to natural killer (NK) and cytotoxic (CD8+) T cell function (Gregg, Lit, et al., 2008). Further analyses uncovered several differences in NK cells derived from the ASD group when compared to the typically developing controls (Enstrom, Lit, et al., 2008). Increased expression of various NK cell receptors and effector molecules was found in resting cells from ASD children. Functional analysis also demonstrated that NK cells from ASD subjects had diminished cytotoxic ability, suggesting dysregulation on several levels among ASD children. Similar expression profiles were observed in a study of NK cells stimulated with IL-2 (Dybkaer, Iqbal, et al., 2007). The link between NK cells and ASD is not yet clear,

however, NK cells produce cytokines and cytotoxic substances that could impact the CNS (Lambertsen, Gregersen, et al., 2004; Czlonkowska, Ciesielska, et al., 2005; Gilmore, Jarskog, et al., 2005). Interestingly, NK cells have various roles in both controlling and exacerbating autoimmunity (Perricone, Perricone, et al., 2008). As discussed below, autoimmune conditions have also been linked to ASD in several studies.

The major histocompatibility complex (MHC, types I and II) is a group of highly polymorphic genes on chromosome 6p known as human lymphocyte antigens (HLA). These genes are well known for their central role in the adaptive immune system, as they encode proteins that present self- and non-self-peptides to T cells for immune surveillance. They also have specific associations with autoimmune disorders, such as rheumatoid arthritis. Genes coding for TNF-α and complement are also located within the MHC and have been implicated in autism (Warren, Burger, et al., 1994; Jyonouchi, Geng, et al., 2005). In addition, MHC I is essential for cellular development of the visual system, demonstrating that immune factors are important for CNS plasticity during early brain development (Huh, Boulanger, et al., 2000; Boulanger, 2004). Association of particular HLA types, especially DR4, has been reported in children with autism (Warren, Odell, et al., 1996; Torres, Maciulis, et al., 2002; Lee, Zachary, et al., 2006), while another study showed no such link (Rogers, Kalaydjieva, et al., 1999). Lee et al. found a significant association with HLA DR4 in families with autism in East Tennessee and suggested that geographical factors may play a role in immune susceptibility (Lee, Zachary, et al., 2006). These same families also reported high rates of rheumatoid arthritis in first-degree relatives, a disorder that is typically associated with DR4. Recently Johnson et al. have demonstrated linkage disequilibrium for HLA DR4 from the maternal grandparents to the mothers of children with autism, thereby supporting a theory of prenatal immunogenetic susceptibility to autism (Johnson et al., 2009).

Autoimmunity in ASD

Various autoimmune phenomena have been described in subjects with ASD, although clinical autoimmune disorders are uncommon (Table 24-2). Exploration of autoimmunity in ASD began with several studies that demonstrated increased rates of autoimmune disorders among family members (especially mothers), including rheumatoid arthritis, psoriasis, type I diabetes, thyroid disease, and asthma (Comi, Zimmerman, et al., 1999; Sweeten, Bowyer, et al., 2003; Croen, Grether, et al., 2005; Molloy, Morrow, et al., 2006; Mouridsen, Rich, et al., 2007). In contrast, a study based on medical record review showed no increased rates of autoimmune diseases (Micali, Chakrabarti, et al., 2004). Differences in the occurrence of autoimmune disorders in families from different geographical areas may reflect local environmental factors and represent sampling biases (Lee, Zachary, et al., 2006). Another complicating factor may be that the onset of autoimmune disorders in family members may arise after the time of inquiry.

The largest study to date, from the Danish National Registry, found increased rates of ulcerative colitis in mothers and type 1 diabetes in fathers of children with autism (Mouridsen, Rich, et al., 2007). Additional studies are needed to determine the nature and relevance of autoimmune disorders in families with autism.

Many independent studies have described circulating antibodies that are specific to various components in the central nervous system (CNS) in persons with autism (Wills, Cabanlit, et al., 2007). As early as 1982, Weizman et al. demonstrated that 13 of 17 patients with ASD had a cell-mediated response to brain tissues using a macrophage migration inhibition factor test (Weizman, Weizman, et al., 1982). Other putative CNS targets include myelin basic protein (Singh, Warren, et al., 1993), brain serotonin receptors (Todd & Ciaranello, 1985; Singh, Singh, et al., 1997), neurofilament proteins (Singh, Warren, et al., 1997), brain endothelial cell proteins (Connolly, Chez, et al., 1999), brain derived neurotrophic factor (Connolly, Chez, et al., 2005), heat shock protein (Evers, Cunningham-Rundles, et al., 2002), and caudate nucleus (Singh & Rivas, 2004). A recent study by Singer et al. identified a variety of brain-specific autoantibodies in the serum of subjects with autism spectrum disorders (Singer, Morris, et al., 2006). Interestingly, both subjects with autism and their nonautistic siblings had antibody reactivity to the cerebellum and cingulate gyrus that was different in intensity from controls (Singer, Morris, et al., 2006). A 2004 study suggested an increased prevalence of antibodies to cerebellar proteins found in Purkinje cells. These antibodies were also thought to cross react with the dietary protein gliadin (Vojdani, O'Bryan, et al., 2004). More recently, Zimmerman and colleagues reported antibody reactivity to fetal rat brain in plasma from subjects with autism and their mothers (Zimmerman, Connors, et al., 2007). It was further demonstrated that children with ASD had a different pattern than their siblings and typically developing control children. However, there was no clear delineation of patterns between children with ASD and children with other neurodevelopmental disorders.

Autoantibodies to proteins in human hypothalamus and thalamus, which appear to be specific for a subpopulation of children with ASD, were recently described by Cabanlit et al. (Cabanlit, Wills, et al., 2007). To further explore the possibility of autoantibodies directed toward proteins in their native state, or toward a protein of low abundance in the brain, immunohistochemical studies were performed using brain sections from the nonhuman primate macaque monkey (*Macca fascicularis*). Observations thus far have been restricted to the cerebellum and demonstrate that 21% of patients with ASD have intense staining of cerebellar Golgi cells, compared with 0% of controls (Wills, Cabanlit, et al., 2008). Moreover, there appeared to be a correlation between the cerebellar staining and the presence of an approximately 52 kDa band in cerebellum using Western blot analysis.

Autoantibodies such as those described herein have the potential to exert their effects through several different mechanisms. For example, some may act as ligands for a target

Table 24–2.
Autoantibodies and allergy in subjects with autism

		Study Description	Reference
Circulating Autoantibodies and ASD Subjects	**Myelin Basic Protein and Other Identified antigens**	Serum antibodies to Myelin Basic Protein more prevalent in ASD subjects compared to control groups (typically developing children, children with mental retardation or Down syndrome, normal adults)	(Singh, Warren, et al., 1993)
		Serum antibodies to Myelin Basic protein and *neuron axon filament protein* found more often in ASD children than in non-age-matched controls.	(Singh, Lin, et al., 1998)
		Serum antibodies to Myelin Basic Protein, *endothelial cells, BDNF* more prevalent in ASD subjects than healthy controls and controls without neurological illness.	(Connolly, Chez, et al., 2005)
		Subjects with ASD (wide age range) had serum antibodies against dietary antigens like *gliadin* more often than healthy age- and sex-matched controls. These antibodies cross-reacted with *cerebellar peptides,* myelin basic protein*, myelin-associated glycoprotein, gandlioside, sulfatide,* and other neural antigens.	(Vojdani, Campbell, et al., 2002), (Vojdani, O'Bryan, et al., 2004)
	Nonneural Antigen	Occurrence of serum antibodies against Heat shock protein 90 higher in autism group compared to normal controls and a group with autoimmune diseases	(Evers, Cunningham-Rundles, et al., 2002)
	Identified Neural Antigens	ASD subjects have serum antibodies to glial fibrillary acidic protein and neuron-axon filament protein more often than mentally retarded and healthy controls. Subjects vary greatly in age.	(Singh, Warren, et al., 1997)
		ASD subjects have serum antibodies to human serotonin receptors. ASD serum blocks serotonin receptor binding more heavily than healthy control serum.	(Todd & Ciaranello, 1985), (Singh, Singh, et al., 1997)
	Antibodies Directed toward Unidentified Neural Antigen(s)	Increased incidence/staining density of serum IgG specific to brain protein homogenate in ASD subjects compared to their parents and healthy control subjects. Antibodies not specific to MBP as determined by inhibition assay.	(Silva, Correia, et al., 2004)
		ASD subjects had antibodies to temporal cortex endothelial cells and nuclei more frequently than healthy controls and controls with nonneurological illness	(Connolly, Chez, et al., 1999)
		ASD subjects had serum antibodies to rat caudate nucleus, cerebral cortex, cerebellum more frequently than healthy controls.	(Singh & Rivas, 2004)
		ASD subjects had serum antibodies to human caudate nucleus, putamen, and prefrontal cortex more frequently than siblings and non-age-matched healthy controls.	(Singer, Morris, et al., 2006)
		Increased serum antibodies against protein homogenates from fetal rat brain (gestational day 18) in small group of ASD subjects, their mothers, and subjects with other neurological illnesses compared to healthy controls.	(Zimmerman, Connors, et al., 2007)
		IgG reactive to human hypothalamus and thalamus homogenates was found in plasma from ASD subjects more frequently than age-matched controls.	(Cabanlit, Wills, et al., 2007)
		Immunohistochemistry showed a higher prevalence of plasma IgG antibodies to rat cerebellum golgi cells in ASD subjects compared to plasma from age-matched healthy and mentally retarded control subjects.	(Wills, Cabanlit, et al., 2008)

Allergy and ASD Subjects	Peripheral Allergic Sensitization	No Allergy Link Found	Small group of ASD subjects had serum IgE levels within the normal range for their ages. No control group was included.	(Menage, Thibault, et al., 1992)
			ASD subjects showed no difference in serum IgE, frequency of allergic disorders, or positive skin prick tests compared to an age-matched healthy control group.	(Bakkaloglu, Anlar, et al., 2008)
			No diff in plasma IgE between ASD subjects and age-matched controls, even when considering location and season of birth.	(Heuer, 2008)
		Possible Allergy Link Found	ASD subjects had more blood eosinophils than a group of sex and age matched mentally retarded controls, but there was *no difference* in serum total and allergen-specific IgE levels.	(Renzoni, Beltrami, et al., 1995)
			Increased blood basophil sensitization and positive skin prick tests in a small group ASD subjects compared to small groups of healthy and neurological illness controls.	(Bidet, Leboyer, et al., 1993)
	Allergy and Diet		36 ASD subjects were given specific allergen–free diets (allergen for which they had a positive skin prick test). Subjects demonstrated improved behavior after 8 weeks, though no control group was present.	(Lucarelli, Frediani, et al., 1995)
			Comparison of cytokine production by PBMCs in response to stimulation by various dietary proteins (cows milk protein, Gliadin, and soy) in a group of ASD subjects, siblings, and healthy controls. ASD PBMCs were found to produce more IFN-gamma and TNF-alpha with stimulation at a higher rate than controls.	(Jyonouchi, Sun, et al., 2002)
			Increased cytokine production by blood mononuclear cells in response to dietary antigens in ASD subjects (especially those with gastrointestinal symptoms) compared to healthy controls.	(Jyonouchi, Geng, et al., 2005)
			As mentioned above, antibodies were found in serum of ASD subjects that were specific to dietary many antigens. These antibodies also cross-reacted with many neural antigens.	(Vojdani, Campbell, et al., 2002), (Vojdani, O'Bryan, et al., 2004)
		No Allergy Link	This study of current evidence shows that the link between elimination diets, autism, and improved behavior is weak. It calls for future well-controlled clinical studies to further explore any association.	(Millward, Ferriter, et al., 2008)

receptor. Such autoantibody-receptor interactions have the potential to induce excitotoxic death through excessive signaling (Portales-Perez, Alarcon-Segovia, et al., 1998; Sisto, Lisi, et al., 2006). Alternatively, autoantibodies to neural antigens can act antagonistically, and block an essential pathway. Such interference may lead to abnormal neural development and/or function. Finally, autoantibodies can mediate tissue destruction through complement fixation and cell-mediated cytotoxicity. If any of the above scenarios were to occur during a critical developmental window, consequences might include impaired neuronal function, altered receptor density and/or distribution, or improper release of neurotransmitters and/or cytokines. However, it is currently premature to speculate whether antibodies found in ASD subjects are pathogenically significant or merely an epiphenomenon. Thus, additional studies are under way to characterize any possible deleterious effects in animal models.

Allergy in Subjects with ASD

Some researchers have postulated that allergic disease may be associated with ASD, despite a number of studies suggesting no relationship. In 1992, six children with ASD were found to be within normal ranges for levels of total IgE and histamine (Menage, Thibault, et al., 1992). However, the small sample size and lack of control group require that these results be interpreted with caution (Menage, Thibault, et al., 1992). A larger study, including 43 ASD patients and age-/sex-matched, developmentally disabled non-ASD controls, showed no differences in total or allergen-specific IgE, though eosinophilia was more prevalent in the ASD group (Renzoni, Beltrami, et al., 1995). A neurotypical control group was not included in this study. A more recent study of over 116 subjects with autism and 96 neurotypical controls demonstrated that there was no difference in plasma IgE levels when the subjects were controlled for age, season, and geographic location (Heuer, 2008). There are additional reports of increased basophil sensitization and positive skin prick tests among ASD subjects compared to controls (Bidet, Leboyer, et al., 1993), though independent studies have contradicted these findings (Bakkaloglu, Anlar, et al., 2008).

The relationship between food allergy and ASD is highly controversial (Cormier & Elder, 2007). Over a decade ago, a study of 36 ASD patients suggested that a specific allergen-free diet was associated with improved behavior (Lucarelli, Frediani, et al., 1995). Whether these behavioral improvements were due to neurological phenomena, or simply increased comfort and disposition in the absence of allergic activity is unclear. There is little additional nonanecdotal evidence supporting any behavioral benefits of allergen-free diets (Cormier & Elder, 2007). Furthermore, several subsequent studies have reported negligible behavioral changes after elimination diets (Millward, Ferriter, et al., 2008).

Vojdani et al. have published a series of studies linking food hypersensitivity and CNS-specific autoantibodies. ASD subjects were observed to have an increased incidence of neural-protein-specific autoantibodies that cross-reacted with dietary antigens like milk butyrophilin (Vojdani, Campbell, et al., 2002) and gliadin (Vojdani, O'Bryan, et al., 2004). However, these studies have not been confirmed. A large 2005 study explored the cellular response to various food allergens in ASD subjects versus controls (Jyonouchi, Geng, et al., 2005). This study found an association between cytokine production against dietary proteins and GI symptoms in ASD. A large proportion of ASD subjects with GI symptoms were included in the study (75 out of 109), so it is possible that food allergy is most relevant among this subset of ASD subjects. One should also note that there is a difference between food allergy that is IgE mediated, and a food sensitivity that is not directly mediated by the immune system, such as lactose intolerance due to an enzyme deficiency.

In comparison to the literature linking autoimmunity and other immune dysfunctions to ASD, there is a dearth of evidence concerning associations of allergic diseases. Future studies that utilize large, well-described patient groups and well-matched controls will help to resolve lingering ambiguity.

Infections, Immunizations and Responses to Fever in Subjects with ASD

Although anecdotal evidence suggests that children with ASD appear to have frequent infections, available data show the overall infection rate to be similar to controls (Comi, Zimmerman, et al., 1999; Rosen, Yoshida, et al., 2007). Children with ASD have been shown to have fewer upper respiratory infections, more frequent genitourinary infections, and more total infections during the first 30 days of life when compared to neurotypical controls (Rosen, Yoshida, et al., 2007).

Childhood immunizations frequently have been perceived by families as causing autism due to the temporal relationship with regression, or loss of skills, and the emergence of autistic symptoms (Woo, Ball, et al., 2007). However, multiple epidemiological studies have negated a causative relationship (Taylor, Miller, et al., 1999; DeStefano & Chen, 2000). With respect to measles vaccine, a recent study found no evidence of RNA measles virus transcripts in bowel tissue from autism subjects (Hornig, Briese, et al., 2008). Furthermore, antibody responses to measles vaccine are similar in children with autism and controls (Baird, Pickles, et al., 2008). This is in contrast to previous studies (Singh & Jensen, 2003). Despite many reassuring studies, individual cases of regression following immunizations may occur due to underlying mitochondrial dysfunction on a genetic and cellular basis, which may also be exacerbated by the stress of fever and infection (Poling, Frye, et al., 2006). Further, one cannot rule out the possibility that a subset of children with autism react differentially to immunization due to underlying immune dysfunction. However, systematic evaluation of the immune response immediately following vaccination needs to be performed to examine this hypothesis.

Behaviors in children with autism frequently improve rapidly during fever, including reduced stereotypy, hyperactivity, irritability, and inappropriate speech (Curran, Newschaffer, et al., 2007). Although this "fever effect" can be difficult to separate from sickness behavior, up to 80% of families observe some degree of improvement, and anecdotal reports of marked changes occur frequently. There are many hypothetical reasons for these changes, including immune-mediated effects from cytokines, changes in synaptic membrane properties, and intracellular signaling. Further studies are needed to verify this intriguing, and potentially enlightening phenomenon.

Maternal Immunity and Autism Spectrum Disorders

Mothers of children with ASD have been shown to have various immune system abnormalities compared to mothers of neurotypical children (Ashwood, Wills, et al., 2006; Wills, Cabanlit, et al., 2007). This might be explained by genetic factors that relate to both ASD susceptibility and immune function. Given that several genes are linked to both ASD and the immune system (discussed above), it is likely that mothers of ASD children may possess similar genetic and immune profiles. Additionally, aberrant maternal immune activation during pregnancy can have a profound impact on fetal brain development.

Maternal Immunity and the Gestational Environment

Maternal immune responses (including infection, autoimmunity, and allergy) generate factors that have a direct impact on the gestational environment. Factors like cytokines, chemokines, and antibodies produced during pregnancy may carry various developmental consequences for the fetus. Increased rates of infection and other environmental factors may account for increased autism rates among children born in the spring months (Lee, Newschaffer, et al., 2008). This is consistent with early observations that autism can be associated with congenital rubella (Chess, 1977) as well cytomegalovirus (Stubbs, 1978; Markowitz, 1983), which were some of the earliest indicators of the neurobiological basis of autism.

Maternal Inflammation and Cytokines

Under normal conditions, the maternal immune system is uniquely regulated during pregnancy to maintain a pathogen-free yet noninflammatory environment for the developing fetus (Wegmann, Lin, et al., 1993; Chaouat, 2007). Robust maternal immune activation is associated with obstetrical, developmental, and/or behavioral complications (Jenkins, Roberts, et al., 2000; Shi, Fatemi, et al., 2003; Samuelsson, Jennische, et al., 2006; Smith, Li, et al., 2007; Raghupathy & Kalinka, 2008). During pregnancy, maternal cytokines may cross the placenta (in the case of IL-6; Zaretsky, Alexander, et al., 2004; Aaltonen, Heikkinen, et al., 2005; Ashdown, Dumont, et al., 2006; Samuelsson, Jennische, et al., 2006), or act on placental cells to stimulate the downstream production of mediators in the fetal compartment (Hauguel-de Mouzon & Guerre-Millo, 2006). Cytokines are involved in many diverse aspects of normal brain development including proliferation and differentiation of neural and glial cells (Mehler & Kessler, 1998). Fluctuations in levels of these molecules may alter neurodevelopment. Therefore, changes in maternal immune homeostasis can impact the fetus in many ways.

The effect of maternal immunity on the developing immune and central nervous systems has been studied extensively using both epidemiological studies and animal models (Holladay & Smialowicz, 2000; Meyer, Yee, et al., 2007) (Table 24-3). Findings from these studies may be relevant to psychiatric disorders such as autism and schizophrenia. Independent studies carried out in mice have shown that pregnant dams injected with immune-stimulating agents, including IL-6, IL-2, influenza, LPS, Poly I:C, and turpentine, gave birth to pups with behavioral differences, some of which are thought to be reminiscent of autism (Shi, Fatemi, et al., 2003; Samuelsson, Jennische, et al., 2006; Ponzio, Servatius, et al., 2007; Smith, Li, et al., 2007). A study by Meyer et al. showed that immune challenges during two critical periods of fetal development resulted in differential effects on future behavioral modifications, neuropathology, and fetal brain cytokine responses (Meyer, Yee, et al., 2007). These experiments suggest that the gestational environment may contribute to abnormalities in offspring born to mothers with excessive immune activation. The effects of such agents on the developing immune and nervous systems are likely dependent on the period of exposure and genetic susceptibility (Holladay & Smialowicz, 2000). This research supports the hypothesis that early immune/nervous system disturbances are capable of permanently altering either or both systems.

Maternal Autoantibodies

Cytokines are not the only link between maternal immune activity and fetal development. Maternal antibodies (IgG) are passed to the fetus to provide passive immunity throughout pregnancy (Simister, 2003). These antibodies serve this protective role until the child's immune system matures, and can be found in a child's circulation up to 6 months after birth (Heininger, Desgrandchamps, et al., 2006). Maternal antibodies are passed without regard to their specificity, meaning that both protective and autoantibodies have equal access. Therefore, maternal autoantibodies produced during pregnancy can target tissues in the developing fetus. In the case of autoimmune conditions like myasthenia gravis, the neonate may display transient signs of the disorder, which usually resolve soon after birth (Djelmis, Sostarko, et al., 2002). Alternatively, with systemic lupus erythematosus (SLE), maternal autoantibodies can cause long-term irreparable harm to developing organ systems (Motta, Rodriguez-Perez, et al., 2007).

Table 24–3.

Gestational exposure and offspring behavior

	Prenatal Exposure		
	LPS	Poly IC	Cytokines
Demonstration of behavioral phenotypes among offspring exposed in utero	Disrupted sensorimotor gating (Prepulse inhibition, PPI), reversed by antipsychotics (Borrell, Vela, et al., 2002)	Disrupted PPI w/acoustic startle, deficient open field exploration, novel object test and social interaction (Shi, Fatemi, et al., 2003) (Smith, Li, et al., 2007)	Macrophage IL-10 overexpression REDUCES behavioral problems in mice exposed in utero to Poly I:C (exploratory behavior, PPI, LI (Meyer, Murray, et al., 2008)
	Lower locomotive activity in elevated plus maze and more skips on beam walking (Bakos, Duncko, et al., 2004)	Decreased exploratory behavior, PPI, selective associative learning (LI, US-pre-exposure effect), spatial working memory, enhanced locomotor response to amphetamine, reversal learning. (Meyer, Feldon, et al., 2005), (Meyer, Feldon, et al., 2006).	Pups exposed prenatally to IL-2 had increased open-field activity, grooming and rearing behavior, abnormal motor learning (acquisition of classically conditioned eyeblink response) (Ponzio, Servatius, et al., 2007)
	Altered object recognition, passive avoidance, social interaction lower locomotive activity in elevated plus maze, water maze, and open field exploration (Golan, Lev, et al., 2005; Golan, Stilman, et al., 2006)	Deficient reversal learning, disrupted latent inhibition, both alleviated w/antipsychotics, enhanced locomotor response to amphetamine (Zuckerman, Rehavi, et al., 2003) (Zuckerman & Weiner, 2005)	Adults exposed prenatally to IL-6: impaired working memory (Morris water maze: increased escape latency and time spent near the pool wall) (Samuelsson, Jennische, et al., 2006)
	enhanced amphetamine-induced locomotor response and startle reflex (Fortier, Joober, et al., 2004)	disrupted sensorimotor gating (PPI) (Wolff & Bilkey, 2008), (Meyer, Nyffeler, et al., 2008) Disrupted PPI, open field, amphetamine-induced locomotion, cognitive impairment (Ozawa, Hashimoto, et al., 2006)	IL-6 deficient mice, or mice coadministered anti-IL-6 lack behavioral problems of WT mice exposed prenatally to Poly I:C alone (Smith, Li, et al., 2007)
Demonstrations of Neurobiological Differences among Offspring exposed in utero	Increased tyrosine hydroxylase in bed nucleus of the stria terminalis and shell nucleus acumbens, activated microglia and astroglia (increased MHCII), increased GFAP-in adult offspring (Borrell, Vela, et al., 2002)	Increased responses to antipsychotic (clozapine and chlorpromazine) and psychomimetic (ketamine) drugs (Shi, 2003)	Adult rats exposed prenatally to IL-6 had -neuronal loss and astrogliosis, with some sex differences. -Increased expression of GABA (Aalpha5), NR1, and GFAP mRNA. -Increased levels of the apoptosis marker caspase-3 (Samuelsson, Jennische, et al., 2006)
	Less myelin basic protein (MBP), more GFAP, altered microglial staining (Cai, Pan, et al., 2000) Decreased dopamine in nucleus accumbens (Bakos, Duncko, et al., 2004) Less tyrosine hydroxylase in mesencephalon, reduced striatal dopamine, increased microglia (Ling, Chang, et al., 2004)	Cerebellar pathology: Purkinje cell deficit, delayed granule cell migration (Shi, Smith, et al., 2009) GABAA receptor increase (Meyer, Feldon, et al., 2005), (Nyffeler, Meyer, et al., 2006), (Meyer, Feldon, et al., 2006)	

	Less oligodendrocyte-protein staining (Proteolipo Protein (PLP), MBP, 2', 3'-cyclic nucleotide phosphodiesterase (CNP)) (Bell & Hallenbeck, 2002), (Poggi, Park, et al., 2005, (Paintlia, 2004)		Large adult brain, Purkinje cell deficit (Fatemi, Earle, et al., 2002), (Smith, Li, et al., 2007)	
	Increased numbers and packing density of hippocampal pyramidal neurons and granular cells-(Golan, Lev, et al., 2005; Golan, Stilman, et al., 2006)		Increased dopamine turnover, decreased receptor binding (Ozawa, Hashimoto, et al., 2006)	
	Cell death in striatum, white matter, ventricular zone, increase GFAP, decreased MBP, astrogliosis, enlarged ventricles, gray matter lesions (Rousset, Chalon, et al., 2006), (Wang, Hagberg, et al., 2007)		Hippocampal necrosis, altered hippocampal morphology, increased dopamine release (Zuckerman, Rehavi, et al., 2003), (Zuckerman & Weiner, 2005)	
	Increased GFAP, fewer oligodendrocytes, increased cell death in fetal brain (Elovitz, Mrinalini, et al., 2006) Increased microglial activation and axonal injury, fewer oligodendrocytes (Nitsos, Rees, et al., 2006)		Delayed myelination, less MBP, smaller axon diameters (Makinodan, Tatsumi, et al., 2008)	
Demonstrations of Immunological Differences in Offspring exposed in utero (measured in stated compartments)	Amniotic fluid	Increased IL-1a (Fidel, Romero, et al., 1994)	**TNF-a** (Gilmore, Jarskog, et al., 2005)	Radio labeled **IL-2** administered to pregnant dam was found in amniotic fluid (Ponzio, Servatius, et al., 2007)
		Increased IL-8 (Nitsos, Rees, et al., 2006),(Kramer, Moss, et al., 2001)		
		Increased IL-1B (Gayle, Beloosesky, et al., 2004) Increased IL-6 (Fidel, Romero, et al., 1994), (Urakubo, Jarskog, et al., 2001), (Nitsos, Rees, et al., 2006),(Kramer, Moss, et al., 2001), (Gayle, Beloosesky, et al., 2004) Increased TNF-a (Urakubo, Jarskog, et al., 2001), (Gayle, Beloosesky, et al., 2004), (Xu, Chen, et al., 2006)		
	Fetal Brain	Increased IL-1B (Cai, 2000), (Paintlia, Paintlia, et al., 2004), (Elovitz, Mrinalini, et al., 2006), (Liverman, Kaftan, et al., 2006)	Increased IL-1B (Meyer, Nyffeler, et al., 2006), (Meyer, Feldon, et al., 2005)	Overexpression of **IL-10** reduces expression of inflammatory cytokines in animals exposed to Poly I:C (Meyer, Murray, et al., 2008)
		Increased TNF-a (Cai, Pan, et al., 2000), (Bell & Hallenbeck, 2002), (Paintlia, 2004), (Elovitz, Mrinalini, et al., 2006)	Increased TNF-a (Meyer, Nyffeler, et al., 2006)	
		Increased IFN-g (Bell and Hallenbeck 2002), (Elovitz, 2006)	Altered IL-10 (Meyer, Nyffeler, et al., 2006)	Pups prenatally exposed to **IL-6** had increased IL-6 levels in the hippocampus (Samuelsson, Jennische, et al., 2006)
		BDNF (Golan, Lev, et al., 2005)		

(*Continued*)

Table 24–3. (*Contd.*)

Prenatal Exposure			
	LPS	Poly IC	Cytokines
Placenta	Increased IL-6 (Elovitz, Mrinalini, et al., 2006), (Liverman, Kaftan, et al., 2006), (Golan, Lev, et al., 2005)	Increased IL-6 (Meyer, Nyffeler, et al., 2006)	
	Increased **IL-1a** (Rounioja, Rasanen, et al., 2003), (Urakubo, Jarskog, et al., 2001),(Gayle, Beloosesky, et al., 2004)	Increased TNF-a (Gilmore, Jarskog, et al., 2005)	
	Increased **IL-1B** (Rounioja, Rasanen, et al., 2003),(Nitsos, Rees, et al., 2006), (Kramer, Moss, et al., 2001), (Ashdown, Dumont, et al., 2006), (Elovitz, Mrinalini, et al., 2006)		
	IL-6 (Urakubo, Jarskog, et al., 2001), (Gayle, Beloosesky, et al., 2004), (Nitsos, Rees, et al., 2006), (Kramer, Moss, et al., 2001), (Bell & Hallenbeck, 2002), (Ashdown, Dumont, et al., 2006), (Elovitz, Mrinalini, et al., 2006), (Xu, Chen, et al., 2006), (Beloosesky, Gayle, et al., 2006)		
	TNF-a (Urakubo, Jarskog, et al., 2001), (Gayle, Beloosesky, et al., 2004), (Nitsos, Rees, et al., 2006), (Kramer, Moss, et al., 2001), (Bell & Hallenbeck, 2002), (Ashdown, Dumont, et al., 2006), (Elovitz, Mrinalini, et al., 2006), (Xu, Chen, et al., 2006), (Beloosesky, Gayle, et al., 2006)		
	IL-8 (Nitsos, Rees, et al., 2006), (Kramer, Moss, et al., 2001)		
	IL-10 (Bell & Hallenbeck, 2002)		
	IFN-g (Elovitz, Mrinalini, et al., 2006)		
Nonneural Fetal/Offspring Samples	**IL-1a** (Rounioja, Rasanen, et al., 2003)		Radio labeled IL-2 administered to pregnant dams was found in embryonic tissue (Ponzio, Servatius, et al., 2007)
	IL-6 (Rounioja, Rasanen, et al., 2003), (Beloosesky, Gayle, et al., 2006) serum **IL-6** (Borrell, Vela, et al., 2002)		
	IL-1B, (Rounioja, Rasanen, et al., 2003), (Ashdown, Dumont, et al., 2006)		Pups prenatally exposed to IL-6 had increased IL-6 serum levels (Samuelsson, Jennische, et al., 2006)
	TNF-a (Rounioja, Rasanen, et al., 2003) increased serum **IL-2** (Borrell, Vela, et al., 2002) Reduction in offspring body weight (Bakos, Duncko, et al., 2004)		Pups exposed prenatally to IL-2 had accelerated T cell development, TH1 skewed differentiation, increased proliferative and cytotoxic responses to syngeneic B lymphoma cells or allogeneic splenocytes. (Ponzio, Servatius, et al., 2007)

Interesting murine models have demonstrated a link between the gestational immune environment and offspring behavior. NZB and BSXB are mouse strains that spontaneously develop autoimmune diseases, and often demonstrate behavioral abnormalities that are linked to cortical ectopias (Sakic, Szechtman, et al., 1997). It is unclear whether the ectopias are related to the autoimmune disease, or if they are the consequence of an unfavorable gestational environment due to maternal autoimmune disease. Denenberg et al. designed an elegant embryo transfer study to delineate the relationship between maternal autoimmunity, fetal brain development, and cortical ectopias. They demonstrated that mouse strains transferred to the uterus of an autoimmune mother demonstrate deficits in learning and increased autoimmune activity (Denenberg, Mobraaten, et al., 1991; Denenberg, Sherman, et al., 1996). The reverse situation, in which an autoimmune-prone strain was transferred to a nonautoimmune mother, resulted in offspring with improved learning and decreased autoimmunity compared to those that developed in a syngeneic autoimmune uterus (Denenberg, Mobraaten, et al., 1991; Denenberg, Sherman, et al., 1996).

Autoimmunity in Mothers of ASD Subjects

Autoimmune factors have been demonstrated in both subjects with ASD and their family members (Wills, Cabanlit, et al., 2007) (Table 24-4). As discussed above, primary relatives of subjects with ASD have a higher incidence of autoimmune disease than those of typically developing children (Money, Bobrow, et al., 1971; Sweeten, Bowyer, et al., 2003; Croen, Grether, et al., 2005). In 1990, Warren et al. observed that 6 of 11 mothers of children with autism had antibodies that were reactive to lymphocytes of their autistic child (Warren, Cole, et al., 1990). Additionally, a growing body of evidence suggests that some mothers of ASD children produce antibodies that target brain proteins. Recently, it was noted by Braunschweig et al. that a subset of mothers whose children have autism demonstrate antibodies that recognized human fetal brain proteins in a disease-specific pattern of reactivity when compared to mothers of typically developing controls (Braunschweig, Ashwood, et al., 2007). Similarly, Zimmerman and colleagues observed specific patterns of plasma reactivity to fetal rat brain protein by immunoblotting in mothers of ASD children. These antibodies differentially recognized fetal rat brain proteins when compared with plasma from mothers of typically developing children (Zimmerman, Connors, et al., 2007). Similar fetal brain–specific reactivity was also noted in samples taken during the second trimester of pregnancy (Croen, Braunschweig, et al., 2008). Subsequent studies by another group have confirmed that a subset of mothers with ASD children produce circulating antibodies reactive to human fetal brain proteins (Singer, Morris, et al., 2008).

While the role of these antibodies in ASD is currently unknown, in an early model, Dalton et al. utilized a murine model to test the pathogenicity of maternal serum to the fetus during pregnancy. Serum from a mother of three children (a typically developing child, a child with autism, and a child with severe language impairment) was introduced by intraperitoneal injection into gestating mice (Dalton, Deacon, et al., 2003). The offspring of the injected mice demonstrated behavioral changes and antibody deposition on Purkinje cells and other neurons. This was in contrast to the offspring of gestating mice injected with sera from mothers of typically developing children. This study suggested that a factor(s) present in the sera of mothers of children with ASD, possibly immunoglobulin, led to altered neurodevelopment behavioral changes in the offspring.

More recently, a primate model was used to assess behavioral consequences of prenatal exposure to the maternal antibodies described by Braunschweig et al. (Braunschweig, Ashwood, et al., 2007); (Martin, Ashwood, et al., 2008). IgG was isolated from mothers of children with ASD and typically developing controls, and injected into pregnant rhesus monkeys. The resulting offspring were assessed from birth until 15 months of age by trained observers. Significant increases in stereotypic behavior were observed in 3 of 4 offspring who received IgG from mothers of children with autism. In contrast, behavioral anomalies were not observed in the monkeys from control IgG-treated pregnancies. The stereotypic behaviors surfaced after weaning, and were more prevalent in unfamiliar situations. Stereotypic behaviors are one characteristic of ASD, suggesting a potential link between maternal anti–fetal brain IgG and changes in offspring behavior. An analogous study by Singer et al. demonstrated the transfer of serum antibodies from mothers of children with autism to gestating mice, led to behavioral changes in the offspring, including hyperactivity and decreased sociability (Singer et al., 2008). Immunohistochemical studies in this model showed immune activation of astrocytes and microglia in the offspring, similar to that observed in humans with autism by Vargas et al. (Vargas, Nascimbene, et al., 2005).

Maternal Allergy and ASD

There is very limited evidence linking the presence of maternal allergies to ASD. However a recent study suggested that midgestational allergic/asthmatic immune profiles may relate to the development of ASD. Croen et al. reported that mothers diagnosed during their second trimester with asthma or allergy are twice as likely to have a child with ASD than mothers without asthma or allergy (Croen, Grether, et al., 2005). A retrospective analysis of blood collected during the second trimester is currently underway to confirm these epidemiological findings with clinical evidence. It is possible that a subset of ASD may involve exposure to allergic/asthmatic immune activation during gestation. The development of ASD is likely dependent on the duration of the exposure, and whether it occurred during a critical neurodevelopmental window. Future, well-controlled epidemiological studies and animal modeling will be necessary to lend further credence to these findings.

Table 24–4.

Familial autoimmune and other noninfectious pathology related to autism

		Study Description	Reference(s)
Epidemiological Associations for Familial Non Infectious Diseases		Case study describing a family of ASD subject with high incidence of autoimmune disorders.	(Money, Bobrow, et al., 1971)
		More autoimmune disorders among primary family members of ASD subjects than typical controls.	(Comi, Zimmerman, et al., 1999)
		Increased familial autoimmunity among primary family members of ASD subjects.	(Sweeten, Bowyer, et al., 2003)
		Familial familial anxiety and obsessive compulsive disorder among ASD subjects, no autoimmune connection	(Micali, Chakrabarti, et al., 2004)
		Greater risk of ASD with maternal diagnosis of allergy/asthma during second trimester. No strong autoimmune association during pregnancy, however, there was a trend toward increased Type I diabetes and psoriasis.	(Croen, Grether, et al., 2005)
		Regressive ASD associated w/familial autoimmunity.	(Molloy, Morrow, et al., 2006)
		Increased Type 1 diabetes in fathers of ASD subjects, and ulcerative colitis among mothers of ASD subjects.	(Mouridsen, Rich, et al., 2007)
Antibodies to fetal tissue in mothers of ASD Subjects	**PBMC antigen**	Mothers of ASD subjects demonstrated increased antibody reactivity against the lymphocytes of their ASD children.	(Warren, Cole, et al., 1990)
	Rat Brain Antigen	Mothers of ASD subjects were shown to have IgG reactivity to rat fetal brain proteins.	(Zimmerman, Connors, et al., 2007)
	Human Brain Antigen	Plasma from mothers of ASD subjects showed IgG reactivity to human fetal brain proteins at 37 and 73kd unlike mothers of controls	(Braunschweig, Ashwood, et al., 2007)
		Mothers of ASD subjects were confirmed to have IgG reactivity to human fetal brain proteins.	(Singer, Morris, et al., 2008)
		Serum collected during the second trimester from mothers of ASD subjects showed increased IgG reactivity to human fetal brain proteins compared to serum from control pregnancies.	(Croen, Braunschweig, et al., 2008)
Animal Models: gestational exposure to maternal antibodies and offspring behavior		Conventionally reared mice from autoimmune-prone/behaviorally impaired strain of mice were compared to same strain transferred as embryos into mothers of alternative, non–autoimmune/behaviorally impaired strain. Behavioral improvements were observed in transferred offspring based on several measures.	(Denenberg, Sherman, et al., 1996)
		Serum from mother of ASD subject injected into pregnant rats. Offspring had altered exploration, motor coordination, and cerebellar magnetic resonance spectroscopy. Ig deposition was observed on offspring purkinje cells. Results not observed in rats exposed in utero to serum from control mothers.	(Dalton, Deacon, et al., 2003)
		Stereotypic behavior observed in monkeys exposed prenatally to IgG from mothers of ASD subjects who had previously demonstrated IgG reactivity to fetal brain. This was not observed in monkeys exposed to IgG from control mothers.	(Martin, Ashwood, et al., 2008) building on (Braunschweig, Ashwood, et al., 2007)
		Offspring from pregnant SLE mice producing DNA-specific, NMDAR-specific autoantibodies throughout gestation were observed. Histological abnormalities were observed in the fetal brain of exposed offspring, and adult offspring demonstrated cognitive impairments.	(Lee, Huerta, et al., 2009)

Conclusions

At this time, an overarching question with respect to the immune system in autism is whether it contributes to the pathogenesis of the disorder. Evidence of significant "immune anomalies" in autism has accumulated over the past 30 years, raising serious questions as to their origin and role in the development of the disorder. Many findings regarding the immune system in ASD have been inconsistent due to numerous methodologic factors, the most notable of which are the use of inappropriate and non–age matched control groups, as well as heterogeneous, ill-defined subject populations. However, more recent studies are gaining credibility through the use of age-matched controls and well-characterized subject populations. Additionally, promising animal models are under development that mirror characteristics of ASD (Crawley, 2007; Tordjman, Drapier, et al., 2007). Such models will expand our understanding of the disorder, and pave the way for more focused clinical studies. They will be especially useful for determining the effects of human antibodies from children with ASD, their mothers and other family members, on brain development and behavior.

The presence of autoantibodies in subjects with ASD and their mothers is intriguing, and suggests a previous exposure of CNS antigens to the immune system. This may be the result of injury or abnormal development that led to an immune response to brain antigens in some subjects with ASD. However, it must be emphasized that these autoantibodies have not as yet been firmly associated with pathology. In some cases, similar antibodies are found in diseases other than ASD, and they are not present in all subjects with ASD. It is not abnormal to detect autoantibodies in normal healthy controls, although elevated titers have usually been associated with CNS disorders. Increased prevalence of such antibodies among ASD subjects is possibly representative of ongoing immune activation. It is also possible that subjects with ASD are more prone to form these and other antibodies, even if they do not cause or maintain the disorder.

To date, there is extensive data suggesting that some mothers of ASD children have immune-related abnormalities. Maternal immune activity can influence the gestational environment, and impact fetal neurodevelopment. Accordingly, behavioral issues have been noted in offspring from pregnancies exposed to various insults that affect immune function. Currently, the majority of data correlating maternal immunity to ASD in human populations comes from analysis of a single blood sample collected years after the birth of an ASD child. This approach is only partially revealing for several reasons. First, cross-sectional retrospective analysis does not account for the dynamic nature of immune activity and fetal neurodevelopment, and fails to identify critical windows of susceptibility to exposure. Second, immune profiles in maternal plasma do not necessarily reflect the immune activity at the maternal-fetal interface. In order to lend strength to the mid- and postpregnancy findings, prospective longitudinal studies of maternal immune function measured in various biological specimens collected throughout relevant windows of development would be ideal. Current studies are attempting this study design by following the subsequent pregnancies of mothers who have an existing child with autism. Younger siblings of ASD children have an increased chance of developing the disorder compared to the general population (Ritvo, Jorde, et al., 1989), and are thus ideal subjects for a well-targeted prospective study. Clinically relevant immune profiles could then be obtained during pregnancy and postnatally, and analyzed for a link between early immunity and the manifestation of ASD (Landa & Garrett-Mayer, 2006). Given the importance of the intrauterine milieu and the possibility that ASD results from an early insult, prospective maternal-fetal immune studies hold considerable promise.

Finally, one must ask the question: Do these immune anomalies occur as epiphenomena with the varied genotypes and phenotypes of autism, or are they in fact responsible for initiating, maintaining, or exacerbating the disorder, at least in some patients? An attractive hypothesis is that in some children with ASD, immune dysregulation is indicative of disturbances in cellular or signaling pathways that are common to both the immune and neural systems. As evidence of detectable immune differences in autism subjects accumulates, the possibility of identifying biological markers of the disorder nears. Continued research may eventually allow for further clinical differentiation of the disorder with concomitant development of meaningful medical treatments, and an overall better understanding of pathogenic mechanisms in ASD.

Challenges and Future Directions

There remain many additional unexplored questions with respect to the immune system in autism. Among others, these include:

- The basic correlation of laboratory immune profiles to varying phenotypes of autism.
- A detailed analysis of the responses to immunization in children with and without autism.
- The characterization of antigenic proteins that are targeted by autoantibodies in both mothers and children with autism.
- Analysis of the cellular mechanisms of the "fever effect."
- The relationship between immune anomalies observed in mothers of ASD children and those observed in the ASD subjects themselves.

Gastrointestinal Problems in Individuals with Autism Spectrum Disorders

▦ Points of Interest

- Gastrointestinal problems appear to be relatively common in children with autism.
- Speculation on a gastrointestinal cause of autism has not been supported by findings.
- The clinical presentation of gastrointestinal symptoms in children with autism may include behavioral problems including self-injury, aggression, and sleep disorder.
- Dietary restriction trials have not shown a benefit for the treatment of autism.
- The use of nutritional supplementation such as vitamin therapy is discussed.
- Inflammation in the GI tract and the potential neurological impact is reviewed.

Leo Kanner (1943) coined the term "autism." In his seminal paper, 11 children were described as having unusual neurobehavioral presentations but were otherwise reported to be healthy. Interestingly, eating disorders were identified in 6 of these children. Kanner believed these symptoms to be behavioral in nature rather than having a medical etiology. One child required a gastrostomy for nutrition support, and eventually the GI issues were reported to have resolved spontaneously.

We currently understand autism to be a condition with manifold presentations, complex genetic and potential environmental associations, and likely therefore no single cause or pathway. When training medical professionals, we point to conditions like Down's syndrome or William's syndrome with well-characterized medical presentations. These conditions have, through consistency of outcomes, taught us to be aware of a variety of medical complications seen as a result of the genetic condition. In autism, we lack this characteristic or phenotypical pattern.

Medical providers often hear from families that some children improve with dietary alterations or vitamin supplements, yet when these interventions are applied under study conditions, the response is often not seen. Perhaps an unrecognized subset of individuals with autism would respond to such treatments, but the research has provided no evidence of this.

Discussion of gastrointestinal issues in individuals with autism is important for several reasons:

1. A variety of studies support a high frequency of gastrointestinal complaints in this patient population.
2. Although the gastrointestinal complaints may or may not be related to the cause of autism, underlying gastrointestinal problems may exacerbate behaviors in children with autism.
3. There may become evident a phenotypical subgroup of individuals with autism who have characteristic gastrointestinal problems.
4. Ongoing genetic and environment studies may help to explain linkage of gastrointestinal problems and the neurobehavioral problems in autism.

This chapter will discuss the prevalence of gastrointestinal symptoms in individuals with autism. Some of the unusual clinical presentations of pain will be characterized. Speculated dietary and nutritional issues in children will be addressed. Inflammation in the GI tract will be discussed. Finally, some reflection on research pathways involving the GI problems in children with autism will be offered.

▦ Overview of GI Problems in Children with ASD

Gastrointestinal function is profoundly complex, involving the gut (esophagus, stomach, the small and large intestines)

and the central nervous system, which are impacted by exterior factors such as food intake, psychological influences, and the environment. In his book *The Second Brain* (1998), Gershon discusses the concept "neuro-gastroenterology." He describes the interaction between the big brain in the head and the nervous system of the GI tract (the second brain). We know little about the messages the gut sends to the brain and how that information is processed.

Prevalence

The prevalence of GI problems in individuals with autism must be understood relative to the prevalence of GI problems in the general population. Gastroesophageal reflux disease may be experience by 1 in 4 children at some time during childhood (Rudolph et al., 2001). Constipation accounts for 2% of all visits to the pediatrician (North American Society for Pediatric Gastroenterology, Hepatology, and Nutrition [NASPGHAN], 2006). Food allergy has been reported to be on the rise in the last few decades. All food allergies are currently reported at a prevalence of 5–8% (Sampson, 1999a) in pediatric patients. Peanut and nut allergy reports have doubled in the last 20 years to a prevalence of 2% of the population (Skripak, 2008). At a minimum, comorbidity of these GI conditions should be expected with similar frequency in individuals with autism.

Earlier papers evaluating gastrointestinal symptoms or problems in individuals with autism suggested a relatively low frequency. In a retrospective study presented by Fombonne & Chakrabarti (2001), a medical record review of 261 autistic children found a history of gastrointestinal symptoms in 18.8%. Taylor (2002) reported that 17% of individuals with autism had associated bowel problems, including 9% with constipation, 1.4% with constipation and diarrhea, 4% with diarrhea, 1.5% with food allergy, and 0.04% reporting non-specific colitis with ileal lymphoid hyperplasia. Constipation and food allergy actually have a higher reported frequency in the general pediatric population (Bernheisel-Broadbent, 2001; Yong, 1998), which might suggest that the medical data were not complete in this study or that ascertainment of GI symptoms in these groups were difficult.

More recent papers show a wide range of prevalence of GI problems in individuals with autism. Malloy et al. (2003) reported a prevalence of GI problems in 24% of a general autism population, based on medical history intake information. Horvath and Perman (2002) reported a prevalence of GI disturbance in 76% of children in a survey study of a general autism population in the Baltimore area. This broad prevalence discrepancy could be due to differences in the groups evaluated or differences in the interpretation of GI problems assessed.

Perhaps the most compelling study that suggests a high prevalence of GI problems among individuals with autism was conducted by Valicenti-McDermott (2006). In this study, three groups of children were evaluated: children with autism, children with other neurological conditions (e.g., cerebral palsy or mental retardation), and children without neurological problems. Seventy percent of the children with autism had

GI complaints, compared with 42% of the children with other neurological conditions and 28% of the nonneurologically impaired children. This not only suggests a higher frequency of GI issues in individuals with neurodevelopmental disorders but also suggests the problem is not simply related to nonspecific neurological dysfunction. The consistent pattern in most studies showing a higher-than-"baseline" frequency of GI issues continues to fuel discussion about possible autism/GI etiological relationships. Might we find reasons for a higher frequency of GI disease in this community of individuals?

Clinical Presentation

Children with autism have impaired or at least atypical communication. Because of this, families report difficulty recognizing when their child is sick. Certainly some children have obvious GI symptoms. Horvath (2002) described diarrhea (3 or more loose, watery stools per day) in 27% of 112 children with autism compared to 44 unaffected siblings who had no chronic diarrhea. This survey also reported constipation in 9.5% of children with autism (no greater frequency than unaffected comparisons), and that gaseousness, bloating, abdominal pain, and GE reflux were more frequent in children with autism than comparison. Afzal (2003) studied children with autism and unaffected children presenting to the gastroenterologist with abdominal pain; 36% of the children with autism had evidence of constipation by radiograph compared to 10% of the unaffected children. Both groups showed a higher frequency of constipation than reported in the general pediatric population. This study suggested that an abdominal x-ray may be useful in evaluating for constipation in children with autism. This may be valuable for two reasons: history of stool frequency may not be easily obtained from communication-impaired children, and even if regular stools are seen, it is not possible to assess for incomplete evacuation symptoms in many children with autism.

The Horvath study also described many non-GI presentations of GI pain or distress including sleep disturbance: "Children with ASD and GI symptoms had a higher prevalence of sleep disturbances (55%) compared with those who did not have GI symptoms (14%)." In this study of 36 children with autistic spectrum disorder, 61% of those with ASD and reflux esophagitis had nighttime wakings compared with 13% of those without reflux esophagitis. It is well known that sleep disturbance occurs frequently in this population (Honomichl et al., 2002). Many studies speak of difficulties with sleep induction as well as night awakening and early awakening (Patzold, 1998). GE reflux may be one of several potential factors in sleep disturbance, but should be considered. A trial of treatment for reflux may be warranted if this symptom is present.

The Horvath study also describes sudden irritability, unexplained crying, or aggressiveness as manifestations of pain. We have observed tapping or rubbing areas of the body where pain has occurred. Self-injurious behavior such as head-banging or self-biting may be a way of communicating distress in nonverbal individuals. Posturing behaviors as seen

in Sandifer's syndrome have occurred in our practice. One nonverbal child went to the freezer and put an ice cube on her chest. She responded well to antiacid therapy for GE reflux. Another clinical observation suggested by several GI professionals is that children with autism and abdominal distress will seek pressure on the abdomen. This may include asking a parent to rub or press the abdomen or leaning over furniture to exert pressure.

The idea that children with autism merit consideration of medical treatment for GI disturbance seems to be common sense. However, because of communication impairment, many of the presentations are behaviors such as sleep disorder, aggression, and sudden irritability among others. Caregivers are taught to take a behavioral approach, prompting the child to calm down, have quiet hands or redirect the behaviors. In verbal children who may be able to explain their behaviors, we would ask What's wrong? or Why did you do that? It seems important to ask the same from children who are not able to explain. We should consider the possibility that some children acting out may have pain or distress in addition to other reasons for acting out.

Burd (1995) describes children with ASD who exhibit food selectivity or textural selectivity. Feeding difficulties are common (>30%) in children with developmental delays (Gouge, 1975), but reports of mealtime or feeding problems in unaffected children are common as well (18). Ahearn (2001) evaluated 30 ASD children with difficult eating behaviors and found food type or texture selectivity in 17 of 30 children. Palmer (1975) used applied behavioral analysis to broaden food acceptance in a child with food selectivity. Using a behavioral treatment plan, acceptance of a normal variety was achieved and maintained. Palmer makes the point that medical reasons should be considered when there is prolonged subsistence on pureed foods, delay or difficulty in sucking, swallowing, or chewing, and delay in self-feeding.

Toilet training is often delayed in ASD as in other developmental disorders. Dalrymple (1992) described problems of toilet training in autism. Of his surveyed patients with a mean age of 19.5 years, 22% did not have full success with toileting. Underlying medical issues such as constipation may present a barrier to successful toilet training.

Dietary and Nutritional Factors That May Be Seen in Children with ASD

Perhaps the greatest interest among researchers and families alike considering GI issues in autism focuses on the possibility that diet and nutrition play a role in autism causation and management.

When considering this relationship, several food-related factors need to be considered:

1. Allergy.
2. Food intolerance, as might be seen with inadequate

digestion (e.g., lactose intolerance), which could be a cause of symptoms (abdominal pain, gas, and diarrhea).
3. Deficiency of vitamins or building block substances affecting normal neurotransmission.

Food Allergy and Celiac Disease

Food allergy and inflammation of the gut for other reasons could account for problems and symptoms in children with autism by several mechanisms. The GI symptoms of allergy could include pain, constipation, diarrhea, rash, and sleep disturbance. Determining food allergy is difficult, and various types of testing for allergy have pitfalls. Food elimination trials are fairly reliable at defining food intolerance, but do not lead to an exact diagnosis of food allergy, which by definition is an immune-mediated response (Sampson et al., 1999). Allergy can be evaluated by skin testing such as IgE RAST testing or IgG RAST testing among others. All tests risk identifying a clinically nonrelevant result and probably best serve as a guide to consider certain foods that could be an allergy culprit.

Studies concluding that children with ASD have a dietary allergy are often debated. Lucarelli (1995) evaluated 36 children with autism. These patients were evaluated by allergy skin testing for IgE levels, along with serum levels of IgG, IgA, and IgM specific antibodies for cow milk and egg proteins. The findings included: positive skin testing in 36% of children with autism compared to 5% in a control group of unaffected children. IgE level elevation was noted in 33% of the children with autism. In a separate study, Reichelt (1990) found IgA specific antibodies for gluten, gliadin, B-lactoglobulin, and casein in individuals with autism. Gluten proteins, which are present in wheat, rye, barley, and malt, have been suggested to contribute to autism and behavioral problems. In addition to the possibility of specific allergy to these foods, celiac disease or gluten enteropathy may occur. Celiac disease is an immune sensitivity to gluten proteins, which requires lifelong elimination of these foods.

Pursuing the question of the gut permeability and the potential for food sensitivity, D'Eufemia et al. (1996) evaluated 21 children with autism and 42 unaffected control children. The purpose of the study was to determine if increased passage of larger molecular sized substances across the gut barrier was present in children with autism, as increased permeability of larger molecular substances from the gut into the bloodstream might explain the potential for an increased sensitivity to certain peptides or proteins. The study found that 43% of the children with autism had increased permeability compared to unaffected control children, who showed no increased permeability, and suggested that with increased permeability, food-based or like-sized peptides that enter the bloodstream might induce allergic sensitization or cause "pharmacological" effects. This study attempted to address a theory known as opioid-excess theory (Panksepp, 1981).

Endogenous opioids may control developmental processes (Zagon, 1978). Self-stimulatory and self-injurious behavior has been linked to B-endorphin levels (Barron, 1983). Altered pain sensitivity has also been reported, and opioid antagonists such as naloxone and naltrexone have been used extensively in children with autism in attempts to modulate opioid associated symptoms (Panksepp, 1981). Sandyk (1986) briefly focuses on specific symptoms of autism that can be caused by abnormal endogenous opioid regulation. Sahley and Panksepp (1987) delineated the idea that abnormal brain opioid activity could play a role in the genesis of many autistic symptoms.

Maldigestion of dietary peptides forms the basis of the opioid peptide theory of autism. Several investigators have proposed that maldigestion of dietary proteins, particularly foods containing casein and gluten, produces small peptide molecules that may function as exogenous opioids. Peptides described as casomorphin (derived from milk) and gliadomorphin (derived from gluten foods) were identified in the urine of patients with schizophrenia and autism by Reichelt (1991). These peptides were shown, in vitro, to bind to opioid receptors and therefore are speculated to cause CNS effects by modulating opioid levels in the brain. Shattock (1990) supported this theory. Opioid peptide theory could provide a possible explanation for reports of clinical improvement when some autistic children are placed on restrictive diets without proof of allergic sensitivity. One criticism of the theory is the observation that these urinary peptides are also present in asymptomatic children and therefore may not exhibit a physiological effect.

Knivsberg (1990) placed a selected group of autistic children in a residential school on a gluten-free diet and reported improvement. He had screened these children prior to the diet and found evidence of the peptide gliadomorphin in their urine. He suggested this finding identified children who may have a problem with gluten. The gluten-free diet prescribed in this study would have potentially been helpful for children with celiac disease, food allergy to gluten products, or maldigestion of these food products. The conclusions may support the notion that at least a subgroup of patients could benefit from dietary change. Sponheim (1991) offered a limited study evaluating autistic children placed on a gluten-free diet and observed no behavioral improvement. He did not qualify the participants by identifying a gluten sensitivity marker. Several studies attempting to evaluate dietary reductions have been put forward since (Lucarelli, 1995; Whiteley 1999; Cade, 1999). These studies suggest that some participants do show behavioral response to dietary restriction.

A more recent trial by Knivsberg (2002), which addressed earlier limitations to tracking progress, suggested developmental progress was seen in individuals who had elevated urinary peptides to milk and gluten. Patients were divided into 2 groups, a casein-free, gluten-free group and a group that continued on milk and gluten. Ten children per group were monitored for a year by a blinded tester, and the dietary restricted group showed beneficial progress over unrestricted comparisons. This may represent a clear subset of proper candidates for dietary withdrawal.

Elder (2006) evaluated 15 children who were placed on a 12-week treatment cycle of a casein-free and gluten-free diet. This study was a blinded study, where the children received a diet that was free of casein and gluten for 12 weeks or a diet spiked with casein and gluten, and then the children were crossed over for 12 weeks to the alternative diet. Caregivers and observers were not aware what the child was receiving. No differences in developmental markers or behaviors were seen. This was a group of children with autism, unselected by any markers suggesting food intolerance. Interestingly, urinary peptides were evaluated for milk and gluten peptides during the diets and no differences were identified in children's urinary peptides while on or off milk or gluten.

At this time, the studies attempting to treat autistic symptoms with diet have not been sufficient to support the general institution of a diet for autism. Symptoms suggesting food allergy or dietary intolerance may prompt institution of a diet for these symptoms.

As we move forward, we need to consider the heterogeneity of the autism population. It seems unlikely that any diet, supplement, medicine, or even educational modality will work for every individual. Especially for dietary interventions, identifying a subgroup with characteristic presentation may allow a better prediction of response.

Celiac Disease

There is research that argues against a link between celiac disease and autism. Pavone (1997) evaluated a limited number of autistic children (11) for markers of celiac disease and found no correlation. He also conducted evaluations on 120 children documented with identifiable celiac disease for any indication of behavioral abnormalities. He found that none of the children exhibited autistic-like behaviors, concluding there was no connection between celiac disease and autism. This study is too small to conclude that celiac disease is no more frequent in autism, however with the high prevalence of both conditions in the general population (ASD seen in 1/166 individuals or even greater; Yeargin-Allsopp, 2003; and celiac disease seen in 1/133 individuals; Fasano, 2003), there will be an expected coincidence of these conditions. With such a common prevalence of celiac disease in the general population, celiac screening may be prudent in children with autism and any issues with GI disturbance or growth issues.

There is often disagreement between parent and professional (Ho, 1994) on the management of children with autism and what constitutes therapeutic benefit. Many parents institute dietary restrictions and report anecdotally that various benefits have occurred. Validated tracking tools are lacking to assess progress from therapeutic or nutritional trials. In her paper, Elder et al. (2006) reported that although measurable changes were not identified in children on a casein-free, gluten-free diet, some parents did notice subtle differences in their children when the diet was restricted. Perhaps alternate assays will allow recognition of currently subtle changes with intervention.

Dietary Intolerance

Beyond allergy or immune-mediated food problems that may account for dietary contribution to behavioral problems, food intolerance or nonimmune reaction to foods could result from inadequate digestion of food (e.g. lactose intolerance). Horvath (1999) described diminished lactase activity, measured via intestinal biopsy of autistic children with diarrhea who underwent endoscopies, 58% of the time. The reported prevalence of lactose intolerance in the general pediatric population falls well below the frequency reported in the Horvath study (Kretchmer, 1981). Possible reasons for lactase enzyme deficiency might include intestinal injury or diminished genetic expression of these enzymes. In the same study, Horvath measured pancreatic enzyme activity by performing secretin stimulation studies during endoscopy. He did not identify pancreatic enzyme deficiency when a limited number of children were evaluated.

Alberti (1999) suggests that poor breakdown of some food products could allow them to have a neurotransmitter effect, potentially accounting for altered behavior. He tested sulfation by dosing Paracetamol (acetaminophen) in children with autism and measuring metabolites in the urine compared to an age-matched unaffected control group. The sulfated metabolite of acetaminophen was lower in autistic children, raising the question whether consumption of certain foods requiring sulfation processing might exacerbate a metabolic dysfunction. Murch et al. (1993) discussed disruption of sulfation in intestinal inflammation (colitis). McFadden (1996) suggests that impaired sulfation has been found with increased frequency in individuals with several degenerative neurological and immunological conditions and might account for chemical and diet sensitivities in some children with autism.

Nutritional Deficiency

Model research regarding vitamin supplementation and neurological functioning is seen with the condition tryptophan deficiency. Young (1991) looked at the effects of dietary components including amino acids, carbohydrates, and folic acid supplementation on behavior. He reported that tryptophan depletion decreased serotonin levels and affected mood. Other studies suggest that tryptophan depletion alters pain perception. Some types of pain may improve with supplementation of tryptophan; others, including postoperative pain, actually worsened when supplemented with tryptophan. McDougle et al. (1996) found that autism symptoms worsened with tryptophan depletion.

Considering the model of tryptophan deficiency, debate has ensued regarding the use of specific vitamin supplementation as a potential treatment for autistic symptoms. Researchers have reported that various supplements may bring clinical improvement, including Vitamin B-6, Vitamin B-12, folic acid, calcium, magnesium, and zinc.

One theoretical reason that folate, B-6, and B-12 may have value is that they are necessary for serotonin production. It is also possible that these agents may alter metabolic pathways or modulate gene expression. Folic acid deficiency has been identified in patients with depression (Young, 1989), schizophrenia (Godfrey, 1990), and affective disorders (Coppen, 1986). Vitamin B-12 deficiency has been considered a potential factor contributing to neurological dysfunction perhaps because it aids protein synthesis and myelination (Herbert, 1975). Lowe (1981) could not identify deficiency of either folic acid or vitamin B-12 in autistic patients. More recent discussion of vitamin B-12 supplementation, particularly methyl B-12, focuses on the potential of methylation processing defects (James, 2009).

Vitamin B-6 (pyridoxine) supplementation was noted to improve behavior in autism (Rimland, 1974). A subsequent double blind, placebo-controlled trial supported the earlier report (Rimland, 1978). Discussing the metabolic approaches to the treatment of autism spectrum disorders, Page (2000) suggests that several well-designed studies including Coleman (1989), Kleijnen and Knipschild (1991), and Lelord (1988) support the idea that pyridoxine improves some symptoms of autism. Although the potential value is discussed, a Cochrane review (2005) of 14 studies evaluating B-6 supplementation did not find adequate data to support supplementation.

Several studies looking for nutritional deficiencies raise preliminary red flags. Hediger et al. (2008) reported decreased cortical bone thickness in a group of 75 children with ASD. This finding was present despite normal growth and unrestricted diet. Of the children studied, 12% had been in a milk-free diet, and this group had a significantly greater loss of cortical thickness. The long-term implications are not clear, but those children on calcium supplementation in their study were not spared. More work investigating malabsorption or required supplementation may be needed. Arnold et al. (2003) reported that children with autism had plasma amino acid profiles showing more essential amino acid deficiencies than age-matched controls and a trend for children on restricted diets to show greater deficiency. These studies do suggest there may be potential negative outcomes from restrictive diets and the need to continue a diet should be supported.

Many children with autism spectrum disorders receive vitamin and mineral supplements and other products every day on the basis of limited data. This limited information underscores the need for well-constructed clinical trials to evaluate these nutrients and better clarify if supplementation is a value and for whom it provides a benefit.

Mucosal Inflammatory Conditions Described in ASD

There are a number of reports discussing the findings of inflammation at endoscopy in children with autism. It is important to begin by saying that inflammation is going to be identified only in children who have presented with symptoms justifying an endoscopic procedure. This is true for all of the reports. Therefore discussion of GI findings cannot imply any known prevalence in the autism population, and at best describes abnormalities in a subset of individuals.

In his study of 36 children with GI symptoms and ASD brought to endoscopy, Horvath (1999) described esophagitis in 69.4%, gastritis in 42%, and duodenitis in 67% of these children. The high frequency of esophagitis was especially noteworthy because the children were primarily under evaluation for diarrhea.

Wakefield (1998) was the first to discuss inflammation in the lower GI tract among children with developmental disorders. This study evaluated 12 children with "regressive developmental disorder." Eleven of the patients were reported to have colitis by histology, and all had the endoscopic finding of prominent lymphoid nodules in the ileum (lymphoid nodular hyperplasia or LNH), colon, or both. He suggested that measles virus from vaccine potentially caused these intestinal changes, which led to GI symptoms and increased intestinal permeability and the subsequent development of autistic regression. In a larger study (Wakefield, 2000), he evaluated a group of 60 children with "regressive" autism. This study also evaluated a control group of unaffected children undergoing colonoscopy. In the affected group, 93% had ileal LNH; 14.3% of the unaffected children had these changes. Histologic colitis was seen in 88% of the affected but only 4.5% of the unaffected children.

Several contentious questions were raised by these reports:

1. The frequency of inflammation found was quite high. This may have reflected the severity of the patients being evaluated. As was seen in Horvath's study, there was a notable frequency of inflammation in endoscopy testing.

2. The finding of lymphoid nodular hyperplasia (LNH) was interpreted as an abnormality. Pediatric gastroenterologists have reported this finding as a developmentally normal or prominent following allergy or constipation (Turunen, 2004; MacDonald, 2007). The finding of lymphoid nodular hyperplasia has been noted in other conditions (Sabra, 1998). Allergy has been associated with LNH. Kokkonen (2002) reported that LNH was seen in the colon in 46 of 140 children undergoing colonoscopy for persistent and severe gastrointestinal symptoms. These children were not noted to have autism or other developmental issues. In this same study, ileal LNH was seen in 53 of 74 children tested, suggesting that LNH is common in children and not specific to the ASD population. He suggests LNH may be an expression of immune response. Wakefield et al. (2005) supports the contention that LNH is more prominent in autism and seems independent of allergy or constipation. This topic is one of ongoing discussion in the literature.

3. Wakefield suggested that the potential reason for colitis and LNH was measles virus infection from the measles, mumps, and rubella vaccination (MMR) accounting for the lesion. A large number of papers refute the idea that MMR administration is associated with the development of autism (Chen, 2004; Dales, 2001; DeStefano, 2004; Fombonne & Chakrabarti, 2001; Honda, 2005; Madsen, 2002; Afzal, 2006; D'Souza, 2006; among others).

Taylor (2002) saw no change in the frequency of regression before and after the institution of MMR vaccination in England. He did note a possible association between nonspecific bowel problems and regression, but did not find that this related to MMR vaccination. Fombonne and Chakrabarti (2001) evaluated patient groups before and after the institution of MMR vaccination. He found no difference in the age of parent concern, the rate of developmental regression did not differ before and after MMR vaccine, and the intervals from MMR vaccine to parental recognition of autistic symptoms were comparable in autistic children with or without regression.

In 2008, Hornig et al. reported that in 25 children with autism and 13 unaffected controls, measles RNA was identified in only one affected and one unaffected child on intestinal biopsy. Although the presenting perception of most parents of children with autism was that they regressed following vaccination with MMR (regression was identified in 88% of the children with autism), the sequence of symptoms that would support Wakefield's theory was not present. Eighty percent of the children with autism did not present with a sequence of vaccination -> onset of GI symptoms -> autistic regression.

The discussion about vaccination as a cause of autism profoundly overshadowed the GI findings. If the children studied had significant GI pathology, regardless of suspected etiology, symptoms of pain, GI dysfunction, and perhaps behavioral issues would benefit from treatment of these noted GI disturbances.

Furlano (2001) reported that, although the histologic findings of colitis described in the autistic children were less severe than classical inflammatory bowel disease (IBD), immunohistochemical testing showed increased basement membrane thickness and mucosal gamma delta cell density compared to IBD. The significance of these findings is unclear.

Torrente (2002) described duodenal biopsy findings in 25 children with "regressive" autism. The biopsy findings were compared to 11 celiac patients, 5 patients with cerebral palsy and mental retardation, and 18 control patients with normal histology. Twenty-three of 25 autistic children had normal histology or nonspecific increased cellularity. Immunohistochemical studies showed an overall marked increase in mucosal lymphocyte density in autistic children compared to controls and MR-CP patients. The density of CD8 T-cells was also greater in the autistic patients than controls and MR-CP patients. IgG deposition in the basolateral enterocyte membrane and subepithelial basement membrane was seen in 23 of 25 autistic children but was not seen in the control or MR-CP patients. The significance of these findings remains unclear, as this specialized testing is not usually done on all patients undergoing intestinal biopsy. Evaluating the group of children Wakefield studied, Ashwood (2006) reported, "There is a unique pattern of peripheral blood and mucosal CD3+ lymphocytes intracellular cytokines, which is consistent with significant immune dysregulation, in this ASD cohort."

We may need to reconsider what we consider normal biopsies. We also need to consider the significance of

microscopic inflammation. It may be that these findings are important in children with autism because these are a source of inflammation. Because children with autism have sensory processing abnormalities, perhaps low-grade inflammation can cause significant dysfunction in this population. It may be that the findings are not always clinically relevant. This is a primary focus of ongoing research.

Other considerations of impaired bowel health include an unhealthy bowel flora. Sandler et al. (2000) suggests that disruption of indigenous gut flora might promote colonization with bacteria that produce neurotoxins. He treated autistic children with oral Vancomycin, and 8 of 10 showed transient behavioral improvements. Brudnak (2002) and Linday (2001) describe the potential use of probiotic (nonpathogenic bacteria and yeast) agents such as Lactobacillus species and Saccharomyces Boulardii. The value of these organisms may be to normalize intestinal flora, provide digestive enzymes aiding nutrient absorption, minimizing allergen exposure, and to stimulate local immune responses in the intestine.

Evaluating children with ASD and GI symptoms, Horvath (1998) performed endoscopy and pancreatic function testing by administering secretin. Secretin is a neurotransmitter produced in the duodenum and stimulates the washout of pancreatic enzymes into the intestine. Following the procedure, he reported improvements in social behaviors including better eye contact, increased social awareness, and improved expressive language in 3 children. A flurry of studies followed, in effort to assess if secretin had a therapeutic benefit to treat the greater community of autistic children. Sandler (1999), Lightdale (2001), Roberts (2001) and others reported no sustained gastrointestinal or neurological benefit of secretin over placebo.

Functional GI issues include gastroesophageal reflux, recurrent abdominal pain, and irritable bowel syndrome. Population-based survey studies remain sorely lacking to fully determine how often children with ASD have gastrointestinal function problems. We cannot speculate on how frequently this will be seen in ASD, but should not assume that these conditions happen less frequently in the nonverbal child than in the verbal child.

Conditions such as recurrent abdominal pain, abdominal migraine, and irritable bowel syndrome (IBS) have no defining test to clarify the diagnosis. Symptom history is the best current method to identify these disorders and therefore may be difficult to ascertain in this population. Many children with ASD exhibit significant sensory processing dysfunction. Symptoms seen in sensory integration disorder such as altered pain perception are a primary component of IBS as well and may be a reason to consider this diagnosis in children with GI issues and ASD.

Speculations and Conclusions

In 2009, Campbell described the results of an exploratory, retrospective study indicating a genetic association of a functional variant of the MET gene (chromosome 7) in ASD patients in families with affected individuals who are reported to have co-occurring gastrointestinal conditions. A functional variant in the promoter of the gene encoding the MET receptor tyrosine kinase is associated with autism spectrum disorder, and MET protein expression is decreased in the temporal cortex of subjects with autism spectrum disorder. MET is a pleiotropic receptor that functions in both brain development and gastrointestinal repair. On the basis of these functions, the authors hypothesized that association of the autism spectrum disorder–associated MET promoter variant may be enriched in a subset of individuals with co-occurring autism spectrum disorder and gastrointestinal conditions. The sample consisted of 992 individuals from 214 families. Because the C allele disrupts transcription of the MET gene, the biological translation of these genetic findings is consistent with a hypothesis that reduced MET signaling may contribute to a syndrome that includes ASD with co-occurring gastrointestinal conditions. This finding may be one "biomarker" that if present may suggest a subgroup of individuals vulnerable to autism and comorbid gastrointestinal issues.

Another topic that may be relevant to GI issues and autism is the description of a higher frequency of children with mitochondrial dysfunction exhibiting autism (Oliviera et al., 2007). Children with mitochondrial dysfunction often have generalized motor dysfunction of the GI tract causing GER or constipation symptoms (Chitkara, 2003). The subgroup of children with autism and GI issues may suggest a subgroup of children meriting additional work-up for mitochondrial dysfunction.

Berney (2000) stated, "In the absence of a cure, the implementation of ideas will continue to outstrip factual evidence." Medical providers need to recognize that families of children with autism are not only looking for a cause or cure for autism, they are trying to assure that their child is as healthy as possible to prevent barriers to progress. As part of this, many children will be on diets or supplements. The use of complementary approaches to care is common in this population. Families have reported that 31.7% to 52% of children with autism have been treated with complementary approaches (Levy, 2003; Wong, 2006). Diets and complementary treatments are not unique to autism. Pediatric patients with chronic diseases often receive supplements to traditional treatments. Forty percent of pediatric patients with chronic disease report using CAM as part of their management (McCann, 2006). As we provide more definitive data about pathology and expectations in this population, one may expect speculative care to be reduced.

As a result of research to date, GI practitioners are now being asked to participate in the evaluation of children with ASD and GI symptoms. Pediatricians, family physicians, and gastroenterologists, first and foremost, need to be willing to consider that children with autism have a right to comorbid GI issues. The conditions of reflux, food sensitivity or allergy, constipation, diarrhea, and inflammatory bowel conditions are common in general pediatrics and should be expected to be identified in children with autism. As more prevalence

data are available, we may find that some of these issues are more common in children with autism and may even be related to the phenotype of a subgroup. Until then, thoughtful care and evaluation should be offered to children with autism presenting for evaluation is needed.

Conclusions

Gastrointestinal conditions are common in children with autism. They may represent a comorbidity, but their presence may well exacerbate behaviors of autism. There remains debate about whether an underlying inflammatory condition of the bowel or environmental, dietary triggers might account for a contribution to causation of autism.

Challenges and Future Directions

- Broader understanding of the impact of medical comorbidity (including gastrointestinal illness and functional GI disorders such as constipation, acid reflux, and food allergy) on the well-being and behavior in children with autism is imperative.
- Evaluation of intestinal microflora in the setting of food allergy, inflammation, and functional GI motility conditions in children with autism may be valuable in explaining immune variation or autoimmune response in some individuals.
- Prospective tracking of GI conditions in children at risk for developing autism may help in characterizing GI phenomena versus outcomes that have resulted from intervention such as dietary selectivity, diet therapies, or other treatments.

Sleep Problems

Points of Interest

- Sleep disorders affect approximately 20 to 30% of the general pediatric population. In the ASD population the prevalence is much higher and is estimated at between 44 and 86%. The most commonly reported problem is insomnia, which can include inability to initiate sleep and difficulty maintaining sleep.
- Children with ASD are at risk for other medical problems and frequently receive psychotropic medications, both of which can impact sleep. The etiology of sleep problems in children with ASD is likely multifactorial, including genetic and environmental factors as well as medical and behavioral issues.
- The most common parasomnia reported in children with ASD is bruxism (18%). Other reported parasomnias include sleepwalking and night wakings associated with either inconsolable screaming or a frightening dream.
- Sleep problems experienced by children are frequently associated with disturbances in neurocognition and behavior. In children, common consequences of poor sleep include difficulty with mood regulation and impulse control, hyperactivity or daytime sleepiness, poor concentration and impaired memory. The impact of impaired sleep on daytime functioning may be even more severe in children with poor self-regulation, a deficit common in children with ASD. Poor sleep may exacerbate existing behavioral problems.
- Parent report measures are a quick and easy way for clinicians to screen for sleep problems. The two most commonly used measures in the pediatric population are the Children's Sleep Habits Questionnaire (CSHQ) and the BEARS. Objective measures of disturbed sleep include at home use of a physical activity monitor, or actigraph, and clinical polysomnography.
- Sleep problems should be treated first with behavioral therapy. If problems persist, consideration can be give to use of pharmacologic sleep aids.

Introduction

Sleep problems in children with autism spectrum disorders (ASD) are a significant issue and warrant a place in routine clinical evaluation. Evidence consistently indicates that children with an autism spectrum disorder are more likely to have a sleep disorder than typically developing children. A wide range of sleep disorders are reported in this population, with the most common being insomnia, including difficulty falling asleep and staying asleep. Furthermore, sleep disorders negatively impact the daytime functioning of both the child and family members, as well as exacerbate coexisting medical, psychiatric, psychosocial, and developmental problems. Progress has been made in understanding pediatric sleep disorders that will contribute to better care for children with ASD and sleep problems. Reliable and valid methods for identifying and characterizing sleep problems in children exist, including short screening questionnaires that can be easily administered at any point of contact. When sleep problems are identified, effective treatments are available. In this chapter we will consider an overview for the clinician of the clinical presentations of sleep disorders in children with autism spectrum disorders, as well as discuss the evaluation and treatment of these disorders.

Epidemiology

Prevalence and Correlates

Sleep disorders affect approximately 20 to 30% of the general pediatric population (Owens, Spirito, et al., 2000b; Sadeh, Raviv, et al., 2000). In the ASD population the prevalence is much higher and is estimated at between 44 and 86% (Richdale & Prior 1995; Wiggs & Stores, 1996; Patzold, Richdale, et al., 1998; Allik, Larsson, et al., 2006). This high prevalence cannot be explained by level of cognitive functioning alone. A study of parent-reported sleep problems in children with pervasive developmental disorder (PDD) and normal intelligence found that 78% of parents reported sleep problems in these children, compared to 26% of parents of an age- and gender-matched group of typically developing children (Couturier, Speechley, et al., 2005). Further, a large study comparing children with ASD (n = 303; ADI and ADOS confirmed) to children with developmental delays, but no ASD (n = 63) and typically developing children (n = 163) found that children with ASD had a higher prevalence of parent-reported sleep problems than either of the two comparison groups. Fifty-three percent of children in the ASD group had at least one frequent sleep problem, compared to 46% and 32%, respectively, of the developmentally delayed and typically developing groups (Schreck, Mulick, et al., 2004). It appears ASD may be a risk factor for sleep problems independent of level of cognitive functioning.

The most commonly reported problems include inability to initiate sleep and difficulty maintaining sleep (Table 26-1). Parents have reported that their children with ASD have trouble going to bed on time, wake frequently during the night, and wake early (Richdale & Prior, 1995; Johnson et al., 2008; Krakowiak et al., 2008; Richdale et al., 2009). Also reported are irregular sleep-wake patterns and poor sleep routines (Hoshino, Watanabe, et al., 1984; Clements, Wing, et al., 1986; Quine 1991; Patzold, Richdale, et al., 1998; Owens, Spirito, et al., 2000b; Schreck & Mulick, 2000; Honomichl, Goodlin-Jones, et al., 2002; Meltzer, 2008). During objective evaluations using actigraphy, children with ASD exhibited less total sleep time in 24 hours than children with developmental delay without ASD and typically developing children (Goodlin-Jones et al., 2008). The children with developmental delay exhibited more and longer awakenings after sleep onset than the ASD or typically developing children. The presentation of sleep problems in children with ASD is discussed in more detail later in this chapter.

As with other aspects of the ASD phenotype, sleep problems are a complex and variable phenomenon in this group. The high number of children who experience at least one sleep problem warrants screening for sleep problems in all children with ASD. There are some subgroups that are at increased risk. A 2008 study using the Children's Sleep Habits Questionnaire found that children with developmental regression were significantly more likely to experience sleep problems than children who did not have a regressive-onset of autism (Giannotti, Cortesi, et al., 2008). Similarly to typically developing children, sleep problems are more likely to be reported in children younger than 5 years and are more severe in children with intellectual disability (Richdale & Prior, 1995).

Typical Sleep Architecture

Children with autism are subject to the same general sleep expectations as typically developing children, and deviation from these norms is significant even when the child "doesn't seem to need much sleep." It is therefore important to understand the sleep patterns that typically developing children manifest at different ages.

Toddler: Ages 0 to 2 Years

Just after birth, infants lack a circadian rhythm, and their sleep/wake cycle varies without regard to dark and light cycles. During the first few months of life they develop a diurnal sleep cycle and by 9 months 70% of infants are sleeping primarily in the evening with one to two naps during the day. By age 1 year, toddlers typically require 10 to 12 hours of sleep per night and may take one or two naps of 2 to 3 hours duration during the day (Meltzer & Mindell, 2006). The most common problems at this age are night wakings, which may be as common as 42% of toddlers, and bedtime resistance (Glaze, 2004). Behavioral patterns that are established at this time can impact the child later in life, including cosleeping and developing a bedtime ritual (Glaze, 2004).

Preschool: Age 3 to 5 Years

During this period children's sleep needs typically decrease from 13 hours to 11 hours by 5 years of age (Glaze, 2004).

Table 26–1.

Commonly reported sleep problems in autism spectrum disorders

Sleep Problem	Reported Prevalence
Insomnia	40–80%; General Pediatric Population 10–30%
Circadian Rhythm Disorder	4–35%; General Pediatric Population 1%
Delayed Sleep Phase	
Irregular Sleep Schedule	
Parasomnias	Not known; in a small case report study RBD occurred in 45%
Bruxism	
NREM Parasomnias (Sleep walking; Night Terrors)	
REM Sleep Behavior Disorder	

Note: Sleep Disordered Breathing (Obstructive sleep apnea) and Sleep Related Movement Disorders not listed; prevalence not known, but may be similar to the general pediatric population.

Napping also decreases, and children may take only one nap and for a shorter time. Night wakings become less common, with somewhere between 15 to 30% affected (Mindell & Owens, 2003). Further reinforcement of a bedtime routine is important at this age, as some children will continue to demonstrate their increasing independence through bedtime resistance. Cosleeping is a common cause of sleep disturbance at this age (Mindell & Owens, 2003).

School-age: Age 6 to 12 Years

Children of this age require approximately 10 to 11 hours of sleep and no longer require a nap. Daytime sleep may be present, although it may be a symptom of abnormal sleep patterns (Mindell & Owens, 2003; Glaze, 2004). Common issues at this age include sleepwalking, nightmares, bruxism, and sleep disordered breathing. This period is also associated with changes in circadian rhythm, and children may shift from an externally enforced sleep schedule to intrinsic preferences, e.g., morning versus evening alertness (Mindell & Owens, 2003). Children should be allowed to direct their own bedtime to some degree in order to establish a routine that fits the child's circadian rhythm and maintains a full night of sleep (i.e., staying up later by 30 minutes is only appropriate if the child is able to alter his or her morning routine.

Adolescents: Age 12 to 18 Years

Sleep requirements drop further in this period. Most teens require approximately 9 hours of sleep per night, although the average teen gets 7 hours of sleep per night. Approximately 11 to 30% of adolescents and teenagers experience a sleep disorder at this age (Glaze, 2004). The increasing independence during these years, as well as increased responsibility at home and at school can contributed to compromised sleep. Environmental factors, such as caffeine, nicotine, alcohol, or drugs may reduce the quantity or quality of a child's sleep, while resulting daytime sleepiness may increase the use of these substances. Further, the onset of puberty may cause changes in circadian rhythm, shifting sleep phase later by approximately 2 hours. Children in this age group in the United States are frequently getting less sleep than is needed, and insufficient sleep is a primary problem in this group.

Sleep Problems in ASD

The term "sleep problems" encompasses a variety of phenotypes, including several well-characterized sleep disorders. Although there is no official system for classifying pediatric sleep disorders, common systems have developed around the adult literature and clinical practice.

The most widely used system is the International Classification of Sleep Disorders: Diagnostic and Coding Manual (American Academy of Sleep Medicine, 2005), which defines the following classes of sleep disorders: insomnia, sleep related breathing disorders, hypersomnias, circadian rhythm disorders, parasomnias, sleep related movement disorders, isolated

symptoms, and other sleep disorders. Each of these classes is further subdivided based on etiology or presentation. Children with ASD most commonly present with a subset of these sleep disorders, and this chapter will focus on this subset.

Insomnia

The most common sleep problem experienced by children with ASD is insomnia. Over half of 167 parents surveyed with a modified Children's Sleep Habits Questionnaire (see section on screening) reported that their child with ASD experienced insomnia 5 to 7 nights per week (Liu, Hubbard, et al., 2006). In practice, insomnia is an umbrella term that includes problems that contribute to difficulty initiating sleep or difficulty maintaining sleep. Diagnostically, the American Academy of Sleep Medicine defines insomnia as persistent difficulty with sleep initiation, maintenance, or quality that occurs despite opportunities for sufficient sleep and that results in daytime impairment (The American Academy of Sleep Medicine). In many cases the diagnosis may come from parent report rather than directly from the child. A child with insomnia may present with difficult behavior surrounding bedtime routines, impaired daytime functioning, or daytime sleepiness.

Two major contributors to insomnia are difficulty falling asleep once in bed and waking during the night. This same previously mentioned study found that the average sleep latency, or the time that it takes for a child to fall asleep once in bed, was 33 minutes, although it was reported to be as long as 150 minutes in some cases (Liu, Hubbard, et al., 2006). This large variation is supported by another study that compared parent assessment of sleep problems to objective laboratory assessment (Malow, Marzec, et al., 2006). Children who were assessed by their parents as having moderate or severe sleep problems were found to have an average sleep latency of 97 minutes. This was significantly longer than the average 30-minute sleep latency in children with ASD but mild or no sleep problems. This suggests that when sleep problems are present, difficulty initiating sleep is a common occurrence. Difficulty falling asleep is also reported as a primary concern among parents (Malow, Marzec, et al., 2006). Bedtime resistance may be a behavioral issue, related to hypersensitivity, or other problem behaviors, or it may indicate an underlying abnormality in circadian rhythm.

Another symptom of insomnia is awakening during the night. Night wakings are normal and benign in children less than six months of age, but persist in approximately 25 to 50% of children after this age (Mindell & Owens, 2003). Waking during the night is frequently a result of negative sleep associations. Children who share a bed, or who require a specific stimulus to fall asleep are more likely to wake during the night. If the stimulus, such as parent's presence, is not available during the might then returning to sleep can be difficult. Parents may not be aware that their child wakes during the night if the child stays in his or her own room. Actigraphy can be used to assess sleep/wake patterns. A 1995 study of 39 children with autism found that night wakings were common, occurring as often as 3.2 nights per 2-week period.

In nearly half of these cases the child was awake for longer than 30 minutes (Richdale & Prior, 1995).

Insomnia can be caused by a variety of different factors. The ICSD-2 divides insomnias by causative factor including adjustment insomnia, psychophysiological insomnia, paradoxical insomnia, idiopathic insomnia, insomnia due to mental disorder, inadequate sleep hygiene, behavioral insomnia of childhood, insomnia due to drug or substance, insomnia due to medical condition, and insomnia not otherwise specified (American Academy of Sleep Medicine, 2005). While insomnia is usually considered to be a disorder experienced by adults, many of these factors may be relevant to children with ASD and will be discussed.

Adjustment Insomnia

Adjustment insomnia is marked by the occurrence of a specific stressor and is transient. The stressor may be a new environment but may also be a recent change in the child's life that is not clearly associated with bedtime. Children with ASD may be predisposed to adjustment insomnia due to difficulties in transitions that are inherent to the disorder. Parents who mention a recent onset of insomnia should be queried about the duration and about any changes that may have taken place in the child's life at that time. In many cases this type of insomnia will resolve on its own once the child has adjusted to a new environment.

Inadequate Sleep Hygiene

Sleep hygiene refers to the physical and behavioral environment surrounding sleep. Good sleep hygiene, or positive sleep habits, promote healthy sleep and eliminate factors that might disturb sleep. Good sleep hygiene practices include: maintaining regular and developmentally appropriate bedtimes and out-of-bedtimes; making the bedroom a media-free zone (no television, computers, video games, etc.); establishing a regular bedtime routine that is conducive to sleep (e.g., nightly bath, story, etc.); avoidance of caffeine and stimulation activity in close proximity to bedtime, and appropriate parent/caretaker expectations. Poor sleep hygiene may contribute or exacerbate sleep problems.

Behavioral Insomnia of Childhood, Limit-Setting Type

Limit-setting sleep disorder is an inability to go to sleep due to insufficient enforcement of good bedtime behaviors by parents (Mindell & Owens, 2003). In some cases parents are inconsistent with bedtime. In the absence of consistent structure, children are more likely to resist or completely refuse bedtime on any given night. This results in delayed sleep onset and shorter total sleep time, although sleep quality after onset is usual normal (Meltzer & Mindell, 2006). Children may also experience symptoms of insomnia if parents do not teach them good sleep hygiene. Allowing children to fall asleep with the television on, have access to video games after bedtime, or

fall asleep in the parents bed are all examples of behaviors that will impair sleep by failing to set appropriate limits. Data published in 2006 from a survey of parents regarding their children with ASD reported that over half of the 167 participating children expressed resistance to bedtime and 16% shared a bed with parents (Liu, Hubbard, et al., 2006). This rate of cosleeping in a study with an average participant age of 8.8 years is considerably higher than a typically developing population at the same age. Limit-setting insomnia should be ruled out or identified and addressed through behavioral means in any investigation of pediatric insomnia. Particularly with cosleeping, parents may feel that falling asleep in mom or dad's bed is acceptable if it helps a child who will not fall asleep alone. However, accommodating a child's difficulty with bedtime either masks a potentially treatable intrinsic insomnia or causes primary insomnia. Parents should be queried about their bedtime routine with the child.

Behavioral Insomnia of Childhood, Sleep-Onset Association Type

Sleep-onset association type insomnia refers to a situation in which a child cannot fall asleep without a particular stimulus present (Meltzer & Mindell, 2006). Commonly reported negative stimuli include needing a parent present to fall asleep or needing to be driven around in the car. These behavioral accommodations are typically not sustainable and negatively impact parents' lives to a significant degree. When the required stimulus is not present, bedtime resistance and insomnia develops. As with limit-setting insomnia, the stimulus becomes either a mask for other etiology, or it becomes an obstacle to consistent healthy sleep patterns. This behavioral disorder typically occurs in toddlers or young children, but may be present at older ages in children with developmental disorders. When identified in parent-interview, sleep-onset association disorder can be addressed with behavioral changes called extinction that will gradually wean the child off the stimulus.

Insomnia Due to Other Medical Problems

Children with ASD are at risk for other medical problems and frequently receive psychotropic medications, both of which can impact sleep. Medical problems can include gastrointestinal problems such as gastroesophageal reflux and be particularly bothersome in relation to sleep. Epilepsy, which is resent in approximately one third of children with ASD (Giovanardi Rossi, Posar, et al., 2000), may also impact sleep. Partial seizures of temporal lobe origin have been found to reduce REM sleep in adults, even when the seizures occur during the day (Bazil, Castro, et al., 2000). REM sleep has been implicated in memory consolidation and learning. The possibility that sleep problems may be secondary to an existing medical condition, as well as a review of the medications a child is receiving, deserve consideration when children with ASD are experiencing sleep problems.

Sleep Related Breathing Disorders

Sleep disordered breathing (SDB) is a respiratory sleep disorder that involves some degree of obstruction to upper airways. SDB ranges from primary snoring to severe obstructive sleep apnea (OSA). Primary snoring does occur and can be benign, but snoring is more often a sign that OSA is present. OSA is a severe form of SDB and occurs when airflow ceases completely due to upper-airway obstruction. Signs of OSA include a repeated sequence of a snore, silence (breathing stops), and a gasp or snort as breathing resumes (Mindell & Owens, 2003). This sequence can cause small disruptions in sleep. These disruptions may be imperceptible to the patient but nonetheless fragment sleep and may result in daytime sleepiness and daytime cognitive/behavior problems including inattention and hyperactivity. Risk factors for OSA include tonsilar hypertrophy, obesity, hypotonia, family history, and ethnicity (higher in African American children; Mindell & Owens, 2003). OSA can be treated with weight-loss (when obesity is present), tonsillectomy and/or adenoidectomy, or continuous airway pressure (CPAP) when not otherwise resolved (Meltzer & Mindell, 2006). Children with ASD may have difficulty tolerating CPAP and may need a period of desensitization. Sleep disordered breathing has been reported by parents to occur in nearly 25% of surveyed children with ASD, although more data regarding the exact prevalence is needed (Liu, Hubbard, et al., 2006).

Circadian Rhythm Abnormalities

Circadian rhythm abnormalities include disruptions in the sleep-wake cycle that prohibit normal sleep. The most common type of circadian rhythm abnormality is delayed sleep phase syndrome (DSPS). This is an abnormality in circadian rhythm that results in sleep onset more than 2 hours after normal sleep time (Meltzer & Mindell, 2006). As the name implies, the child's internal circadian rhythm is active but latent. Children with DSPS do not respond to typical cues for sleep onset, such as low light or regular bedtime, but do experience appropriate sleep duration and quality after sleep onset at a later time. The two signs of DSPS are (1) a child who falls asleep easily and consistently at a delayed hour, or (2) a child who is predictably difficult to wake the next morning, but who will wake on their own if allowed to sleep in (Meltzer & Mindell, 2006). DSPS is most often addressed with behavioral changes to the sleep-wake schedule. Specifically, the child is slowly (over a period of several weeks or months) retrained to a more appropriate sleep cycle by using the natural sleep time as a starting point and gradually moving bedtime forward.

It is unclear exactly how common DSPS is in children with ASD but it appears to occur with at an elevated prevalence from the general pediatric population. A 2008 study of regression and disturbed sleep in children with autism found that 16% of children with nonregressive autism and 35% of children with regressive onset autism had DSPS (Giannotti, Cortesi, et al., 2008). Both of these rates were significantly different from the reported 1% of typically developing controls with DSPS. Diagnosis was based on parent report questionnaire and sleep diary. Other studies support the presence and significance of this problem in children with autism. Wiggs and Stores collected sleep data from parent report, sleep diary, and actigraphy on 69 families with an ASD child (Wiggs & Stores, 1996). Of the 44 children who reported disturbed sleep, 4 experienced symptoms of DSPS. This same study found that a second circadian rhythm abnormality, irregular sleep phase syndrome, was reported in 2 of the 44 children. Additional objective studies are needed to accurately assess the prevalence of DSPS in children with ASD, but it does appear to be a prevalent complaint.

Parasomnias

Parasomnias refer to problems that disturb sleep after it has been initiated. These include bruxism, nightmares, night terrors, sleepwalking, and REM sleep behavior disorder. Bruxism is the term used for repetitive teeth grinding during sleep. Approximately 14 to 20% of children in the general pediatric population grind their teeth during sleep, but this prevalence is likely higher in children with developmental or cognitive delays. Children are rarely aware of the condition, and parents who hear the grinding most often identify it. Bruxism can cause dental damage and may also cause muscle pain and headaches. Nightmares or frightening dreams may affect as many as 50% of young children, with decreasing prevalence as children age (Mindell & Owens, 2003). Removing negative or overstimulating images from the bedroom or practicing relaxation techniques prior to bedtime may help alleviate nightmares. Night terrors are episodes of waking during the night and expressing symptoms of intense fear. Night terrors differ from nightmares in that they occur during slow-wave sleep rather then REM sleep, generally occur earlier in the evening, and are rarely recalled by children.

Sleepwalking occurs in as many as 40% of children, and 3 to 4% experience episodes either monthly or weekly (Mindell & Owens, 2003). Sleepwalking has a strong genetic component, and a family history may be present in as many as 90% of cases. Although sleepwalking is benign, parents are able to protect the child from secondary injury by locking doors and windows, gating stairs, and removing obstructions or dangerous objects from the child's environment. If episodes occur at predictable times, scheduled awakenings can be planned to avoid the episode. Waking the child every night 15 to 20 minutes prior to the episode for 1 to 2 weeks may resolve the problem.

REM sleep behavior disorder (RBD) is a less commonly observed parasomnia, but may be more common in children with ASD than typically developing children. During healthy REM sleep there is muscular paralysis. RBD is characterized by loss of this atonia, resulting in patients acting out dreams. Patients may kick or punch the air, run from bed, or demonstrate other complex muscle movements (American Academy of Sleep Medicine, 2005). Daytime sleepiness may be observed if sleep is fragmented as a result of RBD. In the general population RBD most often occurs in adult males and

is associated with neurodegenerative disease such as Parkinson's, Alzheimer's dementia, and multiple sclerosis. Evidence suggests that RBD may also occur at an increased incidence in children with ASD. A polysomnographic study of 11 children with a DSM-IV diagnosis of autism, ages 3 to 9 years, found that 5 met criteria for RBD (Thirumalai, Shubin, et al., 2002). RBD should be diagnosed by polysomnography, but is suggested if parents report observing any of the symptoms above. RBD may occur in combination with other sleep disorders.

As a group, parasomnias are reported to occur in approximately 53% of children with ASD. The most common parasomnia reported in this group is bruxism (18%). A reported 4% of children with ASD sleepwalk, 5% awaken during the night with inconsolable screaming, and 4% awaken from a frightening dream. Questions that may trigger identification of parasomnias are available in the CSHQ (see section on evaluation below).

Sleep Related Movement Disorders

Restless leg syndrome (RLS) is characterized by unpleasant sensations that are associated with a desire to move, and relief with such movement. These sensations occur more frequently at rest or lying down and during the evening (ICSD-2). RLS is usually considered in adults, but can have its onset in childhood. RLS is often, although not always, associated with periodic leg movement disorder (PLMD). PLMD is characterized by brief (second) jerks during non-REM sleep. These rapid movements may be accompanied by short arousals. Although the etiology of these disorders is unknown, RLS may include a history of iron-deficient anemia. Further, there appears to be a genetic component, and a family history of RLS is associated with increased risk. RLS is also associated with a diagnosis of ADHD (Mindell & Owens, 2003). RLS may be difficult to diagnosis in children with autism without polysomnography due to core deficits in communication. RLS may present as difficulty falling asleep or difficulty staying in bed at bedtime. While the diagnosis of RLS is based on clinical criteria, the diagnosis of PLMD is based on the findings of overnight polysomnography ("sleep study"), which may suggest or support the diagnosis of RLS in those children unable to provide sufficient clinical information.

Etiology

The etiology of sleep problems in children with ASD is likely multifactorial, including genetic and environmental factors as well as medical and behavioral issues. Disturbances in the sleep-wake cycle may contribute to the occurrence of sleep problems in these children. The sleep-wake cycle is regulated by many factors but the primary driving force is the circadian rhythm, which is the cycle of sleep-related hormones and internal signals. Disorders of the circadian rhythm can produce sleep problems, most commonly difficulty initiating and maintaining sleep. The circadian clock is located in the suprachiasmatic nucleus of the hypothalamus and, among other things, determines the release of sleep-related hormones such as melatonin. The circadian clock, in combination with changes in light, determines the production of melatonin from the pineal gland. Bright light suppresses melatonin production, but in dim-light conditions the level of endogenous melatonin can be measured using saliva, and the time of melatonin increase, referred to as dim-light melatonin onset (DMLO), can be used as a marker for circadian rhythm. Typically the DMLO should occur just prior to average time of sleep onset. Studies indicate that melatonin regulation in children with ASD may be abnormal compared to controls. Specifically, children with ASD may have elevated melatonin levels during the day and decreased levels of melatonin at night (Ritvo, Ritvo, et al., 1993; Nir, Meir, et al., 1995; Kulman, Lissoni, et al., 2000). This pattern is the opposite from that seen in typically developing children. A 2005 study assessed 6-sulphatoxymelatonin, a primary melatonin metabolite that is excreted in urine, and found that children with ASD showed significantly lower concentrations of 6-SM relative to age- and gender-matched controls (Tordjman, Anderson, et al., 2005). These studies together suggest that circadian rhythm abnormalities may more common in children with ASD and likely contribute to disturbed sleep in children with ASD.

Impact

Daytime Functioning

Sleep problems experienced by children are frequently associated with disturbances in neurocognition and behavior. In children, common consequences of poor sleep include difficulty with mood regulation and impulse control, hyperactivity or daytime sleepiness, poor concentration, and impaired memory. The impact of impaired sleep on daytime functioning may be even more severe in children with poor self-regulation, a deficit common in children with ASD. Poor sleep may exacerbate existing behavioral problems.

Data collected by the Autism Treatment Network (ATN) in 2006 found quantitative impairments in daytime functioning in children with ASD and sleep problems. Participants were 54 parents of children with a diagnosis on the autism spectrum, confirmed by ADI and ADOS. Parents reported their child's sleep using the Children's Sleep Habits Questionnaire (CSHQ) and completed behavioral questionnaires, including the Aberrant Behavior Checklist (ABC), the Child Behavior Checklist (CBCL), the Pervasive Developmental Disorder Behavior Index (PDDBI), and the Behavior Rating Inventory for Executive Functioning (BRIEF). Parents who reported sleep problems on the CSHQ also reported significantly increased scores in several behavioral subdomains.

Children were reported to have increased irritability, stereotypy, and hyperactivity, as well as deficits in executive function, including planning and organization.

These observations are consistent with reports from other studies indicating that poor nighttime sleep negatively impacts daytime functioning. In a study of children with an ADOS confirmed diagnosis of ASD and who underwent polysomnography, children with poor sleep were scored significantly higher by their caregivers on the affective problems scale of the Child's Behavior Checklist (CBCL) than children with good sleep (Malow, Marzec, et al., 2006). A study of questionnaire data from 55 parents who self-identified as having a child with ASD (ages 5–12 years) found that children with sleep problems also had more severe autism symptoms, as assessed using the Gilliam Autism Rating Scale (Schreck, Mulick, et al., 2004). Parent-report data from a study of 32 children with Asperger's syndrome (AS) or high functioning autism (HFA) indicates that children with AS/HFA and insomnia have more severe autism behaviors, as measured by the Autism Spectrum Screening Questionnaire, and worsened social behaviors, as assessed by the Strengths and Difficulties Questionnaire (Allik, Larsson, et al., 2006).

The majority of studies of sleep and behavior have found a statistical association, but do not provide support for a clear causal relationship, However, there is evidence that improving sleep problems improves behavior. A case study a 5-year-old female with pervasive developmental disorder not-otherwise-specified, and sleep disordered breathing found improved socialization and reduced stereotypy (Malow, McGrew, et al., 2006). Studies in typically developing children have also found improved behavior with successful treatment of sleep problems, although these results have not yet been replicated in large number in children with ASD. A study of children ages five to 13 years who underwent adenenotonsillectomy as treatment for sleep-disordered breathing found that hyperactivity was reduced in these children, and that attention improved (Chervin, Ruzicka, et al., 2006).

Sleep problems in children can also impact parents' sleep and cause significant stress for the family. Parents of children with sleep problems are more likely to have difficulty sleeping themselves, in part due to demands placed on them by the child's nighttime arousal. A study of 32 children with ASD and their parents found that not only did children have poorer sleep quality than a control group of 25 typically developing children, but parents of the ASD group reported significantly earlier wake times, shorter time in bed, and shorter actual sleep time than parents of the typically developing group (Meltzer, 2008). Parents of children with ASD also report higher levels of daytime stress, particularly if the child's daytime behavior was worsened due to poor sleep. It is not clear whether there is a causal relationship between poor sleep and parental daytime stress. However, a 2001 study found that when the child's sleep problems were successfully treated, the level of maternal stress was reduced. Paternal stress was not affected by improved sleep in the child, although father's satisfaction with their own sleep was improved in the treatment group (Wiggs & Stores, 2001).

It is possible that the relationship between child's sleep problems and parental stress is bidirectional.

Screening and Identification

Parent Report

Parent report measures are a quick and easy way for clinicians to screen for sleep problems. The two most commonly used measures in the pediatric population are the Children's Sleep Habits Questionnaire (CSHQ)(Owens, Spirito, et al., 2000a) and the BEARS. However, other instruments are available, including screening guidelines for obstructive sleep apnea (American Academy of Pediatrics, 2002). Due to the overwhelming evidence that sleep problems occur frequently in children with autism, significantly impact cognition and behavior, contribute to family stress, and may be treatable, it is imperative that all children with a diagnosis of autism spectrum disorder be assessed for the presence of comorbid sleep problems, either at the time of first diagnosis or during follow-up care.

The BEARS is a clinician-administered questionnaire that consists of five items and allows parents to report the presence of bedtime issues. These include problems with bedtime and initiating sleep, excessive daytime sleepiness, night awakenings, regularity and duration of sleep, and snoring. See below for a list of BEARS items and sample questions. These questions may be modified to best query for the child's age and developmental level.

BEARS (Owens & Dalzell, 2005)

1. Bedtime: Does your child have any problems going to **B**ed or any problems falling asleep?
2. Excessive daytime sleepiness: Does your child seem **E**xcessively sleepy during the day and/or have difficulty waking up in the morning?
3. Awakenings: Does your child **A**waken during the night or have any unusual behaviors during the night?
4. Regularity and Duration of Sleep: Does your child have a **R**egular sleep schedule and get enough sleep each night?
5. Snoring: Does your child **S**nore or have any problems breathing during the night?

If parents answer yes to any of the five questions then the clinician is prompted to ask about the specifics of the problem. This instrument allows clinicians to inquire about sleep problems during a routine clinic visit, and, without being overly burdensome, will provide the clinician with some indication of need for further evaluation or for referral for formal sleep evaluation. The BEARS was developed by Judith Owens and has been used clinically since 2005 (Owens & Dalzell, 2005).

The Children's Sleep Habits Questionnaire (CSHQ) is a parent-report questionnaire developed by Judith Owens for use in children ages 4–12 years (Owens, Spirito, et al., 2000a). Parents are asked to rate each of 33 sleep-disturbance items based on their frequency during a "typical" recent week. Behaviors are rated on a 3-point scale: "usually" if the behavior occurred 5 to 7 times per week; "sometimes" for 2 to 4 times per week; and "rarely" for 1 or fewer times per week. The CSHQ asks parents to report how often their child has experienced each of a list of specific sleep behaviors during the past 7 days, e.g., snoring. Parents are also asked to separately report whether or not the behavior was a problem. Parent responses are numerically coded and classified into eight domain scores: (1) Bedtime Resistance; (2) Sleep Onset Delay; (3) Sleep Duration; (4) Sleep Anxiety; (5) Nightwakings; (6) Parasomnias; (7) Sleep Disordered Breathing; and (8) Daytime Sleepiness. All items contribute to a composite score, which has been shown to be clinically significant. Children who have a composite sleep score greater than 41 are considered to have sleep problems and should be considered for further evaluation. The CSHQ is designed based on common clinical presentations of the sleep disorders most often seen in children, and specific answers will provide some characterization of problems that are present.

Information about the child's sleep-wake cycle over a period of days can be collected using a sleep diary. The clinician can choose the duration of a sleep diary, but a typical period is 1 to 2 weeks. An informative sleep diary should allow parents to complete a continuous measure of their child's sleep over the period, clearly delineating sleep and wake periods. Each 24-hour period should be recorded as fully as possible, including naps and nighttime waking (if observed by parents). Parents should also be asked to provide a daily log of their child's routine and diet, including bedtime, consumption of caffeinated beverages, medications that might affect sleep, or any deviation from the typical routine. An example of a sleep diary is included in Figure 26-1. The sleep diary differs from other parent-report measures in that it is a structured free report rather than guided response, and because it provides more comprehensive child's sleep over a period of days. If parents are encouraged to complete the diary diligently, it may be possible to identify variation in sleep patterns from night to night as well as provide a better understanding of the home environment and some assessment of sleep latency (if the child is put to bed at 8:00 PM but sleep does not begin until 9:00 PM).

Objective Assessment

Nighttime sleep can be assessed objectively at home by using a physical activity monitor called an actigraph. Children can wear the watch-sized actigraph on their wrist or, if necessary, on their ankle. The actigraph contains a motion sensor that records activity over a period of time, often 1 or more weeks. Data from actigraphy provides a measure of all waking and sleep time, including exact times that the child went to sleep and all naps. When combined with information regarding bedtime and out-of-bed time, this data can be used to calculate sleep latency, total sleep time, and sleep efficiency (the percent of time in bed that is spent asleep). Caregivers should be asked to complete a concurrent daily sleep diary to provide a context for the data and aid in interpretation. The most informative actigraphy data relies on compliance from both the parents and the child. Children with sensory issues may have difficulty wearing a novel object, although undergoing a period of desensitization prior to beginning data collection may help address this difficulty.

Polysomnography (PSG) is the "gold standard" for assessing sleep (Meltzer & Mindell, 2006) and provides information regarding sleep architecture and disruption. PSG combines electroencephalogram (EEG), electromyogram (EMG), and electro-oculogram (EOG), with additional assessment of respiratory activity to quantitatively describe all aspects of the child's sleep over the course of a given night. Although PSG is widely acknowledged as the best tool for diagnosing and characterizing the sleep, and specifically sleep disorders such as PLMD and sleep disordered breathing, it has several drawbacks. Chiefly, PSG only provides data from a single or short series of nights rather than an assessment over a larger time period. The children are evaluated in the unfamiliar environment of a clinical sleep laboratory. Many children with ASD may experience difficulty tolerating the placement of the sensors and the novel environment of the sleep laboratory. Careful planning and preparation of the child and the parents are necessary for the successful completion of the polysomnographic study (Mindell, Emslie, et al., 2006).

Treatment

It is critical that sleep problems be reliably identified because there are interventions available that can alleviate or cure the problems and possibly improve the consequent adverse behavioral and cognitive effects. Parents are frequently under the misconception that the sleep problems are "part of the autism" and that they cannot be treated. Both behavioral and pharmacological treatments exist and can be used in this population. Figure 26-2 presents an algorithm for screening children for sleep problems and referral for sleep evaluation or other subspecialty evaluation.

Treatment of sleep problems in children with ASD can be complicated by the many other medications and therapies that are used to treat these children. However, it is import to first manage medical and behavior problems that may contribute or exacerbate sleep problems. Specific sleep disorders such as obstructive sleep apnea should be appropriately evaluated and managed. In general, guidelines published by the American Academy of Pediatrics mandate that sleep problems should be treated first with behavioral therapy (Mindell, Emslie, et al., 2006). If problems persist, consideration can be given to use of pharmacologic sleep aids.

CONTINUOUS SLEEP DIARY

Please shade times during which the child was asleep. If the child is wearing an activity monitor, please indicate time when the watch was taken off and put back on with two vertical bars connected by a line.

Date	12:00 PM	1:00 PM	2:00 PM	3:00 PM	4:00 PM	5:00 PM	6:00 PM	7:00 PM	8:00 PM	9:00 PM	10:00 PM	11:00 PM	12:00 AM	1:00 AM	2:00 AM	3:00 AM	4:00 AM	5:00 AM	6:00 AM	7:00 AM	8:00 AM	9:00 AM	10:00 AM	11:00 AM

DAILY SLEEP DIARY

1. Who completed this diary? (e.g., Mother, Father, caregiver, etc.)

   _____

2. What time did your child go to bed last night? __ __:__ __AM/AM

3. What time did your child get up this morning? __ __:__ __AM/AM

4. Did your child go to school yesterday? Yes or No (circle one)

5. Was your child sick yesterday? Yes or No (circle one)

6. Did your child start any new medications yesterday? (circle one)

       Yes or No

    If so, list medications: _____

7. Did your child stop any old medications yesterday? Yes or No (circle one)
      If so, list medications:

8. How many 8 oz. beverages containing caffeine did your child drink yesterday? _____

9. How would rate your child's sleep last night overall?   (circle one)

    Very good   Good   Fair   Poor   Very Poor

8. Please add any comments you think may be relevant to your child's sleep,
    e.g. travel, specials events, etc: _____

_____

Figure 26–1. Sleep diary.

Behavioral Therapy

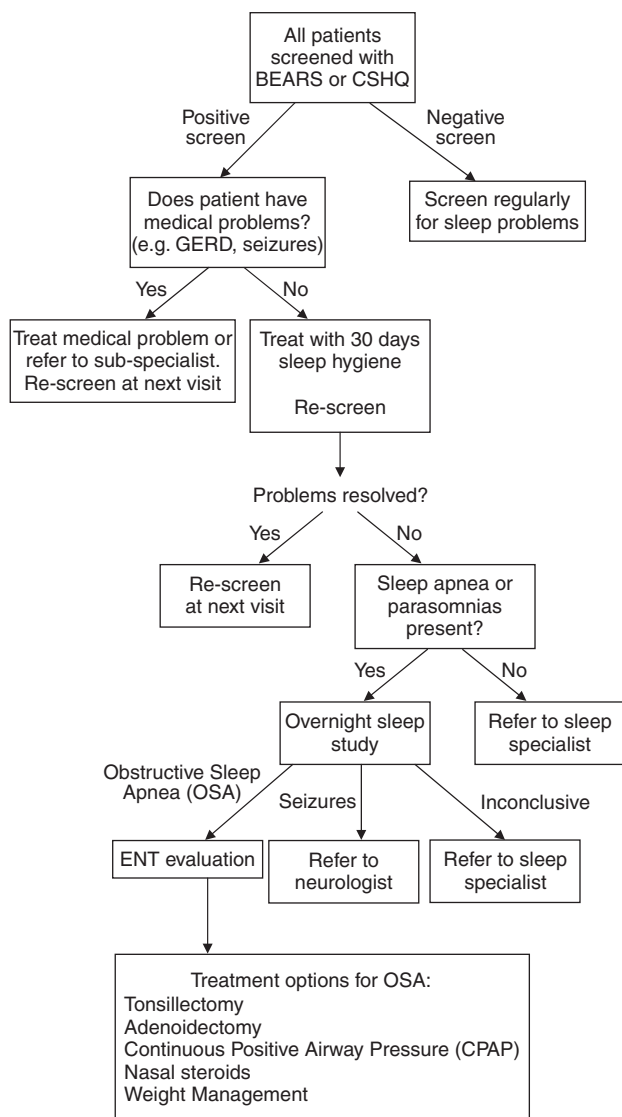
Sleep hygiene refers to bedtime practices, and particularly those that promote sleep onset and healthy sleep. Good sleep hygiene habits include setting a consistent and developmentally appropriate bedtime, removing electronics from the bedroom, avoiding caffeine, developing a step-down routine for bedtime and an appropriate bedtime ritual, and adjusting the environmental conditions to help entrain the circadian rhythm cycle. Low light and cool temperatures in the evening will help promote sleep onset, and bright light and warmer temperatures will help promote wakefulness. Exposure to early morning bright light helps advance the sleep phase, while evening bright light may delay sleep onset. An appropriate sleep hygiene plan should be developed in discussion with the family to meet their needs and ensure appropriate expectations. Sleep hygiene may not resolve sleep problems completely, but can contribute to improvement of the child's sleep and may be used in concert with other behavioral and pharmacological therapies.


Figure 26–2. Decision tree for screening and assessment of sleep problems in children with autism spectrum disorder.

Specific behavioral interventions can be developed to address sleep-onset association and limit-setting type insomnia. Extinction involves putting the child to bed at a particular bedtime and then ignoring the child's inappropriate behaviors until the following morning. This technique forces children to resolve their need for a particular stimulus on their own, although it may be unpalatable to parents. Graduated extinction allows parents to check on the child, but with increasing delay over a period of 1 to 2 weeks. As with extinction, the goal is to wean children off sleep associations that are unsustainable and teach children to "self-soothe"(Mindell & Owens, 2003). Other step-down rituals can be devised based on the child's ability to tolerate bedtime changes and the parents desire to institute good bedtime habits. High-functioning children may respond to incentive-based interventions. In this case it is important to select incentives that are desired and that can be immediately awarded.

Pharmacotherapies

If behavioral therapy fails to address the child's sleep problems, treatment with a pharmacologic agent may be indicated. Many parents treat the symptoms of their child's sleep problem with secondary pharmacologic agents, often without a physician's oversight. Regardless of whether the treatment is prescription or over-the-counter, a physician should work with parents to develop and oversee a good plan for pharmacologic management. However, the lack of evidence supporting most pharmacological treatments has left parents and physicians without a reliable roadmap.

The lack of attention to pharmacologic management of sleep problems in children with autism may be due to the lack of treatment studies children in general. In response to this dearth of published evidence, the AAP has identified children with ASD as a high priority population for clinical trials of pharmacologic sleep therapies (Mindell, Emslie, et al., 2006). However, several studies have been released that build on existing literature to provide evidence for several different pharmacologic treatments of sleep problems in these children. Additionally, a consensus paper was published in 2005 that reviewed commonly used pharmacologic treatments for insomnia (Owens, Babcock, et al., 2005). This statement sets forth recommendations for treatment and dosing that are based primarily on clinical experience rather than evidence based on well-designed and controlled clinical trials.

This consensus statement and other published reviews discuss prescription and nonprescription medications that are commonly used to treat insomnia. Typically these are in the class of sedatives or hypnotics, although some psychotropic medications provide secondary benefits to sleep. As yet there are no pediatric guidelines for pharmacologic management of sleep problems, and the FDA has not approved any medications labeled for treatment of pediatric sleep problems. We present here a summary of the most frequently used medications. In particular, more evidence is needed to fully assess the use of these medications in children with ASD (Mindell, Emslie, et al., 2006). Pharmacologic intervention should be initiated after a thorough sleep evaluation and should be paired with behavioral interventions.

Melatonin

Melatonin is an endogenous neuropetide that is secreted by the pineal gland in response to signals from the circadian clock. Typically, endogenous melatonin levels are low during the day and peak prior to nighttime sleep onset, although evidence (discussed previously in this chapter) indicates that this rhythm may be disrupted in some children with ASD. This explanation of sleep problems in this population theoretically supports treatment with exogenous melatonin, although as yet the literature has not connected a response to treatment with melatonin to an underlying melatonin abnormality. Regardless, exogenous melatonin is a commonly used over-the-counter sleep aid. Melatonin has been studied in children with ASD and found to be a safe and effective treatment for insomnia.

A 2006 double-blinded, placebo-controlled cross-over trial in 11 children found that 5 mg of melatonin daily for 4 weeks significantly reduced both sleep latency and number of night wakings (Garstang & Wallis, 2006). These results have been supported by two open-label trials in children with ASD. An open-label study of the long-term safety and efficacy of melatonin was conducted in a group of 25 children with autism. Children were given 3 mg of controlled release melatonin at the start of the study, but were titrated up to as much as 6 mg per day if necessary. The study found that after 24 weeks patients had improved sleep, as evidenced by sleep diary and CSHQ. Further, children who discontinued melatonin at 16 weeks returned to disturbed sleep patterns but showed improvement after treatment resumed (Giannotti, Cortesi, et al., 2006). A large-scale clinical trial of melatonin in 107 children ages 2–18 showed that melatonin effectively resolved sleep problems in 25% of patients at doses of melatonin starting at 0.75 mg per day and titrated up to 6 mg as necessary. An additional 60% of patients reported improved sleep, although sleep problems were still present. Only three patients in this study reported experiencing side effects including morning sleepiness and increased enuresis, which resolved when the dose was lowered (Andersen, Kaczmarska, et al., 2008). Other studies have found that patients did not experience any side effects as a result of the melatonin. These studies support the use of melatonin to treat insomnia in children with ASD. Possible side effects of melatonin include hypotension, bradycardia, nausea, and headache. Melatonin may also exacerbate comorbid autoimmune diseases (Owens, Babcock, et al., 2005).

Clonidine

Catapres, known by the trade name of Clonidine, is an alpha-adrenergic receptor agonist that was originally developed as a nasal decongestant for adults. During initial clinical trials investigators observed that Clonidine had bradycardic and hypotensive effects, and it has since become a treatment for hypertension (Reed & Findling, 2002). Although Clonidine may cause insomnia in adults, it is soporific in children and is commonly prescribed to treat sleep problems in children with neurological disorders as well as ADHD (Reed & Findling, 2002). Clonidine may also be used to treat problems with impulsivity, inattention, and hyperactivity. Clonidine is not labeled to treat pediatric sleep problems, although studies have shown that it can improve insomnia in some children. A 1996 study found that Clonidine improved sleep problems in 85% of 62 children with ADHD, ages 4 to 17 years (Prince, Wilens, et al., 1996). Data from a 2008 open-label study of Clonidine in 19 children with ASD showed that parent report of sleep initiation improved, and that side effects were tolerable. Reported side effects from this study included lethargy, tachycardia, daytime sedation, and hypotension (Ming, Gordon, et al., 2008). These side effects were rare, and in only one case was the child withdrawn from the study due to side effects. Bradycardia, dry mouth, and depressed consciousness have also been reported (Reed & Findling, 2002).

Benzodiazapines

Benzodiazepines have historically been used to treat adult anxiety disorders and as sedatives and anticonvulsants in pediatric patients. Medications in this class function as gamma-aminobutyric acid (GABA) agonists to decrease neuronal excitability across the central nervous system. A variety of structurally variant benzodiazepines are now used to help children fall asleep and stay asleep for the course of the night. In particular these medications may be used to suppress night terrors or other partial-arousal parasomnias, as well as to treat circadian rhythm disorders (Reed & Findling, 2002; Mindell & Owens, 2003). The most commonly used of this class are clonazepam (Klonopin), lorazepam (Ativan), flurazeam (Dalmane), quazepam (Doral), temazepam (Restoril), estazolam (ProSam), and triazolam (Halcion) (Reed & Findling, 2002). These medications differ primarily on time of onset, which ranges from 15 minutes to an hour, and half life, which can be 3 to 120 hours (Reed & Findling, 2002). Side effects of benzodiazepines include daytime drowsiness, a worsening of insomnia with withdrawal of the drug (rebound insomnia), other withdrawal symptoms such as phonophobia, photophobia, and seizures, as well as anterograde amnesia (Reed & Findling, 2002). Short-acting benzodiazepines are generally associated with the withdrawal effects and amnesia, while longer-acting variants are more likely to produce daytime residual effects. Clinical trials have been limited to adults and no studies exist in an ASD population. No medications in this class are FDA approved for treatment of pediatric sleep problems, and guidelines for pediatric dosing do not exist.

Zolipidem (Ambien) and Zaleplon (Sonata)

Both Zolipidem and Zaleplon are both used clinically to treat adults and adolescents with primary insomnia (Mindell & Owens, 2003). Similar to benzodiazapines, these medicines act as GABA-agonists to inhibit the central nervous system. Unlike the previous class of medications, zolipidem and zaleplon are associated with limited daytime effects and reduced tolerance. Side effects do include daytime sleepiness, confusion, anterograde amnesia, and rebound insomnia (Mindell & Owens, 2003). Results from studies in children in general are lacking, and no studies have been conducted in children with ASD.

Chloral Hydrate

Chloral hydrate is one of the oldest treatments for sleep problems, although its use has declined since it was introduced in the 1870s (Reed & Findling, 2002). Today chloral hydrate is used to treat sleep-onset delay and circadian rhythm abnormalities, particularly in children with neurologic abnormalities or blindness. Adult studies have not shown chloral hydrate to have a benefit over placebo in treating insomnia. Side effects include gastrointestinal distress, nausea, vomiting, liver toxicity, dizziness, light-headedness, and respirator depression (Mindell & Owens, 2003). Discontinuation after prolonged

use can cause withdrawal, including seizures and delirium. Use of chloral hydrate has also been associated with adverse events, including cardiac arrhythmias and central nervous system depression in children (Reed & Findling, 2002).

Antidepressants

Tricyclic and newer serotonergic antidepressants have been used with increasing frequency to treat partial arousals and nocturnal enuresis (Reed & Findling, 2002). Trazadone, nefazodone, and aroxetine are commonly used to treat the former, while imipramine hydrochloride is the most common antidepressant to treat the latter. These medications work by suppressing deep sleep and decreasing arousals during sleep-stage transitions. Side effects of antidepressants include daytime sleepiness and dry mouth. There is also concern for cardiac arrhythmias (Reed & Findling, 2002).

Antihistamines

Antihistamines are the most commonly recommended non-prescription medication for sleep problems. Data published from a survey of community based pediatricians found that 68% of physicians who have recommended a nonprescription medication recommended antihistamine at least once (Owens, Rosen, et al., 2003). Nonprescription antihistamines are also commonly chosen by parents of children with sleep problems without a physician's recommendation. H_1 receptor agonists such as diphenhydramine, hydroxyzine, and chlorpheniramine act by crossing the blood-brain barrier to depress the central nervous system. Decreased alertness and slowed reaction are typically achieved 2 to 3 hours after administration, and half-life ranges from 3 to 9 hours. Side effects include impaired daytime functioning and poor sleep quality (Reed & Findling, 2002). Second- and third-generation antihistamines, such as terfenadine and loraditine, may have fewer residual daytime effects (Mindell & Owens, 2003).

Prognosis (for the Field)

Sleep problems are a frequent and serious concern in children with ASD. Numerous studies have been conducted on the prevalence of sleep problems, and the percent of children with ASD who experience difficulty sleeping ranges from between 44 and 86% (Richdale & Prior, 1995; Wiggs & Stores, 1996; Patzold, Richdale, et al., 1998; Allik, Larsson, et al., 2006). Sleep problems in this group have been consistently found to be more common than in either typically developing or developmentally delayed children. This increased risk and, even at the lowest prevalence estimates, high comorbid occurrence, put sleep problems near the top of the list of medical conditions affecting children with ASD.

Although evidence that children with autism are much more likely than typically developing children to experience disturbed sleep has accumulated over the past decade, the prevailing understanding at one time was that poor sleep was "part of the autism" and did not warrant further clinical attention. In fact, children with ASD and sleep problems may have more impaired neurocognitive functioning and worse behavior than children with ASD and normal sleep (Schreck, Mulick, et al., 2004; Malow, Marzec, et al., 2006).

In response to the high prevalence and clinical severity, sleep problems are diagnosable, often in the pediatrician's office. Expedient screening questionnaires are available, and these can be both administered and assessed by most physicians who see children with ASD (Owens, Spirito, et al., 2000a; Owens & Dalzell, 2005). Referral to a sleep specialist may be necessary, but even in this case screening questionnaires are an efficient and effective way to identify children for further evaluation. Assessment for sleep problems should be a routine part of clinical care for children with ASD.

Available and effective treatments further justify attention to sleep problems in this population. A 2005 consensus statement provides guidelines the use of behavioral and pharmacotherapy by community-based pediatricians (Owens, Babcock, et al., 2005). Behavioral therapy should be tried first, followed by pharmacotherapy if necessary and supervised by a pediatric sleep specialist when possible. Future advancements in this field require data from well-designed clinical trials of sleep medications in children with ASD.

Conclusion

This review supports the opinion that sleep problems in children with ASD are a significant issue that should be part of the routine clinical evaluation of these children. Sleep problems occur frequently in ASD and negatively impact on the child's sleep, as well as the sleep of parents and caretakers. Additionally, sleep problems negatively impact on daytime cognition and behavior of these children, and the quality of life of their families. There is a need for further characterization of specific sleep problems in ASD and comparison of differences and prevalences to children with other developmental problems and typically developing children. Effective treatment has the potential to reverse the nighttime and daytime impact of sleep problems in these children. We are challenged to develop reliable screening paradigms for the primary care physician and the ASD specialists. To develop effective treatment protocols for the sleep problems of children with ASD we need to better understand the pathophysiology and the relationship of other medical problems and medications. Well-designed clinical trials of behavioral and pharmacological therapies are necessary to establish an evidence basis for the management of sleep problems.

Challenges and Future Directions

- Sleep problems should be part of the routine clinical evaluation of children with an autism spectrum disorder.

- Reliable screening paradigms are needed to aid primary care physicians and specialists in evaluating children with ASD.
- Well-designed clinical trials of behavioral and pharmacological therapies are needed to establish an evidence base for management of sleep problems.
- Effective management requires better understanding of the pathophysiology of sleep problems in children with ASD, including relationship to other medical problems and treatments.
- Better understanding of the epidemiology of sleep problems in children with ASD will aid identification and treatment.

Perspective Article ▦ Christopher Gillberg

Autism as a Medical Disorder

Autism spectrum disorders (ASDs)—including autistic disorder, atypical autism (also referred to as autistic-like condition and pervasive developmental disorder not-otherwise-specified/PDD-NOS), Asperger's disorder, and childhood disintegrative disorder—are often lifelong conditions that are, rightly, considered to be the territory of psychiatrists, psychologists, special education teachers, speech and language pathology therapists (SLPs), geneticists, neurophysiologists, neuroradiologists, and neurochemists. In everyday practice, special education teachers, psychologists, and SLPs are probably the specialists who interact the most with children, adolescents, and adults with ASD and their families. Almost by tradition, ASD has come to be regarded as a set of functional disabilities that are best contained within the realm of "psychoeducation." Only rarely, if at all, is autism looked at from the point of view of general clinical medicine, which is quite surprising, given the great amount of data that exist to suggest that autism is a collection of medical disorders rather than a specific disorder in its own right (Gillberg & Coleman, 2000, 2009).

In population-based studies, children with autistic disorder have an identifiable medical disorder—such as tuberous sclerosis or the Fragile X syndrome—in about 25% of all cases (Gillberg & Coleman, 1996). In males with Asperger's disorder, a similar medical condition may currently be identified in about 15% of all cases (Cederlund & Gillberg, 2005). These figures do not include epilepsy—which occurs in 5% to 40% of individuals with ASD, depending on age, gender, and ASD diagnostic subgroup (highest in autistic disorder, lowest in Asperger's disorder)—as a "medical disorder." In children with autistic disorder seen in specialized clinics, these rates of medical disorders can be either higher or lower, depending on the "niche" of the clinic. In child psychiatric clinics, the rate is likely to be low as a consequence of diagnostic overshadowing. For instance, when tuberous sclerosis is diagnosed in a pediatric or neurologic clinic, there is a high risk that the autistic disorder diagnosis will not be made (because

of the stance on the part of the pediatrician or neurologist that *the* diagnosis—tuberous sclerosis—has already been made) and referral to the child psychiatric clinic will not happen, leading to underrepresentation of autism with tuberous sclerosis in the latter setting. On the other hand, in the specialized epilepsy clinic, where the child neurologist may be well aware of the very common co-occurrence of autism, epilepsy, and intellectual disability, the diagnosis of autistic disorder may be made in more than half of the clientele, depending on the number of severely mentally retarded individuals seen in that clinic. This subgroup of children with autism, epilepsy, and severe intellectual disability is likely to have a very high rate of "underlying" or otherwise associated medical disorders.

Conversely, there are a number of conditions, be they "neurological," "neurodevelopmental," or "medical" syndromes, that have a high rate (more than expected by chance, i.e., more than a few percent) or a very high rate (more than twenty percent) of several autism symptoms associated with them, and for which the diagnosis of autistic disorder or ASD is very often appropriate (Gillberg & Coleman, 2000). In the diagnostic category of autistic disorder, each one of these conditions contributes only a small fraction (up to a few percent) of the variance, but, taken together, they account for a very large minority of all cases with autistic disorder.

▦

Conditions that have a More than Coincidental Chance of being Associated with ASD

Several of the "conditions associated with autism" (CAA) are listed in Table PA-1. Some of them, including Down syndrome, have a very much lower rate of autism symptoms than the remainder of these syndromes, but, nonetheless, much higher than expected in the general population. Every medical

doctor working with individuals with ASD needs to be aware of the existence of these conditions so that a correct diagnosis can be made as early as possible. The list is not exhaustive, and "new" autism-associated disorders will be discovered over the next several years, illustrating the need for autism doctors to keep abreast of progress in the field of so called behavioral phenotype syndromes, including genetic and toxic disorders.

Some of the CAA have a rather specific link with autism (e.g., tuberous sclerosis, Moebius syndrome, thalidomide embryopathy, and Smith-Lemli-Opitz syndrome), some increase the risk for a whole host of neurodevelopmental problems, including autism, and others probably co-occur with autism, not because they themselves contribute to the risk of

Table PA–1.

autism, but, just like autism, reflect underlying brain problems that may have identifiable or nonidentifiable underlying causes (e.g., ADHD, DCD, prematurity, and HIE).

Genetic Aspects

Autistic features are highly heritable. The heritability of autistic disorder in cases where there is no diagnosed CAA is on the order of 90%. However, there is no evidence, as yet, that any small number of genes account for most of the variance of this heritability. Instead, a number of different genes have been identified (so far mostly neurodevelopmental, including neuroligin and SHANK-3 genes) that each account for a small proportion of all cases (Lamb, chapter 38, this volume), and it does not seem unreasonable that when they are all taken together, they will explain more than half of the total variance.

Pre-, peri-, neo-, and Postnatal Brain Damage

A number of potentially pre- and perinatal brain damaging factors—including extreme prematurity, postmaturity, and perinatal asphyxia—are known to be statistically associated with a risk of being diagnosed with ASD (Badawi et al., 2006; Limperopolus, 2009; Gillberg & Cederlund, 2005).

What Is the Appropriate Level of Work-up in Individuals Presenting with Autistic Symptomatology?

There is now often animated discussion concerning the need for a "full" medical work-up in ASD. Mental retardation, or learning disability, is present in a large minority of all individuals with ASD, and in the majority of those with autistic disorder (Fernell & Gillberg, 2010). Most clinicians would not question the need for an in-depth medical appraisal of all children diagnosed as suffering from a learning disability. To see colleagues who advocate for a "full" medical work-up for children with mental retardation, regardless of presumed cause, but then argue against the need to go into some depth when it comes to trying to unravel the pathogenetic chain of events in autistic disorder, is conceptually pathetic and scientifically unsound. Children with autistic disorder are more—not less—in need of a full medical evaluation than children with mental retardation without autistic symptomatology. The medical work-up of children with ASD needs to be considered at various levels, including screening, behavioral diagnosis, physical and neuromotor examination, and laboratory investigations of varying kinds.

Screening

Screening for autism can, theoretically, be done in well-baby clinics, schools, and in connection with health checks in adults. These settings represent general population screens, and have been used in a number of epidemiological studies. However, it is still debatable whether general screening for autism should be universally recommended. Screening for autism among 18-month-old babies is successful in identifying severe cases and very few false positives (if false positive is defined as being "normal"). However, a majority of the moderately and mildly affected children with ASD are often missed in such screening efforts (Fernell & Gillberg, 2010). If screening for ASD of young children is done, it appears that 30 months could be a much better age, at which time the majority of cases with autistic disorder and some degree of intellectual disability would probably be picked up (Pandey et al., 2008, Fernell et al., 2010). Nevertheless, it would be important to continue to be on the look-out for ASD at older ages even if thorough screening of 2- to 3-year-olds has been performed. Cases of Asperger's syndrome and atypical autism will continue to cause diagnostic problems well into school age, and it is still common for children with these ASDs to be correctly diagnosed only around age ten years or later.

Screening in clinics is an altogether different issue and is, in the author's opinion, to be recommended. ASD screening would be particularly important in highly specialized clinics (such as learning disability, ADHD, and Tourette clinics) where many children have ASD "comorbidity."

There are several useful screening instruments, including the Checklist for Autism in Toddlers (CHAT; Baron-Cohen et al., 1992), the Modified CHAT (M-CHAT; Robin et al., 2001), and the Social Communication Questionnaire (SCQ; Berument et al., 1999) for 2- to 4-year-olds; the Five to Fifteen Questionnaire (FTF; Kadesjö et al., 2004) for school-age children; Autism, Tics, ADHD, and other comorbidities (A-TAC; Hansson et al., 2005), which can also be used as a telephone interview, and the Autism Spectrum Screening Questionnaire (ASSQ; Ehlers & Gillberg, 1993) for school age children and adolescents; and the Autism Quotient (AQ; Baron-Cohen, 2001) for adults. All these instruments have proven good psychometric properties. The ASSQ has been used in studies of altogether more than ten thousand children and has good to excellent validity for ASD, at least in preadolescent school children.

Diagnosis

For the diagnosis of ASD, a baseline of five different types of instruments should be used in all cases: (1) a parent/caregiver diagnostic interview for ASD, which—depending on age of the individual assessed, need for in-depth overall assessment, and type of ASD diagnosis suspected—could be the Diagnosis of Social and Communication Disorders (DISCO; Wing et al., 2002), the Autism Diagnostic Interview-Revised (ADI-R; Lord et al., 1994), the 3-di (Skuse et al., 2004), the Autism Spectrum

or Asperger Syndrome Diagnostic Interview (ASDI; Gillberg et al., 2001), or another investigator-based interview that the clinician is well acquainted with; (2) questionnaires to parents and teachers, such as the FTF (see above) for coexisting problems, an extremely important part of the diagnostic process given the extremely high rate of coexisting problems, such as learning problems, ADHD, and tics (almost 100%) in ASD (the DISCO, unlike the other investigator-based diagnostic interviews has quite a large portion on such coexisting problems); (3) an ASD observation of the child, which could be the Autism Diagnostic Observation Schedule (ADOS; DiLavore et al., 1995) or another structured observation scheme; (4) a neuropsychological assessment, which must include a measure to cover overall intellectual and adaptive level—if possible, one of the Wechsler scales, portions of the Vineland (Sparrow et al., 1984), and the Global Assessment of Functioning (GAF) scale (APA, 2000); and last, but not least, (5) a thorough medical assessment by a physician well educated in child neuropsychiatry or child neurology, or both.

The Basic Medical Examination of a Child with ASD

All children with a diagnosis of an ASD—regardless of diagnostic subgroup within that category—should have all of the following: thorough physical examination (including specifically for minor physical anomalies and skin lesions), a brief motor screening test, tests of hearing and vision, a chromosomal analysis now including array CGH and a test for the FMR-1 (Fragile X) gene. In addition, the physician must survey the child's medical and developmental history, family history, and pre-, peri-, and postnatal events in interview with the parent/caregiver. If the DISCO is used, much of this part of the medical assessment will already have been covered. This is the minimum level of medical work-up. Most children with ASD will need further tests, as detailed below.

Apart from blood pressure, heart rate, height, and weight (which may all be important from the perspective of possible medication and need for physical training), and head circumference (which can suggest micro- or macrocephalus, both of which are overrepresented in ASD), the physical examination should focus on finding any signs of CAA. For instance, skin lesions could provide important indications that the child might be suffering from tuberous sclerosis (chagrin patches, ash-leaf and confetti hypopigmentations, perinasal rash), hypomelanosis of Ito (hypopigmented loops, whirls), or NF1 (café au lait spots, fibromas, axillar freckles). Some such lesions are best observed under a Wood's lamp (which should be available in the specialist autism clinic). Hypogonadism (especially if combined with obesity) could suggest Prader-Willi syndrome, whereas hypertrophy of the testicles could be a sign of Fragile X syndrome. A characteristic facial morphology is seen in Williams syndrome, 22q11 deletion syndrome, CHARGE association, Moebius sequence, and many other rare disorders. Submucous cleft soft palate and (operated) cardiac abnormalities are encountered in 22q11 deletion

syndrome. Scoliosis is often present in variants of the Rett syndrome complex. Pitting of the nails is typical of tuberous sclerosis. Unexpected tallness could be a sign of XXY, XYY, or XXX syndrome. Minor physical anomalies are overrepresented in ASD and could be either a sign of a specific well-established genetic disorder or an indication that it might be appropriate to consult with a clinical geneticist. Many of these disorders above will now be picked up using modern molecular genetic screening. Low-seated ears are particularly common in autism. This physical anomaly could contribute to the variance of increased rates of otitis media found in ASD (Rosenhall et al., 2003, Skuse et al., 2009). Hypertelorism (increased distance between the eyes) is another common anomaly found in ASD. Occasionally this sign may signal underlying callosal dysgenesis.

The neuromotor examination should have a focus on functional capacity in the fields of gross and fine motor skills (often moderately impaired in Asperger's syndrome, sometimes in other ASD variants), and coordination skills including diadochokinesis (one of the more consistent areas of motor dysfunctions in ASD, sometimes indicating underlying cerebellar pathology; Teitelbaum et al., 1998, Rogers, 2009, Gillberg & Kadesjo, 2003). It is interesting to note that 90%+ of syndromes associated with ASD have significant motor problems associated. Many children with ASD meet full criteria for developmental coordination disorder (DCD), and the motor problems may need targeted interventions in their own right. The medical motor examination suggested by Kadesjö and Gillberg (1999), or the very brief six-item screen published by Gillberg et al. (1983), is usually sufficient when it comes to establishing this type of problem. Muscle tone is important to assess; many children with ASD have moderate to marked hypotonia, and this may seriously affect their daily life skills. If unrecognized, this problem might lead to reduced quality of life throughout the life span in ASD. Conversely, hypertonus, which could be a sign of mild cerebral palsy, is also often missed. Loss of hand skills or "refusal" to use hands for purposeful activities may be an indicator of Rett syndrome.

Actually, in the United States, the actual data is < 1/500 for chromosomal karyotype abnormalities, but 10% to 20% with The chromosomal analysis should include an array CGH (because 10% of all individuals with ASD have chromosomal abnormalities that can be demonstrated by this technique), and, possibly, depending on developments in the field over the next few years, assessment for presence of unusual copy number variants (CNVs), which are more common in ASD compared to other populations.

The FMR-1 gene should be screened for in all individuals with a diagnosis in the autism spectrum. This is both because the Fragile X syndrome is a disorder in the CAA group (in which it accounts, relatively speaking, for a large proportion of cases, and because the clinical examination findings and family history, although quite often very typical and almost diagnostic, may sometimes be very uncharacteristic of the syndrome.

More In-Depth Medical Investigation for Some Children with ASD

All preadolescent children with ASD and concomitant moderate, severe, or profound intellectual disability; all children with ASD and epilepsy or a clinical history suggestive of seizures; and all children with ASD and clear-cut regression (including those diagnosed as having childhood disintegrative disorder) are in need of more extensive medical investigations. Boys and girls with any of the characteristics described should be screened for the Angelman syndrome gene, and for other abnormalities (monosomy, trisomy, or partial tetrasomy) at chromosome 15q11-13. All girls in any of these groups should be screened for the MecP2 gene abnormality, even when the clinical picture is not consistent with classic Rett syndrome. Again, when in doubt, the physician should refer for evaluation by a clinical geneticist. EEGs should be performed and include registration during slow sleep. Depending on the clinical history and presentation, an MRI (sometimes SPECT) should be performed. The possibility of neurometabolic disorders, amino-acidopathies, and mitochondrial disease should be carefully considered on an individual basis.

Children with ASD and a suggested X-linked pattern of inheritance—regardless of IQ—should have testing for neuroligin mutations (Toro et al., 2010). If there is any indication of tuberous sclerosis in the family (poliosis or "white lock syndrome," confetti pigmentations, enamel or nail pitting), a full evaluation for this syndrome may be called for.

The Medical Examination of an Adult with ASD

If a person is diagnosed with ASD for the first time as an adult, the need for an extensive medical investigation may or may not be different from that outlined for children. On the one hand, it is unlikely that a severe disorder such as tuberous sclerosis could have been completely missed (not least because of the severity of the signs and symptoms of tuberous sclerosis in cases associated with autism) for 20 years or more (but there are always exceptions, and the present author has seen a few cases with autism where the tuberous sclerosis diagnosed was missed for 10, 13, and 25 years in spite of glaring clinical signs). Generally speaking, the need for a full medical work-up in adults with ASD is probably somewhat less acute than in children. On the other hand, some of the risk factors for ASD that were relatively common in the past (e.g., rubella embryopathy), and which are not considered likely causes of ASD in young children in the Western world today, need to be looked for specifically. It is perhaps important to mention that thalidomide embryopathy, although very rare, produced a very high proportion of autistic syndromes in affected individuals.

Adults with a diagnosis of ASD, whether given in childhood or later, who develop clear psychotic symptoms in early adult age, should be considered from the point of view of possible 22q11deletion syndrome, even when the physical phenotype is not characteristic of that syndrome.

Follow-up, Reappraisal, and Coexisting Problems

The making of the diagnosis of ASD can never be seen as an end point in itself. Follow-up and reappraisal are always needed. Also, ASD is virtually always an indicator that the individual affected has other problems that need diagnosis and intervention. For instance, intellectual disability, nonverbal learning disability, epilepsy, hearing and visual problems, DCD, ADHD, tics, anxiety, and depression are all very commonly encountered in ASD, not to mention the already discussed very high rate of CAA. Also, it is not uncommon for a toddler to present with extreme degrees of hyperactivity, to be diagnosed with ADHD and put on stimulant medication, only to reveal an "underlying" ASD (sometimes erroneously attributed to the medication). Some children with a core ASD problem presenting with extreme hyperactivity will actually calm down in a structured education setting to the extent that a stimulant is never considered. Conversely, the diagnosis of ASD may overshadow the diagnosis of ADHD (and the current diagnostic manuals actually support not making dual diagnoses of ASD and ADHD, which will hopefully be rectified in upcoming versions of the DSM and ICD), which may lead to a situation in which appropriate ADHD interventions for the child may be withheld for many years.

ASDs are often part of a spectrum of difficulties that involve social, communication, activity, attentional, language, and overall developmental problems. Quite a number of children actually meet criteria for ASD, ADHD, speech-language impairment, learning disability, and disability. Many of these have been diagnosed in Scandinavia as suffering from DAMP (Deficits in Attention, Motor Control, and Perception) with autistic features. When they first come to specialist attention (be it to a pediatrician, child psychiatrist, child psychologist, audiologist, speech language therapist, or a physiotherapist) at the age of 2–4 years, it may be impossible to say exactly which of the neurodevelopmental diagnoses mentioned apply. It is clear that the child has an Early Symptomatic Syndrome Eliciting Neurodevelopmental Clinical Examination ("ESSENCE"; Gillberg, 2009), and equally clear that there will very likely be persistent problems over many years, but unclear whether the most appropriate diagnosis in the longer term is ASD, ADHD, DCD, tic disorder, learning disability, speech-language impairment, or a combination of some or all of these. This means that preschool children presenting with ASD symptomatology need to be followed up and reappraised over a long period of time, usually many years to come. The clinician is faced with a child with a neurodevelopmental disorder presenting at varying ages with slightly or markedly different symptomatology. In the author's practice, it is quite common for a 3-year-old to be diagnosed with autistic disorder, followed by ADHD at age 6 years, and Tourette syndrome at 9 years. At about 10 years, the clinical presentation of the ASD is no longer that of autistic disorder, but, strikingly, of Asperger's syndrome. At age 20 years, the severe ADHD problems are at

the clinical forefront of the ESSENCE syndrome, precluding academic and vocational success.

Epilepsy can develop at any time in the life of the child, adolescent, or young adult with an ASD (Danielsson et al., 2005). Signs of an underlying CAA can arise throughout childhood. Minor to moderate motor coordination, hearing, and visual problems may not present in a sufficiently clear manner leading to diagnoses of DCD, hearing loss or impairment and severe refractory errors being missed at the time of original diagnosis. Again, careful medical follow-up is required.

Medicines/Pharmacological Interventions

The majority of children with ASD should currently not be given any medication, at least not medication for their ASD. It is very important for the physician to keep abreast of developments in the field of biomedical therapies—including psychopharmacotherapy—so that he/she can provide well-founded guidance in the almost nightmarish jungle of suggested biomedical cures for autism that exist and which parents and others will grasp for, sometimes in desperation because psychoeducation and developmental interventions do not always lead to significant improvement.

Even though there is good evidence (see Canitano & Candurra, 2008) that risperidone is moderately effective for treating behavior problems associated with autism, the risk of substantial or even dramatic weight gain is very considerable, and no studies have demonstrated any really overwhelmingly positive results over a longer period of time. There is also good evidence that haloperidol has similar positive effects, including over a period of 6 months (Perry et al., 1989). One study has suggested that risperidone might be a bit more effective than haloperidol (Miral et al., 2008) in reducing behavioral abnormalities in autistic disorder. These classes of drugs (atypical and typical neuroleptics) are the only pharmacotherapies for ASD than can be said to have a relatively stable scientific foundation. They should be seriously considered in cases with the combination of violent behaviors, self-injury, hyperactivity, impulsivity, and sleep problems (see below for treatment of sleep disorder).

Two of the most commonly associated conditions in ASD, epilepsy and ADHD, are very often, if not always, treated with various kinds of medications. When they are present in ASD, they should be treated along similar guidelines as those that are employed for children without ASD. However, there are some caveats. In the case of epilepsy, there is particular concern that the antiepileptic drugs used not lead to further negative behavioral effects.

In the experience of the present author, the two antiepileptic drugs that have the least behavioral toxicity in a majority of ASD cases are lamotrigine and valproic acid. If possible, these drugs should be preferred in the initial stages of medical treatment for epilepsy in ASD. Both appear to have some positive effects on mood, and may contribute toward stabilizing mood in the—not infrequent—cases where there are bipolar swings both as regards mood and autistic features. Equally, however,

it is understood that epilepsy is often difficult to treat in ASD, and several other drugs may have to enter into the equation. Generally speaking, benzodiazepines, especially clonazepam, can have very negative behavioral effects in ASD, and the author has seen many cases who have deteriorated in their autistic symptomatology during treatment with this type of drug (and prompt amelioration when the drug was withdrawn or changed to another class of antiepileptic medication). Also, even though carbamazepine is probably *the* drug with the most clinical "experience" in this field, it can have some rather negative effects, including increase in repetitive behaviors, obsessive questioning, and compulsive rituals of various kinds.

In the case of ADHD, both stimulants and atomoxetine can have some very beneficial effects on hyperactivity, attention deficit, and impulsivity in ASD. However, in the group with moderate or severe levels of intellectual disability, one must not expect dramatic improvements, even though, occasionally, even in this extremely severely disabled group with autism, severe learning disability and autism, unexpected major positive development is produced. It is a possibility that when ASD, ADHD, and tics occur together in the same individual, atomoxetine may be the preferred first-line drug for the treatment of inattention and hyperactivity, given the indications that it usually has no negative effects on tics. However, in the experience of the author, stimulants do not generally increase tic severity in individuals with this combination of symptoms.

It is not rare for a child to have autism, ADHD, and epilepsy. In such cases, stimulants and atomoxetine can be combined with antiepileptic drug treatment, usually with no adverse effects on seizure activity.

Children with ASD very often react in unexpected ways to "normal" doses of commonly used medications. This ranges from overreaction to very small doses all the way through to only minor effects of doses that are considered well above the recommended dose range. One has to strike a balance here, start with very low doses and then increase over a period of several weeks, sometimes even months in order to be able to arrive at the best possible dosage.

Sleep problems are important quality-of-life reducers both for many people with ASD, and, not least, for their caregivers. Before any drug treatment is considered for such problems, there is a need to establish whether or not the child (or adult) actually suffers from a "real" sleep problem or whether diurnal rhythms and other people's needs have produced the experienced need for help. However, sleep problems in ASD are very often severe, and need to be addressed not just with psychoeducation but also with other interventions, including pharmacological treatment. Melatonin appears to be a very effective and safe medication at least in relatively low-functioning individuals with autism and sleep onset problems. Such therapy will be effective only if adequate sleep hygiene measures (including sleeping in a dark, not semi-lit or well-lit, room) are taken in combination with the medication. Physical exercise to the limit of exhaustion during the daytime will also

alleviate sleep problems (and sometimes hyperactivity, violent behaviors, and self-injury as well), as will listening to favorite music (earphones), in some cases.

Fish oils (specifically Omega-3) have become almost a panacea treatment for just about everything during the last several years. Although there is, as yet, no evidence that such treatment has any effects on autism, studies are currently underway looking at the effect of Omega-3 in ASD. There is preliminary evidence that ADHD symptoms, particularly when present in the context of autistic symptoms, could be ameliorated by Omega-3-therapy in a small, but not negligible, proportion of cases (Jonsson et al., 2008).

Medical Information

Parents, siblings, and children with ASD themselves, need oral and written information about the diagnosis, and about specific medical aspects of the disorder (Nydén et al., 2008). It is essential to have available such written information (booklets or brochures) at autism clinics and in neuropsychiatric, general psychiatric, or developmental/neurologic clinics catering to the needs of families affected by ASD.

The Broad Autism Phenotype

Points of Interest

- The broad autism phenotype (BAP) represents a constellation of subtle personality and language characteristics that may reflect genetic liability to autism.
- The BAP is not typically associated with any functional impairment.
- The BAP may be associated with specific neurocognitive features also implicated in autism.
- Studying features of the BAP could aid genetic and biological studies of the etiologic basis of autism, by targeting features that are more amenable to genetic and neurobiological investigation than the full clinical syndrome of autism.

The BAP: Historical Perspective and Overview

More than 60 years have passed since Leo Kanner published his detailed clinical descriptions of 11 children sharing what he described as an "extreme autistic aloneness." That landmark study served as the first formal documentation of autism. Less well recognized, however, is that Kanner's insightful case studies also described a potential *forme fruste* of autism that he observed among relatives. Kanner documented among some parents and relatives of his patients mild characteristics that mirrored in quality many of the core features of autism, noting a preoccupation with "abstractions of a scientific, literary, or artistic nature, and limited in genuine interest in people." (1943, p. 250). A decade later, Leon Eisenberg further described relatives, and fathers in particular as "perfectionistic to an extreme … pre-occupied with detailed minutiae to the exclusion of concern for over-all meanings" (1957, p. 721).

These insightful clinical observations would portend empirical evidence that autism is largely genetic in etiology, and importantly, that genetic liability to autism can be expressed through subtle behavioral and language features among relatives. Initially however, these early observations were misinterpreted in the context of psychodynamic theory, prominent at the time, in which parents were typically branded responsible for the development of children's psychopathology (Freud, 1923; Jung, 1921). Central in propagating the myth that parental behavior was causal in the etiology of autism was Bruno Bettelheim's *Empty Fortress* (1967), which developed the notion of "refrigerator mothers" and helped to launch a harmful legacy of doubt, blame, and misunderstanding of autism and its etiology. Although Kanner's observations of parental characteristics were oft recruited to bolster evidence for this damaging concept, careful review of Kanner's early writings makes clear his strong conviction that the root cause of autism was biological (see excerpt from Kanner's original observations of autism, Box 27-1). It was not for several decades, though, that empirical evidence would demonstrate definitively the biological basis of autism, first through observations that autism frequently co-occurred with epilepsy (Rutter, 1970), and then in the twin study of Folstein and Rutter (1977). This landmark study would also serve to ignite interest in and study of the broad autism phenotype, or BAP. Indeed, this study not only detected markedly higher concordance rates of autism among monozygotic (MZ) than dizygotic twins (evidence for a genetic etiology), but also found even higher MZ concordance for a more broadly defined phenotype including subclinical language and cognitive features that would propel a series of family-genetic studies aimed at studying and characterizing features that could index genetic liability to autism among unaffected relatives.

This broad autism phenotype now figures prominently in contemporary research as a promising avenue for identifying genetically meaningful features and neurobiological substrates involved in autism. To date, however, the BAP remains a poorly understood construct. There currently exists no consensus regarding those key features that comprise the BAP, and measurement tools vary widely across studies and

---

Box 27–1

The children's aloneness from the beginning of life makes it difficult to attribute the whole picture exclusively to … early parental relations with our patients. We must, then, assume that these children have come into the world with innate inability to form the usual, biologically provided affective contact with people, just as other children come into the world with innate physical or intellectual handicaps. If this assumption is correct, a further study of our children may help to furnish concrete criteria regarding the still diffuse notions about the constitutional components of emotional reactivity. For here we seem to have pure-culture examples of *inborn autistic disturbances of affective contact.* Leo Kanner. Autistic Disturbances of Affective Contact *The Nervous Child.*, Vol II, No. 3, 1943

---

research groups. These factors have contributed in no small measure to difficulties implementing BAP features in genetic and neurobiological studies.

The goal of this chapter is to consider in depth the clinical phenomenon of the BAP, as well as to synthesize existing findings and recent developments in the study of the BAP in order to produce a consistent definition of the BAP, and to identify gaps in knowledge and methodological challenges currently inhibiting effective implementation of characteristics of the BAP in gene-finding and neurobiological studies. To this end, we begin by describing methodological considerations in assessment of the BAP and then delve into research describing the clinical picture of the BAP and principal domains of functioning that comprise this phenomenon, as well as the cognitive and neuropsychological features associated with the BAP. Discussion of clinical and empirical significance of the BAP concludes the chapter.

Assessment of the BAP

Since Folstein and Rutter's (1977) twin study findings cast explanatory light on Kanner's original observations of personality styles among parents of autistic individuals, the BAP has been studied using a wide array of measurement tools, ranging from informant questionnaires to direct clinical interview assessments with both subjects and informants. Additionally, studies have differed greatly in subject ascertainment and matching strategies, resulting in a methodological din that complicates synthesis of findings across studies. Therefore, before describing the components of the BAP, we first review the various tools employed for measuring the BAP, and discuss methodological inconsistencies across studies.

Methodological Differences

Measurement Tools

Unlike autism, where standard diagnostic instruments such as the Autism Diagnostic Interview and Autism Diagnostic

Observational Schedule are now widely used, there exists no gold standard measure of the BAP that is applied consistently across groups. Among the earliest developed and most commonly used is the clinically structured family history interview, and the Autism Family History Interview (AFHI) in particular (Bolton et al., 1994). In the AFHI, an informant is asked detailed questions concerning their own behavior and dispositions as well as those of their first- and second-degree relatives across domains that parallel the defining features of autism (i.e., social, communication, and rigid/repetitive interests and behaviors). Both child and adult functioning are queried, and features are typically rated as absent, probably/ mildly present, or definitely present, based either on ratings of interviews or blinded interview vignettes (Bolton et al., 1994; Piven et al., 1997; Szatmari et al., 1993). Using a related approach, the Broad Phenotype Autism Symptom Scale (BPASS; Dawson et al., 2007) assesses similar domains, but measures each trait on a continuous 5-point scale aimed at capturing behaviors ranging from impairment to above average skill in each domain. Like the AFHI, the BPASS includes probes about early development as well as current functioning and was developed specifically to assess features of the BAP among relatives. These informant-based methods have the advantage of efficiently assessing multiple family members. Yet, because they are based on an informant's impression, they may lack the sensitivity and specificity of direct clinical assessment.

Structured subject and informant personality interviews have also been applied to the study of the BAP. Piven et al. (1994) used the Modified Personality Assessment Schedule (MPAS; Tyrer, 1988) to examine traits conceptually related to autism (Piven et al., 1997; Murphy et al., 2000; Losh et al., 2008). In this method, interviewers begin by soliciting autobiographical accounts of dispositions throughout development (e.g., questions about childhood friendships, experiences in school, jobs, spousal relationships). Subjects are then guided through a number of questions to probe personality characteristics relevant to autism and the BAP, namely, *rigid* or *perfectionistic* personality, and *socially aloof* disposition/behavior. These traits correspond to the ritualistic/repetitive and social symptom domains of autism, respectively. Informants are then separately interviewed and asked these same questions. Concrete behavioral examples are solicited through interviews to substantiate trait endorsement. Ratings are assigned by combining both subject and informant interviews. As an extension of a clinical interview and based on a "life story" of an individual as seen through the eyes of both the subject and informant, the MPAS has face validity, but is time intensive and requires considerable training for reliable administration and rating.

Other direct assessment measures have focused on more specific characteristics of the BAP, namely, the Pragmatic Rating Scale (PRS; Landa et al., 1992) and the Friendship Interview (FI; Santangelo & Folstein, 1995). The PRS is a scale for rating conversational ability that taps pragmatic skills that correspond roughly to Gricean Maxims of conversation (i.e., quantity, relation/relevance, and manner). Ratings are based on a conversational sample, and rated by coders blind to

group status. The Friendship Interview was developed to provide a reliable and relatively easy-to-administer measure of one aspect of social behavior—the quality and number of an individual's friendships. It involves a series of questions aimed at measuring the degree to which an individual possesses emotionally reciprocal friendships.

Adequate reliability has been shown for the MPAS (Tyrer et al., 1984), the PRS and FI (Landa et al., 1992; Piven et al., 1997), as well as the family history method and the BPASS (Bolton et al., 1994; Dawson et al., 2007), and these instruments provide a face valid index of features that have been hypothesized to comprise the BAP. However, the interviews involved can be lengthy and require considerable training for reliable administration and rating. As such, several groups have used questionnaires to study the BAP.

Several questionnaire measures used in studies of the BAP were originally developed to study or screen for autism. The Autism Spectrum Quotient (ASQ; Baron-Cohen, Wheelwright, Skinner et al., 2001) is a self-administered questionnaire that was developed initially to identify individuals with high-functioning autism, and has since been applied in studies of relatives at risk for displaying the BAP as well as the general population. Another tool initially used with autistic individuals, but applied to studies of the BAP among siblings, is the Children's Communication Checklist (Bishop, 1998), a parent/care-giver questionnaire designed to assess language and communication deficits in children. This instrument has been shown to discriminate relatives (siblings) of individuals with autism from controls on specific language features (Bishop et al., 2006).

The Social Responsiveness Scale (SRS) is a brief instrument completed by parents or teachers that assesses autism features, and social reciprocity in particular, on a single dimension, ranging from typical functioning to autistic. Twin studies have shown high heritability for SRS scores (Constantino et al., 2003), and an adult version has been developed to study mild traits among parents (Constantino et al., 2005). Because the SRS is measured on a quantitative scale, it is ideal for genetic studies, where quantitative measures typically wield greater power to detect linkage and association in complex disorders such as autism (e.g., van den Oord, 1999). Duvall et al. (2007) have in fact employed this tool in a genomewide linkage study including individuals with autism and their relatives, finding several suggestive linkage signals. The development and implementation of such quantitative measures certainly represents a promising avenue for genetic research. This issue is considered later in greater depth.

One questionnaire instrument specifically developed to study the BAP is the Broad Autism Phenotype Questionnaire (BAPQ; Hurley et al., 2007). This measure was designed to efficiently, validly, and reliably measure particular personality and language characteristics that have been hypothesized to define the BAP, including social personality, rigid personality, and pragmatic language deficits (Piven et al., 1997), in nonautistic parents of autistic individuals. The BAPQ was derived from prior work with the direct assessment measures of personality and pragmatic language, the MPAS and PRS, and

yields three subscales providing quantitative indices relevant to the three DSM-IV domains of autism (American Psychiatric Association, 1994): social deficits, stereotyped-repetitive behaviors and pragmatic language impairments. While originally developed as a tool to screen for the BAP, the BAPQ appears to identify features of the BAP with adequate sensitivity and specificity when compared to ratings derived from gold standard clinical interviews (Hurley et al., 2007). Case-control differences in a large sample of parents of autistic individuals (~ N = 750) compared to a large population sample of parents unrelated to an autistic individual (~ N = 750; Piven, personal communication), have continued to support the validity of this instrument.

Study Design Considerations

A variety of methods exist for studying the BAP, and interpretation of findings across these varying approaches can be fettered by such methodological differences. Other complicating factors important to consider include differences across studies in diagnostic criteria, and ascertainment and matching procedures. For instance, not all studies have been limited to individuals with idiopathic autism (e.g., many did not screen for fragile X syndrome or other monogenic conditions related to autism), and different diagnostic definitions have been employed over time with various iterations of the DSM, thereby introducing sample heterogeneity that could influence findings. Studies have also varied in the inclusion and definition of control groups. Some have included no controls, others have examined relatives of individuals with Down syndrome to control for the stress of parenting a child with a disability, and still others have included relatives of individuals with genetically based conditions that could also result in subtle phenotypic manifestations among family members (e.g., schizophrenia, specific language impairment).

Each of these approaches has its advantages and disadvantages, but when considered together, studies using various control groups have offered complementary perspectives and methods for understanding the BAP. For instance, early studies without control groups provided detailed case study descriptions that highlighted phenotypes for subsequent investigation in systematic case-control studies. The inclusion of control groups is of course necessary for determining whether observed features occur at elevated rates in autism families and for teasing out effects of environmental stressors related to parenting a child with a disability. Studies using comparison groups have therefore been critical in defining the BAP. Important to consider from this work is how best to interpret findings from studies including different control groups, such as those including relatives of individuals with developmental delay caused by noninherited conditions (e.g., nondisjunction Down syndrome) versus those investigations including disorders conferring genetic risk among unaffected relatives.

Examining other inherited conditions can offer a means of examining autism-specific features that aggregate in families.

However, this strategy could also obscure detection of meaningful phenotypes associated with liability to autism and other disorders. That is, given evidence of phenotypic, neurobiological, and genetic overlap of autism with disorders such as specific language impairment and fragile X syndrome (e.g., Kjelgaard & Tager-Flusberg, 2001; deFosse et al., 2004; Belmonte & Bourgeron, 2006), it would follow that relatives of individuals who are carriers of the genes involved in these conditions may show phenotypes overlapping with the broad autism phenotype. In this case, associated phenotypes could be missed unless a control group without genetic liability is studied as well. Recent research is bearing out this scenario, showing, for example, that whereas parents of individuals with autism show elevated rates of pragmatic language violations when compared to parents of individuals with Down syndrome, their pragmatic language use is highly similar to parents of individuals with specific language impairment (Ruser et al., 2008). This in no way diminishes the validity of the concept of the BAP, but rather, adds important information about the continuum of liability to autism and its overlap with other conditions, and highlights an important methodological consideration for studies of the BAP.

An additional factor affecting family-study findings concerns the ascertainment strategies employed, as these have varied in important ways over time. Epidemiological sampling has been employed in a few studies (e.g., Ritvo et al., 1989; Piven et al., 1997), but more commonly cases have been recruited from existing clinical samples, through advocacy organizations, or other means that could introduce selection biases. The types of relatives examined have also varied—parents and siblings are commonly studied, but larger-scale family studies have also examined other collaterals (e.g., grandparents, aunts, uncles). Again, these different approaches all add valuable information that in aggregate provides compelling evidence for the existence of a BAP, but which may also introduce variation that could affect findings (e.g., traits of the BAP might be expected to express more profoundly among first-degree relatives than among more distant collaterals). Brief mention here of these important concerns serves to highlight these issues in interpreting the discussion of features believed to comprise the BAP, to follow.

Domains of the BAP

As touched on already, Kanner's original observations of autism included descriptions of socially reserved and single-minded personality characteristics among parents. With evidence in hand of a biological basis for autism from Folstein and Rutter's (1977) twin study, and encouraged by the potential of studying these fundamental, genetically meaningful traits, a series of family studies were launched in the 1980s and 1990s in an effort to further define the features that comprise the BAP (e.g., Bolton et al., 1994; Bailey et al., 1995; Le Couteur et al., 1996; Piven et al., 1994; Piven Palmer, Jacobi, et al., 1997).

Based on family history informant interviews, as well as direct assessments, this carefully conducted work documented a constellation of personality, language, and cognitive features that while very subtly expressed, mirrored in quality the core features of autism. Below are those chief domains that have been described as comprising the BAP.

Personality Features of the BAP

In an early study by Wolff et al. (1988) and follow-up work with the same sample (Narayan et al., 1990), personality features were assessed among parents of individuals with autism and control parents of individuals with intellectual disabilities using a structured clinical interview for evaluating personality disorders. This pair of studies found that autism parents, and fathers in particular, were more often rated as "schizoid" (16/35 parents rated as such vs. 0/39 control parents of individuals with intellectual disability of unspecified etiology). In these studies schizoid personality was defined by limited empathic responsiveness, emotional detachment, and rigidity and restricted interests, features which were characterized by the authors as real and observable, but at the same time "quite subtle."

Subsequent research with the Autism Family History Interview indicated the presence of similar social features among family members and nonautistic co-twins (Bolton et al., 1994; Bailey et al., 1995; Le Couteur et al., 1996). In the first large-scale systematic study of relatives, Bolton et al. (1994) described among parents and siblings social characteristics including lack of affection, limited friendships, and lack of typical social play among children. Repetitive behaviors and traits akin to the "rigid" personality features observed by Narayan et al. (1990) were also observed among unaffected relatives (Bolton et al., 1994), but were found to be less common than social characteristics. It was in this initial family history study that such traits (along with language characteristics, to be discussed shortly) were first formally described as constituting a broad autism phenotype.

After Bolton's important work, which was confirmed in an expanded twin sample studied by Bailey et al. (1995), several studies followed that were aimed at further investigating and refining measurement of the BAP (see Table 27-1). Employing direct assessment interviews of personality features using the MPAS, described previously, Piven et al. (1994) studied 87 parents of autistic individuals and 38 parents of Down syndrome probands. Comparisons of blind ratings derived from subject and informant interviews indicated that parents of autistic individuals displayed significantly higher rates of three social characteristics—aloof, untactful, and undemonstrative. In a later study of parents from multiplex families using the MPAS, Piven, Palmer, Landa, et al. (1997) confirmed these patterns, finding that relatives of individuals with autism more commonly displayed social reticence or aloofness, and in the Friendship Interview reported fewer reciprocal friendships than controls. Additionally, the autism parent group was more likely than controls to display "rigid" or inflexible and perfectionistic personalities, showing relatively

Table 27–1.
Family studies of relatives of individuals with autism

Study	Sample	n	Method	Findings
August et al., 1981	Siblings	71	Informant and direct	Elevated rates of MR or language delays
Baird & August, 1985	Siblings	51	Informant	Elevated rates of MR
DeLong & Dwyer, 1988	1st- and 2nd-degree relatives	929	Informant	Elevated rates of depression
Piven et al., 1990	Siblings	67	Informant	High rates of social dysfunction and cognitive disorder
Minton et al., 1982	Siblings	50	Direct assessment	Elevated rates of MR
Wolff et al., 1988	Parents	35	Direct assessment	High rates of "schizoid" personality (defined by limited empathy, emotional detachment, rigidity and restricted interests, and "unusual" communication)
Freeman et al., 1989	Parents and sibs	280	Direct assessment	No group differences in cognitive or language ability
Narayan et al., 1990	Parents and sibs	53 (including 35 parents studied in Wolff et al., 1988)	Direct assessment and educational records	Higher vocabulary scores in fathers. No educational differences in siblings
Smalley & Asarnow, 1990	Parents and sibs	25	Direct assessment	No differences in cognition or language
Landa et al., 1991	Parents	41	Direct assessment	Less coherent narratives
Gillberg et al., 1992	Parents and sibs	101		No differences in learning disorders or language problems
Piven et al., 1990	Siblings	67	Informant	Elevated rates of psychiatric disorders
Landa et al., 1992	Parents	43	Direct assessment	Increased rates of pragmatic language violations
Ozonoff et al., 1993	Parents and sibs	118	Neuropsych	No significant differences in executive function
Szatmari et al., 1993	Parents and sibs	181	Informant and direct	No significant differences in cognition or social adaptation
Piven et al., 1994	Parents	87	Direct Assessment	Higher rates of social features (aloof, untactful, undemonstrative)
Bolton et al., 1994	Parents and sibs	332	Informant	Social, communication, and repetitive features more common
DeLong & Nohria, 1994	1st- and 2nd-degree relatives	420	Informant	Higher rates of affective disorder
Szatmari et al., 1995	Parents	103	Informant	Social isolation more common
Smalley et al., 1995	Parents and sibs	96	Direct assessment	Elevated rates of depression and social phobia
Plumet et al., 1995	Parents and sibs	47	Direct assessment	No differences in language skills of parents, difference in sibs
Leboyer et al., 1995	Parents and sibs	48	Direct assessment	No difference in verbal or visuospatial skills in parents. Lower verbal in sibs
Boutin et al., 1997	Parents and sibs	156	Informant and direct	Higher rates of cognitive delays
Hughes et al., 1997	Parents and sibs	97	Neuropsych	Impaired executive functioning
Baron-Cohen & Hammer, 1997	Siblings	30	Neuropsych	Bias toward local processing and impaired theory of mind
Piven, Palmer, Landa, et al., 1997	1st- and 2nd-degree relatives	133	Informant	Higher rates of social, communication, and repetitive features

(Continued)

Table 27–1. (*Contd.*)

Study	Sample	n	Method	Findings
Piven, Palmer, Landa, et al., 1997	Parents	48	Direct assessment, questionnaire, NEO-PI	Higher rates of aloof, rigid, hypersensitivity, pragmatic language violations, and less reciprocal friendships
Piven & Palmer, 1997	Parents	48	Direct assessment	Lower performance on executive function, performance IQ, and reading measures
Bolton et al., 1998	1st-, 2nd-, and 3rd-degree relatives	1238	Informant and direct	Higher rates of depression and OCD
Piven & Palmer, 1999	Parents and 2nd-degree relatives	48	Informant and direct	Higher rates of depression and social phobia
Folstein et al., 1999	Parents and sibs	253	Informant and direct	Higher rates of language related difficulties in parents
Hollander et al., 2003	Parents	114	Informant and direct	Higher rates of OCD in parents whose children showed more severe repetitive behaviors
Micali et al., 2004	Parents	152	Informant	Higher rates of depression and anxiety in mothers
Bishop et al., 2004	Parents and sibs	233	Direct assessment	No significant differences in phonological processing
Bishop et al., 2004	Parents	69	Informant	Social and communication features more common
Kano et al., 2004	Parents	28	Direct assessment	OCD symptoms higher in fathers
Bishop et al., 2006	Siblings	42	Informant	Delays in language related skills
Shaked et al., 2006	Siblings	24	Neuropsych	No significant differences on theory of mind
Wong et al., 2006	Parents and sibs	211	Neuropsych	No differences in executive skill of planning or cognitive flexibility. Weaknesses in generativity
Bolte et al., 2006	Parents	125	Informant	Higher rates of reserved and depressive characteristics
Dalton et al., 2007	Siblings	12	Neuropsych	Decreased gaze fixation, diminished fusiform gyrus activation, and reduced amygdala volume
Schmidt et al., 2008	Parents	22	Informant and direct	Lower PIQ and phonological processing. No differences in receptive/expressive language or family history of language difficulty
Hurley et al., 2007	Parents	86	Informant	Higher rates of aloof, rigid, and pragmatic language violations
Losh & Piven, 2007	Parents	48	Neuropsych	Impairments on theory of mind task
Losh et al., 2008	Parents	65	Direct	Elevated rates of social, communication, and rigid features
Daniels et al., 2008	Parents	1,227	Medical records	Higher rates of schizophrenia, depression, and personality disorder among mothers
Adolphs et al., 2008	Parents	42	Neuropsych	Atypical face processing

little interest in seeking novelty or change in their environment and activities and increased attention to detail. Finally, this study found higher rates of anxiety-related traits of hypersensitivity and anxious/worrying personality. To validate these clinical observations, the NEO Personality Inventory (NEO-PI) was administered to parents (Costa & McCrae, 1985). The NEO-PI is a standardized questionnaire based on the Five-Factor model of personality, and was developed to assess quantitative dimensions of normal personality traits. In nearly all cases, features assessed through the MPAS were

found to correlate significantly with conceptually related domains on the NEO-PI. Social features (e.g., aloof) correlated negatively with components of the Extraversion factor (warmth and gregariousness) measured by the NEO-PI, and the "Rigid" personality feature measured by the MPAS was negatively correlated with the Openness dimension and agreeableness. The former identifies individuals with a preference for routine and familiar experiences, an unwillingness to try new activities and avoidance of novelty. The combination describes individuals (negative openness and negative agreeableness) who are more than just closed to changes in experience but in addition display what has been referred to as "interpersonal rigidity" (Paul Costa, personal communication; Costa & McCrae, 1985), and thus suggests an additional social aspect of this characteristic that is consistent with an overall conceptualization of the BAP as involving both social deficits and rigidity. Further, the MPAS-measured anxiety features (Anxious/worrying and Hypersensitivity) were significantly correlated with several facets of neuroticism on the NEO-PI. Such associations between clinically derived personality ratings and objective standardized instruments supported the validity of the personality traits measured by the MPAS and which were hypothesized to constitute features of the BAP.

The MPAS was subsequently employed in two additional studies, both yielding similar findings. Murphy et al. (2000) used an informant-only version of the MPAS and the AFHI with parents and adult siblings of 99 families of autistic individuals originally studied by Bolton and colleagues (Bolton et al., 1994; Bolton et al., 1998) as well as 36 families of individuals with Down syndrome. They again found among parents of individuals with autism a higher incidence of aloof or shy dispositions, as well as elevated rates of hypersensitivity and anxious/worrying personality style. Factor analysis of MPAS traits indicated three broad factors. Two factors were described as social in nature ("withdrawn" and "difficult"), and the third factor, dubbed "tense," appeared to capture anxiety-related traits. In a later investigation Losh et al. (2008) examined features assessed in the MPAS among parents from families differing in genetic liability to autism—multiple-incidence families (MIAF) with two or more children with autism, single-incidence autism families (SIAF), and control families of individuals with Down syndrome (DWNS). Because families with multiple incidences of autism are likely to represent cases of higher genetic loading than single-incidence cases (Piven & Folstein, 1994), it was hypothesized that "dosage" effects would be observed for the principal characteristics conferring genetic susceptibility to autism, in which such features would express most profoundly among MIAF parents, less strongly among SIAF parents, and least of all among comparison parents from DWNS families, who should display population base rates.

Results confirmed this prediction for both the social (aloof) and rigid features of the BAP. Aloof was present among 29% of MIAF parents, 17% of SIAF parents, and 3% of the DWNS parent group. This finding was bolstered by
Figure 27–1. Quality of friendships across family types varying in genetic liability to autism. Higher scores represent fewer and/or less emotionally reciprocal friendships.

results from the Friendship Interview, also administered to parents, where an identical pattern was observed with multiplex parents reporting the fewest friendships, DWNS the most, and simplex parents falling intermediate between the two groups. Figure 27-1 depicts these findings, showing the mean quality of friendships, with higher scores corresponding to fewer and lower quality (i.e., less emotionally reciprocal) friendships. Similarly, the rigid feature was present in 48% of MIAF parents, 23% of SIAF parents, and 10% of parents in the DWNS groups.

Szatmari et al. (2000) previously found a similar "dosage" effect in BAP expression across families differing in genetic liability to autism. Szatmari's findings were particularly compelling in that they included not only multiple- and single-incidence families, but also nonbiological relatives of adopted individuals with autism. As predicted, adoptive parents showed no evidence of the BAP, whereas single- and multiple-incidence families showed increasing expression.

Together, these converging findings suggest that particular personality features are sensitive markers of genetic liability to autism. Important to note, however, is that the traits of the BAP were not observed among all parents. Furthermore, evidence suggests that when present, such traits were expressed quite subtly (as noted early on by Wolff et al., 1988; and Narayan et al., 1990). To illustrate, we present a vignette of a parent participating in this study, who was rated as BAP (+) for displaying both traits of rigid and aloof (Box 27-2). As is apparent from this brief account, this individual's preference for routine is relatively subtle, with the only hint that this trait may interfere with daily life coming from his spouse. And socially, this individual displays no evidence of autistic impairment, but instead simply a more reticent social disposition. As such, it may be that the features of the BAP are most aptly described as personality styles, rather than functional impairment within any particular domain. Studies of psychiatric disorders among relatives of individuals with autism have addressed this question, and are described below.

Box 27–2

Parent of an autistic individual rated as having the broad autism phenotype (rigid and aloof personality)

Mr A., a 41 year old college professor, describes himself as very organized and a planner. He gives as an example the fact that he always writes out his lectures verbatim before class. He is most comfortable in life with routine and says he is happiest with no surprises. He requests that all his courses be scheduled at the same time each semester and feels out of sorts when his routine is interrupted. His wife notes that he protests when asked to drop off a letter on the way to work because it disrupts his routine.

He has always been uncomfortable socially and describes himself as a loner with no interest in having friends. As a child he spent more time with books than people. He doesn't see the point of "chit chat". He prefers there be a purpose to conversations and avoids unstructured social gatherings (e.g., having coffee with colleagues at work).

Psychiatric Disorder and the BAP

A number of studies have observed elevated rates of axis I psychiatric disorders in first-degree relatives of autistic individuals, including affective disorder in adult siblings (Piven et al., 1991), and major affective disorder, and anxiety disorder in parents (including social phobia and generalized anxiety disorders; Bolton et al., 1998; Daniels et al., 2008; Hollander et al., 2003; Micali et al., 2004; Piven & Palmer, 1999; Smalley et al., 1995). Elevated rates of obsessive-compulsive disorder in relatives have been reported in some studies (Bolton et al., 1998; Hollander et al., 2003; Micali et al., 2004) but not in others (Piven et al., 1991; Piven & Palmer, 1999).

Given the familiality of these conditions, it is possible that these behavioral manifestations may be expressions of the underlying genetic liability for autism. The overlap in the phenomenology of generalized anxiety, social phobia, and obsessive-compulsive symptoms could be construed as reflecting aspects of the autistic phenotype, while the phenomenology of major affective disorder is qualitatively distinct from the defining features of autism. Bolton et al. (1998) using the family history method, and Piven and Palmer (1999) using direct assessment of both the BAP and psychiatric disorder, explored whether high rates of psychiatric disorder were occurring in parents with the BAP. Neither study found elevated rates of affective disorder occurring disproportionately in those individuals with the BAP. The number of parents with anxiety disorder was insufficient to examine this relationship in the study by Piven and Palmer. However, Bolton et al. (1998) reported that a high rate of OCD in parents occurred in association with social and communication manifestations of the BAP, suggesting that it may be a variable manifestation of the same genetic liability leading to the BAP. Piven and Palmer (1999) found suggestive evidence that affective disorders may occur at higher rates in those parents who do *not* display the

BAP and who have a spouse with the BAP, suggesting that high rates of affective disorder in parents of autistic individuals may result from assortative mating of an individual with major affective disorder to an individual with the BAP.

Finally, the observation that particular personality characteristics are common in relatives of autistic individuals raises the question of whether these characteristics are associated with impairment and warrant diagnosis as a personality disorder. Piven (2002) examined the parents from 25 multiple-incidence autism families and 30 Down syndrome (DS) families using the Structured Interview for DSM-III-R Personality Disorder (SIDP-R) (Pfohl, 1989). While four autism and none of the control parents were found to have an avoidant personality disorder (Fischer's Exact, p = .045) for the most part, the majority of autism parents did not have evidence of personality disorder or impairment related to the presence of particular personality characteristics such as aloof or rigid personality. On the whole, then, while psychiatric disorders may occur more commonly in parents of individuals with autism, whether or not they are to be considered a component of the BAP is still unclear.

Language and Academic Profiles Associated with the BAP

Severe language impairment is a defining feature of autism (APA, 1994) and among the most debilitating among the constellation of features that characterize this serious disorder. Twin and family studies have repeatedly documented qualitatively similar, but generally more subtly expressed language profiles among relatives, in the key domains that most robustly define the autism language phenotype—delayed language acquisition and pragmatic language abilities (Table 27-2).

A growing body of literature has documented delays in early language milestones among siblings of individuals with autism, including delayed lexical (i.e., word acquisition) and morphosyntactic (i.e., grammatical) development (Gamliel et al., 2007; Shaked et al., 2006; Yirmiya et al., 2001, Yirmiya et al., 2006, Yirmiya et al., 2007). Additionally, elevated rates of delayed first words and phrase speech have been reported retrospectively

among parents of individuals with autism (Bolton et al., 1994; Folstein et al., 1999; Murphy et al., 2000; Pickles et al., 2000; Piven, Palmer, Jacobi, et al., 1997). Indeed, delayed language was among the characteristics observed among nonautistic co-twins in Folstein and Rutter's twin study (1977). Using the AFHI, subsequent studies noted delayed language milestones, articulation problems, and delays in reading and spelling among relatives (Bolton et al., 1994; Bailey et al., 1995; Piven et al., 1990).

The most consistently observed language feature among relatives was pragmatic language use. Pragmatic language skills include connected speech in specific social-communicative contexts (conversation, narrative, etc.) and is the facet of language most closely tied to interpersonal interaction (Tager-Flusberg, 2000). Impaired pragmatic language use is universally observed across the autistic spectrum (Capps et al., 1998; Capps et al., 2000; Losh & Capps, 2003, 2006; Loveland & Tunali, 1993; Tager-Flusberg, 1995, 2000), even in those very high functioning individuals who do not show delayed language acquisition. Evidence of impaired pragmatic language skills among parents appeared in Leo Kanner's original clinical descriptions, in which he noted among parents a disdain for conversational interaction and a pedantic communicative style (1943). Wolff and colleagues (Wolff & Morris, 1971; Wolff et al., 1988) further described both over- and under communicativeness and verbal disinhibition among parents.

More systematic characterization of such pragmatic language styles was reported in two influential studies conducted by Landa and colleagues (Landa et al., 1991; Landa et al., 1992). In the first, parents were provided with story stems and asked to produce a complete narrative based on the initial prompt. Analyses revealed among autism parents a tendency to produce more tangential, fragmented accounts (i.e., non-contingent discourse), and stories that were rated on a global scale (by raters blind to group status) as significantly lower in quality than those from controls. In a second investigation, focusing on pragmatic language abilities of parents, Landa et al. (1992) employed the Pragmatic Rating Scale (PRS, described earlier). Applying the PRS to language samples from a semistructured conversation with parents of individuals with autism and controls, Landa et al. found the language samples from autism parents to be most notably characterized by topic preoccupation, overly talkativeness, detailed and confusing accounts marked by multiple tangents and abrupt topic changes with insufficient causal links and background information. Importantly, such features are qualitatively similar to the pragmatic language profiles noted among autistic individuals (Capps et al., 1998; Tager-Flusberg, 1991).

These findings were replicated in a later study of multiple-incidence families (Piven, Palmer, Landa, et al., 1997). Ruser et al. (2008) also confirmed this pattern in a study comparing parents of individuals with autism, parents of individuals with specific language impairment (SLI), and parents of individuals with Down syndrome. Some evidence exists to suggest that SLI and autism may overlap in etiology and phenotypes (e.g., Kjelgaard & Tager-Flusberg, 2001), and this study aimed to determine whether shared pragmatic language profiles may

exist in relatives at increased liability to autism and SLI. Using a modified version of the PRS, in which several items were combined and emotional expression and grammatical errors were also assessed, both parents of individuals with autism and parents of individuals with SLI scored higher on the modified PRS (i.e., committed more pragmatic language violations) than parents of individuals with Down syndrome. These results provide intriguing evidence that pragmatic language use may provide a marker of the genes involved in autism, and potentially in a related language disorder (SLI).

Findings from the Losh et al. (2008) study of multiple- and single-incidence autism families further suggest that pragmatic language profiles provide a sensitive marker of genetic liability to autism. Using the PRS to compare multiple- and single-incidence families, investigators found that as with the personality features, rigid and aloof, pragmatic language violations were most common among MIAF parents, who averaged ~4 pragmatic language violations during semistructured conversation, less so among SIAF parents, averaging ~2.5 errors, and the least frequent among DWNS parents, who committed on average fewer than one pragmatic language violation during conversation (Figure 27-2).

In addition to language delays and particular pragmatic language styles, early twin studies and family studies using family history methods reported cognitive delays, intellectual disability, and difficulties with early reading and spelling among siblings and family members (Folstein & Rutter, 1977; August et al., 1981; Baird & August, 1985; Folstein et al., 1999; Minton et al., 1982; Piven, Palmer, Jacobi, et al., 1997), raising the possibility that genetic liability to autism could manifest as a pervasive cognitive deficit, rather than more specific and subtle personality and language features. Later studies did not find evidence for intellectual disability among relatives that was not associated with autism (Fombonne et al., 1997; Piven & Palmer, 1997; Szatmari et al., 1993; Bailey et al., 1995), although developmental problems in reading and spelling have been reported repeatedly (Folstein et al., 1999; Piven & Palmer, 1997).
Figure 27–2. Mean number of pragmatic language violations measured by the PRS, across families differing in genetic liability to autism.

To further investigate whether cognitive and language disability may comprise part of the manifestation of genetic liability to autism, relatives' performance on standardized cognitive and language tests has been examined. This body of work has yielded equivocal results. On standardized intelligence tests, a discrepancy in verbal and performance abilities has been described in several separate case-control studies. Minton et al. (1982) found lower verbal IQ than performance IQ among siblings of individuals with autism. LeBoyer et al. (1995) also found a verbal-performance split, with performance IQ significantly higher among siblings, but this was specific to brothers of female autistic individuals. Investigating, parents' IQ profiles, several groups have reported lower performance IQs than controls (Folstein, Santangelo, Gilman, Piven, et al., 1999; Piven & Palmer, 1997; Schmidt, Kimel, Winterrowd, et al., 2008), and higher verbal IQs were observed in another study of parents and siblings (Fombonne et al., 1997). Other studies, however, have failed to detect differences in IQ (e.g., Bishop, et al., 2004; Pilowsky, et al., 2003; Szatmari et al., 1993; Szatmari et al., 1995).

Not unlike the picture in autism, conflicting findings present a somewhat muddled picture of the cognitive profiles of relatives, and studies employing standardized language tests of language have yielded similarly inconsistent results. Examining parents' performance on standardized tests of language, and phonological processing, Folstein et al. (1999) and Piven and Palmer (1997) reported deficits among the autism parent group on nonsense word reading, which taps phonological awareness. A later study also reported problems in nonword repetition among parents (Schmidt et al., 2008), a deficit that has also been observed in autism (Kjelgaard & Tager-Flusberg, 2001). These findings bolstered arguments favoring a shared etiology of autism and specific language impairment, where such phonological processing deficits are a hallmark (see Williams et al., 2008 for review), and could indicate overlapping pathophysiology and potential shared targets for intervention particular to specific symptom domains in autism. Yet studies have failed to replicate these findings consistently (e.g., Bishop et al., 2004), and therefore the findings require further study before their relevance to autism and the BAP can be evaluated.

What is the BAP? Clinical Phenotype and Associated Endophenotypes

Evaluating the array of findings across personality, psychiatric, language, and cognitive domains, the key question is, What actually is the BAP? To begin to address this question, and offer a nomenclature that may assist in structuring theoretical and empirical work on the BAP, returning to Kanner's original case studies of autism may be instructive. Among his original 11 patients, Kanner described clinical features and functional impairment in three key domains. These children displayed functional impairments in their ability "to relate themselves in the ordinary way to people and situations from the beginning of life," along with impaired social communicative behaviors marked by "monotonously repetitious" language, and restricted and repetitive interests and behaviors accompanied by "an anxiously obsessive desire for the maintenance of sameness." These clinical observations focused foremost on functional impairment associated with the features Kanner observed.

Applying this paradigm to findings from studies of the relatives of individuals with autism, the picture emerging is one of a subtle constellation of personality and language features among nonautistic relatives that parallel the defining features of autism, and which are distinct from a pervasive developmental disorder or autism spectrum disorder by virtue of a *lack* of functional impairment—i.e., particular social dispositions (social reticence or aloof personalities), particular profiles of communication that are similar in quality to those observed in autism [literal language, some problems with the social use of language (pragmatics)], and rigid or perfectionistic personality style. (Further study will determine whether language and cognitive delays reported retrospectively, and now being observed in the infant-sibling literature, may be developmental precursors to such features.) Thus, whereas the BAP has at times been characterized broadly as an autism spectrum disorder or pervasive developmental disorder (and often captured by cutoff scores on scales also intended to assess autism, e.g., Bishop et al., 2004), most family-study research has described a much more subtle phenotype that would not qualify as an autism spectrum disorder by virtue of a lack of associated functional impairment (this issue is considered in greater depth in a later section). And whereas psychiatric disorders and cognitive measures (e.g., IQ profiles or intellectual disability) have in some studies shown familial aggregation or heritability among families of individuals with autism, findings are somewhat inconsistent, and these features are not qualitatively similar to the core characteristics of autism. They may therefore be most fruitfully considered as associated but not constitutional features of the BAP.

How then should we conceptualize other associated features that do not correspond to the clinical features of autism, and yet show robust segregation within families of individuals with autism, such as the neurocognitive abilities described in the section to follow (e.g., social cognition)? Are they part of the BAP? Defined in this way, such features are not part of the BAP per se, but instead, associated characteristics that may throw into sharper relief understanding of the pathogenesis of the BAP (and autism). This important distinction may also help to clarify the often fuzzy boundary separating subthreshold clinical variant from endophenotype (or intermediate phenotype) which may or may not be present in affected individuals. The endophenotype concept was originally introduced by John and Lewis (1966), who in their studies of insect biology argued the merits of an empirical approach focused not on "obvious and external" *exo*phenotypes, but instead on *endo*phenotypes, which are "microscopic and internal" (p. 152). Later applied to psychiatry by Gottesman

and Shields (1967, 1972), the endophenotype concept has since been used to decompose complex psychiatric disorders into more fundamental components that are more proximal to underlying biology, are assessed by experimentally based methods rather than clinical observation, and which hold the possibility of more direct genotype-phenotype associations than the complex clinical phenomena that comprise clinical diagnoses (Allen et al., 2009). In the case of autism and related disorders, then, the "microscopic and internal" endophenotype can therefore offer a foothold between complex clinical phenotype and genetic mechanisms. Presented below are findings from a handful of studies that point toward specific neurocognitive features associated with the BAP, which may serve as promising endophenotype candidates.

The Neurocognitive Underpinnings of the BAP: Identifying Endophenotypes

The validity of the BAP as a clinical phenomenon is apparent from the numerous case-control studies that have documented repeatedly a constellation of personality and language features among relatives, paralleling in quality the core features of autism. However, like autism, this construct is still considerably removed from underlying mechanisms that could give rise to these profiles, and which are mediated by those genes and neural circuits underlying autism. The BAP is also difficult to measure in a way that can be efficiently and reliably applied to genetic studies, where phenotypes reflecting specific biological substrates are ideal.

Language Processing

Whereas profiles from omnibus tests of cognition and language have produced inconsistent results, more specific tests of language processing have shown some promise in the way of defining particular cognitive-linguistic systems related to the BAP. In particular, robust patterns of difference have been documented on tests of rapid automatized naming (RAN). RAN is a sensitive index of reading ability (Wolf & Bowers, 2000), and is known to tap such fundamental language skills as phonological processing and memory, articulation, and linguistic processing speed (Denckla & Cutting, 1999; Denckla & Rudel, 1972, 1974, 1976; Holland, McIntosh, & Huffman, 2004). The rapid automatized naming (RAN) task first appeared in *The Mental Examiner's Handbook* as a bedside measure of recovery from brain injury in the mid-1900s. Patients were shown a series of randomly repeating squares printed in primary colors and instructed to name the colors as quickly as possible, with speed and accuracy serving as measures of recovery. The RAN was soon used experimentally in patients with focal brain lesions to study brain-behavior relationships (Geschwind & Fusillo, 1966). These early studies revealed that the RAN taps a number of important language processing skills that could be localized to specific regions of

the brain, and which reflected stages of brain development (Denckla, 1972). In particular, subsequent research has shown that response speed measured by the RAN is linked to myelin deposition over the course of development, and resulting advances in language related skills (Mabbott et al., 2006). Deficits in rapid naming have also been associated with decreased connectivity (Deutsch et al., 2005), establishing further a link to neurocognitive underpinnings of this language related skill.

Piven and Palmer (1997) first reported slower RAN among parents of children with autism in contrast to controls, and in an expanded study involving over 300 parents of children with autism Losh et al. (2010) again found slower times and more errors among parents, as well as among a smaller group (n = 38) of high-functioning individuals with autism (see Figure 27-3). Further, significant parent-child correlations were detected for time and number of errors, supporting a genetic influence. Associations were also detected with features of the BAP. Both aloof personality style and language features of the BAP were associated with longer times to complete the task, a finding that could implicate limited verbal fluency in the language and associated social features of the BAP. Results further indicated that parents who were rated positive for the rigid personality trait were more likely to commit errors, or to become momentarily "stuck" on a prior color. This latter finding could reflect underlying difficulties in cognitive flexibility among parents showing the rigid trait of the BAP, as limitations therein could conceivably relate to this personality style. Because this task has been linked with particular neural circuitry, the RAN and similar tasks may provide neurocognitive markers of genetic liability to autism. Such links have begun to be addressed more directly through studies of neuropsychological abilities among relatives, as well as more direct research into brain activity, described below.

Social Cognition, Executive Function, and Central Coherence

In an effort to understand the underpinnings of the personality features of the BAP, Losh et al. (2009) conducted a neuropsychological assessment of high-functioning individuals with autism
Figure 27–3. RAN performance in individuals with autism and parents.

and parents of autistic individuals (both with and without the BAP, defined by personality characteristics of aloof and rigid), across the three principal neurocognitive domains that have each been proposed as key cognitive abilities in which impairments may explain the autistic phenotype—social cognition, central coherence, and executive function. The study's aims were threefold: (1) to provide an in-depth characterization of the neuropsychological profile of the BAP; (2) to identify patterns of performance within and across neuropsychological domains that were common to both autistic individuals and parents with and without the BAP; and (3) to identify cosegregation between clinical phenotype (aloof, rigid, pragmatic language) and neuropsychological functioning that might serve to carve out specific phenotypic subtypes and that could form the basis for stronger genotype-phenotype associations.

The study assessed performance using a battery of tasks selected to assess processing comprehensively within a given domain and which could provide links to studies of subjects with circumscribed neurological lesions and fMRI studies that could shed light on specific neural structures that are involved in autism, and potentially the BAP. In particular, measures of social cognition, executive function, and central coherence were selected based on (1) their ties to the neuropsychological domains of interest, both theoretically and from their usage in prior neuropsychological investigations; (2) psychometric properties, including reliability and indication that each was appropriate for administration to all participants (i.e., suitable for both individuals with autism, parents, and controls) without danger of floor or ceiling effects; and (3) additional empirical evidence from fMRI and/or lesion studies suggesting associations with particular structures or regions of the brain thought to be important for the three domains and putatively implicated also in autism.

In brief, measures of social cognition tapped the ability to infer social-emotional information from various channels—the eye region of the face (via the Reading the Mind from the Eyes Task (Baron-Cohen, Wheelwright, Hill et al., 2001), facial information in general (through the Movie Stills and Trustworthiness of Faces tasks, Adolphs et al., 1998), and biological motion (through pointlight stimuli in which an actor was adorned with light emitting diodes and instructed to move across a stage in ways that conveyed different emotions—e.g., trudging slowly, dancing, lively strutting, etc.). Images were presented with only the points of light visible, such that no facial or contextual information was available. Measures of executive function included the commonly used Tower of Hanoi, which involves planning a sequence of moves that transfer an initial configuration of rings onto a particular peg, abiding by certain rules; and the trail making test, which is a measure of set shifting and cognitive control of interference in which sequences of numbers and letters must be alternately used to trace to an end point as quickly as possible. Central coherence was tapped through three measures used in prior work—(1) the embedded figures test, which involves detection of simple geometric figures obscured within a more complex design; (2) sentence completion, in which subjects must complete sentence stems and responses are rated as local

or global based on their interpretation within the context of the whole sentence [e.g., the sea tastes of salt and *pepper* (local) vs. *water* (global)]; and finally (3) a block design task that taps the relative salience of parts over wholes through presentation of unsegmented designs followed by segmented designs in which the participant's task is to construct a design using blocks based on a model that is either presented complete or presegmented. The latter condition (segmented) breaks the gestalt for typically developing subjects and renders processing of figure-parts easier.

Findings revealed that individuals with autism displayed impairment on all of the social cognitive measures, but performed comparably to controls on measures of executive function, and 2/3 measures of central coherence (showing a tendency to complete sentences with local responses). Findings within the parent groups indicated that those autism parents who did not display features of the BAP performed comparably to controls on all measures, yet parents with the social features of the BAP (aloof) showed marked differences from controls on measures of social cognition (see Figure 27-4 for examples of tasks). As illustrated in Table 27-3, in all social cognitive measures, differences were observed in *both* individuals with autism and parents with the social BAP. By contrast, parents (with and without the BAP) performed similarly to controls on tasks of executive function and central coherence.

Others have reported differences between autism relatives and controls on social cognitive measures (e.g., Baron-Cohen & Hammer, 1997; Baron-Cohen, Wheelwright, Hill, et al., 2001; Gokcen et al., 2009), yet the present findings suggest that such differences may cosegregate specifically with the clinically expressed social features of the BAP. Further, these data suggest that specific social cognitive profiles shared by individuals with autism and a subgroup of parents (i.e., those with the BAP) may involve a number of different social cognitive skills—making complex social judgments of trustworthiness from facial information (trustworthiness of faces), interpreting the emotional content of complex scenes with and without affective facial information (movie stills), inferring emotions from very subtle variations in facial expression (morphed faces), and interpreting complex emotional content from biological motion (point light).

Importantly, patterns of performance were in some instances qualitatively different in the autistic and parent groups, perhaps suggesting a pathoplasticity in these features, where common underlying mechanisms manifest variably in autism and the BAP. In the trustworthiness of faces task, for instance, individuals with autism judged negative faces as significantly "more positive" than controls (i.e., they were overly trusting), whereas BAP (+) parents judged positively valenced faces as "more negative" than controls and BAP (-) parents (illustrated in Figure 27-5). Such a divergence in performance demonstrates how the underlying *forme fruste* of the disorder (trouble characterizing social stimuli) may manifest variably based on experience, and level of functioning (i.e., autism vs. clinically unaffected parents). The BAP may therefore provide a mechanism for investigating the role of experience in autism

Figure 27–4. Measures of social cognition defining autism and the broad autism phenotype. Morphed Faces involve interpretation of faintly expressed emotions. Point Light stimuli tap the ability to read emotions from biological motion. The Movie Stills task indexes reliance on facial expressions when making emotional judgments. The Eyes Test requires interpretation of complex thoughts and emotions from only the eye region of the face. Finally, the Trustworthiness of Faces task measures complex social judgments based on facial stimuli varying gender, facial expression, and positioning.

(as will the emergent literature on infant siblings of individuals with autism).

Executive function and central coherence measures did not discriminate parents with or without the BAP in this study. Several prior studies have demonstrated among relatives executive control deficits and a local processing bias as well as limited drive for central coherence (Jolliffe & Baron-Cohen, 1997; Bolte & Poustka, 2006; Happe et al., 2001; Hughes, Leboyer, & Bouvard, 1997; Hughes, Plumet, & Leboyer, 1999; Piven & Palmer, 1997). However, some other studies have also failed to detect differences in these domains (Szatmari et al., 1993; Ozonoff et al., 1993; de Jonge et al., 2009), raising the possibility that effects within these domains are more subtle and/or heterogeneous. Also, the net cast by the executive function task battery in the study by Losh et al. (2009) was not as broad as some other studies' and this may have reduced the ability to capture group differences. A related issue concerns the neurocognitive correlates of the rigid/perfectionistic features of the BAP. It is possible that this feature may not constitute as valid a construct as the social features of the BAP, or alternatively,
Figure 27–5. Judgments of the trustworthiness of faces by high functioning adults with autism, parents with and without the BAP, and respective control groups.

may relate to additional cognitive mechanisms not considered in this study (e.g., sensorimotor processing, which has been associated with repetitive behaviors in autism, Perry, Minassian, Lopez, et al., 2007). Nevertheless, the consistency of differences in social cognition, detected both in autism and parents with social features of the BAP point toward this domain as an important focus for future work teasing out the brain, and ultimately gene basis of autism and the BAP.

Further evidence that social cognition may be important to study in the BAP comes from an eye tracking study of face processing in parents of individuals with autism.

Adolphs et al. (2008) studied face processing among parents with the BAP using the "bubbles" method (Gosselin et al., 2001). In this procedure, subjects were presented with obscured facial expressions containing randomly revealed "bubbles" of clarity of an underlying whole face and asked to determine whether each stimulus represented happiness or anger. That is, in some trials portions of the eye region were visible, whereas segments of the mouth, nose, and other regions were randomly revealed on other trials. Analyses examined those regions of the face that were present when accurate judgments were made, thereby providing a direct measure of perceptual processing strategies while judging emotional information. The number of bubbles (i.e., size of the region revealed) was adjusted on a trial-by-trial basis in order to maintain a relatively stable performance accuracy of ~80%. Whereas neurotypical control parents were found to rely heavily on the eye region, parents of individuals with autism who displayed social personality features measured by the MPAS (aloof and/or untactful) showed significantly reduced reliance on the eye regions (see Figure 27-6), and enhanced focus on the mouth region. Prior work by Spezio et al. (2007) showed an identical pattern among high-functioning individuals with autism on this task. These findings are consistent with those of Klin et al. (2002) and Pelphrey et al. (2002), suggesting a specific pattern of face processing that may constitute a sensitive marker of genetic liability to autism.

Brain Activity and Structure

Moving beyond behavioral data, neurocognitive features have been studied among relatives using more direct indices of brain activity. Using ERP, Dawson et al. (2005) showed that when viewing faces and nonsocial stimuli, parents of individuals with autism exhibited atypical neural responses. As has been observed in autism, parents of children with autism failed to show the typical shorter latency N170 to faces than nonface stimuli. Furthermore, they did not exhibit the typical right hemisphere lateralization when viewing faces. Abnormal brain activation has also been noted among siblings of individuals with autism. In a study of face processing ability in unaffected siblings, Dalton et al. (2007) found that siblings showed
Figure 27–6. (A) shows facial regions used by controls when making accurate judgments; (B) depicts those regions used more often by control parents than BAP (+); and (C) depicts the difference between controls vs. BAP (−) parents.

reduced gaze fixation to eye regions of still faces, and fMRI conducted during the face viewing task revealed reduced activation in the fusiform gyrus, a brain structure largely devoted to face processing. Taken together, these findings are notable in their similarity to what has been observed in autism, suggesting they may serve as neural trait markers of genetic liability.

Just as studies of the BAP have trailed behind those of autism, cognitive neuroscience studies of the BAP have emerged only relatively recently. To date these studies have reported similarities between what has been found in prior studies with autism. Established findings on the neurobiological basis of autism may therefore provide a logical guide for pursuing this investigation—i.e., given what is known from neurobiological studies of autism, one can formulate hypotheses about what one might expect to find in the BAP. These first-order hypotheses would include the amygdala and visual cortices in the temporal lobe as key brain structures that mediate abnormal processing of faces and eye gaze (Pelphrey et al., 2005). They would include structural connectivity, specifically the idea that there may be altered white matter and reduced long-range connectivity in the brain. And they would include functional connectivity, such as the prediction that the "default network" of the brain would not be normally activated during rest. Evidence briefly reviewed here supports these hypotheses. Further work using magnetic resonance imaging (structural, BOLD-based, and diffusion-imaging) as well as complementary careful postmortem studies of brains will be required to delineate the neurocognitive basis of the BAP.

It will also be critical eventually to test hypotheses about how the brains of people with the BAP might *differ* from those with autism. Rather than assuming that, like the full syndrome, all biological measures in the BAP will look qualitatively similar to those in autism, only milder, it may be that there are other patterns. For instance, it might be that only certain brain regions in the BAP share features with autism. Alternatively, it may be that the endophenotype that mediates between genetic liability and phenotype looks rather different in the BAP and in autism (as observed in findings of differing patterns of trustworthiness judgments among parents with the BAP and high-functioning individuals with autism; Losh et al., 2009). Attention to such complexities will be important for establishing not only the biological basis of autism, but also the range of phenotypic expression arising from such biological substrates.

Summary: The Significance of the Concept of a BAP

Defining Boundaries Between Autism, the BAP, and Typical Development

The BAP can provide a useful tool for defining the varied clinical expressions of genetic liability to autism, and demarcating the clinical boundaries of autism in particular. Autism has been

conceptualized as both a categorical entity (DSM-IV) and as constituting one end of a continuum of continuously distributed traits in the population (e.g., Constantino, 2009). The former characterization makes sense in the clinical arena, where autism is a syndrome associated with functional impairment and warranting treatment. The latter conceptualization has had increasing relevance in research studies aimed at understanding underlying pathogenesis. Clinical and research fields have wrestled with the interface of these overlapping domains in developing a nomenclature applicable to their purpose. This issue is evident in the gradual evolution from the terms "autism" and "pervasive developmental disorder" to the increasingly common use of the term "autism spectrum disorders" for identifying this group of related clinical conditions.

A question then arises about the boundary between the BAP and "autism spectrum disorders" and the usefulness of making this distinction. As reviewed earlier, Piven and Palmer (1999) examined parents with the BAP using a structured interview for personality disorder and for the most part found that these individuals did not have evidence of a personality disorder (i.e., they had no evidence of significant clinical impairment). While understanding the characteristics of the BAP may be useful in understanding families, and parents in particular, of individuals with autism and in providing optimal care, the BAP does not appear to be an indication for treatment. Therefore conceptualizing the BAP as part of an underlying continuum of distributed traits in the population that are genetically related to but not equivalent to autism or an autism spectrum disorder may be a useful distinction to make in the clinical arena. Given the increasing demands on the health care system for services for autism spectrum disorders, defining this upper boundary of autism (as opposed to a lower boundary between individuals with so-called low-functioning autism and those with mental retardation without autism) between individuals with an autism spectrum disorder (i.e., high-functioning autism and Asperger's syndrome) and those with the BAP may be an important distinction for clinicians to keep in mind when they see characteristics in family members that are qualitatively similar to autism, and that may have a determining role in lifestyle preferences, but are not associated with significant functional impairment.

In a related vein, studies of the BAP may also inform studies of the underlying nature of personality traits in the general population. For instance, do features of the BAP actually differ in etiology from these personality and language traits that can occur (though at much lower rates) in the general population? In other words, is social reticence in one who has no family history of autism etiologically distinct from the aloof dispositions described as comprising the BAP among relatives of individuals with autism? And how do environmental factors contribute, potentially differentially, in these different cases? Implicit in Kanner's original writings, and generally explicit in current empirical treatment of the BAP is the notion that features of the BAP are due to shared genetic variance associated with autism and thus distinct in etiology from personality traits observed in the general population.

A definitive answer to this question will require systematic studies of neurobiology and genetic variation related to such traits in populations varying in genetic liability to autism.

Genetic Significance of the BAP

Progress in understanding the etiology of autism may be hastened by parallel studies of the BAP. Whereas autism by definition involves all three symptom domains, in the BAP, features disaggregate and may occur independently, consistent with twin studies indicating that although the component features of autism all have strong genetic effects, they seem largely independent in patterns of transmission, with relatively little phenotypic or genetic overlap (Ronald et al., 2005, 2006). As a distilled expression of latent liability, the BAP can therefore provide a glimpse at the *forme fruste* of the disorder of autism, and its often complex and variable phenotypic manifestation. For example, in findings discussed earlier, Losh et al. (2009) identified impairments among individuals with autism and parents with the BAP, who shared differences in reading social cues across various social cognition tasks relative to controls. However, they were at times expressed in different ways (e.g., varying profiles judging trustworthiness). In this way, the BAP may prove critical in focusing on core behavioral and neuropsychological features and helping to narrow the empirical target from an otherwise highly complex and heterogeneous phenotype (i.e., a diagnosis of autism), to more specific component features that are likely to be more amenable to genetic and neurobiological study.

Whereas the clinically observable features of the BAP (aloof and rigid personality, pragmatic language profiles) are hypothesized to arise from a smaller constellation of genes (and/or gene-environment interactions) than autism, they do not seem to constitute endophenotypes in the strict sense of this term, at least in the same way as associated neurocognitive features, given the latter category's greater proximity to underlying biology (e.g., social cognition, brain activation, shorter N170 latency to facial stimuli; Allen et al., 2009). However, the BAP may prove critical in the detection of such endophenotypes. Because not all parents show the clinical features of the BAP, endophenotypes would be hypothesized to be present among the subgroup of parents who do. Support for this hypothesis comes from studies previously reviewed showing that language processing (RAN) and social cognitive profiles segregate with features of the clinically defined BAP (Adolphs et al., 2008; Losh & Piven, 2007; Losh et al., 2009; Losh et al., 2010). Thus, while the distinction between clinical phenotype (e.g., the BAP) and endophenotype (e.g., brain structure) is important to consider, these constructs are likely to be studied most profitably when considered jointly.

The BAP may therefore help to guide genetic studies by offering, as an alternative to the search for "autism genes," a more focused detection effort involving specific endophenotypes underlying components of the BAP, and that are linked in a more straightforward way to underlying susceptibility genes.

The promise of the BAP for guiding genetic studies is supported by recent molecular genetic studies implementing phenotypic subgrouping in affected individuals and their parents (e.g., Alarcon et al., 2005; Duvall et al., 2007; Buxbaum et al., 2004; Autism Genome Project Consortium, 2008). Though still in its incipience, this approach of more precise phenotyping using features of the BAP and, eventually, endophenotypes, has already proven to be a method that strengthens power to detect linkage and association. When implemented into the large-scale collaborative efforts currently underway, such techniques may afford increased power and sensitivity for defining different etiologic pathways and, ultimately, leading to important new knowledge of the pathogenetics of autism.

Conclusions

As reviewed in this chapter, considerable evidence now exists to suggest that genetic liability to autism may be expressed through subtle behavioral and language features among relatives. Such features are similar in quality to the defining features of autism, but much milder in expression and do not appear to be associated with any functional impairment. Furthermore, the features of the BAP appear more common among relatives from families with multiple incidences of autism, providing further support for the idea that such features index genetic liability. Research is beginning to document the neuropsychological basis of the BAP, and such findings will be critical in moving forward in defining the brain and gene basis of autism.

Challenges and Future Directions

- Findings reviewed in this chapter support further study of the component features of the BAP and the neuropsychological characteristics that underlie the components of this construct.
- Evidence suggests that as a distilled expression of genetic liability, the BAP may offer a useful guide in studies of the brain and gene basis of autism.
- An important direction for future work will be to identify and/or develop efficient and standardized methods for measurement of the BAP that may be helpful for large-scale population and genetic studies.

The Biological Broader Autism Phenotype

Points of Interest

- To be a member of the Biological Broader Autism Phenotype, the rates of a biological alteration must be elevated above that of the general population in individuals with autism, in unaffected relatives generally, and in autism families specifically.
- No biological feature is currently required for the diagnosis of autism. Macrocephaly and increased rate of head and brain growth during early childhood are not included in the diagnostic criteria for autism. The absence of any biological feature does not exclude a diagnosis of autism at present.
- Hyperserotonemia is the only biological feature that has been shown to meet all criteria for inclusion in the Broader Autism Phenotype.
- Most intermediate phenotypes of the Biological Broader Autism Phenotype have yet to be discovered.

Introduction

At present, the Broader Autism Phenotype (BAP) is comprised of milder and partial cognitive, behavioral, and biological characteristics that are qualitatively the same as or conceptually similar in nature to the individual characteristics associated with autism. The biological subset of the present-day BAP is its smallest and most vital subdivision. The Biological Broader Autism Phenotype (BBAP) is the group of alterations in the development, structure, or function of the brain, other bodily systems, and their components that are inherited with autism in families. The key candidate members of the BBAP are the primary foci of this chapter.

> **Phenotype:** an observable physical, biological, or behavioral characteristic influenced by genetic factors and the interaction between genes and environment.

Box 28–1

Intermediate phenotype (IP, in autism): a behavioral, cognitive, or biological trait found more commonly in affected and unaffected autism family members than in the general population. In the causal chain of developmental events, these phenotypes are in an intermediate position between the cause and the full diagnosis. As a result, the strength of the statistical association may be significantly stronger between a cause and an intermediate phenotype than between a cause and the full diagnosis. Components of the BAP are sometimes referred to as intermediate phenotypes. Gottesman and Shields (1972) introduced the term "endophenotype" during the course of their twin study in schizophrenia. As originally described by these pioneers, intermediate phenotypes and endophenotypes are conceptually identical (Gottesman & Gould, 2003; Szatmari et al., 2007). The first twin study of the genetic influences in autism suggested an inherited clinical phenotype broader than autism itself (Folstein & Rutter, 1972). The notion that a measurable trait, present in individuals with severe disorders such as schizophrenia or autism, could be present in some unaffected family members revolutionized thinking in neuropsychiatry.

It has been nearly 70 years since the clinical evidence that characteristics broader than autism may be inherited in families first emerged. Dr. Leo Kanner, in his eloquent clinical description of 11 children with autism, described particular traits and tendencies in unaffected family members, many of whom were gifted and outstanding individuals

(Kanner, 1943). Research evidence for an inherited phenotype broader than autism was derived over 30 years ago from the first twin study of autism (Folstein & Rutter, 1977). In this landmark study, co-twins of their sibling with autism were found to have increased rates of the disorder. Equally important, co-twins who did not have autism were found to have increased rates of cognitive difficulties, especially those involving language acquisition and socioemotional difficulties. These results led Folstein and Rutter to hypothesize the BAP, namely that autism is linked genetically to a range of difficulties broader than the disorder itself, with autism as the most severe form. Subsequent twin and family studies have confirmed that an inherited phenotype broader than autism exists (Bailey et al., 1995; Bolton et al., 1994; Folstein et al., 1999; Le Couteur et al., 1996; Piven et al., 1997). Nonautistic family members were found to have increased rates of delayed onset of spoken language, articulation problems, reading and spelling difficulties, specific social difficulties, occasionally repetitive interests and behaviors, and other features, alone or in combination. Twenty percent (20%) of members of families having one child with idiopathic autism have communication or social, cognitive, or behavioral features of the BAP (Bolton et al., 1994). The prevalence rate of the BAP has been estimated to be 30% or higher in families that have two or more children with idiopathic autism (Piven et al., 1997). These studies also confirmed that intellectual subnormality (mental retardation) found in many children with autism was not present in unaffected family members any more than in the general population.

Familial resemblance: a phenotype or phenotypes that show greater similarity in family members than in unrelated pairs of individuals (Rice, 2008). Exchangeable terms for familial resemblance are "familiality" and "familial aggregation." Familial resemblance provides essential evidence that a phenotype may be inherited in families, but resemblance within families can also be due to shared environments.

Idiopathic autism: autism without a known and specific medical cause. Roughly 90% of all known cases of autism are idiopathic; the remaining 10% arise from medical causes. Current evidence suggests that multiple genes and gene-environment interactions are involved in idiopathic autism but the majority of these are not yet known. Medical causes of autism include Fragile X syndrome, a genetic disorder in which there are long and abnormally repeated copies of DNA on the X chromosome, and tuberous sclerosis, a genetic disorder of the nervous system and the skin. Congenital rubella, an in utero rubella virus infection, is now known to be a rare medical cause of a form of autism.

If social, communication, and behavioral aspects of the BAP are known, and related neuropsychological aspects are being clarified (Losh et al., 2009), why is it important that research also focus on biological aspects of the BAP, the

BBAP? It is self-evident that biological phenotypes are more proximal to the genetic mechanisms and the causal chain of events leading to autism than are cognitive and behavioral phenotypes. The biological and neurobiological determinants of autism and their potential genetic liabilities, however, remain in large part unknown. The present thinness of biological knowledge is somewhat surprising since autism has long been known to have the highest heritability of any neuropsychiatric disorder, of 0.7 for the narrow phenotype restricted to autism, and as high as 0.9 for the combined narrow and broader autism phenotypes (Geschwind, 2009). In addition, most features of the cognitive-behavioral BAP, as currently understood, are too variable and nonspecific to aid effective identification of the genes and neurobiological mechanisms involved in autism. Features of the cognitive-behavioral BAP, such as impairments in language, reading, and social functioning, can be due to many different genetic, biological, and nonbiological causes. The history of medicine has shown recurrently that the most pivotal advances in the differentiation of disorders with overlapping signs and symptoms and the discovery of different disease subtypes of clinical syndromes such as autism, have been biological. The biology of a disorder can be measured objectively, accurately, and reliably and include specific alterations in development, structure, and function of systems of the body such as the central nervous system and its most important component, the brain.

Biological dimensions of autism and the BAP bring autism research into twenty-first century medicine. Further insights in the biology of autism during development will increase understanding of pathological mechanisms and risk genes involved across the lifespan; identify nongenetic risk and protective factors, gene-environment interactions, and the earliest possible signs of the disorder; hasten development of effective and safe biology-based medical treatments of the disorder at all stages of life; and quantify the risk of recurrence specific to individual families. More detailed biological knowledge of unaffected carriers of autism liability will help answer major questions and concerns of scientist-clinicians and family members, such as why some children in families have autism while some of their siblings and other relatives have only the milder and more isolated difficulties of the BAP. A critical need in autism research today is to understand the alterations in development, structure, and function of the brain and other biological systems in the human body that are linked to the disorder.

Figure 28-1 is a description of the causal chain leading to autism. Genes that increase autism risk are believed to interact with each other and with environmental factors to alter the normal course of brain development and result in pathological processes and mechanisms. Abnormal brain development results in pathological alterations of brain structure, microstructure, function, and chemistry that have yet to be described comprehensively. According to current theory, all such pathologies result in autism when, as a whole, they reach a critical but unknown severity threshold. It is likely that the variable phenotypic expression within the BAP seen clinically results from isolated or combined subthreshold

deviations of brain structure, microstructure, and function. Although the recognition and description of autism as a distinct clinical syndrome was a major advance in child psychiatry and medicine, it is evident from Figure 28-1 that present-day research falls far short of the required understanding of its biological basis.

Box 28–2

The present-day Broader Autism Phenotype

At present, the working BAP is a set of observable behaviors and cognitive tendencies that occur at increased rates in family members of children and adults with autism. These appear to be inherited in families in addition to the "narrow phenotype," the phenotype restricted to autism (and also Asperger's syndrome and PDD-NOS). The behaviors appear identical or conceptually similar to some of the behaviors observed in autism but occur in more isolated form and tend to be milder. New characteristics of the BAP are being discovered in infant siblings of autism probands (Elsabbagh et al. 2009a; Elsabbagh et al., 2009b). In an example family, the many behaviors of the child with autism may include lack of interest in and response to other children, no spoken language, hand-flapping, and intellectual subnormality. Family members without autism (or PDD-NOS) are all of average or above average intelligence but some have single or multiple isolated tendencies conceptually similar to some of the behaviors seen in the affected child. For instance, the child's father may be an expert in computer programming and have difficulty conversing with others and behaviors indicative of a tendency toward social aloofness. The child's mother, a physician, may have a history of reading and spelling problems as a child. One sibling may have had articulation problems, delayed onset of spoken language during early childhood, and mild impairments in eye contact. Three other siblings may exhibit typical development in these and other areas. In this example family, the father, mother and one sibling have had manifestations of the BAP.

Three key questions drive BBAP research, and these three questions must be answered precisely to determine if a biological feature is a member of the BAP. First, is the rate of the biological characteristic increased in individuals with autism when compared to that of the general population? Second, is this rate also increased in nonautistic family members: monozygotic co-twins, siblings, or parents? Third, and very important, does the biological feature show resemblance within families? When familial resemblance is present, family members of an individual with autism who has the biological feature are, by definition, more likely to have the feature themselves when compared to family members of individuals with autism in whom it is not present.

Example

The general strategy for answering the three key questions when identifying new intermediate phenotype (IP) members of the BBAP, and some of the complexities involved, are described using the volume of amygdala as an example. Biostatistical terms have been included in the following description; their definitions and further examples in the BBAP can be found in Appendix A. References for the studies mentioned below are cited in the amygdala and hippocampus part of Section 2.

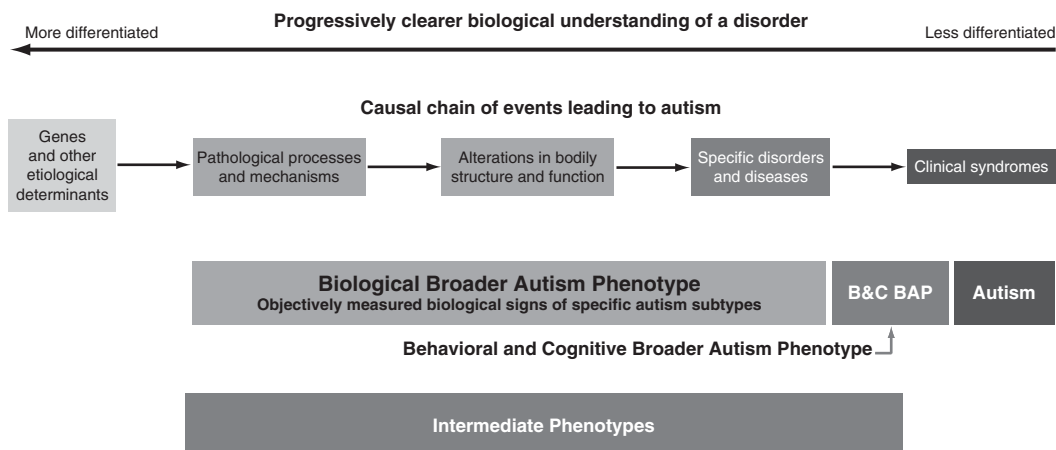
First, there must be sufficient evidence that a particular alteration of amygdalar volume is associated with autism. Case-control studies provide this evidence and suggest that mean amygdala volume is increased in young children with autism and decreased in older children and adolescents with autism relative to that of healthy control subjects. Some studies report no case-control differences. When the findings across studies are not consistent, meta-analysis is often performed to determine the standardized overall effect size of all of the studies combined. In a meta-analysis, the overall effect size of the autism-control difference in amygdala volume was insignificant, as indicated by its 95% confidence interval.


Figure 28–1. Description of the causal chain leading to autism.

In the case of amygdala volume, high variation was found between reported group differences in mean volume and their standard errors. When the heterogeneity of study results does not arise from the disorder itself, it can limit the statistical power to detect true volumetric differences and in some cases annul the meta-analytic findings altogether. Controlling the false discovery rate is an alternative way to assess the veracity of multistudy findings, especially when the number of studies is large.

An initial, small, and insignificant overall effect size may suggest that amygdala volume is not associated with autism. Amygdala volume appeared, however, to decrease with age in the autism but not the control groups, a significant age by group interaction. This finding raises the possibility that amygdala volume, as a potential IP, may vary with age, or that a pattern of age-related changes in amygdala volume, as could be ascertained by a longitudinal study, may be more significantly associated with autism than a single volume measurement at any age. If additional studies of volumetric changes in the amygdala in older children replicate the association with autism, and relationships between amygdala volume and specific symptoms of autism continue to be found, such would suggest that amygdala volume may mediate the effect of causative mechanisms on some signs of the disorder.

> **Proband:** the first individual in a family who comes to clinical attention and is diagnosed with a particular disease or disorder. In this chapter, proband refers to the index case of autism in a family.

The next step in identifying the potential IP examines amygdala volume in unaffected family members: members of twin pairs without autism, and unaffected parents and siblings. Two exploratory studies found decreased mean volumes in unaffected older siblings but not in parents. Due to their small sample sizes, these studies are not sufficient to rigorously test amygdala volume as a potential IP. Sample size is an important consideration since autism is a heterogeneous disorder clinically and genetically. In addition, mutations in autism risk genes identified to date are sometimes inherited but often occur de novo (spontaneously, not inherited) in affected individuals. There may be inherited and noninherited (sporadic) forms of idiopathic autism (Zhao et al., 2007). Large sample sizes and elegant statistical modeling are needed to account for these factors properly. Additional replication studies may confirm that overall mean amygdala volume is decreased in unaffected older siblings and parents.

The third step is to determine if alterations in amygdala volume in autism are familial. Are unaffected relatives of children with autism who have alterations of amygdala volume more likely to have decreased amygdala volume compared to unaffected relatives of autism probands who have normal amygdala volumes? At a simple level, familial resemblance can be tested quantitatively with correlation statistics and categorically using the odds ratio. The participants for analysis need to be probands with autism and their unaffected relatives. Familial resemblance is tested more rigorously with multilevel mixed effects models. A simple mixed-effects model combines and separates odds ratios by treating them as repeated measures of a common association. If amygdala volumes in affected individuals and their unaffected relatives remain significantly correlated, then these volumetric deviations would meet the three necessary criteria for a potentially genetically informative member of the BBAP.

The fourth step is to determine how useful the IP is in identifying individuals with autism and unaffected family members. This step requires a shift from the comparison of case-control means to phenotypic classifications of individuals. The classification ability of a variety of amygdala size alterations is tested by balancing sensitivity and specificity depending on the purpose of the classification. For family genetic studies, specificity is often maximized to minimize false positives. In addition, the classification strategy must have high predictive values for the presence and absence of autism family membership and be highly reliable. To be a useful IP, the relative risk and the odds ratio should be high; the phenotype of decreased amygdala volume should occur in probands and their unaffected relatives at a much higher rate than in the general population. Because autism is a heterogeneous disorder, it is possible that a particular IP may be helpful in only a subgroup of autism families.

The final step is to further refine the amygdala volume phenotype for use in molecular genetic studies. This refinement requires additional research to describe in the finest detail possible the alteration in amygdala development that is most specific to affected and unaffected autism family members. Such refinement will increase the sensitivity (more power), specificity (fewer false positives) and predictive value of the phenotype to help identify new autism risk genes and biological mechanisms involved in the disorder.

As autism research moves into the era of personalized and genomic medicine in the twenty-first century, the preceding example raises another important issue: reliability. Proper assessment of the reliability and validity of imaging measurements, for instance the reliability of measurement of amygdala volume in vivo across time and across different sites, is more complex than many clinicians and researchers currently realize (Lange et al., 2010; Brain Development Cooperative Group, corresponding author: Nicholas Lange, 2011).

Section 1. Craniofacial Features

Macrocephaly

Macrocephaly, a head circumference greater than the 97th percentile equivalent to 1.88 standard deviations (SDs) above the mean specific to age and sex, is one of the most common physical features associated with autism. Macrocephaly in autism is usually due to megalencephaly, abnormal enlargement of the brain, at some time during development (Bailey et al., 1993; Courchesne et al., 1999; Kemper & Bauman, 2002).

Affected Individuals

On average, macrocephaly is present in 20% of affected individuals (Fombonne et al., 1999). There is an increased rate of macrocephaly in twins with autism (Bailey et al., 1995), an intriguing finding because head circumference tends to be smaller in typically developing twins than in singletons (Buckler & Green, 2008). The significant association between autism and macrocephaly has been replicated in multiple independent samples, in singletons and twins, simplex and multiplex families, children and adults, cognitively high- and low-functioning affected individuals, and in epidemiological and clinical samples (Lainhart et al., 2006). Published rates of macrocephaly range from 14% to 42% of cases (Bailey et al., 1995; Bolton et al., 1994; Courchesne et al., 2003; Davidovitch et al., 1996; Dementieva et al., 2005; Deutsch & Joseph, 2003; Fidler et al., 2000; Fombonne et al., 1999; Gillberg & de Souza, 2002; Lainhart et al., 1997; Lainhart et al., 2006; Miles et al., 2000; Sacco et al., 2007; Stevenson et al., 1997; Woodhouse et al., 1996).

Simplex, multiplex: the type of family as determined by number of its members with an autism spectrum disorder (ASD). If only one individual in a family is affected with an ASD, it is a simplex family. Families are termed multiplex if two or more of its members are so affected.

Box 28–3

Associated Features. Biological features that occur at higher rates in individuals with autism are termed "associated features" at present, as they are found in some but not all children and adults with the disorder. For example, some infants and young children who develop autism have an increased rate of head and brain growth during early childhood but some do not. Some older individuals with autism have macrocephaly but most do not. Because associated features occur in some but not all children with autism, they are not required for a diagnosis of autism. Similarly, the absence of any associated feature does not exclude a diagnosis of autism. For example, a normal rate of head and brain growth during infancy or early childhood does not mean that a child does not have autism. The diagnosis of autism is currently based on clusters of significantly impairing characteristic behaviors in the three areas of development in every affected child (reciprocal social interaction, communication, and range and flexibility of interests, behaviors, and tendencies) and clinical onset before three years of age. Biological features that occur in unaffected individuals with the BAP are also associated features. They occur at higher rates in unaffected family members but are not all present in every family member who carries risk genes for autism. Research efforts are underway to discover biological features that are present in all children with autism or at least all children with a biological subtype of autism. As such biological features are discovered, validated and found reliable, it will become increasingly likely that medical tests will be developed to diagnose autism.

Macrocephaly and megalencephaly develop in some but not all children with autism during the first few years of life, the period in which postnatal brain growth is the most rapid and when signs and symptoms of autism become apparent (Courchesne et al., 2003; Hazlett et al., 2005; Lainhart et al., 1997; Sparks et al., 2002). During the final, slower period of brain growth, from roughly 5–12 years of age, rates of macrocephaly remain increased (Lainhart et al., 2006) but brain growth may be less in children with autism compared to that in typical development although the head continues to grow at a normal rate (Aylward et al., 2002). By late adolescence and early adulthood, mean brain volume is no different from that of typical controls even though the rate of macrocephaly is still elevated. Evidence supporting the latter hypothesis, however, comes solely from combining the results of cross-sectional studies of head circumference and brain volume performed at different stages of late development (Lainhart et al., 2005). The trajectory of brain growth during late neurodevelopment in autism is only now being studied longitudinally in the same individuals over time (Bigler et al., 2010; Lange et al., 2010). Megalencephaly is found occasionally in postmortem examination of older individuals with autism, indicating that brain enlargement is still present in some people with autism later in life (Bailey et al., 1998).

Macrocephaly appears to be a component of a more general tendency toward larger head size in autism. The distribution of standardized head circumferences in autism appears unimodal with larger mean and greater variance when compared to that found in typical development (Lainhart et al., 2006). Taller children and adults with autism tend to have larger heads (Lainhart et al., 2006; Sacco et al., 2007) as in typical development. Increased height, however, does not explain all cases of macrocephaly in twins or singletons with autism (Bailey et al., 1995; Lainhart et al., 1997; Lainhart et al., 2006; Miles et al., 2000). Differences between standardized head circumference and height in autism also appear unimodal and symmetric with larger mean and greater variance relative to typical individuals, as in standardized head circumference (Lainhart et al., 2006). Rates of macrocephaly are also increased in other ASDs, such as PDD-NOS (Woodhouse et al., 1996).

Macrocephaly may identify unique subgroups of individuals with autism who have clinical features and risk genes that are different from the majority of individuals with autism who are normocephalic (i.e., have normal sized heads). There are no significant differences between macrocephalic and normocephalic autism with respect to sex ratio, age at onset, history of early regression, verbal and performance IQ and their discrepancy, total ADI-R algorithm score, verbal versus nonverbal language, incidence of seizures, minor/major congenital anomalies, sibling recurrence risk, maternal education, or parental socioeconomic status (SES; Lainhart et al., 2006; Miles et al., 2000). Evidence suggests that macrocephaly in autism is associated with an increased rate of delay in the onset of spoken words (Lainhart et al., 2006), a positive history of allergic/immune disorders in the affected child and first-degree relatives (Sacco et al., 2007), and greater cognitive

processing difficulty when switching from local contextual detail to global processing (White et al., 2009). The latter neuropsychological finding appears to be specific to macrocephaly in autism; it is not found in healthy children with benign macrocephaly or in children with autism who are not macrocephalic. Recent genetic findings, described in the next section, indicate that macrocephaly, particularly extreme macrocephaly, appears to be a genetically informative covariate in autism.

Extreme Macrocephaly

Some children with autism have extreme macrocephaly, a head circumference that is three or more standard deviations above the mean for their age and sex. It is well known in medicine that distributional extremes may arise from developmental mechanisms separate from those affecting central distributional tendencies (Szatmari et al., 2007). Extreme macrocephaly is sometimes associated with a mutation in the PTEN gene on chromosome 10q23.3 (Buxbaum et al., 2007). The mutation may be inherited from a parent or it may occur de novo. When the PTEN mutation is inherited, the transmitting parent often has extreme macrocephaly, and siblings without autism may have macrocephaly and developmental delays. The rate of a mutation in the PTEN gene in children with autism accompanied by extreme macrocephaly is not yet known. When children with autism and any degree of macrocephaly (extreme or not extreme) are examined, the mutation is present in about one in 88 cases (1.2%) (Buxbaum et al., 2007). The rate in epidemiological samples of macrocephalic children with nonautistic idiopathic developmental is not yet known. A mutation in the PTEN gene is found more frequently in clinical samples of referred individuals. In children with macrocephaly whose families were referred for genetic counseling, a PTEN mutation was found in 10.5% of 19 children with ASD and 5% of 20 children with idiopathic nonautistic developmental delay (Orrico et al., 2008). A mutation in the PTEN gene was found in 18.6% of 59 macrocephalic individuals who had a neurodevelopmental disorder and had been referred for mutation testing; about half of the individuals with a PTEN mutation had an ASD and half had nonspecific developmental delay (Varga et al., 2009). The rate of a PTEN mutation increased with increasing head circumference: 11.6% of referred individuals whose head circumferences ranged from two to 3.9 standard deviations above the mean and 23.1% in individuals whose head circumferences were four or more standard deviations above the mean for age and sex (Varga et al., 2009).

PTEN gene: the phosphatase and tensin homolog gene. PTEN encodes a protein involved in tumor suppression and in brain development and brain function, including neuronal survival and growth, synaptic plasticity, memory, and learning (Butler et al., 2005; Buxbaum et al., 2007; Delatycki et al., 2003; Goffin et al., 2001; Greer & Wynshaw-Boris, 2006; Herman et al., 2007; Kwon et al., 2006; Parisi et al., 2001; Zori et al., 1998). A mutation in the PTEN gene may be inherited from a parent or may occur de novo (i.e., occurring spontaneously in the child). When inherited, the recurrence risk for PTEN-related hamartoma tumor syndromes, a spectrum of disorders in which multiple benign tumor-like malformations termed hamartomas that occur in the skin and other parts of the body may be as high as 50% and possibly associated with autism.

Microcephaly

Microcephaly, a head circumference roughly two standard deviations below average for an individual of a particular age and height, occurs in 3–7% of individuals with autism (Fombonne et al., 1999; Lainhart et al., 1997; Lainhart et al., 2006; Miles et al., 2000). In most studies, the microcephaly rate is identical to that of the general population.

Unaffected Family Members

In a twin study of autism, macrocephaly was only found in twins and co-twins who had autism (Bailey et al., 1995). No monozygotic (MZ, identical) or dizygotic (DZ, nonidentical) co-twins who did not have autism, including nonautistic co-twins who had signs of the cognitive-behavioral BAP, were macrocephalic (Bailey et al., 1995). When unaffected parents and siblings are compared to the general population, the rate of macrocephaly appears to be increased significantly in parents but not siblings (Fidler et al., 2000; Lainhart et al., 2006; Miles et al., 2000; Stevenson et al., 1997).

Familial Resemblance

For singletons with autism, resemblance between head circumference in parents and their children with autism is similar to parent-child resemblance in the general population (Fidler et al., 2000; Lainhart et al., 2006). In MZ twins concordant for autism, the within-twin pair variance for head circumference is no less than the between-twin variance (Le Couteur et al., 1996), indicating that head size is equally similar in members of identical twin pairs and in twins from different families. Macrocephaly, in general, does not appear to cluster in child-parent pairs within families; recall, however, the previous exception for extreme macrocephaly. The rate of macrocephaly in at least one parent appears to be identical for macrocephalic and nonmacrocephalic individuals with autism (Lainhart et al., 2006; Miles et al., 2000).

Increased Rate of Head Growth During Infancy

Affected Individuals

An atypical rate of head and brain growth during infancy is found in some but not all children with autism. The percent of children with autism who have an abnormal rate of head and brain growth during infancy varies widely from study to study,

from almost 0 to over 70% (Courchesne et al., 2003; Dawson et al., 2007; Dementieva et al., 2005; Hazlett et al., 2005; Mraz et al., 2007; Torrey et al., 2004; van Daalen et al., 2007). Some studies suggest that the increased rate of growth occurs in early childhood but only after the first year (Dissanayake et al., 2006). One study, which analyzed growth curves for individual children with autism, suggests that an abnormally increased rate of head growth during the first year is followed by a deceleration to a more normal rate of growth from 12 to 36 months of age (Dawson et al., 2007). If the findings are replicated, they would suggest that, for individuals with autism, abnormally increased rate of head and brain growth occurs during the appearance of subtle subclinical manifestations of autism and that a normative deceleration of growth commences as severity of clinical symptoms increase and the full disorder unfolds. Similar to decreases in brain volume with age during later neurodevelopment in autism, an atypical normalization of head and brain growth rates during early childhood may be pathologic.

Unaffected Family Members

Rate of head growth during infancy appears to be increased in some very young siblings of children with autism. Increased head and brain growth have been found both in infant siblings who have high symptom levels and are therefore at highest risk of a future autism diagnosis, and in young siblings who have few symptoms and are most likely to be unaffected (Elder et al., 2008). A dose-response effect may exist, in which "dose" refers to the level of autistic symptoms observed by parents. Young siblings who showed the highest level of autistic symptoms on the Modified Checklist for Autism in Toddlers and the Early Developmental Interview (Werner et al., 2005) had the largest head circumferences at 12 months of age. Children who had the largest head circumferences at 12 months of age had the greatest observed deceleration in rate of head growth thereafter.

Facial Features

Facial features are of interest in autism as potential intermediate phenotypes or covariates that may identify genetic and other etiological subtypes of the disorder (Miles et al., 2005). Prenatal craniofacial development is related to prenatal brain development, and many risk genes involved in abnormal craniofacial development have been discovered (Kjaer, 1995; Wilkie & Morriss-Kay, 2001).

Affected Individuals

Craniofacial anomalies, usually minor but sometimes major, are known to occur in about one third of individuals with idiopathic autism (Miles et al., 2000), and a recent meta-analysis showed a high overall effect size for an increased minor anomaly score (Cohen's D = 0.84; Ozgen et al., 2010). Significant facial asymmetry has been found using modern methods of objective measurement in a large sample of boys with multiplex autism, with case-control differences in facial depth in the supra- and periorbital region overlying the right hemisphere frontal pole of the brain (Hammond et al., 2008).

Unaffected Family Members

Right-dominant facial asymmetry, similar to that found in the boys with autism described above, has also been found in unaffected mothers but not fathers in multiplex autism families (Hammond et al., 2008). The pattern of facial asymmetry correctly classified two thirds of the unaffected siblings (sight unseen) in the multiplex families as having facial features closer in similarity to the average facial features of the autism group than those of the typically developing control group.

Summary of Potential Craniofacial Features of the Biological BAP

Table 28B-1 is a summary of present-day research findings on head circumference, macrocephaly, and early childhood head growth rate in relatives of individuals with idiopathic autism (see Appendix B).

Lack of familial resemblance between affected individuals and unaffected co-twins, parents, and siblings nullifies the hypothesis that macrocephaly is usually inherited with autism in families. In MZ twins and nuclear families, macrocephaly associated with idiopathic autism is increased in affected individuals but not in unaffected twins or siblings. Macrocephaly does not appear to cluster in families. Findings to date suggest that affected macrocephalic individuals are no more likely to have a parent with macrocephaly than are affected normocephalic individuals. The biological underpinnings of these phenomena are yet to be understood. Extreme macrocephaly may provide an important exception and a reliable, genetically informative covariate in autism that may identify a subgroup of affected individuals and families with a distinct set of risk genes. Macrocephaly may be genetically linked to autism in these uncommon families.

Current findings also suggest that an atypical pattern of head and brain growth during very early childhood and possibly into adolescence may prove to have a stronger association with autism in general than macrocephaly itself. A more refined understanding of macrocephaly associated with autism is needed, including associated neuropsychological features and changes in brain structure, white matter microstructure, and functional connectivity. In addition, segregation of specific atypical patterns of head growth during early and later childhood within autism families needs to be tested.

A pattern of rightward facial asymmetry has been identified as a potential intermediate phenotype in at least a subgroup of multiplex autism families. Craniofacial features can now be easily, objectively, and reliably measured using 3D digital photogrammetry (Wong et al., 2008) and other developing technologies.

⬚
Section 2. Brain Structure, Function, and Connectivity

Total and Regional Brain Volume, Gray Matter Volume, and White Matter Volume

Although there is a multitude of structural neuroimaging studies of children and adults with autism, there are very few corresponding studies of unaffected twins, parents, and siblings. This section describes only the strongest replicated results to date in affected individuals and on regions of the brain that have been examined in unaffected relatives. For twin studies, data are not yet available on brain structure alteration frequencies in nonautistic co-twins compared to the co-twins in the general population; only comparisons to singletons and familial resemblance within twin pairs have been reported.

Affected Individuals

According to the combined findings of cross-sectional imaging studies, total brain volume (TBV) in singletons is statistically increased in young children but not older individuals with autism (reviewed in Lainhart et al., 2005; Rojas et al., 2004). Nevertheless, a meta-analysis of imaging studies published between 1984 and 2006 (Stanfield et al., 2008) showed significantly larger brain volumes in autism without any significant age-related effect (mean age of 3.9 to 30.3 years across studies) or IQ, with overall effect sizes of 0.32 for TBV, 0.51 for total intracranial volume (TICV) and 0.62 for the cerebrum. Generalized increases in total gray matter (GM) and white matter (WM) volumes have been found in very young children with autism (Hazlett et. al., 2005). Volumetric differences in older affected individuals vary greatly from study to study but appear to be more striking in GM than in WM (Lainhart et al., 2006), appearing as complex patterns of localized increases and decreases in left temporal lobe GM, parietal lobe GM bilaterally, and, in some studies, the occipital and frontal lobe GM (Brun et al., 2009; Hardan et al., 2006; Hyde et al., 2009). A cross-sectional study of cortical thickness suggests an age by group interaction; cortical thickness decreased between 10 and 60 years of age in typically developing but not in ASD groups (Raznahan et al., 2009). Cortical thickness was decreased in children and increased in adults with ASD in most but not all studies (Raznahan et al., 2009; Jiao et al., 2009, Hyde et al., 2009; Hadjikhani et al., 2006, Hardan et al., 2006).

Unaffected Family Members

A voxel-based analysis comparing parents of children with autism and control parents found widespread local increases in GM volume in frontal, occipital, parietal, and temporal lobes (Peterson et al., 2006). Increased GM volume in the parents of children with autism included areas involved in "mentalizing," i.e., considering the mental state of others, important in empathy, which is known to be impaired in many individuals with autism. Large increases in GM volume have also been seen in the mirror neuron system, regions important in the development of social cognition and implicated in autism. Decreased GM volume has been observed in vermal lobules XIII and IX of the left cerebellum (Peterson et al., 2006). Cortical thickness has not yet been examined in unaffected family members.

No differences between unaffected parents and controls have been found for TBV, TICV, total GM volume, total WM volume, lobar volumes, or the lateral and third ventricles (Rojas et al., 2004; Palmen et al., 2005b; Peterson et al., 2006). The absence of increased TICV in parents differs from the results of head circumference studies that report increased macrocephaly rates in parents of children with autism. This discrepancy does not appear to be due to changes in skull thickness that could increase head circumference but not TICV (Tate et al., 2007) but may be due in part to a detection problem caused by the generally smaller sample sizes of parents in imaging studies compared to those in head circumference studies.

Familial Resemblance

Familial resemblance of TBV in autism has not yet been examined in parent-affected child or unaffected-affected sibling pairs. A brain volume study of MZ twin pairs with autism and twins discordant for autism (most of the discordant twins have PDD-NOS or cognitive/behavioral characteristics of the BAP) shows twin resemblance on TICV, TBV, and cerebral and lobar WM volumes (Kates et al., 2004). The intraclass correlation coefficients for pairs concordant and discordant for autism do not significantly differ, and the correlations are similar to those reported in typically developing twins (Wallace et al., 2006). Patterns of cerebral cortical folding, assessed with a gyrification index, are highly discordant across MZ twin pairs that included twins concordant and discordant for autism (Kates et al., 2009).

Amygdala and Hippocampus

Affected Individuals

Replicated recent findings in volumetric studies of the amygdala show increased mean volume in preschool-age children with autism (Mosconi et al., 2009; Schumann et al., 2009) and decreased volume in older individuals (Nacewicz et al., 2006; Rojas et al., 2004; Salmond et al., 2003). Potential functional implications of abnormal volumetric development of the amygdala are found in a study of preschool-age children with autism, where increased size of the amygdala was correlated with severity of social-communication impairment at 5–6 years of age (Munson et al., 2006; Schumann et al., 2009). Some studies of children and young adults with autism have found no differences from typically developing controls (Corbett, 2009; Palmen et al., 2006; Zeegers et al., 2009). The recent meta-analysis of very heterogeneous studies of amygdala volume in autism published up to the year 2006 found

no significant group effect and an age-related decrease in autism relative to controls (Stanfield et al., 2008).

A significant degree of heterogeneity is also present in studies of hippocampal volume in autism. Although hippocampal volume appears stable with age and unaffected in autism in a recent meta-analysis (Stanfield et al., 2008), several other studies have reported increased volume of the left hippocampus in older children and adults with autism (Rojas et al., 2004; Rojas et al., 2006; Salmond et al., 2005). Subtle shape differences have also been observed (Dager et al., 2007; Nicolson et al., 2006).

Unaffected Family Members

Mean amygdala volume appears to be decreased in unaffected siblings (Dalton et al., 2007), while parents of children with autism appear unaffected (Rojas et al., 2004). Mean left hippocampal volume, by manual tracing, was larger in parents of simplex children with autism compared with control adults (Rojas et al., 2004) but this finding was not replicated in a voxel-based comparison of parents (Peterson et al., 2006).

Familial Resemblance

In MZ autism twins pairs (five co-twins with autism, four with PDD-NOS, and five with no diagnosis), the intra-twin correlation coefficients for amygdala and hippocampal volumes were 0.66 and 0.91 respectively (Mitchell et al., 2009). Resemblance has not yet been examined within families.

Corpus Callosum and Caudate Nucleus

Affected Individuals

Decreased size of the corpus callosum in autism is a highly replicated finding (reviewed in Lainhart et al., 2005), including a small yet significant effect size (-0.28) found in a recent meta-analysis (Stanfield et al., 2008). Increased caudate volume has also been observed, with a moderate effect size (0.41) in studies published before 2007 (Stanfield et al., 2008). More recent studies are in agreement and show that caudate volume is associated with repetitive behaviors in autism (Langen et al., 2007; Langen et al., 2009; Rojas et al., 2006). Cross-sectional data suggest aberrant volumetric changes in the caudate between childhood and young adulthood (Langen et al., 2009). The corpus callosum and caudate have not yet been examined in unaffected family members.

Cerebellum

Affected Individuals

Increased cerebellar volume (effect size 0.72) and small to moderate effect sizes for reduced volumes of vermal lobules VI–VII and VIII–X (-0.27 and -0.43, respectively) have been reported (Stanfield et al., 2008). Studies of vermal lobules VI–VII produced heterogeneous results affected by age and

IQ; increasing age and IQ were associated with smaller vermal area (Peterson et al., 2006; Stanfield et al., 2008).

Unaffected Family Members

The small number of parents of children with autism studied to date show no differences in total cerebellar volume relative to control adults (Palmen et al., 2005b), but increased GM volume in the left cerebellum and decreased GM volume in verbal lobules XIII and IX has been suggested (Peterson et al., 2006).

Brain Stem

Affected Individuals

Reduced midbrain volume has been observed in autism (effect size, -0.77), while the medulla and pons appear unaffected (Stanfield et al., 2008). The reliability of these findings, however, is compromised by large observed between-study heterogeneity. The brain stem has not been examined in unaffected relatives of autism probands.

Brain Function and Brain Connectivity

In other neuropsychiatric disorders, neurophysiological measures of brain function are among the strongest candidates for genetically informative IPs. In autism, these measures include eye movements ("eye-tracking"), neural activity measured on the scalp with electroencephalography (EEG) and magnetoencephalography (MEG), and in vivo neuroimaging of neural activity using positron emission tomography (PET), single-photon computed tomography (SPECT), and functional magnetic resonance imaging (fMRI). PET and SPECT studies of the serotonin system in the brain are reviewed in Section 3.

Affected Individuals

Though not yet reported in unaffected family members, several MEG findings in individuals with autism are particularly noteworthy as potential intermediate phenotypes (reviewed in Roberts et al., 2008). In typically developing children and adults, peak magnetic responses evoked by auditory stimuli presented at 50 and 100 milliseconds earlier (M50, M100) measured in time windows of short duration (roughly 40 milliseconds) indicate very early rapid temporal signal processing in the auditory cortex. In addition, the expected M100 in the right hemisphere is greater than that in the left hemisphere of the brain (termed "rightward asymmetry"). Children with autism, however, exhibit M100s that are equal on the right and left (hemispheric symmetry). This lack of typical asymmetry may be related to language impairment in the disorder (Schmidt et al., 2009). The delay ("latency") of right-hemisphere M50 in childhood appears to account for a substantial amount of variance in overall language ability in specific language impairments and in autism. A delay time of 84.6 milliseconds between

stimulus presentation and the initial evoked response ("latency cutoff") has been found to indicate receptive language impairment in children with 70% sensitivity and 92% specificity (Oram Cardy et al., 2008).

A variety of neurophysiological measures have shown significant case-control differences in samples of individuals with autism and have been used to test family members. Differences in individuals with autism include abnormalities of eye-gaze fixation, evoked response, local oscillatory activity, localization of brain areas activated and rapid temporal aspects of brain activation in response to a variety of stimuli.

A preliminary family study using SPECT reports a variety of patterns of hypoperfusion in frontal, parietal, and temporal cortex as well as the caudate nucleus in 8 affected children (Degirmenci et al., 2008).

Unaffected Family Members

Parents and unaffected siblings have shown decreased perfusion in frontal and parietal regions, and siblings have shown additional hypoperfusion in the caudate nucleus (Degirmenci et al., 2008). Eye-tracking studies have indicated that unaffected siblings of children with autism have decreased fixation on eyes when looking at faces, similar to the decreased fixation found in individuals with autism (Dalton et al., 2007). This study also found that in individuals with autism, unaffected siblings, and typically developing controls (to a lesser extent), variation in the duration of eye fixation is strongly related to variation in the extent of right and left fusiform gyri activation measured by fMRI. No significant association was found between eye fixation duration and amygdala activation in individuals with autism in unaffected siblings or controls (Dalton et al., 2007). Parents of children with autism have exhibited atypical evoked responses when looking at faces (Dawson et al., 2005), atypical patterns of fMRI brain activation during visual search and empathy tasks (Baron-Cohen et al., 2006), and decreased synchronization of oscillatory brain activity as recorded by MEG (Rojas et al., 2008). Taken together, these atypical responses may indicate deficits in the binding of perceptual stimuli and abnormalities in neuronal connectivity and function in specific cortical areas.

Summary of Brain Structure, Function, and Connectivity in the Biological BAP

Table 28B-2 is a summary of structural brain imaging studies of unaffected twins, parents, and siblings to date. Table 28B-3 is a summary of brain function and brain connectivity studies to date. (See Appendix B for both tables.)

Structural imaging data contributed by unaffected relatives of children with autism are far too limited to draw any preliminary conclusions about whether or not particular alterations in brain volume may be part of the BBAP. Regional increases in GM volume in localized areas in all lobes of the brain and in the cerebellum in parents and decreased amygdala

volume in unaffected siblings have yet to be replicated. Inconsistent differences in the left hippocampal volumes of parents may be due to heterogeneity of the BBAP, but the small sample sizes and the variety of image analysis methods used to date contribute to this ambiguity.

Structural imaging studies of unaffected family members are severely lacking, and testing for familiality nonexistent. Decreased size of the corpus callosum and midbrain, increased caudate volume, and emergent findings of regional alterations in cortical thickness have been found and replicated in children and adults with autism, but have yet to be evaluated in unaffected relatives. Twin studies have the potential to help understand how variations in brain structure and function mediate genetic and environmental effects on cognitive, behavioral, and emotional characteristics of autism and the BAP. Imaging studies comparing autistic and nonautistic members of twin pairs are in very early stages of development (Belmonte & Carper, 2006; Kates et al., 1998; Kates et al., 2004; Mitchell et al., 2009), have extremely small sample sizes, and thus have very limited statistical power to detect any differences if they exist. Also, it is not clear if these preliminary findings are due to autism or confounding factors related to twinning. To date, neuroimaging studies of twins with autism have not considered the prenatal, perinatal, and postnatal factors known to differ in twins and singletons or perinatal factors such as birth order effects in twinning that may also differ and influence brain development. Carefully designed studies that enable the direct comparison of MZ and DZ twins with autism and control twins are needed to evaluate these potentially separable effects.

The many mixed, inconsistent, and negative volumetric findings in children and adults with autism may suggest that the future yield of studies examining alterations in regional brain volumes as possible components of the BBAP is low except in a few brain regions. Recent studies showing complex patterns of increased and decreased GM volume within brain structures suggest that newer methods allowing more detailed examination of anatomy may be much more powerful than older methods that yielded only volumetric measures of whole structures. Almost all volumetric brain imaging studies in autism have been cross-sectional in design, and many age-related changes that have driven research in the field are based on cross-sectional data combined across studies. Limited conclusions about developmental processes can be drawn from cross-sectional data, and more longitudinal studies are needed (Kraemer et al., 2002). Longitudinal growth trajectories may be more informative phenotypic measures in affected and unaffected individuals than cross-sectional volumes at any given age. Many neuropathological changes due to autism may be detectable only at higher resolutions than usually used. Methods that bridge the gap between in vivo (during life) imaging studies of children and adults with autism at currently available resolutions and in vivo nonhuman studies at the very high resolutions provided by bright field, immunofluoresence, and electron microscopy are critically needed.

The identification of specific measures of neural function as potential IPs in autism research is severely lacking when compared, for instance, to corresponding research in schizophrenia and bipolar disorder (Ivleva et al., 2009; Jeste & Nelson, 2009). Structural and functional brain connectivity studies of unaffected relatives are lacking, as are tests of connectivity pattern aggregation within families. Normal short-range and intra- and interhemispheric long-range connectivity is essential between cortical areas whose functions must be tightly synchronized within very brief and rapidly evolving temporal windows to enable efficient and effective information processing. The paucity of studies of long-range underconnectivity between cortical areas in autism seems at odds with this major, replicated finding that is currently driving much interdisciplinary research in the field.

Section 3. Other Biomedical Features

Serotonin

In children with autism, elevated levels of serotonin in the blood, a measurable biological trait, was first reported in 1961. This finding remains one of the oldest and most robust biological findings in autism research (Anderson, 2002).

Box 28–4

Serotonin. Serotonin is a neurotransmitter that plays an essential role in sleep, appetite, mood, anxiety, social affiliation, impulsivity, arousal, aggression, and reaction to stress (Anderson, 2002). Brain serotonin was discovered in 1953. Serotonin, often abbreviated as 5-HT (5-hydroxytryptamine), is synthesized from the dietary amino acid precursor tryptophan and found in the brain, intestines, blood platelets (regulating blood clotting), blood vessels, and in the muscle of some organs. Serotonin plays critical roles in both fetal brain development and postnatal brain function throughout life, is present in the oocyte (egg cell), and is involved in very early embryonic patterning (Levin et al., 2006), in embryonic thalamocortical axonal guidance, in the formation of cortical sensory maps (Bonnin et al., 2007), and in craniofacial development (Moiseiwitsch, 2000).

Affected Individuals

Hyperserotonemia has been found repeatedly in individuals with autism. Mean levels of blood serotonin are 25–50% higher in autism than in typical control samples. A recent study shows a bimodal distribution with roughly 50% of affected children and young adults having blood serotonin levels greater than one standard deviation above that of typically developing controls; 20% have levels greater that two standard deviations above this normal level compared to 0% typically developing controls (Mulder et al., 2004). The same study showed that although a small proportion of the nonautistic comparison

children with mental retardation have hyperserotonemia, they do not have increased mean levels of serotonin, suggesting some specificity to autism. Hyperserotonemia has also been found in children with PDD-NOS (Mulder et al., 2004).

> **Hyperserotonemia**: elevated levels of serotonin in whole blood or platelet-rich plasma—a measurable biological trait possibly linked genetically to autism.

Several abnormalities of the serotonin system in the brain in autism are noteworthy. There is evidence of autism-related altered functioning of serotonin receptors in the brain from at least the late 1980s (McBride et al., 1989). A number of PET studies show alteration of brain serotonin synthesis and atypical neurodevelopmental trajectories in children with autism (Chugani et al., 1997; Chugani et al., 1999). In children with autism 2–4 years of age, increases in total and frontal lobe cortical GM volume of 10% and 16% respectively are reported to be associated with a particular form (allele) of one of the serotonin transporter genes (the 5HTTLRP short polymorphism of the SLC6A4 gene), a relationship that is absent in adults with the disorder (Raznahan et al., 2009; Wassink et al., 2007). The association between brain anatomy and serotonin transporter genotype in children but not adults with autism suggests that the effects of serotonin transporter genes on brain morphometry may be age-dependent.

By employing SPECT, a preliminary but important study of adults with Asperger's syndrome has provided evidence of decreased cortical density of 5-$HT2_A$ serotonin receptors, as indexed by decreased receptor binding, relative to that of typical control adults (Murphy et al., 2006). Decreased binding is found in the anterior and posterior cingulate, bilateral frontal, and superior temporal lobes and in the left parietal lobe. Decreased receptor binding in the cingulate and frontal cortices is related to increased severity of impairment in reciprocal social interaction as measured by the Autism Diagnostic Interview-Revised (ADI-R). Decreased serotonin transporter binding is also found in individuals with autism. Adults with autism show highly significant decreases in serotonin transporter binding in widespread areas throughout the brain, including in all four lobes, limbic and subcortical regions, and the cerebellum (Nakamura et al., 2010). Children and adolescents with autism appear to have a decrease in cortical serotonin transporter binding, particularly in the medial frontal cortex, which is more pronounced with increasing age (Makkonen et al., 2008).

Unaffected Family Members

The observation that hyperserotonemia is also present in a sizable proportion of unaffected relatives is an important and complex finding that is not yet fully understood. A recent PET study of unaffected parents of children with autism and control adults has shown that mean cortical serotonin receptor binding potential in unaffected parents is decreased in all four lobes of the brain (effect sizes ~0.9), its standard deviation is reduced by 50%, and it is negatively correlated with

blood platelet serotonin levels but not in controls (Goldberg et al., 2009).

Familial Resemblance

Hyperserotonemia in autism is familial and appears to be related to the degree of genetic liability to autism and recurrence risk (Abramson et al., 1989; Cook et al., 1990; Leboyer et al., 1999; Leventhal et al., 1990). Serotonin levels are elevated in multiplex individuals compared to simplex individuals with autism (Abramson et al., 1989; Cook & Leventhal, 1996; Piven et al., 1991). Serotonin levels are also elevated in children with autism compared to their first-degree relatives and are correlated positively with those of their unaffected parents and siblings (Leventhal et al., 1990). First-degree relatives are 2.4 times more likely to be hyperserotonemic if the child with autism is hyperserotonemic. Further research on molecular genetic differences in the serotonin system of unaffected relatives who are hyperserotonemic compared to relatives who are not is underway (Cross et al., 2008).

Summary of Serotonin Components of the Biological BAP

Table 28B-4 is an up-to-date summary of brain and blood serotonin system studies in autism and unaffected relatives and siblings (see Appendix B).

Hyperserotonemia meets criteria for a potential genetically informative IP, thus a possible component of the BBAP. It is increased in affected individuals and in unaffected parents and siblings and also tends to cluster in the families of hyperserotonemic individuals with autism. Although hyperserotonemia in autism has been known for many years, its genetic and molecular mechanisms remain unknown. Emerging biostatistical evidence of associations between brain and blood platelet levels of serotonin and brain structure and function may provide further clues. To our knowledge, serotonin transporter and serotonin receptor densities have not yet been studied in the same individuals to help discern their functional relationship in autism. Further integrative research advances in molecular genetics, animal models, neuroimaging, and biostatistics are needed for a thorough understanding of this oldest candidate biomarker in autism.

Immune Factors

Normal functioning of the immune system requires finely balanced, complex interactions of its many components, including a wide variety of immune cell types, proteins, and other biochemicals, tissues, and organs of the body. A number of studies have investigated the potential dysfunction of the immune system in individuals with autism and their relatives. The work of the late Dr. Reed Warren in Utah during the 1980s and early 1990s first brought the potential role of immunologic factors and the genes that control them to the forefront of autism research (Warren et al., 1986). The plausibility

---

Box 28–5

Biological marker (biomarker): a characteristic that is measured objectively and evaluated as an indicator of normal biological processes, pathogenic processes, or pharmacologic responses to a therapeutic intervention (Biomarker Definitions Working Group, 2001). One may refer to a characteristic or phenotype as a biomarker if it is minimally affected by the will, behavior, and attitudes of subjects or the evaluator or by transient environmental influences (Kraemer et al., 2002). If such a characteristic or phenotype is a statistic derived from an image, it must also be shown to be on a causal pathway of a clinical endpoint to fulfill the additional requirement for an imaging biomarker. The potential to identify useful biomarkers of autism will be greatly expanded by the further understanding of its pathogenesis. At present, however, without useful theory or models of its pathogenic underpinnings, biomarker research in autism is and needs to be conducted in the opposite direction.

---

of immune system differences in unaffected family members was soon introduced. Dr. Warren was very careful in his earliest autism research to focus his immune hypotheses and their specificity on some but not all children with autism and their families, positing the existence and identifiability of familial subgroups in which immune factors were somehow linked to the disorder. He also acknowledged that if immune system abnormalities were involved in some cases of autism, then they may be related directly or indirectly to its pathogenesis, and hence that their presence may contribute to autism risk or be a consequence of the risk or atypical brain development. Recent studies employing advanced immunologic and molecular genetic technology have provided convergent evidence supporting Dr. Warren's original hypotheses.

Affected Individuals

In autism, studies have found abnormalities of cell-mediated and antibody-mediated components of the adaptive immune system that responds to new health threats throughout the lifespan. A preliminary comprehensive examination of immune components in individuals with autism and their unaffected siblings suggests subtle but important impairment of the cell-mediated part of the immune system in some children with autism (Saresella et al., 2009). Alterations are found in the levels of a number of different types of cells in different stages of immune function maturation and in levels of the substances they secrete (cytokines) that are important in cellular communication. Decreases in mean levels of fully differentiated cell subtypes that direct other immune cells (CD4+ T lymphocytes, also known as "helper" cells) have been observed. Mean levels of subtypes of "killer cells" (CD8+ T lymphocytes) that kill cells dangerous to the body, such as cells infected with viruses, are altered. Levels of "naive killer cells" (cells that have not yet been exposed to antigens such as viruses) are increased and levels of "effector memory cells" (cells that remember and

quickly recognize infectious agents long after the original infection) are decreased (Saresella et al., 2009). A decrease in mean levels of immunoglobulins, specifically IgG and IgM, has been observed recently in a sample of individuals with autism compared to typically developing controls (Heuer et al., 2008). A minority of children with autism appear to have antibodies to fetal and adult brain proteins and to brain proteins from the basal ganglia, frontal lobe, cingulate gyrus, and cerebellum (Silva et al., 2004; Singer et al., 2006; Zimmerman et al., 2007; Wills et al., 2009). Finally, an association of a functional variant of the gene for the macrophage inhibitory factor (MIF) with autism and increased mean levels of plasma MIF indicates abnormality of the innate immune system that provides natural defenses against invading microorganisms (Grigorenko et al., 2008). The variant of the MIF gene appears to be associated with stereotyped repetitive behaviors in autism.

> **Macrophage migration inhibitory factor (MIF):** a cytokine protein encoded by a gene on chromosome 22q11.2. MIF is part of the innate immune system, the body's first-line defense system against infection, and is produced by a wide variety of immune cells including macrophages and by cells and tissues of the body that are in direct contact with the natural environment such as the lungs, the skin, and the gastrointestinal and genitourinary tracts. MIF is also produced by endocrine tissues involved in the body's response to stress: the hypothalamus, pituitary, and adrenal glands (Calandra & Roger, 2003). MIF activates macrophages and T cells, promoting the function of both innate and adaptive immune responses. Although it is an important general defense against pathogens that cause infections, abnormally high levels during infections or at the wrong time could potentially affect early brain development.

Unaffected Family Members

The finding that antibodies to brain proteins are found in some children with autism led to studies that tested the hypothesis that in some cases of autism maternal antibodies to brain tissue may cross the placenta during pregnancy and affect the brain of the developing child. These studies yielded tantalizing preliminary evidence in mice and rhesus monkeys showing that offspring had behavioral deficits including hyperactivity and stereotypic behaviors (Dalton et al., 2003; Martin et al., 2008). A number of human studies find antibodies to brain tissue in unaffected mothers of children with autism and increased rates of autoimmune diseases in mothers and other relatives (Braunschweig et al., 2008; Comi et al., 1999; Croen 2005; Croen et al., 2008; Molloy et al., 2006; Singer et al., 2008; Sweeten et al., 2003). Several studies have measured the rates of autoimmune diseases in relatives of individuals with autism but not yet in these individuals themselves. A very large epidemiological study of autoimmune disorders in parents and siblings of children with autism, using the Denmark Medical Registry, found that of the 3325 children studied who had ASD, including 1089 with autism, 6.8%

had a parent or sibling with a diagnosed autoimmune disease prior to their diagnosis of autism. This study confirmed an increased risk of autism in children born to parents who have type-1 diabetes and an increased risk of an ASD when mothers have rheumatoid arthritis or celiac disease (Atladóttir et al., 2009). It is important to note, however, that the majority of children with autism are born to parents who do not have these autoimmune disorders. Unaffected children in autism families show signs of immune dysregulation similar to the affected children with autism in a preliminary study (Saresella et al., 2009). If confirmed by replication and familial resemblance is demonstrated, the findings described here would indicate that a particular pattern of immune dysregulation is an IP of an immune-related subtype of autism.

Familial Resemblance

It appears that only one study to date has investigated the intrafamilial resemblance of immune findings, specifically those protein bands reactive to human brain tissue, in children with autism and their parents (Silva et al., 2004). No significant correlations were found.

Summary of Potential Immune Factors of the Biological BAP

Table 28B-5 is an up-to-date summary of studies of the immune system in children and adults with autism and their affected and unaffected siblings and first-degree relatives (see Appendix B).

Preliminary studies point to candidate intermediate phenotypes that may be found in patterns of immune system imbalance in some autism families. The association between autism and specific types of autoimmune diseases in fathers and mothers suggests the involvement of various a number of complex mechanisms. There appear to be at least two potentially separable mechanisms operating independently or in tandem: (1) a common genetic background may increase risk of autoimmune disease in a parent and autism in an offspring, and (2) the effects of maternal autoimmune disease during pregnancy may alter the intrauterine environment of the developing child in a way that increases autism risk. It appears certain that parental history of specific autoimmune diseases identifies a potential and very important etiological and clinical subtype of autism. Twin studies and carefully designed family studies are needed to further clarify what immunological characteristics are genetically informative biological phenotypes, which are not, and how immunological factors are related to alterations in brain development.

Section 4. Classification Research

The utility of any modern scientific method can be measured in large part by its context-specific predictive performance.

One important goal of scientific research of the BBAP is to employ routine medical tests, such as blood tests, eye-tracking measures, and brain scans, to phenotype individuals with autism or identify those at risk for autism objectively. Biological phenotypes are needed to correctly identify babies who carry autism risk genes and are therefore at increased risk of developing the disorder. If they become available, such biological phenotypes could be used to diagnose individuals with specific subtypes of autism, to identify unaffected family members who carry risk genes for autism, to help predict long-term outcome, and to determine what interventions are most likely to be effective for individuals at different stages of the disorder. Biological phenotypes have the potential to bring the practice of personalized medicine to autism, to make preventive interventions tailored specifically to the needs of individuals across the lifespan and improve the lives of people with autism or at risk for autism.

Classification research in autism seeks to discover biological methods that identify individuals with the disorder and discriminate them from individuals who are typically developing and individuals who have other developmental and neuropsychiatric disorders. Classification methods must have very high sensitivity, specificity, reliability, and predictive performance to be clinically useful. Table 28B-6 is a summary of current published findings (see Appendix B). Intensive research is currently underway to develop and test additional novel classification methods not summarized in Table 28B-6 in autism and their extensions to the BAP. Diffusion tensor imaging (DTI) technology is being developed to identify valid, accurate, and reliable autism versus control differences in white matter microstructure in key regions of the brain (Lange et al., 2010 and to locate differences in the shape and diffusion properties of white matter fiber bundles (Chung et al., 2010; Fletcher et al., 2009). Functional MRI is being used to measure functional brain connectivity in the default mode network and during performance of specific tasks (Anderson et al., 2010). If biological phenotypes with high classification ability for autism are discovered, it will be important to determine if they can correctly classify a large proportion of unaffected individuals who are related to persons with autism (BAP sensitivity), and individuals who do not have any relatives with ASDs (BAP specificity). Only one study that objectively measured right-dominant facial asymmetry (Hammond et al., 2008) tested the sensitivity of this measure in unaffected family members (67% in siblings) and none, to our knowledge, have tested specificity or replicated these findings in independent samples.

Summary of Classification Research in the Biological BAP

Table B6 is a summary of autism classification methods published to date, providing the proportion of individuals with autism who were identified correctly by the method as indeed having autism (sensitivity) and the proportion of nonautistic individuals who were identified correctly by the method as

unaffected (specificity). Also included is a biological measure that may identify children with receptive language impairment associated with autism and other disorders.

Classification research in autism is producing many exciting preliminary results. Brain imaging analysis, electrophysiological methods, and 3D measures of craniofacial features now provide some ways to find patterns of alteration that are associated with autism and that perform well in discriminating individuals with autism from typically developing individuals. Among these are alterations in brain structure sizes, gyral morphometry, regional cortical thicknesses, spatial distributions of GM and WM density, white matter microstructure, reconstructed WM tract shapes, ocular function, and facial asymmetry. Studies are now needed that determine if the findings can be replicated in independent samples. To our knowledge, none have been replicated to date, except for Lange et al. (2010). Also required are performance-based comparisons of classification methods, testing discriminating ability for autism subgroups, including group comparisons of individuals with other developmental and neuropsychiatric disorders, and extensions to unaffected relatives.

Conclusion

How far has autism research progressed in identifying alterations in development, structure, and function of the brain and other body systems that indicate liability to autism in families, not only in individuals with the disorder but also in unaffected relatives? This chapter concludes with a critical appraisal of progress in identifying components of the biological BAP and suggested guidelines for future research.

Most biological alterations hypothesized to be members of the BAP do not meet genetic epidemiology criteria for potential genetically informative intermediate phenotypes. Biological findings associated with autism result from small-sample and very heterogeneous case-control studies lacking probative power. Many relevant published reports include only significant differences between group means. Typically, individuals in these groups are not phenotyped on the trait or characteristic of interest. The ability of the biological finding to classify individuals is rarely tested. Even when a biological feature is used to phenotype individuals, the performance of the classification method has yet to be tested in an independent sample, a major omission which can in some cases yield misleading and spurious results perhaps due to circular analysis (Kriegeskorte et al., 2009) and other analytic traps. In addition, most of the biological findings associated with autism have yet to be investigated in unaffected relatives. Some biological features studied in unaffected parents or siblings have not yet been measured in individuals with autism. When affected and unaffected relatives have been examined, they are usually not related, and thus familial aggregation cannot be determined. Finally, the relative performance of biological features that are increased in affected and unaffected relatives

have yet to be compared to that of ASDs per se in identifying individuals who are likely to carry autism risk genes. In order to be more useful than ASDs per se, the intermediate biological phenotype should be at least 50 to 100 times more common in members of autism families than in general population (Szatmari et al., 2007). Biological alterations will be most helpful in identifying unaffected relatives who may have liability to autism when the alterations have high sensitivity and high specificity.

Biological Broader Autism Phenotype findings to date are consistent with biological subtypes of autism and risk genes being inherited or occurring de novo. Although macrocephaly does not appear to show familiality, extreme macrocephaly may cluster in a subset of autism families. Approximately 4.8% of individuals with autism have extreme macrocephaly (Lainhart et al., 2006), and these individuals appear to be at increased risk of having inherited or de novo mutations in the PTEN gene. Case series studies suggest that when the mutation is inherited, macrocephaly and developmental delay may be inherited along with autism in these families. Similarly, hyperserotonemia, which occurs in approximately 20% of individuals with autism, may identify a biological subtype of autism and autism families. Present-day findings suggest that the biological broader phenotype of autism is heterogeneous, as is autism itself (Geschwind, 2009). Alterations of bodily structure and function that are linked genetically to autism may not be identical in all families.

Major advances in Biological Broader Autism Phenotype research require innovative cross-disciplinary combinations of the scientific methods of autism clinical research, neuroscience, genetic epidemiology, neurostatistics, immunology, and other areas of medicine, in addition to novel ideas concerning developmental neuropsychiatric phenotypes. Recent genotype-phenotype relation discoveries in neuropsychiatry have shown strikingly complex and heterogeneous phenotypes associated with specific genetic loci (see Suggested Reading). Neuroimaging and neurophysiologic research are being rapidly transformed by powerful new ways of examining brain developmental, microstructure, function, local and global neural networks, connectivity, and biochemistry. As described in the Classification Research section of this chapter, autism research is on the brink of an explosion of individual biological characteristics as potential biomarkers and intermediate phenotypes of autism and the broader autism phenotype. Which of these will meet the criteria for a potentially informative intermediate phenotype, if any? Which combinations of biological phenotypes suggested by classification methods have the best diagnostic and subtyping ability for affected individuals and for identifying unaffected relatives who may have autism risk genes? How are the various phenotypes related within and across affected individuals and their families? What is the molecular biological and microstructural basis of the phenotypes? How do these phenotypes develop in autism families, and why? Do the phenotypes only discriminate individuals with autism and their relatives from typically developing individuals and their relatives, or are they also able to separate individuals with other developmental and neuropsychiatric disorders? Over three decades since the Broader Phenotype of Autism was first described, autism research now has the collaborative methods and technology to determine exactly what is inherited with autism in families.

Challenges and Future Directions

- Biological autism research needs to progress from a predominant focus on case-control mean differences to examination of distributions, classification and phenotyping of individuals, and testing for sensitivity, specificity, accuracy, and positive and negative predictive value.
- Large-scale biological studies of individuals with autism, their families, and control families, with replication in independent samples, are needed. The most effective studies will combine epidemiological and advanced statistical methods with reliable neuroimaging and other sophisticated biological phenotyping.
- Etiological heterogeneity, de novo as well as inherited mutations, phenotypic complexity, and individual heterogeneity are major research challenges in the search for the Biological Broader Autism Phenotype.

ACKNOWLEDGMENTS

▦ APPENDIX A. DEFINITIONS AND DESCRIPTIONS OF BIOSTATISTICAL TERMS AND CONCEPTS

Accuracy: the percentage of correct test results, whether positive or negative, if the test is unbiased. For example, suppose that in a population of N = 100 individuals, 9 have autism and 91 do not. If the entire population is tested and it is found that 7 individuals with autism were identified as such (true positives, TP = 7) and 76 of those without autism were also identified correctly (true negatives, TN = 76), then the accuracy of the test for autism is (7 + 76)/100 or 83%. Formula: Accuracy = (TP + TN)/N. See *Bias, Precision*.

Bias: the amount by which a measurement, test or any statistic misses its "bulls-eye," its expected accurate value. See *Accuracy, Precision*.

Case-control study: a study of a select number of participants with autism (cases) and selected typically developing or nonautistic subjects, perhaps with dyslexia, OCD or ADHD (healthy or psychiatric controls) with respect to one more characteristics. If the cases and controls have similar characteristics other than the characteristic of primary interest, either by group or in case-control pairs, then the study is a **matched case-control study**. Case-control studies can be *retrospective* (looking back in time after the cases are already known) and *prospective* (looking forward in time when the cases are not yet known).

Coefficient of variation: the standard deviation expressed as a percentage of the mean; see *Mean, Standard deviation*. The coefficient of variation is preferred to standard deviation as a measure of variability when comparing an ensemble of measurements having different means and standard deviations and when mean and standard deviation are correlated (van Belle et al., 2004). Since the coefficient of variation normalizes standard deviation with respect to the mean, standard deviations can be compared on the same scale across brain regions or other measurements in health and in autism (Caviness et al., 1999; Kennedy et al. 1998; Lange et al., 1997). Formula: Coefficient of variation = Standard deviation/Mean.

Correlation (linear, Pearson): a number between -1 and 1 (inclusive) that represents the strength of the linear association between two sets of measurements. An association is linear if it can be characterized completely by a straight line on a plot of one set of measurements against the other; see *Regression (linear)*. Any association that appears curved or otherwise nonlinear is not accounted for in this definition of correlation. Other definitions of correlation exist to acknowledge these types of association, such as those based on the ranks of the observations (Kendall and Spearman correlations) and not the observations themselves.

Covariate: a characteristic, such as extreme macrocephaly, that is able to subtype autism families, given the characteristic's presence or absence. When present, the characteristic may show familial aggregation and be more strongly linked to potential risk genes.

Cross-sectional: a study or set of data that contain information on a subject or subjects collected at only one point in time, space, or space-time for all subjects. For instance, a study of fractional anisotropy in the genu of the corpus callosum in autism in which each subject has been scanned only once is a cross-sectional study, and the data collected constitute a cross-sectional data set. Also see *Mean, Standard Deviation, Longitudinal*.

Effect size: a research result that has been standardized for use in meta-analysis or hypothesized during the design of a research study or experiment; see *Meta-analysis*. For example, a standardized difference between the average brain size in a sample of subjects with autism and that of a comparison group, such as a two-sample t statistic, is an effect size. When effect sizes differ significantly across autism studies having the same goal, in an attempted meta-analysis

for instance, then researchers not only have an opportunity to design and conduct better studies and meta-analyses but also to identify possible biological sources of autism heterogeneity. Effect size is best not used, however, as the sole criterion to formulate study objectives because it is but a single-number summary of several other useful results from a study, such as the mean, standard deviation, and correlation, that are useful in their own right (van Belle, 2002).

False discovery rate (FDR, its realized value): the percentage of incorrect positive test results ("false positives," FP) among a large number of positive test results that is designed to properly interpret the multitude of results. Examples of its use include crosswalks through genome-wide association studies (GWAS) for differentially expressed genes and in vivo imaging studies that involve a large number of images or image elements. For example, suppose that the test described in the previous examples for sensitivity and specificity has been replaced by a genetic test that has much greater specificity but identically poor sensitivity, and further that it has been administered to an entire high-risk population of 100,000 in which 9000 individuals have autism (see *Sensitivity, Specificity*). Suppose that the number of individuals identified incorrectly as having autism is 1 (FP = 1) and that the number of individuals identified correctly as having autism is 7000 (TP = 7000). (The test indeed has poor sensitivity, missing 2,000 autism cases in this hypothetical example.) The realized FDR of the test is 1/(1 + 7000) or 0.00014, a possibly acceptable low rate for this test. Controlling the false discovery rate is a wiser although less stringent approach to assessing the veracity of a scientific discovery than is the p-value concept and its variations for interpreting a multiplicity of research findings and their comparisons; see *P-value*. Principled control of the FDR requires the choice of an acceptable rate akin to the a priori significance level of 5% below which a single p-value is interpreted by convention as significant. The FDR method yields a value that is in between the potentially overconservative Bonferroni correction for multiple comparisons and an uncorrected p-value.

Intraclass correlation coefficient: See *Reliability*.

Longitudinal: a study or set of data that contains measurements of a subject or subjects at one or more points in time, space, or space-time for one or more subjects. For instance, a study of fractional anisotropy in the genu of the corpus callosum in autism in which one or more subjects have been scanned two or more times is a longitudinal study and the data collected constitute a longitudinal data set. Some but not all subjects may have only one data point or a varying number of repeated measurements. Autism studies with repeated measures per subject are often more powerful than those having only one measurement per subject to detect group differences when they exist (Lange, 2003). Also see *Mean, Standard Deviation, Cross-sectional*.

Mean (arithmétic mean): the simple average, the sum of measurements divided by their number. For instance, in autism research, a comparison of mean fractional anisotropy (FA), one measure of local directional flow coherence along axons showed that FA is lower in the autism group in the genu of the corpus callosum (Alexander et al., 2007) when only one measurement per subject was available; these are cross-sectional means; see *Cross-sectional*. If more than one measurement is available for some or all subjects, over time for example, then there are two sets of means, one for each individual and one for each of the groups; these are longitudinal means; see *Longitudinal*. Although the group means remain equal to the average in each group, the standard deviation of the group means and of their difference are often significantly lower because standard deviations of the individual means can be taken into account. See *Standard deviation*.

Meta-analysis: a systematic method for analyzing and synthesizing results from independent autism research studies, taking into account all pertinent information (van Belle et al., 2004). Meta-analyses attempt to mimic multicenter studies (such as multicenter controlled clinical trials) to increase statistical power; see *Sensitivity*. The aggregation of many small and heterogeneous autism studies, however, does not guarantee an increase in power; in fact, power can decrease. The validity of an increase in meta-analysis depends strongly on decisions of experts in autism research on which data or study results to combine and how to combine them, and depends on two conditions applied impartially: the quality of each study must be ascertained prior to combination, and the studies to be combined must be homogeneous. The first condition is met by expert review, and there are methods to assess the magnitude of possible inhomogeneity across studies of autism (DerSimonian & Laird, 1986). Also see *Effect size.*

Odds ratio: the ratio of the odds of having autism when a (biological) factor associated with the disorder is either present or absent. The odds of an event (having autism) is defined as the chance that the event occurs divided by the chance it does not occur. Case-control studies are most often best analyzed using the odds ratio rather than the relative risk; see *Case-control study, Relative risk*. The odds ratio and relative risk are nearly equal when the estimated prevalence of autism barely differs when the factor is present or absent. The odds ratio can be very different from the relative risk, which considers the effect of the factor on the chances of having the disorder and not on the chances of *not* having the disorder. The difference between the odds ratio and relative risk is important when, for instance, the rates of the disorder with and without the factor may be small but differ greatly. For example, autism spectrum disorder (ASD), including Asperger's syndrome and PDD-NOS, was estimated by the CDC in 2010 to affect as many as 1 out of 150 individuals in the United States. This rate may be much higher when a high-risk gene for autism (currently unidentified) is either present or absent, and the odds ratio will be greater than the relative risk. The odds ratio is always greater than the relative risk when autism is more prevalent (as can be determined from cross-sectional or longitudinal data) or incident (as can be determined from longitudinal data) when the factor is present (Holland, 1989; Schmidt & Kohlman, 2008). Although an individual may be rightfully concerned about the risk of autism when the gene is present, another and perhaps more relevant concern may be knowing the chances of autism with or without the gene compared to those of *not* having autism when the gene is either present or absent. The first type of odds, in the numerator of the odds ratio, is defined as the chance of having the disorder divided by the chance of not having the disorder when the gene is present. The second type of odds, in the denominator of the odds ratio, is defined again as the chance of having the disorder divided by the chance of not having the disorder, but when the gene is absent.

Precision: the reciprocal of the variance of a measurement, test, or any statistic. For example, if the variance of measurements of the volume of Heschl's gyrus, a small brain region important in language development, obtained by manual tracing performed on each of 100 MR images from different individuals is 11, then the precision of these measurements is $1/11 = 0.091$. It is important to note that greater precision does not necessarily imply greater accuracy; it is possible that some or all measurements taken in a study of autism are precise yet inaccurate . See *Bias.*

Predictive value, negative: the percentage of correct negative test results among all negative test results, whether correct or not. For example, if 9 individuals in a high-risk population of 100 have autism, the number of individuals the test correctly identifies as not having autism is 76 (true negatives, TN = 76), and the number of individuals the test incorrectly identifies as not having autism is 5 (false negatives, FN = 2), then the negative predictive value of the test is 76/(76 + 2) or 97%. The test to predict if an individual does not have autism is valuable. Formula: Negative predictive value = TN/(TN + FN).

Predictive value, positive: the percentage of correct positive test results among all positive test results, whether correct or not. For example, if 9 individuals in a high-risk population of 100 have autism, the number of times the test correctly identifies the individuals with autism is 7 (TP = 7), and the number of individuals the test incorrectly identifies as having autism is 15 (FP = 15), then the positive predictive value of the test is 7/(7 + 15) or 58%, slightly greater than a chance coin flip. The test to predict if an individual has autism is not valuable. Formula: Positive predictive value = TP/(TP + FP).

P-value: the probability of observing an event at least as extreme as an event that could be observed under a null hypothesis. The p-value will be small if an alternative hypothesis provides a better description of the observed event, as in courtroom logic: innocent (the null hypothesis) until proven guilty (an alternative hypothesis) beyond a reasonable doubt (the p-value). A well-designed research study defines and applies a careful procedure to collect evidence (data) in an attempt to demonstrate that an alternate state of nature may be more likely than the default state. Accepted statistical principles are then applied to the data to yield a p-value. If small enough, for instance less than 5%, the p-value is then an indication that the study has yielded a statistically significant finding suggesting that the actual state of nature is different from the state presumed by the null hypothesis. For instance, suppose a researcher believes that there are less than 10 individuals with autism spectrum disorder (ASD), including Asperger's syndrome and PDD-NOS, in a specific population of 1500 individuals. The null hypothesis is that there are exactly 10 individuals with autism in this population according to the 2010 CDC estimate. A test for autism is applied to this population and identifies 2 individuals with autism, an extreme finding according to the null hypothesis. The p-value associated with this finding is 0.0103, the probability that the event would be observed in this population when 10 are present (under the null hypothesis). This p-value may be is an acceptably low value to reject the null hypothesis since it is less than the conventional **significance level** of 0.05 adopted for a single hypothesis test. In general, a study finding becomes more significant statistically, but not necessarily scientifically, as its p-value decreases. Also see *False Discovery Rate.*

Regression (linear): a principle or method that quantifies the association of an uncertain measurement with one or more measurements that are considered to be certain. For instance, when the ages of subjects with autism are known (that is, considered to be certain) the hemispheric asymmetry of diffusivity along localized regional brain circuitry in all directions (mean diffusivity, an uncertain measurement) has been shown by an application of linear regression to increase with age. This regression effect of age on mean diffusivity is not equivalent to the correlation between mean diffusivity and age, which is obtained by treating both measurements, symmetrically, as uncertain; see *Correlation (linear)*. The magnitude of age-related increases in mean diffusivity can, however be easily obtained from this correlation by multiplying it by the standard deviations of age and dividing it by the standard deviation of mean diffusivity; see *Standard deviation*. Whereas a correlation treats both measurements as uncertain, regression methods break this symmetry and treat one set of measurements as being certain. Analysis of variance (ANOVA), analysis of covariance (ANCOVA) and many other statistical methods are special cases of linear regression. As a historical note, the term "regression" in this context was used by the inventor of this approach,

Sir Francis Galton, first cousin of Charles Darwin, who studied how the heights of sons "regressed" toward the heights of their fathers and coined the term "regression toward the mean" which is a central idea behind the technique.

Relative risk: the chance that an individual having a certain (biological) characteristic has autism divided by the chance that a similar individual without this characteristic has autism. Suppose, for instance, that a hypothetical study has found a significant and positive correlation between autism and hyperserotonemia (see Section 3. Serotonin) and estimates that the chance an individual with an elevated blood serotonin level (hyperserotonemia) greater than two standard deviations above the normal level has a 4.7% chance of having autism. The hypothetical study has also found that an individual with hyperserotonemia that is only 0.2 standard deviations above the normal level has a 1.3% chance of having autism. The hypothetical relative risk of autism for the individual with extreme hyperserotonemia is 4.7%/1.3% = 0.047/0.013 = 3.6. In this hypothetical example, the individual with extreme hyperserotonemia is 3.6 times more likely to have autism than is the individual having a blood serotonin level that is only slightly elevated. Obtaining the relative risk is feasible only when autism prevalence (from cross-sectional or longitudinal data) or incidence (from longitudinal data) is available. A benefit of using the relative risk to quantify autism risk is that it is a single-number summary that is easy to calculate and begin to understand, a benefit that may also be its major detriment. A considerable disadvantage of using the relative risk in autism research is that many different autism-biology relationships can give rise to the same relative risk because information about serotonin levels and potentially important autism features is missing, making it difficult to generalize a relative risk finding to heterogeneous populations (van Belle, 2002; Schmidt & Kohlman, 2008). Also see *Odds Ratio*.

Reliability: the ratio of measurement variance between individuals to the total variance of the measurements. Total variance includes measurement variance between individuals and the variance of repeated measurements for each individual. For instance, suppose one needs to know the reliability of volume measurements of Heschl's gyrus, and a researcher has measured the volume of Heschl's gyrus manually three times for each subject in a sample of subjects with autism. If the volumetric variance between subjects in this sample is 11 and the average variance of repeated measurements for each subject is three, then the reliability of the manual tracing method (performed by this researcher) is 11/(11 + 3) or 79%, an acceptably high fraction for research and some clinical purposes. This definition of reliability is equivalent to the definition of the **intraclass correlation coefficient**, which is in turn equivalent to Cohen's κ (Fleiss & Cohen, 1973).

Sensitivity: the percentage of correct positive test results ("true positives," TP) for the presence of a condition among all test results from a population having the condition, both correct (TP) and incorrect ("false negatives," FN). For example, if nine individuals in a population of 100 have autism and the number of correct results for a test of autism is 7 (TP = 7 and FN = 2), then the sensitivity of the test is 7/(7 + 2) or 78%, an unacceptably low fraction. The sensitivity of a test is equivalent to its statistical **power**, which by current scientific convention should be at least 80%. Formula: Sensitivity = TP/(TP + FN).

Specificity: the percentage of correct negative test results ("true negatives," TN) for the presence of a condition among all test results over a population not having the condition, both correct (TN) and incorrect ("false positives," FP). For example, if 91 individuals in a population of 100 do not have autism, and the number of correct results of a test for autism is 76 (TN = 76 and FP = 15), then the specificity of the test is 76/(76 + 15) or 84%, an unacceptably low fraction. The **significance level** of a test is equal to one minus its specificity, which by current scientific convention should be no greater than 5%. Formula: Specificity = TN/(TN + FP).

Standard Deviation (SD): a measure of spread around a mean of measurements; see *Mean*. The SD is the square root of the variance; see *Variance*. It is in the same units (for instance cm^3) as the measurements themselves and of their mean. It is often true that roughly 68% of the measurements lie within 1 SD of their mean and 95% within two SDs when most the data are spread symmetrically on either side of the mean. The SD is a measure of uncertainty in the value of a single measurement and not of the uncertainty in the value of their mean. The standard deviation of the mean is termed the *standard error* (SE) or *standard error of the mean* (SEM) to make the distinction clear. The standard error of the mean is equal to the SD divided by the square root of the number of measurements. Formula: SEM = SD/$\sqrt{n}$. For instance, research suggests that fractional anisotropy (FA), one measure of local directional flow along brain circuits, is low for individuals with autism in the genu of the corpus callosum, a major "information superhighway" between the brain hemispheres (Alexander et al., 2007). The SD of an FA measurement for each of the 43 individuals in the study with autism was 0.042, and the mean FA in the autism group was 0.663. The SD and mean FA for the 34 healthy control individuals were 0.037 and 0.692 when taking performance IQ into account for all subjects. Is FA in the genu of a subject with autism different from that of a healthy individual, on average, or are the observed differences due only to chance fluctuations? Critical in answering this question are the SEs of the mean in the autism and control groups and, more importantly, of their difference. The SEM in the autism group was 0.0010 (= 0.042/43) and that of the control group was 0.0011 (= 0.037/34), not significantly different from each other. The SE of the mean group difference was roughly 0.0046 when taking performance IQ into account since it is correlated with a diagnosis of autism. (This SEM was obtained from the published data by a common albeit seemingly complex formula found in many textbooks.) The standardized difference in FA means was -2.97 = (0.663 - 0.692)/0.00976, a difference that is unlikely if FA is identical in the two groups, having a p-value of 0.002, which is significant statistically; see *P-value*.

Variance: the sum of squared differences between a group of measurements and their mean, divided by their number less 1 (for an unbiased measure if the mean is unknown prior to data collection); see *Mean, Standard Deviation*.

▓ APPENDIX B. TABULAR SUMMARY OF LITERATURE REVIEW

Table 28B–1.
Macrocephaly

Family Study Design: Twin Study

Measurement: Head circumference was compared.

Autism sample: An epidemiological sample of N = 25 same-sex pairs of monozygotic (MZ) and N = 20 same-sex pairs of dizygotic (DZ) twins were examined.

Control sample: Typical twins reference data were used.

(Continued)

Table 28B–1. (*Contd.*)

Association in autism: For male twins less than 16 years of age, macrocephaly was present in 38.9% of twins with autism versus 9% of typically developing (TD) twins.

Association with nonautistic relative: There was no increased rate of macrocephaly in nonautistic co-twins.

Familial resemblance: The within-twin pair variance for head circumference was not significantly less than the between-twin variance in MZ twins concordant for autism.

Reference: Bailey et al., 1995; Le Couteur et al., 1996

Family Study Design: Autism Probands and their Parents

Measurement: Head circumference was compared.

Autism sample: N = 100 autism probands were examined. The number of parents included in the study is not reported.

Control sample: Reference data were used.

Association in autism: Twenty-four percent (24%) of autism probands were macrocephalic.

Association with nonautistic relative: The rate of macrocephaly for parents is not provided.

Familial resemblance: The resemblance was uncertain. Sixty-two percent (62%) of autism macrocephalic probands had at least one parent with macrocephaly. Data for parents of nonmacrocephalic probands were not provided.

Reference: Stevenson et al., 1997

Family Study Design: Autism Probands, Parents, and Unaffected Siblings

Measurement: Head circumference was compared.

Autism sample: N = 41 autism probands, N = 23 fathers, N = 30 mothers, and N = 44 unaffected siblings were examined.

Control sample: N = 21 children with nonautistic tuberous sclerosis or seizure disorder, N = 5 fathers, N = 12 mothers, and N = 19 siblings were examined.

Association in autism: Macrocephaly was present in 12.2% of autism probands versus 9.5% of comparison children, a statistically negligible difference.

Association with nonautistic relative: Macrocephaly was not specific to autism families. It was present in 18.9% of parents and 11.4% of siblings in autism families versus 17.6% of parents and 0% siblings in comparison families, again a statistically negligible difference.

Familial resemblance: A father-proband correlation of 0.52 was observed (p < 0.001), and the mother-proband correlation of 0.38 was also significant (p < 0.02). The estimated heritability in autism families was 47%, indistinguishable from that observed in the control families.

Reference: Fidler et al., 2000

Family Study Design: Autism Probands and their Parents

Measurement: Head circumference was compared.

Autism sample: N = 137 autism probands and N = 121 parents were examined.

Control sample: Existing reference data were used.

Association in autism: Macrocephaly was present in 23.3% of autism probands.

Association with non-autistic relative: Macrocephaly was present in 39% of parents of the combined sample of macrocephalic and normocephalic probands.

Familial resemblance: None was observed. Forty-five percent (45%) of 20 macrocephalic autism probands and 37% of 59 normocephalic autism probands had at least one parent with macrocephaly (p > 0.6, binomial proportions test).

Reference: Miles et al., 2000

Family Study Design: Autism Probands, Parents, and Siblings

Measurement: Head circumference was compared.

Autism sample: Collaborative Programs of Excellence in Autism (CPEA) Network Study data were used. N = 208 autism probands and N = 71 affected siblings were examined. Unaffected relatives examined included N = 76 mothers, N = 71 fathers, and N = 78 siblings.

Control sample: Typical controls and reference data were used.

Association in autism: Macrocephaly was present in 17.3% of autism probands versus 4.3% of controls. Macrocephaly was also present in 20.8% of autism probands having parental data and in 14.1% of their affected siblings.

Association with nonautistic relative: Macrocephaly was present for parents but not unaffected siblings. Macrocephaly was present in 19.7% of mothers, 16.9% of fathers, 2.9% of both parents, 33.3% of either parent, and 5.1% of unaffected siblings.

Familial resemblance: Thirty-five point seven percent (35.7%) of macrocephalic autism probands had at least one parent with macrocephaly, and 32.7% of autism probands without macrocephaly had at least one parent with macrocephaly. For head circumference, parent-proband child resemblance was similar to the resemblance between the parents and their TD children in the general population.

Reference: Lainhart et al., 2006

Family Study Design: ASD Probands and Younger Siblings

Measurement: Head circumference was compared.

Autism sample: N = 28 male children with autism or PDD-NOS were examined. In a separate study, N = 77 infant siblings, male and female, of children with ASD were examined.

Control sample: CDC reference data were used.

Association in autism: For the ASD children, mean rate of head growth during the first year of life and mean head circumference at 1 year of age were greater than those of the reference data. Individual growth curves had been estimated.

Association with nonautistic relative: An abnormal rate of head circumference growth during the first year of life was also observed. Quantitatively similar findings to those observed in the ASD children were observed in their infant siblings, including infants who had high levels of signs indicating risk for autism and siblings who had low levels of the signs.

References: Dawson et al., 2007; Elder et al., 2008

Table 28B–2.
Total brain volume and regional brain volume

Family Study Design: Twin Study

Measurement: Total and regional brain volumes were compared.

Autism sample: N = 1 pair of MZ male twins discordant for autism (7.5 years of age) was examined. The twin with autism also had ADHD (verbal IQ (VIQ) 73, performance IQ (PIQ) 91) and the non-autistic twin was had signs of the BAP and also mild ADHD (VIQ 97, PIQ 95).

Control sample: N = 5 age-matched male TD singletons (mean full-scale IQ (FSIQ 119) were examined.

Association in autism: Compared to the nonautistic MZ twin, the autism twin had smaller total intracranial volume (TICV), and when adjusting for TICV the following were smaller in autism: caudate, amygdala, hippocampus (by 34–55%), cerebellar lobules VI–VII (by 26%). Compared to the singleton controls, the autism twin had smaller TICV (z score difference: -2.35). The following regional volumes were disproportionately smaller than TICV (z-score difference): frontal lobe (Lt -5.78, Rt -3.13), superior temporal gyrus (STG) (Lt -3.22, Rt -2.12), amygdala (Lt -4.22, Rt -3.19), hippocampus (Lt -4.09, Rt -5.20).

Association with nonautistic relative: Compared to the singleton controls, the nonautistic twin had smaller TICV (z score difference: -1.02) and disproportionately smaller frontal lobe than TICV (z score difference: Lt -3.48, Rt -1.97).

Familial resemblance: The frontal lobe was disproportionately smaller than expected for TICV in the twin with autism and the co-twin with the BAP.

Reference: Kates et al., 1998

Family Study Design: Twin Study

Measurement: Total and regional brain volume were compared.

Autism sample: N = 16 pairs of MZ twins (N = 7 concordant for autism; N = 9 discordant for autism) were examined.

Control sample: N = 16 age- and gender-matched unrelated singletons were examined.

Association in autism: Compared to the nonautistic MZ twin, the autism twin had decreased cerebral white matter (WM) volume (due to frontal, temporal, and occipital regions) and increased ventricular total volume. No differences were found in TICV, cerebral gray matter (GM) volume, and cerebellar GM or WM volume.

Association with nonautistic relative: Compared to the singleton controls, the nonautistic twin had decreased cerebral WM volume (due to frontal, temporal, and occipital regions). No differences were found in TICV, cerebral GM volume, cerebellar WM or GM volume, and ventricular volume.

Familial resemblance: The MZ twins concordant for autism had high intraclass correlation coefficients (ICCs) for volumes of cerebral GM and WM, cerebellar GM and WM, and ventricles. The MZ twins discordant for autism also had high ICCs for cerebral GM and WM and ventricular volumes but had significantly decreased ICC for volumes of cerebellar GM and WM.

Reference: Kates et al., 2004

Family Study Design: Twin Study

Measurement: Total and regional brain volumes were compared.

Autism sample: N = 1 pair of MZ male twins discordant for autism (13 yrs old) was examined. The twin with autism had a VIQ= 106 and PIQ= 88, the nonautistic twin was a BAP and had a VIQ= 108 and PIQ= 96. N = 13 age-matched singletons were also examined.

Control sample: N = 25 age-matched TD controls were examined. Association in autism: Smaller total brain volume (TBV) was found in the autism twin compared to the singleton autism and typical controls. Regional brain volume differences (as percent of TBV) as well as greater left frontal lobe and smaller right cerebellum were also found. No cerebrum differences were found.

Association with nonautistic relative: Smaller TBV was found in the BAP twin compared to the singleton autism and typical controls. No regional brain volume differences were found.

Familial resemblance: TBV was smaller in autism and BAP twins.

Reference: Belmonte & Carper, 2006

Family Study Design: Twin Study

Measurement: Total and regional brain volumes were studied.

Autism sample: N = 14 pair of MZ twins (ages 5–14 yrs old) with at least one twin with an autism diagnosis were examined (36% concordant for autism, 28% co-twin PDD-NOS, 36% co-twin no diagnosis).

Control sample: N = 14 singleton age- and gender-matched TD comparison subjects were examined.

Association in autism: ICC for TBV was 0.93 in MZ twins. Right (but not left) dorsolateral prefrontal cortical volumes for autism were significantly larger than those of comparison subjects but not co-twins. The genu and anterior of the corpus callosum were smaller for children with autism relative to comparison subjects but not to co-twins. Relative to comparison subjects cerebellar lobules VI and VII were significantly smaller in co-twins and tended to be smaller in children with autism.

Association with nonautistic relative: Differences in those concordant for autism versus not concordant for autism were not tested.

Reference: Mitchell et al., 2009

Family Study Design: Nuclear Families (Parents)

Measurement: Total and regional brain volumes were compared.

Autism sample: N = 19 parent couples of autistic probands were examined.

Control sample: N = 20 matched healthy control parent couples were examined.

Association in autism: From the researchers' prior work, TBV was increased above the control mean in 17 of the 19 autism probands (Palmen et al., 2004; Palmen et al., 2005a).

Association with nonautistic relative: No significant differences were found in TICV, TBV, or regional brain volumes between the autistic proband parents and the control parents.

Reference: Palmen et al., 2005b

(Continued)

Table 28B–2. (*Contd.*)

Family Study Design: Nuclear Families (Parents and Unrelated Adults with Autism)

Measurement: TBV, hippocampus, and amygdala volumes were compared.

Autism sample: N = 17 parents of autism proband children and N = 15 adults with autism were examined.

Control sample: N = 17 control adults were examined. Association in autism: In the autism adults, left hippocampal volume was increased and left amygdala volume was decreased.

Association with nonautistic relative: Left hippocampal volume was increased in parents. No amygdala differences in parents were found.

Reference: Rojas et al., 2004

Family Study Design: Nuclear Families (Parents)

Measurement: Regional GM volumes were compared.

Autism sample: N = 23 parents of autistic probands (N = 18 families, N = 15 mothers, N = 8 fathers) were examined.

Control sample: N = 23 control participants (8 males) were examined. Association in autism: Not tested.

Association with nonautistic relative: GM was altered in ASD parents compared to controls. No TBV or hippocampal differences were found.

Reference: Peterson et al., 2006

Table 28B–3.
Brain function and brain connectivity

Family Study Design: Nuclear Family (Twin)

Measurement: Functional magnetic resonance (fMRI) activation in response to a frequent congruent visual condition versus a rare incongruent condition was examined. The functionally demanding task required simultaneous attending to location, color, and orientation.

Autism sample: One pair of MZ male twins discordant for autism, age 13 years (Twin L autism: VIQ 106, PIQ 88; Twin M BAP: VIQ 108, PIQ 96), was examined.

Association in autism: In the autistic twin, there was a significant differential activation only in the left superior temporal gyrus (STG) (Broadmann Area [BA] 22) and similar network activated in the two conditions.

Association with nonautistic relative: In the BAP twin there was activation in two separate networks for the two different conditions where easy and accurate performance of the cognitively high-demand task occurred.

Familial resemblance: No resemblance.

Reference: Belmonte & Carper, 2006

Family Study Design: Nuclear Family (Siblings)

Measurement: Eye movements, facial recognition and emotion discrimination, and fMRI brain activation were examined.

Autism sample: The following participants were examined: Study I: N = 14 males with autism (11 verbally fluent); Study II: N = 16 males with autism (14 verbally fluent); Study III: N = 12 children with autism, N = 10 unaffected siblings (ages 8–25yr old).

Control sample: The following control participants were studied: Study I: N = 12 TD males; Study II: N = 16 typical males; Study III: N = 12 matched typical children.

Association in autism: In Studies I & II, the autism group spent less time fixating on eyes, but there was marked variability within the group. In the autism but not control group, brain activation in the amygdala and right anterior fusiform gyrus was strongly positively related to the amount of time spent fixating on eyes.

Association with nonautistic relative: Similar to the children with autism, unaffected siblings spent less time fixating on eyes than controls (Study III). There was no significant difference between the autism group and the unaffected sibling group on time spent fixating on eyes. The eye fixation time was strongly positively related to right and left fusiform gyrus but not amygdala activation in unaffected siblings.

Reference: Dalton et al., 2005; Dalton et al., 2007

Family Study Design: Nuclear Family (Parents)

Measurement: event-related potential (ERP) response to face and nonface stimuli was compared.

Autism sample: N = 21 parents of autistic children were examined.

Control sample: N = 21 parents of TD children were examined.

Association in autism: Previous studies had shown that children and adults with autism have atypical ERPs to faces. These studies had failed to show a negative component (N170) latency advantage to face compared to nonface stimuli, and a bilateral, rather than the normal right-lateralized, pattern of N170 distribution.

Association with nonautistic relative: Parents of children with autism had atypical ERP response to faces that mirrored the response seen in affected individuals.

Reference: Dawson et al., 2005

Family Study Design: Nuclear Family (Parents)

Measurement: fMRI brain activation was recorded during a visual search task (Embedded Figures Task) and an empathy task (Reading the Mind in the Eyes Task).

Autism sample: N = 12 parents of children with Asperger's syndrome were examined.

Control sample: N = 12 matched parents of TD controls were examined.

Association in autism: Not reported.

Association with nonautistic relative: Both mothers and fathers of children with Asperger's syndrome showed atypical brain functioning compared to control parents on both tasks—they had less activation in visual cortex bilaterally (BA 19) and more activation in left medial temporal gyrus and dorsolateral prefrontal cortex (PFC).

Reference: Baron-Cohen et al., 2006

(*Continued*)

Table 28B–3. (*Contd.*)

Family Study Design: Nuclear Family (Parents)

Measurement: Magnetoencephalography (MEG) transient evoked and induced gamma-band power and inter-trial phase-locking consistency were recorded.

Autism sample: N = 11 adults with autism and N = 16 parents of children with autism, not related to the adults with autism, were examined.

Control sample: N = 16 control adults were examined.

Association in autism: In adults with autism, higher induced and lower evoked gamma-band power (40 Hz) and lower phase-locking factor measure of phase consistency of neuronal response to external stimuli was found. The potential endophenotypes in autism are MEG gamma-band phase consistency and changes in evoked verse induced power.

Association with nonautistic relative: The parents of children with autism had the same results as the adults with autism.

Familial resemblance: The adults with autism and the parents were not related.

Reference: Rojas et al., 2008; Wilson et al., 2007

Table 28B–4.
Serotonin

Family Study Design: Nuclear Family (Parents)

Measurement: Serotonin ($5-HT_2$) receptor cortical binding potential (BP) density was measured by positron emission tomography (PET, [^{18}F]setoperone PET in this case) with 12 cortical regions of interest and cortex-to-cerebellum ratio. Left and right cortical areas examined: frontal, inferior frontal, parietal, inferior parietal, lateral temporal, occipital.

Autism sample: N = 19 parents (8 females, 11 males) from 11 autism multiplex families, with no neurological or psychiatric disorders during 6 months prior to study and no medicine or substance use, were examined.

Control sample: N = 17 typical control adults (9 females, 8 males) were examined. Age and sex were covariates in all analyses.

Association in autism: There are no data concerning the affected children.

Association with nonautistic relative: Mean whole blood platelet serotonin showed no difference. The mean composite cortical $5-HT_2$ receptor BP was significantly lower in parents (effect size 0.9). The mean $5-HT_2$ BP was significantly lower in parents in every left and right cortical area examined (range: means 77–88% lower in parents versus controls). Also, variance of 5-HT BP was less in parents. There was significant negative correlation of mean platelet 5-HT with cortical $5-HT_2$ BP in parents but not in the controls (composite BP r = -0.59; 8 of 12 cortical regions of interest (ROIs), r = -0.52 to -0.65).

Familial resemblance: Not examined.

Reference: Goldberg et al., 2009

Family Study Design: Nuclear Family (Children with Autism, Parents and Siblings)

Measurement: Plasma serotonin levels were compared.

Autism sample: N = 17 children with autism and their mothers (N = 17) and fathers (N = 12) were examined. All parents were nonautistic.

Control sample: Control mothers were examined.

Association in autism: No comparison sample was examined.

Association with nonautistic relative: Plasma serotonin levels in autism mothers were significantly different than in mothers of TD children (P = 0.002).

Familial resemblance: Plasma serotonin levels correlated between autism mothers and their children, but differed between autistic children and their fathers and siblings.

Reference: Anderson, 2007; Connors et al., 2006

Family Study Design: Nuclear Family (First-Degree Relatives)

Measurement: Whole blood serotonin was compared.

Autism sample: N = 62 autism subjects and N = 122 of their first-degree relatives were examined.

Control sample: Age- and sex-matched controls were examined.

Association in autism: Increased rate of hyperserotonemia was found.

Association with nonautistic relative: Hyperserotonemia was found in 51% of mothers, 45% of fathers, 87% of siblings of autism probands.

Reference: Leboyer et al., 1999

Family Study Design: Nuclear Family (Parents and Siblings)

Measurement: Quantity of platelet $5-HT_2$ serotonin binding sites was compared.

Autism sample: N = 12 autism probands, N = 6 of their siblings, and N = 22 of their parents were examined.

Control sample: Adult and child controls were examined.

Association in autism: No case-control differences in platelet serotonin receptor binding sites, whole blood serotonin, or plasma norepinephrine (noradrenaline) were found.

Association with nonautistic relative: No autism relative-controls differences were found.

Familial resemblance: Significant correlation of total number of platelet serotonin binding sites in 11 autism probands and their fathers was found.

Reference: Perry et al., 1991

Family Study Design: Nuclear Family (Parents and Siblings)

Measurement: Levels of whole blood serotonin and plasma norepinephrine (noradrenaline) were compared.

Autism sample: N = 47 autism probands and their siblings, mothers, and fathers were examined.

Control sample: Not reported.

Association in autism: The mean whole blood 5-HT level was higher in autistic probands than parents and siblings.

Table 28B–4. (*Contd.*)

Association with nonautistic relative: Twenty-three of 47 families had at least one member with hyperserotonemia and 10 had two or more members with hyperserotonemia; in five families every member had hyperserotonemia.

Familial resemblance: Familiality of hyperserotonemia. If the autistic child of a family was hyperserotonemic, the first-degree relatives were 2.4 times more likely to be hyperserotonemic than if the autistic child was not hyperserotonemic.

Reference: Leventhal et al., 1990

Family Study Design: Nuclear Family (Parents and Siblings)

Measurement: Whole blood serotonin and plasma norepinephrine (noradrenaline) were compared.

Autism sample: N = 16 children with autism, N = 21 of their siblings, and N = 53 of their parents were examined.

Control sample: Not reported.

Association in autism: Not reported.

Association with nonautistic relative: Rate of hyperserotonemia increased.

Familial resemblance: Seven of 10 families with one hyperserotonemic member had two or more hyperserotonemic members.

Reference: Cook et al., 1990

Table 28B–5.
Immune factors

Family Study Design: Nuclear Family (Siblings)

Measurement: Antibodies reactive to human adult cerebellar extract, adult monkey cerebellar extract, and adult monkey brain sections.

Autism sample: N = 63 children with ASD and N = 25 of their unaffected siblings were examined.

Control sample: N = 63 age-matched healthy control children and N = 21 children with nonspecific developmental delay were examined.

Association in autism: 21% of the children with ASD had antibody to a 52kDa band protein from human adult cerebellum, compared to 2% of healthy control children and 5% of children with nonspecific developmental delay. Only antibodies from the ASD children reacted with a 52kDa protein band from adult monkey cerebellum. Antibodies from children with ASD showed specific immunohistochemical staining of slices of adult monkey brain cerebellum. Staining of cerebellar white matter was infrequently observed in the ASD children but was more common than in controls. Twenty-one percent of the ASD children, but none of the healthy children or developmentally delayed children, showed intense staining of cerebellar Golgi cells, large granule cell layer interneurons. The correlation between immunoreactivity to the Golgi cells and reactivity to the 52kDa band was strong in the ASD children (r = 0.76, p = 0.0001). There was no significant correlation in control children. No immunoreactivity to cerebellar Purkinje cells was observed.

Association with nonautistic relatives: None of the unaffected siblings had antibody to human or monkey cerebellar proteins. Intense immunoreactivity to cerebellar Golgi cells was found in 1 (4%) of the siblings.

Familial Resemblance: Not reported.

Reference: Wills et al., 2009

Family Study Design: Nuclear Family (Siblings)

Measurement: Multiple immune parameters were compared.

Autism sample: N = 20 children with autism ages 5–17 years and N = 15 of their unaffected siblings age 3–16 years were examined.

Control sample: N = 20 healthy control children ages 3–15 years were examined.

Association in autism: Mean numbers of subpopulations of CD4+ and CD8+ T lymphocytes, including naive and post-thymic differentiated cells, and mean levels of some cytokines were found to be altered in autistic children, suggesting dysregulation of the cell-mediated immune system.

Association with nonautistic relative: There was a similar pattern of immune dysregulation in healthy unaffected siblings as found in the children with autism.

Familial Resemblance: Not reported.

Reference: Saresella et al., 2009

Family Study Design: Nuclear Family (Mothers)

Measurement: Tissue protein medleys from human fetal and adult brain, duodenum (small intestine), and kidney were examined in mothers of children with autism.

Autism sample: N = 61 mothers of autism probands (AU) (36 regressive onset, 25 early onset) were examined.

Control sample: N = 62 mothers of TD children and N = 40 mothers of non-ASD children with developmental disabilities (DD) were examined. The case-control mothers were matched on maternal age, parity, and age of offspring (average age 3.5 years, range 2–5 years).

Association with nonautistic relative: Rate of plasma antibodies tested against human fetal (but not human adult) brain proteins was increased in some of the autism mothers. No association was found between maternal reactivity to human fetal proteins and history of current maternal autoimmune disorder. Reactivity to 37kDa and 73kDa protein bands from human fetal brain was significantly more common in the autism mothers including: a) reactivity to 37kDa fetal brain protein (found in 25–26% of Au mothers; 2–5% of DD mothers; 8.1% of TD mothers; odds ratio (OR) = 5.96 AP versus TD mothers; b) reactivity to both 37kDa and 73dDa fetal brain proteins: 11.5% (7 of 61) AP mothers; 0% of DD and TD mothers. The autism children of six of these seven mothers (86%) had a regressive onset.

Reference: Braunschweig et al., 2008

Family Study Design: Nuclear Family (Mother)

Measurement: Maternal blood drawn at midpregnancy was tested for maternal autoantibody to fetal brain protein.

Autism sample: N = 84 mothers of children with autism, where 19% of the autism offspring had a regressive onset, were examined.

Table 28B–5. (*Contd.*)

Control sample: N = 49 mothers (TD) of children with mental retardation (MR) or DD and N = 160 mothers of children not requiring DD services were examined.

Association with nonautistic relative: Reactivity to fetal brain 39kDa protein band was found in 7% of Au mothers versus 0% of MR mothers and 2% of TD mothers (p = 0.09 and 0.07); 1.2% (1 of 84) of autism mothers versus 0% of MR mothers and 2.6% of TD mothers had autoantibody reactivity to both 37kDa and 73kDa.

Reference: Croen et al., 2008

Family Study Design: Mothers Only

Measurement: The antibody source was serum. The tissue source was homogenated rodent fetal and adult brain and human fetal and adult brain of the following regions: BA9, caudate, cerebellum, and cingulate gyrus.

Autism sample: N = 100 mothers of children with autism, where 48 of the autism children had a history of social and language regression, were examined. (Some analyses had N = 20–25 autism mothers.)

Control sample: N = 100 age-matched control mothers (TD) were examined. Some analyses had n = 20–25 TDs.

Association in autism: Children with autism were not tested for the antibodies; only their mothers were tested.

Association with nonautistic relative: A personal history of autoimmune disease was present in 24 of 100 autism mothers and 12 of 100 TD mothers (OR = 2.32, p = 0.028).

There was little overlap in the antibodies autism mothers had to fetal and adult tissue in both rodent and human brain. Autism and TD mothers did not differ in antibodies to glial fibrillary acidic protein (GFAP) or myelin basic protein (MBP). No autism versus TD mother difference was found in serum levels of a brain-derived neurotrophic factor (BDNF). Mean serum immunoglobulin G (IgG) concentration was not different in Au and TD mothers. Sera from autism mothers contained antibodies that differed from TD mothers against prenatally expressed brain proteins. Antibodies to human fetal brain proteins were found in 10% of Au mothers (36kDa band) and 2% of TD mothers. Mean levels of human adult brain antibodies, against the caudate (155kDa) and frontal lobe (BA9, 63kDa), were significantly different in the mothers. It is not known if the antibodies in Au mothers have pathological consequences.

Reference: Singer et al., 2008

Family Study Design: Nuclear Family (Children with Autism and Siblings)

Measurement: IgG antibody source was plasma. Tissue source was protein extracts from thalamus and hypothalamus of the adult human brain.

Autism sample: N = 63 children with autism were examined.

Control sample: N = 25 unaffected siblings, N = 63 TD children and N = 21 children with other DD controls were examined.

Association in autism: Multiple bands of autoreactivity were observed: 52kDa band for the thalamus and 46 and 42kDa bands for thalamus and hypothalamus. Autoreactivity for the thalamus in plasma from children with autism was significantly greater than TD children, unaffected siblings, and DD controls. Circulating autoantibodies against thalamus and hypothalamus in children with autism but not their unaffected siblings suggest potential autoimmune sequelae specific to the disorder. The autoantibodies could be pathogenic or an epiphenomenon suggesting damage/injury to these areas of the brain.

Association with nonautistic relative: Autoreactivity for thalamus or hypothalamus was not increased in plasma from unaffected siblings; their levels were similar to TD and DD children.

Reference: Cabanlit et al., 2007

Family Study Design: Nuclear Family (Mothers and their Children with Autism; Unrelated Unaffected Siblings)

Measurement: The antibody source was serum. The tissue sources were fresh rat brain protein homogenates (fetal, postnatal, and adult rats) and tissue slices, and human GFAP and MBP.

Autism sample: N = 11 mothers of autism children (Au) 2–18 years after the birth of the autism proband and N = 12 male children with autism (7 regressive onset; 2 seizures) were examined.

Control sample: N = 10 mothers of TD children, 14 male children with other neurodevelopmental disorders (DD), 10 TD siblings (5 female, 5 male) of autism children (unrelated to probands and mothers in the study) and 4 TD children (2 female, 2 male) were examined.

Association in autism: Multiple varied reactive bands to postnatal and adult rat brain protein homogenates did not differentiate the groups. The pattern of reactivity to fetal rat brain proteins did differentiate Au mothers, their autism children, and DD children, from TD mothers, TD children, and TD siblings of autism probands unrelated to ones in the study. Reactivity to human GFAP and MBP did not differentiate Au verses TD mothers. No correlation of reactivity to regression, epilepsy, birth order in autism children, or to age, history of autoimmune disease, or parity in Au mothers was found. Antibodies from children with autism also recognized/reacted against different fetal rat brain proteins than TD controls and unrelated autism siblings; DD children reacted similarly to autism children (therefore, no specificity to autism).

Association with nonautistic relative: Autism mothers had different patterns of serum immunoreactivity to fetal rat brain protein, but not postnatal or adult rat brain proteins, than control mothers. Maternal reactivity persisted up to 18 years postdelivery.

Familial resemblance: Not reported.

Reference: Zimmerman et al., 2007

Family Study Design: Nuclear Family (ASD Children and Some of their Unaffected Siblings)

Measurement: The antibody source was serum. The tissue source was fresh human brain of the following regions: PFC (BA10), caudate, putamen, cerebellum, deep cerebellar nuclei, and cingulate gyrus.

Table 28B–5. (*Contd.*)

Autism sample: N = 29 children with ASD (3–12 yrs old) were examined: 22 low-functioning autism and 2 high-functioning autism, 1 Asperger's, 3 syndromal autism, 1 childhood disintegrative disorder. N = 9 nonautistic siblings (4–8 yrs old) of 8 of the children with autism.

Control sample: N = 13 unrelated typical controls (9–17 yrs old) were examined.

Association in autism: More autism and ASD children had 100 kDa bands than TD children (caudate: autism 100%, ASD 97%, TD 77% [$p = 0.017$]; putamen: autism 100%, ASD 100%, TD 69%; [$p < 0.0001$]; PFC [BA 10]: autism 95%, ASD 97%, TD 69% [$p = .012$]). Band density was measured as peak height and/or area under the curve. The autism children had increased density in the 73 kDa band in cerebellum and cingulate, the 160 kDa band in PFC (BA10), and the 36 kDa band in cerebellum. To date, the precise structural proteins involved are not known. Antibody repertoires may be pathological factors or secondary immune responses to previously damaged tissue. More autism than TD children had autoimmune complexes in the basal ganglia and frontal lobe and greater intensity of antigen-antibody complexes in the cingulate gyrus and cerebellum. Autism children had higher 73kDa density bands in cerebellum and cingulum.

Association with nonautistic relative: As mentioned above, mean levels of antibrain antibodies against cingulated gyrus and cerebellum were increased in a small number of unaffected siblings (N = 9), similar to their siblings with autism (N = 8), in comparison to TD children (N = 13). It is not clear if the latter represents an inherited tendency for a genetically determined defect or if it is an irrelevant trait.

Reference: Singer et al., 2006

Family Study Design: Nuclear Family (Children with Autism and their Parents)

Measurement: The tissue source was frozen human brain tissue. Reactivity to adult human brain extracted from a male 39 years of age, containing many different protein antigens, was measured.

Autism sample: N = 171 autism children 2–14 years of age and N = 171 parents of the autism children were examined.

Control Sample: N = 54 otherwise healthy children who were surgical patients were examined. Parent controls were the parents of 100 nonautistic patients.

Association in autism: The presence of numerous bands on immunoblot against human tissue was found in both autism and controls. Reactivity to protein 20kDa occurred in affected children but not their parents. The protein was not MBP.

Association with nonautistic relative: No reactivity to protein 20kDa in autism parents was observed.

Familial resemblance: No parent-autism child correlations for Section 32 (the 20kDa protein) were observed, and very low heritability estimates were found.

Reference: Silva et al., 2004

Family Study Design: Nuclear Family (Mother)

Measurement: Maternal serum antibodies to rodent Purkinje cells and neurons were used.

Autism sample: One mother had three children: a 9-year-old unaffected boy, a high-functioning girl 8 years of age with autism without a history of regression, and a boy 6 years of age with severe specific language disorder with onset after a regression at 18 months. Only the mother was examined.

Control Sample: N = 4 control mothers who each had one to four children.

Association with nonautistic relative: The autism mother had IgG that reacted to adult rat brain, specifically to the cytoplasm of cerebellar Purkinje cells, some large brain stem neurons, and to the Purkinje cell layer in developing mouse cerebellum. When serum from the mother was injected into a pregnant mouse, the mice offspring pups had behavioral deficits (less exploratory behavior and impaired performance on rods, but no impairment in memory acquisition). Immune staining and metabolism (studied with magnetic resonance spectroscopy) of the mice offspring cerebella was altered. There was no reaction from control mothers' serum.

Reference: Dalton et al., 2003

Family Study Design: Children with Autism, their Parents, and Unaffected Siblings

---

Measurement: Presence of plasma antibodies to serotonin receptors in human hippocampal membranes was measured.

Autism sample: N = 15 children with autism, N = 42 of their parents, and N = 17 of autistic unaffected siblings were examined.

Control sample: N = 12 unrelated TD controls were examined.

Association in autism: No evidence was found of plasma antibodies from children with autism binding to serotonin receptors $5HT_{1A}$ or $5H_{T2}$. There was no evidence of autoantibodies to serotonin receptors in autism probands or their relatives.

Association with nonautistic relative: There was no evidence of plasma antibodies from parents or unaffected siblings of autism probands binding to serotonin receptors.

Reference: Cook et al., 1993

Family Study Design: Nuclear Family (Mothers)

Measurement: Frequency of maternal immunologic disorders was compared.

Autism sample: Mothers of N = 407 children with autism were examined.

Control sample: Mothers of N = 2095 control children were examined.

Association with nonautistic relative: Mothers of autism probands showed no increased rate of autoimmune diseases in the 4–year period surrounding the pregnancy with the child who developed autism.

Reference: Croen et al., 2005

Family Study Design: Nuclear Family

Measurement: Frequency of autoimmune disorders.

Autism sample: Parents of N = 101 autism probands were examined.

Control sample: Parents of N = 101 children with an autoimmune disorder and N = 101 control children were examined.

Table 28B–5. (*Contd.*)

Association with nonautistic relative: There was an increased rate of autoimmune disorders in families of PDD-NOS children, especially in parents. Hypothyroid disease and rheumatic fever were more common in autism families.

Reference: Sweeten et al., 2003

Family Study Design: Nuclear Family

Measurement: Frequency of autoimmune disorders was compared.

Autism sample: N = 61 families of patients with autism were examined.

Control sample: N = 46 healthy controls were examined.

Association with nonautistic relative: There was an increased rate of autoimmune disorders in mothers and first-degree relatives in general.

Familial resemblance: As the number of family members with autoimmune disorders increased, the risk of autism in the family was greater.

Reference: Comi et al., 1999

Family Study Design: Nuclear Family

Measurement: Frequencies of null alleles at the C4A and C4B loci was compared.

Autism sample: N = 19 individuals with autism and unaffected family members were examined.

Control sample: TD controls were examined.

Association in autism: The rate of the C4A null allele was increased.

Association with nonautistic relative: Mothers of autism probands had significantly increased frequencies of C4A null allele (58% in mothers, 27% controls). Unaffected siblings also had increased C4A null alleles, although it was nonsignificant from controls.

Reference: Warren et al., 1991

Family Study Design: Nuclear Family (First-Degree Relatives of Children with ASD)

Measurement: Frequency of familial autoimmune disorders was measured.

Autism sample: Medical records of children born in Denmark from 1993 to 2004 with an ASD diagnosis (N = 3325, of which 1089 had an infantile autism diagnosis) were examined.

Control sample: Unaffected family members (siblings and parents) of children with autism and families of children born during the same time without an autism diagnosis (N = 685,871) were included in the study.

Association with nonautistic relative: Maternal history of celiac disease and rheumatoid arthritis were associated with increased risk of ASD. Type-1 diabetes in fathers and mothers was associated with an increased risk for autism. Maternal and familial thyrotoxicosis was related to lower risk for ASD.

Reference: Atladottir et al., 2009

Table 28B–6.
Classification

Method: Shape Representations of WM Fibers Passing Through the Splenium of the Corpus Callosum Extracted from Diffusion Tensor Images (DTI).

Sample: N = 41 males with high-functioning autism and N = 32 TD controls, matched for age, handedness, IQ, and head size, were examined.

Autism sensitivity: 72%

Autism specificity: 72%

Reference: Adluru et al., 2009

Method: A Combination of Cerebellar and Cerebral WM and GM Volumes, and Areas of Anterior Vermis and Posterior Vermis in the Medial Lobe of the Cerebellum.

Sample: N = 30 low-functioning autism, N = 12 high-functioning autism, and N = 13 normal controls (all boys, 1.7–5.2yrs of age) were examined.

Autism sensitivity: 94.7%

Autism specificity: 92.3%

Reference: Akshoomoff et al., 2004

Method: White Matter Cumulative Distribution Related to Size of Gyral Window.

Sample: N = 14 males with autism (8–38yrs of age, IQs 65–107) and N = 28 TD control males, matched for age and handedness, were examined.

Autism sensitivity: 67%

Autism specificity: 89%

Reference: Casanova et al., 2009

Method: A Whole-Brain Structural MRI Pattern Classification Approach in a Spatially Distributed Neural Network (Limbic, Frontal-Striatal, Frontotemporal, Frontoparietal, and Cerebellar Systems).

Sample: N = 22 ASD and N = 22 healthy controls (all adult males, matched for age, IQ, and GM, WM, and TBV) were examined.

Autism sensitivity: 77% for GM images (predictive power 81%); 73% for WM images (predictive power 68%).

Autism specificity: 86% for GM images; 64% for WM images.

Reference: Ecker et al., 2009

Method: Computerized Binocular Infrared Pupillography, with Transient Papillary Light Reflex Latency and Constriction Amplitude.

Sample: N = 24 males with ASD and N = 43 TD males (6–16 yrs of age) were examined.

Autism sensitivity: 91.7%

Autism specificity: 93%

Reference: Fan et al., 2009

Table 28B–6. (*Contd.*)

Method: Cortical Thickness and Cortical Volume of 33 Cortical Regions in Each Hemisphere were Used. Classification Methods Identified Seven Key Regions. Decreased Areas Included Bilateral Pars Triangularis, Left Medial Orbitofrontal and Parahippocampal Gyri, and Left Frontal Pole. Increased Areas Included Left Caudal Anterior Cingulate and Left Precuneus.

Sample: N = 22 children with ASD (mean age 9.2 +/- 2.1 years) and N = 16 age-matched community volunteer children were examined.

Autism sensitivity: Cortical thickness: 95%; Cortical volume: 77%

Autism specificity: Cortical thickness: 75%; Cortical volume: 69%

Reference: Jiao et al., 2009

Method: A Combination of Left Fusiform Gyrus GM, Right Temporal Stem WM, and Right Inferior Temporal Gyrus GM Volumes.

Sample: N = 33 males with high-functioning autism and N = 24 control males were examined.

Autism sensitivity: 85%

Autism specificity: 83%

Reference: Neeley et al., 2007

Method: Voxelwise Cortical Thickness Based on 40,000 Points, by Measuring the Goodness of Each Point as a Classifier and the Discriminative Characteristics of Regions.

Sample: N = 16 high-functioning males with autism and N = 11 TD males (mean age 14.5 years, SD 4.6) were examined.

Autism sensitivity: Classification accuracy: 89%

Reference: Singh et al., 2008

Method: Automated Vocalization Analysis of 12-hour Audio-Recordings from the Natural Home Environment.

Sample: Young children, N = 34 autism, N = 30 nonautistic language delay, and N = 76 TD, were examined.

Autism sensitivity: Classification accuracy: 77 to 90%

Reference: Xu et al., 2009

Method: MEG Latency of Right-Hemisphere M50.

Sample: N = 14 autism, N = 10 Asperger's syndrome, N = 5 nonautistic specific language impairment, and N = 6 TD controls (all children 7–18 yrs old) were examined.

Impaired language sensitivity: 70%

Impaired language specificity: 92%

Reference: Oram Cardy et al., 2008

Method: MEG Latency of Right-Hemisphere 500 Hz M100.

Sample: N = 25 autism spectrum disorder (9 with language impairment, 16 without language impairment) and N = 17 TD controls (all children, ASD mean age 10.20 years, sd 2.15) were examined.

Sensitivity for ASD: 75%

Specificity: 81%

Reference: Roberts et al., 2010

Autism as a Quantitative Trait

Points of Interest

- Across several different measurement methods, the symptoms and traits that uniquely characterize autism spectrum conditions have been found to be continuously distributed in the general population. Thus, it may be arbitrary where cutoffs are drawn for the categorical designation of affected versus unaffected status, when those designations are made exclusively on the basis of behavioral symptoms.
- Variation in subclinical autistic traits is highly heritable, and subclinical autistic traits aggregate in the first-degree male relatives of individuals with familial autistic syndromes.
- Quantitative characterization of autistic severity can be conducted rapidly and feasibly, such that clinical course and response to intervention can be reliably ascertained by repeated measures over time.
- Quantitative autistic symptomatology may constitute an autism endophenotype in multiple-incidence autism families.

Research in child development over the past several decades has revealed that clinical neuropsychiatric syndromes often represent the severe ends of continuous distributions of core competencies and/or deficiencies that occur in nature. This concept was seminally applied to child psychopathology by Achenbach and colleagues (see Achenbach & Ruffle, 2000), who developed and validated an empirically based dimensional system of measurement; the implementation of that system in studies involving hundreds of thousands of children has revolutionized the way in which disorders of behavior and development are understood. Although on the surface, the difference between categorical ("all-or-nothing") and dimensional classification systems may appear trivial, a paradigm shift between the two can have profound implications for the exploration of

neural mechanisms underlying behavior, the enhancement of statistical power in molecular genetic studies, the monitoring of effects of intervention, and helping parents understand (and accept) the nature of a psychiatric condition in a child. In recent years, the conceptualization of autistic syndromes as the severe end of a quantitative distribution of social impairment in nature has garnered considerable attention in science.

Genetic Mechanisms Underlying Quantitative Traits

The fact that a variety of rare single-gene disorders now account for some 10–15% of autistic syndromes (at the time of this writing) might seem to reinforce a categorical concept of autism; that the "autisms" actually represent a collection of such discrete disorders of social cognition. It is indeed possible that quantitative variation in autistic severity might be accounted for by variation in the severity of each rare-but-discrete disorder, or by variable penetrance within each condition. There are now documented examples of both phenomena occurring in autism, however it is still not known whether rare, as-yet-undiscovered causes comprise the bulk of the remaining 85% of autism cases, or whether multigenic mechanisms, strongly suspected in familial cases of autism, are predominantly at play. Multigenic mechanisms of causation have been identified for other complex conditions (diabetes, obesity, hypertension) and specific diseases (see below), in which common susceptibility alleles of relatively minor effect exert joint or interactive effects on the condition of interest. It is furthermore possible that some autistic syndromes arise from deleterious epistatic interactions involving both common and rare genetic factors.

When considering the manner in which disparate genetic mechanisms map to autistic syndromes, it is helpful to consider whether genetic variations are rare or common, operate

singly or in combination with other genes, whether they are inherited or arise "de novo" in a given generation and whether they produce autism alone or autism accompanied by other major developmental disorders or anomalies. These factors have known associations with the likelihood of recurrence in families, such that approaches to gene-finding may be optimized by hypothesizing specific mechanisms of transmission within specific subsets of families in which autistic syndromes arise. For example, common inherited susceptibility alleles may be more likely to be identifiable in families in which multiple members are affected to varying degrees, whereas rare de novo (germline) mutations of large effect are more likely to be responsible for sporadic cases of ASD.

Advances in the elucidation of the genetic structure of other complex diseases have revealed ways in which specific genetic mechanisms can result in quantitative distributions that bear striking similarities to those observed in autism spectrum conditions. For example, in the short-segment variety of Hirschsprung's disease—a disorder of neuronal migration to the large intestine affecting boys 5 times more commonly than girls—the length of the gut that is affected (a straightforward quantitative index measured in centimeters) is associated with the number of recessive susceptibility alleles possessed by the patient, and is predictive of sibling recurrence risk (Amiel et al., 2008). This multifactorial genetic mechanism contrasts with the rarer and more severe long-segment Hirschsprung's disease, which follows a dominant pattern of autosomal transmission of single gene mutations of major effect. In schizophrenia, a neurodevelopmental disorder in which the normal process of synaptic pruning in adolescence is believed to be dramatically accelerated (in contrast to the disruption in synapse formation that is believed to occur in autism), sporadic cases have been associated with an elevated occurrence of de novo copy number variations (CNVs), some of which are the same as those observed in excess among sporadic cases of autism. Understanding how specific inherited susceptibilities affect the time course of the development of functional connections in the brain will no doubt bring us closer to understanding how phenotypic overlap in mental disorders such as autism, ADHD, schizophrenia, and bipolar disorder might occur.

Whatever the cause, what is observed in nature is a very wide, and in essence, continuous distribution of autistic symptoms and traits (Constantino & Todd, 2003; Ronald, Happe, Price, Baron-Cohen & Plomin, 2006; Skuse et al. 2009) comprising the so-called autism spectrum. Existing taxonomies attempt to subdivide this spectrum into discrete clinical syndromes (Asperger's syndrome, PDD-NOS, autistic disorder) but to date there is no evidence that these conditions breed true in families or are caused by their own specific genetic or neural mechanisms. It is possible that such syndromes represent the phenotypic result of interactions between specific quantitative abilities (e.g., intelligence) and disabilities (e.g., autistic social impairment), in which there are threshold effects for the phenotypic expression of such parameters as language and stereotypic motor behavior (see below). In addition to its implications for understanding causal mechanisms

in the development of autistic syndromes, the conceptualization of autism as a quantitative trait has potentially far-reaching implications for understanding how autistic syndromes change in severity over the course of development or in response to intervention.

Quantitative Variation in Autistic Symptomatology in Affected Families

Numerous studies, using various methods of measurement, have documented the aggregation of autistic syndromes, symptoms, or traits in the close relatives of children with autism. Such observations of familial aggregation have ranged from a full diagnosis of autistic disorder (for which siblings of children with autism have a relative risk of 20 or higher; see Lauritsen, Pedersen, & Mortensen, 2005), to milder autistic syndromes (Asperger's syndrome, Pervasive Developmental Disorder Not-Otherwise-Specified; see Pickles et al., 2000), to subclinical behavioral features of the autistic syndrome (Constantino et al., 2006; Sung et al., 2005; Szatmari et al., 2000; Virkud Todd, Abbacchi, Zhang, & Constantino, 2009; Constantino et al., 2010b), to personality traits that are akin to autistic symptoms (Piven, Palmer, Jacobi, Childress, & Arndt, 1997). Lauritsen and colleagues (Lauritsen et al., 2005) additionally observed that the siblings of children with Asperger's syndrome in the Danish National Register had a 13 times higher-than-general-population risk for the development of full-blown autism, which constitutes some of the strongest evidence to date that the two disorders share common underlying genetic susceptibility factors. In addition to this aggregation of behavioral traits in family members, it has recently been suggested that electrophysiologic abnormalities (Dawson et al., 2005) and functional magnetic resonance imaging (fMRI) variations (Dalton, Nacewicz, Alexander, & Davidson, 2007) similar to those associated with autism are appreciable in the unaffected first-degree relatives of some children with autism.

Most recently, studies that have carefully differentiated simplex autism (single family member affected, also referred to as sporadic autism) from multiplex autism (two or more family members affected, also referred to as familial autism) have suggested that familial aggregation of subclinical autistic traits may occur only in multiplex autism (Losh, Childress, Lam, & Piven, 2008; Virkud et al., 2009; Constantino et al., 2010b), providing further evidence for differentiation of mechanisms of genetic transmission for sporadic versus familial forms of the disorder. Furthermore, differences in patterns of aggregation of quantitative autistic traits between male and female family members of multiplex autism families—as depicted below (Virkud et al., 2009)—suggest that the gender disparities that have been observed for nearly all familial autistic syndromes are reflected also in raw scores for subclinical traits among unaffected first-degree relatives (Constantino & Todd, 2003; Skuse et al., 2009), see Figure 29-1.
Figure 29–1. Distribution of RAW teacher-report Social Responsiveness Scale (SRS) scores for ALL assessed children in each family type (all of the boys in the simplex families, all of the boys in the multiplex families, all of the girls in the same set of multiplex families). A teacher-report SRS T-score of 60, the quantitative threshold used for comparison of less-affected/unaffected male siblings in multiplex versus simplex families (see text) is denoted by the hatched line in the right hand panel. Each bin is shaded to depict the respective numbers of children categorically-designated as affected or unaffected.

The Factoral Structure of Quantitative Autistic Traits

A key aspect of quantitative variation in autistic symptomatology involves the extent to which the three components of the autistic syndrome (social deficits, communicative deficits, and stereotypic behavior/restricted interests) covary. Although some methodologic approaches have yielded data suggesting that symptoms comprising the three respective criterion sets for a DSM-IV diagnosis of autism might arise independently of one another (Happe & Ronald, 2008), factor, cluster, and latent class analyses of autistic symptomatology in large samples of clinically affected families have revealed substantial overlap in these symptom sets. For example, Spiker and colleagues (Spiker, Lotspeich, Dimiceli, Myers, & Risch, 2002) studied affected sibling pairs with autism, and found that empirically derived clusters of symptoms within families differed not by specific symptom sets, but by the degree of impairment that existed (mild, moderate, or severe) across all three DSM-IV criterion domains for autism. Their findings were most consistent with a model of autistic symptomatology arising from a single, heritable, continuously distributed deficit that might influence dysfunction in all three symptom domains.

Similarly, Sung and colleagues (Sung et al., 2005) examined features of the broader autism phenotype in the relatives of autistic probands and found evidence for the primary aggregation of highly heritable social deficits that explained variation in symptomatology across other domains of the

autistic syndrome. Constantino and colleagues (Constantino et al., 2004; Constantino et al., 2007; Constantino & Todd, 2000) applied factor, cluster, and latent class analysis to diagnostic interview and quantitative trait data from families affected by autism and consistently observed a unitary factor structure across data sources and methods of analysis, reinforcing a unitary, syndromic structure for autistic impairment (whether clinical or subclinical in severity) in families affected by autism. A recent principal components factor analysis of an accumulated Washington University sample of 1,799 boys from 1,799 separate families, representing the full range of variation in autistic severity from unaffected to severely affected (by full-blown autistic disorder), yielded the factor structure depicted in the Scree Plot below (Figure 29-2), indicating that a primary factor accounted for over one third of the variance with all other possible factors contributing only minor components of variance (Constantino et al., manuscript in preparation). It is noteworthy that in this observation and in previous studies, the symptoms that loaded most strongly onto the principal factor represented all three of the DSM-IV criterion domains for autism. Subsequent to the original reports summarized above, Gotham, Lord, and colleagues (Gotham, Risi, Pickles, & Lord, 2007; Lord et al., 2006) factor analyzed data from thousands of structured diagnostic observations of children with autism and concluded that the symptoms comprising social deficiency and the communicative deficiency loaded onto a single factor.

Even at face value, a review of typical autistic traits reveals aspects of overlap across symptom domains that provide insight into key unifying constructs. The tendency for the

Figure 29–2. Scree plot of principal components analysis of SRS sample of 1,799 boys from 1,799 separate families, representing the full range of variation in autistic severity from unaffected to severely affected by clinical autistic syndromes.

intellectual functioning), can be viewed as an autistic syndrome that is compensated by a level of intellectual functioning that is adequate to sustain normal language development, even in the presence of a level of social impairment that is otherwise typically associated with language impairment. In that sense it may be the preservation of a relatively high level of general cognition—not the existence of a separate pervasive developmental disorder entity—that uncouples the usual association between social and communicative impairment observed in autistic syndromes.

Molecular genetic studies are now just beginning to add to our knowledge of the factoral structure of autistic syndromes. While many disparate mutations have been associated with the same triad of symptoms observed in autism, quantitative trail loci (QTL) analyses have indicated that common autism susceptibility alleles may preferentially confer risk for joint phenotypes comprised of subclinical symptoms in all 3 criterion domains for autism (St. Pourcain et al., 2010) or among specific subsets of autistic patients, for example those with versus without severe language delays (Alarcon, Yonan, Gilliam, Cantor, & Geschwind, 2005) or those with versus without gastrointestinal symptoms (Campbell et al., 2010). It has also been observed that a given large chromosomal rearrangement or allelic variation associated with autism (i.e., occurring more commonly in ASD than in the general population) might have highly variable phenotypic expression, as observed for 16p11 deletions that are found in patients with autism, patients with mental retardation without autism, and in normal individuals within autism-affected families (Bijlsma et al., 2009). Finally, it is well recognized that syndromes of specific language impairment (SLI) can be inherited independently from autism, however a number of studies have observed that language disorders with distinct autistic qualities (pronoun reversal, socially inappropriate phrases) and/or accompanied by very mild levels of social deficiency aggregate in the unaffected siblings of autistic probands (Constantino et al., 2010b). Ultimately molecular genetic studies are poised to make major contributions to our understanding of how (and in what combinations) the various clinical manifestations of autism arise, and this in turn will inform strategies for intervention for specific subgroups. It is highly conceivable that the severity distribution that constitutes familial autism is fully continuous with the distribution of subclinical autistic symptomatology that is appreciable in the general population (described below). It has recently been demonstrated for other complex diseases such as hypertension that variation within the normal phenotypic range can be caused by variation in the same genes that are responsible for clinical disease states (Ji et al., 2008) and this has been preliminarily observed for autism (St. Pourcain et al., 2010). From an evolutionary standpoint, it is possible that inherited factors that are actually adaptive when phenotypic expression is mild may be highly preserved in the population and may result in clinical disease states only when severely expressed or in interaction with other genetic or environmental factors.

social ability of individuals with ASD to be compromised by an over focus on the details of a social context ("missing the forest for the trees") is highly reminiscent of the over focus on details that characterizes young affected children's unusual (stereotypic) play with toys and older children's restricted range of interests. Thus, it is conceivable that an underlying deficit in the assignment of salience (Klin, Jones, Schultz, Volkmar, & Cohen, 2002) and the consequent absorption with details could underlie the social, stereotypic/behavioral, and even the communicative deficits (e.g., sentence comprehension compromised in the context of preserved decoding of individual words) that characterize autistic syndromes. Such unifying neuropsychological deficits in autism are beginning to be supported by neuroimaging studies that suggest an overabundance of short-range rather than long-range functional neural connections (reviewed elsewhere in this volume).

These observations provide a new framework for understanding quantitative variation in autistic symptomatology and challenge the 3-criterion taxonomy for differentiating specific pervasive developmental disorders (PDDs) in DSM-IV, by raising the possibility that each of the common disorders (autistic disorder, Asperger's syndrome, Pervasive Developmental Disorder Not-Otherwise-Specified) lie along a continuous distribution of impairment with a more parsimonious underlying factor structure. In such a reconceptualization, variation in autistic severity interacts with variation in other domains of development (general cognition, temperament, proneness to anxiety) to produce specific profiles of individual adaptation. For example, Asperger's syndrome, which is described in DSM-IV as a separate disorder (defined as autistic impairment without substantive language delay, and generally characterized by average to above average

Quantitative Variation in Autistic Symptomatology in the General Population

Several large general population studies involving symptom counts (Ronald et al., 2006; Skuse et al., 2009), or quantitative measurements of the severity of autistic social impairment (Constantino & Todd, 2003) have revealed that the distribution of autistic symptoms is continuous in nature; this is shown for a general population twin sample in the histogram below (Figure 29-3). Thus it may be highly arbitrary where distinctions are drawn between the designation of affected versus unaffected status as suggested above, ASD can be viewed as the extreme end of a normative distribution for reciprocal social behavior (and its associated traits) that occurs in nature. The average male with a current designation of PDD-NOS scores at about the 1st percentile of this distribution for severity of autistic social impairment. Females who score at the 1st percentile of the distribution for girls are less than half as likely to be clinically diagnosed as boys at this percentile cutoff (Constantino et al., 2010b) which may in part explain the gender ratio reported for clinical autistic syndromes as they are currently defined (see below).

It is important to note that variation in the general population is highly heritable, at the same level of genetic influence that autism itself is believed to be inherited (Constantino & Todd, 2003; 2005; Ronald, Happe, Price, Baron-Cohen, & Plomin, 2006).This appears to be true throughout the distribution, i.e., both for social competency and social deficiency. This does not necessarily imply that social competency and social deficiency are controlled by the same genetic factors, but that possibility exists, and is being actively explored. What is known about genetic influences on "subthreshold" autistic traits is that they overlap at least partially with those that influence some forms of autism, because, as discussed above, they preferentially aggregate in the unaffected family members of many children with ASD (Constantino et al., 2006; Virkud et al., 2009), particularly those for whom other members of the family are also fully affected by ASD (so-called multiple-incidence or "multiplex" ASD; see Table 29-1).

A consistent feature of autistic traits throughout the general population distribution is sexual dimorphism; raw severity
Figure 29–3. Distribution of Social Responsiveness Scale (SRS) scores as a function of sex (n = 1576) in a general population twin sample.

Table 29–1.

Mean Social Responsiveness Scale (SRS) scores as a function of gender, ASD-affectation status, and family type

	Simplex Autism Families	Multiplex Autism Families	p Student's t-test
Affected Boys *(raw teacher-report SRS)*	87.8 (SD = 28.3) n = 80	104.7 (SD = 33.8) n = 262	.0001
Unaffected Boys *(raw teacher-report SRS)*	30.7 (SD = 23.5) n = 89	40.3 (SD = 28.8) n = 29	.035*
Affected Girls *(raw teacher-report SRS)*		97.5 (SD = 36.0) n = 81	
Unaffected Girls *(raw teacher-report SRS)*		23.0 (SD = 16.3) n = 45	
Fathers *(spouse-report SRS)*	23.8 (SD = 17.5) n = 41	34.3 (SD = 23.3) n = 58	.01
Mothers *(spouse-report SRS)*	23.9 (SD = 20.1) n = 41	27.0 (SD = 17.8) n = 58	*ns*

scores for boys are slightly but significantly shifted toward the pathological end, in comparison to scores for girls. In order to ascertain whether gender-specific genetic effects account for this shift, Constantino & Todd (2003) studied opposite sex dizygotic twins. Opposite-sex twin pairs represent a gender-comparison condition in which common environmental influences can be modeled and controlled for. The results of structural equation modeling applied to these data indicated that the genes influencing autistic traits appeared to be the same for males and females in the general population. Lower prevalence (and severity) of autistic traits in females was found not to be a function of sex-linked genetic influences, but rather the possible result of increased sensitivity to early environmental influences (in females), which operate to reduce the phenotypic expression of genetic susceptibility factors and promote social competency (Constantino & Todd, 2003). If the same genetic structure holds true for autistic traits in the clinical range of severity, it would indicate that given similar levels of genetic susceptibility, girls are relatively protected (compared to boys) from phenotypic expression of this liability.

The question also arises whether inherited influences or quantitative autistic traits are the same as or different from those influences involved in other dimensional domains of psychopathology. Twin designs are capable of answering such questions about genetic overlap, as long as the various traits of interest are all measured in the subjects in a given genetically informative sample. A series of studies in the general population have indicated that (1) scores for internalizing behavior

and externalizing behavior explained only a minority of the variance in quantitative autistic trait scores (Constantino & Todd, 2003); (2) there is moderate phenotypic and/or genetic overlap between attention problem syndromes and quantitative autistic traits (Constantino & Todd, 2003; Lichtenstein et al., 2010); (3) elevation in quantitative autistic trait scores may exacerbate co-occurring psychopathologic syndromes (Constantino & Todd, 2000); and (4) youths with severe mood or anxiety disorders exhibit substantially higher autistic trait scores than healthy controls (Pine, Guyer, Goldwin, Towbin, & Leibenluft, 2008) and the level of impairment incurred by these and other variations in personality and behavior may be predicted in part by co-occurrence of subclinical autistic symptomatology (Kanne, Christ, & Reiersen, 2009). Recently Lichtenstein et al., (2010) analyzed data from one of the largest twin studies (n= 10,895 – twin pairs) ever to ascertain data on symptoms of neurodevelopmental disorders in children. It revealed that while about 80% of the variation in liability for autism spectrum disorders was due to genetic effects, bivariate analyses suggested that a substantial share of the genetic variance was shared respectively with ADHD, developmental coordination disorder, tic disorders and learning disorder. Taken together, these results indicate that autistic traits represent an inherited component of developmental abnormality that is largely independent of some domains of child psychopathology, but overlapping with a number of other neurodevelopmental syndromes. When subclinical autistic traits co-occur with other (nonautistic) child psychiatric syndromes, they operate to exacerbate the latter, and can compound functional impairment.

Intergenerational Transmission of Quantitative Autistic Traits

As would be expected for any inherited trait, general populations studies have revealed that correlations for quantitative indices of social impairment are moderate between first-degree relatives (intraclass correlations on the order of 0.30–0.40)—this is true within and across generations, i.e., for correlations between siblings, and for correlations between parents and their children (Constantino & Todd, 2005). There is also substantial correlation for quantitative autistic traits between spouses in both the general population (Constantino & Todd, 2005) and in clinically affected families (Virkud et al., 2009), consistent with the phenomenon of preferential mating. In the general population, when both parents score in the upper quartile for quantitative autistic trait characteristics, mean trait scores of their offspring are significantly shifted toward the pathologic end of the distribution (effect size 1.5). In clinically affected multiplex families enrolled in research studies, however, it has not yet been apparent (at the time of this writing) that there exists gross overrepresentation of such concordantly elevated couples among autism-affected families, in comparison to what would be expected by chance (Virkud et al., 2009).

The Clinical Ascertainment of Autistic Severity

A variety of established and emerging rating scales for social impairment in autism are capable of reliably quantifying its severity—these include checklists or questionnaires of current functioning completed by adult informants (usually parents, teachers, or both) who have observed a child routinely in his/her naturalistic social contexts, assessments of developmental history as provided by parents, or direct observations of social behavior in response to structured or semistructured social prompts. Each domain of observation can provide a unique and valuable vantage point for assessing the severity of autistic social impairment (as well as its relationship to other domains of development and psychopathology) in a given child. There are many ways in which multi-informant characterization of a developing child can help avoid misclassification that would otherwise arise from single-informant or single-context assessment (Kanne, Abbacchi, & Constantino, 2009). Young children with milder forms of ASD who might be rapidly identified by an experienced day-care teacher could go unrecognized if observed exclusively at home, since young parents are often inexperienced with respect to normative trajectories of social development. Moreover, such children can be reasonably competent in one-on-one social interactions with caring adults who can support and scaffold their interpersonal behavior, but have a great deal of difficulty in less structured social contexts in the company of larger numbers of close-aged peers. This extends into childhood and adolescence as well—there are many children who respond reasonably appropriately to a clinician-examiner in the context of a structured diagnostic assessment, but may be observed by teachers to display floridly inappropriate social behavior when in an unstructured context at school (lunch, gym, recess, bathroom breaks between classes). For these reasons it is useful to acquire information from multiple sources (ideally direct clinical observation, parent-report, and teacher-report, see Constantino et al. (2007)) in the clinical evaluation of social impairment in a child suspected of having an ASD.

Other Implications of a Quantitative Structure for Autism

The quantitative distributions depicted in this chapter suggest that it may be arbitrary where a line is drawn between the condition of being affected versus unaffected by autism; the place where that line is drawn (a percentile cutoff versus a cutoff that correlates with clinical or other psychometric designations) has serious implications for epidemiologic, genetic, and neurobiologic studies that might be confounded by misclassification. For example the seemingly straightforward calculation of recurrence risk becomes complicated by the

possibility that subtle degrees of affectedness may be appropriate to include as episodes of recurrence (Constantino et al., 2010b). A new generation of clinical epidemiologic research will need to explore the extent to which quantitative "recurrence" relates to patterns of aggregation in families and extended pedigrees as potential moderating variables such as twin versus singleton gestation.

Recognizing that a wide range of quantitative autistic traits may be present in the siblings of children with autism, it is possible to explore whether the association between phenotype and underlying genetic or neurobiologic mechanisms might be more appreciable when considering quantitative autistic trait information from all siblings in affected families rather than restricting analysis to the transmission of categorical disease states. A quantitative molecular genetic analysis utilizing quantitative trait information from all children of participating families (not just the fully affected subjects) has indicated that linkage signals in a multiplex family registry were substantially enhanced when adopting this approach as depicted below in Figure 29-4 (Duvall et al., 2007). The principal linkage signal derived from this approach has now been replicated in an independent sample (Coon et al., 2010) and overlaps with a strong linkage signal declined from the autism genome project (Autism Genome Project Consortium et al., 2007).

Quantitative Autistic Traits and Endophenotypes

In addition, a quantitative conceptualization of autism motivates the search for endophenotypes, which are inherited, quantitative phenotypic components of a syndrome. Endophenotypes, if they exist for autism, should be appreciable in some or many of the unaffected family members of clinically affected individuals, and might more closely map to specific genetic, neurobiologic, or psychologic factors that contribute to (but are not by themselves sufficient to cause) the phenotypic expression of the syndrome itself. Endophenotypes are not the same as associated symptoms of a condition (e.g., self-injurious behavior in Lesch-Nyan syndrome), but rather core components of the syndrome that appear in subclinical forms in unaffected relatives. Subclinical autistic traits exhibiting a unitary factor structure (as described earlier in this chapter) appear to constitute a social endophenotype for males in multiple-incidence (multiplex) autistic families (Virkud et al., 2009; Constantino et al., 2010b), and the search for more precise endophenotypic components of the autistic syndrome is under way. The findings from sibling and family studies that explore candidate endophenotypes can generally be interpreted on the basis of the matrix of possible results depicted in Table 29-2.
Figure 29–4. Linkage analysis of 99 AGRE families comparing results from Quantitative Trait Locus (QTL) analysis (top and middle) incorporating unchanged analysis of 99 AGRE families, showing contrasting results of a quantitative approach in which phenotypic information and genotypes of all siblings in each family were incorporated (top and middle panels, illustrating accentuation of a number of linkage scan across the genome) versus a qualitative scales in which only the information from affected sibling pairs was incorporated.

Table 29–2.

Matrix of interpretation of results from family studies of candidate autism endophenotypes

	Autistic Proband	ASD-Affected Degree Relatives	Unaffected 1st Degree Relatives in multiplex Families	Unaffected 1st Degree Relatives in Simplex Families	Unrelated Controls	Interpretation
Test Result	+	-	-	-	-	Poss. Severity Index
Test Result	+	+	-	-	-	ASD Phenotype
Test Result	+	+	+		-	ASD Endophenotype
Test Result	+	+	+	+	-	Inherited Trait*

*Possibly not Specific to autism, OR an endophenotype associated with genes <u>shared</u> by simplex and multiplex ASD.

As an example of the way in which two candidate endophenotypes might interact to confer susceptibility to autistic social impairment, Reiersen, Constantino, and Todd (2008) analyzed data on inattention and motor coordination deficits (separately inherited domains of quantitative neurodevelopmental deficiency) in over 800 children in the general population and showed how their co-occurrence is associated with the development of autistic social impairment, as shown below. These associations are reminiscent of a syndrome of Deficits in Attention, Motor Coordination, and Perception (DAMP) that has been observed and described in the child psychiatric literature in Figure 29-5 (Landgren, Pettersson, Kjellman, & Gillberg, 1996).

The current list of proposed candidate endophenotypes for autism is long, but the series of investigations required to establish them as true endophenotypes (through studies confirming heritability, patterns of familial aggregation, trait-like stability, and specific association with autism) is long as well. Some of the more promising endophenotypic

candidates (in addition to subclinical behavioral autistic traits, see above) include head circumference trajectory in infancy (Constantino et al., 2010a), laterality (handedness), electrophysiologic and brain activation responses to socially-relevant auditory and visual stimuli, sensory dysfunction, EEG/ERP abnormality, neuroimaging phenotypes (Di Martino et al., 2009; Scott-Van Zeeland et al., 2010; Kaiser et al., 2011), an array of neuropsychologic deficits (theory of mind, self-other representation, social motivation, capacity for shared intentionality, abnormalities in gaze cueing and/or joint attention), a variety of language endophenotypes (prosodic deficits, sentence comprehension abnormalities, timing of developmental milestones such as age of first word or first phrase), motor coordination problems, involuntary/repetitive motor movements, obsessionality, and inattention. Each of these might be uniquely influenced by specific brain networks that could become targets of preventive or therapeutic interventions.

The Interface Between Social Impairment and General Cognition

Finally, it is important to consider the implications of the interaction between quantitative distributions of social deficiency (accompanied by relative deficiency in communication and the presence of stereotypic behaviors and/or restricted interests as occurs in the autistic syndrome) and quantitative variation in general cognition, which are orthogonal developmental constructs that can be differentiated from one another within the normal distribution of IQ in the population. Autism can occur in the context of low IQ (narrowly-defined, severe autistic disorders were once believed to be accompanied by intellectual disability in some 70 per cent of cases), high IQ, or anything in between, and it is often difficult to know whether syndromes of combined social and cognitive impairment represent a cognitive disorder with secondary social impairment, the reverse, or some combination of two independent conditions. And even if largely uncorrelated within the general
Figure 29–5. Percentage of subjects with clinically significant autistic traits, stratified by presence or absence of DSM-IV attention-deficit/hyperactivity disorder (ADHD) and by endorsement of Child Behavior Checklist (CBCL) motor problem items. N = 851. Number of subjects in each group is shown above each bar. DAMP = deficits in attention, motor control, and perception.

population, clinical syndromes of severe deficiency in any developmental domain can exert expectable consequences on other developmental domains.

Co-occurrence of deficiencies across multiple domains can make it difficult (but crucial) to disentangle the relative contributions of impairments in each respective domain to the clinical syndrome of an individual child. A common example is the clinical scenario of a toddler who presents with language delay; it is perplexing (yet potentially relevant to the choice of intervention strategy) to determine whether that delay is most attributable to a primary cognitive deficit, an autistic syndrome, a specific language impairment, or some combination of dimensional variants of these conditions. If each domain is fundamentally quantitative in nature, it will ultimately require established maps of the expectable relations between the variables (analogous to the height versus weight norms used in pediatric practice) to accurately ascertain their relative contributions in a given case of developmental delay. We eagerly await a next generation of developmental-epidemiologic studies (some of which are currently under way) that will map the ways in which quantitative variations in such fundamental domains of development (especially cognition, capacity for reciprocal social behavior, language, emotional regulation, sensorimotor function and interpersonal experience) interact with one another over the course of development from infancy to adulthood. It is possible that such studies will pave the way for a new system of characterizing *all* syndromes of developmental delay, along measurable quantitative axes, each of which might allow more precise associations with contributing neural mechanisms (Constantino, 2009).

Conclusion

The deficits that characterize autistic syndromes–including those in the current diagnostic criterion domains of reciprocal social behavior, social communication and repetitive behavior/restricted interests–are continuously distributed in nature and may share common underlying genetic and neural mechanisms. Integrating quantitative approaches to characterization of neurodevelopmental syndromes will help advance the search for genetic, psychologic neurobiologic and endophenotypic components of their underlying cause(s), and provides a basis for repeated-measurement strategies that can track developmental course and response to intervention. Given what is currently known, the designation of autism affectation status (in a categorical sense) for any given individual a) should be contextualized with respect to published distributions in clinical and non-clinical populations; and b) is best informed by data from multiple social contexts.

Challenges and Future Directions

- The fundamental factor structure of quantitative autistic traits is a subject of ongoing controversy and some of the findings have varied as a function of different measurement methods. Clarification of the factor structure—specifically whether autism is truly syndromic or rather a function of the convergence of separable components of dysfunction—will have significant implications for studies of the causes and early development of ASD, as well as for approaches to intervention.
- The question of whether a high degree of social competence represents simply the absence of deficiency in reciprocal social behavior, or subsumes other abilities and developmental competencies remains unanswered. Future research on the roots of social competence may reveal key characteristics inherent in resiliency as well as contribute to better understanding of the genetic architecture of social development.
- It is hoped that a next generation of genetic-epidemiologic studies will map the ways in which quantitative variations in various developmental competencies interact with each other over time (see chapter by Cantor). Thus, rather than characterizing children on the basis of presence or absence of deficiency of one kind or another, a more comprehensive approach to assessment that simultaneously assimilates the contributions of quantitative variation in all major developmental domains (e.g. cognition, language, reciprocal social behavior, attention, affect regulation, life events) will allow for a more precise understanding of the contributing factors (and therefore potential targets of intervention) in children with syndromes of developmental delay. Such assessment will also help clarify the boundaries and interactions between such conditions as autism, specific language impairment, and intellectual disability.

Commentary

Jeremy R. Parr, Kerstin Wittemeyer, Ann S. Le Couteur

The Broader Autism Phenotype: Implications for Research and Clinical Practice

Over the last two decades, the broader autism phenotype (BAP) has become a focus for researchers and clinicians alike; this is in part due to its central role in the conceptualization of autistic spectrum disorders (ASD) and its importance for identifying ASD susceptibility genes. Studies of very young children with ASD, and prospective studies of siblings of children with ASD (at-risk, or high risk sibling studies) have provided important insights about "typical" development, our understanding of early ASD characteristics and subsequent developmental trajectories, and the range of possible outcomes for affected individuals (which includes BAP). For clinicians and researchers, who await the publication of the DSM-V and ICD-11 clinical conceptualizations of ASD phenotypes, the need to have a better understanding of what constitutes the BAP is a priority. Using the context of the findings reported in this series of chapters, this commentary will summarize some of the important challenges and opportunities for BAP research and the implications for clinicians who diagnose and provide services for children with ASD, and their families.

Research Aspects

In Chapter 27, Losh et al. provide a welcome overview of the historical context of BAP research. The parental phenotype was once considered an etiological factor in the development of ASD in their children (see Bettelheim, 1967); during this period joint working between parents (who were understandably distressed by these erroneous theories) and researchers was a challenge. Perhaps inevitably, research then focused on core autism to identify the biological underpinning of this severe organic neurodevelopmental disorder (Rutter, 1970). As discussed in several of the Chapters in this section, the 1990s saw a surge in interest in the BAP. Following twin and family studies published in the mid-late 1990s and more recent research over the last decade (reviewed by Losh et al., Chapter 27),

we now have a better understanding of the behaviors and traits associated with BAP. Core characteristics include social communication difficulties and behavioral rigidity (see Chapter 27, and Parr et al. and the International Molecular Genetic Study of Autism Consortium [IMGSAC] (in preparation)). A broad range of social (see Chapters 27 and 29), and communication impairments (in particular reciprocal communication impairments, and pragmatic difficulties) (reviewed by Groen & Buitelaar, Chapter 10) are frequently reported. In common with ASD, qualitatively similar elements of rigidity, perfectionism, and obsessive-compulsive disorder are also present (see Jacob et al., Chapter 17). Delineation of these repetitive BAP traits has been particularly difficult (Bailey et al., 1998). Furthermore, disentangling these repetitive traits from other psychiatric disorders (for example obsessive-compulsive disorder per se) remains challenging, and progress has been slow (Jacob et al., Chapter 17). Finally, as discussed by Losh et al. (Chapter 27), the relationship between mood disorders (particularly affective disorder) and the BAP remains poorly understood. Depression and/or anxiety may be related to the BAP itself, rather than a consequence of having a child (or children) with ASD (see Losh et al., Chapter 27). For both BAP and ASD, further research is needed to ascertain whether affective disorder is integral to the phenotypes, or present as a consequence of the impact of their behavioral characteristics.

Historically, in contrast with other areas of ASD research, a small number of groups have investigated the BAP, and overall research capacity has been limited. However, understanding the BAP has become of critical importance to our conceptualization of ASD, and its etiology. As a consequence, the BAP will continue to receive increased attention during the next decade. As with other complex neurodevelopmental disorders (for example attention-deficit/hyperactivity disorder [ADHD] and schizophrenia), careful characterization of the whole phenotypic spectrum, rather than a focus on the more severe phenotypes is necessary in order to fully investigate their neurobiological basis (Bailey & Parr, 2003).

In ASD research, the BAP was first identified in families with twins, or affected relative pairs ("multiplex families") with ASD (see Losh et al., Chapter 27). More recently, researchers have described BAP characteristics in the context of normative trait variation in general population samples (reviewed by Constantino, Chapter 29, and Losh et al., Chapter 27). This approach investigates common social communication difficulties and rigidity traits in the population and proposes that these lie on a dimension with ASD itself (see Constantino, Chapter 29). As discussed by Losh et al. in Chapter 27, different approaches to investigating the BAP have resulted in the development of different methods of BAP assessment (for example structured interviews and observation measures vs. parent and self-report questionnaires), undertaken on different populations (ASD families vs. the general population; see Losh et al., Chapter 27). Similar variability exists in the approaches taken in biological BAP research (Lainhart & Lange, Chapter 28). Losh et al. also highlight that few studies have controlled for the effect of having a child with a neurodevelopmental disorder (although see De Jonge et al. & IMGSAC, in preparation). There has been little opportunity to compare the validity of these different methodologies and potentially contrasting or complementary approaches.

The lack of comparative data from studies using different methods in the same population severely limits our conceptual understanding of the BAP (see Lainhart & Lange, Chapter 28; and Losh, Chapter 27). In the future, investigating general population samples, and samples of relatives from ASD families using the same BAP measures, for example the revised Family History Interviews (Parr et al. & IMGSAC, in preparation) and questionnaires such as the Social Responsiveness Scale (Constantino et al., 2003) will assist us in refining our behavioral measures and methods, and identifying how best to conceptualize ASD/BAP. It is possible that a combination of questionnaire screening, more in-depth interviewing, and hypothesis driven neurocognitive and functional imaging/biological investigations of individuals across the behavioral spectrum might advance our understanding of the extent and impact of the phenotype (Losh et al., Chapter 27; Lainhart & Lange, Chapter 28).

Despite progress in better characterizing the BAP and utilizing relatives' data, many aspects remain poorly understood: More is known about the BAP in relatives from multiplex ASD families than singleton families. The relationship between the quality and severity of ASD in affected individuals, and BAP traits in their parents or other relatives requires further study; as discussed by Losh et al. (Chapter 27), understanding familiality (the extent to which traits in parents relate to their children's ASD) has methodological implications for researchers attempting to reduce genetic heterogeneity, by utilizing phenotypic information in the search for autism susceptibility genes (Bailey & Parr, 2003). In molecular genetic studies, relatives' BAP data could be used dimensionally or categorically (for example QTL methods, or haplotype, or parent of origin analysis). Dimensionalization of the BAP has been relatively straightforward (see Constantino, Chapter 29),

but when to classify relatives of individuals with ASD as being "affected" with the BAP remains uncertain. The extent to which BAP status can confidently be assigned according to behavioral thresholds based on an interview or questionnaire scale is not yet known. Considering the utility of relatives' BAP status for genetic studies, as genetic influences may be different in singleton and multiplex families, as highlighted by our recent appreciation of the etiological role of de novo copy number variants (CNVs) in ASD, including parents in genetic studies is not likely to be a useful strategy in all families. This is further complicated by stoppage effects on reproduction, which results in families who might have had multiple children with a disability, deciding not to have further children following the diagnosis of one child (see Jones et al., 1988).

Considering the genetic and phenotypic heterogeneity of ASD, how best can relatives' BAP data be utilized in the search for susceptibility genes? While biological testing in individuals with ASD and those with the BAP is at an early stage, having a better understanding of brain structure, function, and neuronal connectivity, and potentially biological markers will help us understand the phenotypic spectrum (Bailey & Parr, 2003, and Lainhart & Lange, Chapter 28). Lainhart and Lange highlight the limited evidence supporting biological aspects of the BAP; the amount of research in this area is in stark contrast to that undertaken of the core ASD phenotypes. However, both fields suffer from a lack of replicated neurobiological findings. However, as the genetic liability to autism is likely to be expressed at a brain level, psychological (social cognition, executive functioning, face processing), neuroimaging (for example functional MRI or magnetoencephalography), and neurophysiological testing in combination may help us understand differences and similarities between the BAP and ASD, their genetics, and eventually the extent of environmental influences. Relatives (with and without the BAP) should be encouraged to donate brain tissue to repositories (such as the Autism Tissue Program) so that neuropathological studies can explore the cellular and molecular differences in the brains of individuals from across the behavioral spectrum.

Finally, translational research using BAP data has not been a priority to date, partly because the focus has been on characterization and methods. Researchers are starting to think about how relatives' BAP status might directly influence clinical practice, and here, we cite two examples: First, researchers could explore the use of parents' and other relatives' BAP data in genetic counseling for families who request information about the recurrence risk of ASD in their family. If parents with BAP were found to be at greater risk of having a second child with ASD, parental BAP status would allow us to give a revised (if still generic) recurrence risk of having another child with ASD. Such data could be used by parents to make better informed family planning decisions. Second, there are also nonmedical translational uses of BAP status. Parents are increasingly encouraged to deliver social communication and play-based intervention for their children; however, researchers are starting to explore whether parental BAP could potentially affect the delivery of parent-mediated intervention.

One hypothesis is that parents with BAP, who may find it difficult to vary their own social communication style, may find delivering effective intervention more challenging than parents without the BAP. Research evaluating the quality of intervention delivery will be necessary to ensure equal access to potentially effective intervention for all children.

Clinical Aspects

Clinicians in the 1980s and 1990s learned to diagnose autism; in the last decade, diagnosing children with Asperger's syndrome and Pervasive Developmental Disorder Not-Otherwise-Specified (PDD-NOS), has been a challenge. During the next decade, deciding who reaches ASD threshold according to DSM-V and ICD-11 will further challenge pediatricians, child psychiatrists, and their multidisciplinary teams. The majority of clinicians come across the BAP in the context of diagnostic assessments for children, adolescents, and adults. Since Kanner's first description of autism, there has been a shift in clinicians' and researchers' judgment about the threshold of the ASD behavioral phenotype, where that ends, and where the BAP begins. Over recent decades the use of diagnostic terminology has changed from an emphasis on a narrow definition of "core" autism to an acceptance of a broader concept of autism spectrum disorders. The increased awareness among families and professionals of autism, and a preparedness to accept a broader spectrum has contributed to the increase in the detected prevalence of ASD (see Chapter 6 by Fombonne et al.). Correspondingly, what we understand to be "BAP" is likely to change as research and clinical practice evolves further. For example, parents of children with ASD give descriptions of behavior from their own childhood that are compatible with a diagnosis of ASD using current classification. Some of these parents continue to have significant difficulties in adult life and may have developed adaptive strategies to manage some of their difficulties. In some circumstances, it may be appropriate to discuss the merits of referral to adult diagnostic services.

The revisions that result in the DSM-V and ICD-11 classifications may lead to a further widening of the autism spectrum; the implications for clinical and research practice are considerable. In that context, assessment tools such as ADI-R and ADOS were originally constructed for studies of children with autism. They can be used to evaluate clinical presentations across the differential diagnosis of PDD/ASD for individuals whose difficulties impair their functioning. However ADI-R and ADOS were not designed to evaluate individuals with qualitatively similar behavioral traits, but not ASD; such individuals who may have the BAP, are unlikely to reach threshold on either "gold standard" diagnostic measure. The challenge for clinicians and researchers alike is how best to identify and characterize this broader spectrum. Existing BAP measures have been developed to capture those qualitatively similar characteristics not identified by existing diagnostic tools (see Losh et al., Chapter 27, and Constantino, Chapter 29). For instance the Family History Interview was revised with the structure and scoring system of the ADI-R in mind, in order to allow true dimensionalization of the full ASD continuum (Parr et al. & the IMGSAC, in preparation). Whether these measures (or their subsequent revisions) are useful in clinical practice remains to be seen.

One striking aspect of the BAP chapters is the lack of research evidence about the clinical impact of the BAP across the lifespan. In our experience, BAP behaviors and traits may be associated with a certain set of relative strengths, but can also lead to significant functional impairments, including difficulties with social and marital relationships, and problems in the school or workplace. If ASD is indeed a continuum, functional impairment must be associated with the BAP, otherwise, by inference, all individuals with BAP characteristics and functional impairments would be classified as having ASD itself. For clinicians using future classification systems, the critical question will be whether individuals who present with subthreshold behaviors (BAP) and functional impairment should receive an ASD diagnosis. In our current clinical practice, using DSM-IV criteria, this is not the case, and when a clinical diagnosis is not possible due to subthreshold characteristics, clinicians are left to find a "form of words" to summarize the individual's ASD related impairment and potential support that might be beneficial (Parr & Le Couteur, clinical observations). One form of words used in our practice is: "John has social communication difficulties and behavioural rigidity, which are similar to, but less severe than those seen in children with ASD. Nevertheless, support would be beneficial in various settings, such as (to be specified by clinician)." For children who have a sibling with ASD, this wording is more acceptable to parents and service providers, as it can be placed in the context of ASD within the family. A greater challenge is faced by families in which there is no family history of ASD. The term "BAP" is mostly used in relation to families in which there is an index ASD case, is rarely understood outside clinical services, and is not useful to families who need to access support from education or social care services. We suggest also using the above descriptive wording and terminology when there is no ASD family history; however, in our experience accessing appropriate support is likely to be even more difficult in this context.

Evidence about whether we should provide "intervention" (for example support with social skills) to children and adults with BAP traits in order to ameliorate difficulties in their daily life is very limited. For very young children, intervention studies would be possible through identification of children with the BAP from at-risk study cohorts; such studies will increase our knowledge of whether the developmental trajectories of children with BAP can be altered by early intervention. Effective early intervention might reduce the risk of children developing additional behavior problems and comorbidities such as anxiety and mood disorder. Such evidence could be used to make a compelling case for intervention for young individuals with the BAP; however, as capacity to provide

intervention to children with full-blown ASD remains limited in some countries this might not be prioritized. For older siblings of children with ASD, increased developmental surveillance may be appropriate, and intervention commenced when necessary; however, such a strategy would have considerable resource implications for families and local services. For adults with the BAP, social support in the workplace, including mentorship about effectively managing colleagues, may be helpful for some individuals (Parr & Le Couteur, clinical experience). Systematic evaluations of such workplace-based support are currently underway for adults with Asperger's syndrome (Howlin et al., 2005); whether such data are applicable to adults with BAP will require further evaluation. For young people and adults with ASD, bullying is encountered frequently, and is associated with low self-esteem and impacts on patient well-being. Individuals with the BAP may also be at increased risk of being bullied, thus awareness programs within educational settings should focus on a broader spectrum of children, rather than ASD alone.

Conclusions

Further understanding the BAP will have benefits to all. Clinicians, researchers, and families of individuals with ASD keenly await the findings of BAP research studies described in the chapters from this section during the next few years. As BAP research capacity continues to build, critical questions about genetics, developmental trajectories for infant siblings, and the impact of the BAP will become known. Whether the BAP holds the key to understanding the complex spectrum of ASD phenotypes remains to be seen.

Developmental Neurobiology of Autism Spectrum Disorders

Points of Interest

- Many ASD susceptibility genes encode proteins that regulate synapse development and activity-dependent neural responses.
- Postulation of three additional mechanisms that may contribute to ASD:
  - Evolutionary-driven expansion of cerebrum and cerebellar size through signaling systems such as those activated by fibroblast growth factors.
  - Imbalance in the excitatory/inhibitory ratio in local and extended circuits.
  - The hormonal effects of the male genotype.

Autism Spectrum Disorders are extremely heterogeneous. While genetic etiologies are unquestionably involved (see below), one can't ignore epigenetic and environmental mechanisms, although the magnitude of their roles is uncertain. Since ASD have their onset in early childhood, all etiologies must interfere with brain development. In this perspective, I have addressed some of the neurodevelopmental mechanisms whose derailment may lead to ASD. In the introduction, I briefly review the neuroanatomical and genetic features of ASD, because they provide a context for the developmental models that I discuss later.

Neuroanatomical Landscape of ASD

ASD show no simple or single neuroanatomical phenotype that points to obvious neurodevelopment mechanisms. However, structural neuroimaging and histological studies (reviewed in Amaral et al., 2008; Bauman, et al., 2006; Carper et al., 2006) provide evidence for anatomical defects, at least in some individuals. These defects are the subject of another chapter in this volume; here I highlight a few points based on the reviews listed above.

1. Brain volume measurements show evidence for a modest increase in cerebrum growth (~10%; affecting both the white and grey matter) during early childhood (years 1–3), with the largest effect in the frontal lobes (dorsolateral and medial, but not orbital); the growth rate then decreases.
2. Cerebellar defects: cerebellar size increases (~7%) in children under age 5, but decreases in older patients; there are reduced numbers (~30% decrease) of Purkinje neurons in patients age 4–67 years.
3. Reduced cell size and increased density in the "limbic" areas (amygdala, hippocampus, entorhinal cortex, medial septal nucleus, mammillary body, and anterior cingulated; the increased density in the amygdala was not replicated by Amaral et al., 2008). There appears to be decreased dendrite complexity in the hippocampus. The dorsolateral prefrontal cortex also shows increased cell density, because of reduced space between cortical "minicolumns" in layer III (Casanova, 2006). There are decreased numbers of neurons in the amygdala and in the fusiform gyrus based on unbiased stereological studies in subjects without epilepsy. The earlier density findings were based on anatomical techniques open to bias and in brains of subjects most of whom also had epilepsy.
4. Increased amygdala size (15%) in 8- to 12-year-old ASD boys, followed by reduced postadolescent neuronal number (Amaral et al., 2008).

Genetic Landscape of Autism Spectrum Disorders (ASD)

The genetic landscape of Autism Spectrum Disorders (ASD) has several salient features that provide the boundary conditions

for considering the breadth of its etiological mechanisms (Abrahams & Geschwind, 2008; Bonora et al., 2006; Sutcliffe, 2008; Walsh, Morrow, & Rubenstein, 2008):

1. ASD are heritable—concordance rates in monozygotic twins (~60–90%) are roughly 10-fold higher than in dizygotic twins and siblings, and first-degree relatives show a ~50-fold increased risk for autism compared to the population prevalence (1/150) (Bailey et al., 1995; Smalley et al., 1988).

2. ASD affect four times as many boys as girls. The mechanism(s) for this remains elusive; its elucidation could be fundamental to understanding the factors that predispose to ASD.

3. ASD are genetically heterogeneous. Defined mutations, genetic syndromes, and de novo copy number variation probably account for about 10–20% of cases; none of these causes individually accounts for more than 1–2% (Walsh, Morrow, & Rubenstein, 2008).

4. The genes currently linked to the ASD do not appear to selectively cause ASD. For instance, mutations of many genes cause mental retardation without ASD, and alleles of Neurexin1 and AHI1 are associated with ASD and schizophrenia (Ingason et al., 2007; Walsh et al., 2008).

5. Many cases of ASD may result from more complex genetic mechanisms, including co-inheritance of multiple alleles and/or epigenetic modifications (Freitag, 2007; Gupta & State, 2007).

6. Approximately 10% of sporadic cases of ASD are associated with de novo copy number variations in either single genes or sets of genes (Sebat et al., 2007).

7. Analysis of families of shared ancestry has identified recessive alleles of several genes that previously were unknown to cause ASD (Morrow et al., 2008).

Therefore, ASD, or at least risk for ASD, may be caused by a very large number of genes and alleles of those genes; the magnitude of that number is unknown. Gene variants that weaken the development and/or function of critical components of cognitive and emotional processing can alone, or in combination with other genes or environmental variables, increase the probability of ASD. While this poses a huge problem for understanding and treating ASD, it does suggest a paradigm for their conceptualization. The paradigm is to elucidate the developmental and neural pathways (anatomical, cellular and molecular) which tie together the known molecular/genetic defects causing ASD, and that cause neural systems defects that are postulated to contribute to ASD. Herein, I attempt to lay a foundation for this paradigm, by examining some of the pathways that appear to be disrupted by known causes of ASD.

Neural System Dysfunction: Localized Versus Distributed Developmental Defects

ASD are probably caused by alterations in the structural organization and/or function of neural systems that process social information, language, and sensorimotor integration.

Neural system lesions can be localized or distributed (Rubenstein, 2006). A localized lesion that weakens or disables one component of a circuit can impede the function of the entire circuit, generating a behavioral phenotype. This phenotype can likewise be generated by defects in another component of the same circuit. Thus, related behavioral syndromes can be generated by a variety of anatomical defects.

Distributed lesions can be caused by defects that are common to many regions of a given neural system, or to multiple neural systems. For instance, mutation of genes that are broadly expressed, such as those that cause Fragile X mental retardation (FRAXA; FMR1), Rett syndrome (MeCP2), or tuberous sclerosis (TSC1 & 2), will disrupt neural function throughout the nervous system.

Developmental defects can alter the connectivity between brain regions; these can be distributed or localized. Distributed defects include general abnormalities in axon or dendrite growth, synaptogenesis, action potential initiation/propagation, or myelination. It is not known whether these types of abnormalities are found in autism, although there is evidence for connectivity defects from functional imaging studies (Kana et al., 2006; Geschwind & Levitt, 2007) and from mutations in or near genes that encode proteins implicated in the development of axon tracts: PCDH10 (protocadherin 10; Morrow et al., 2008), neurexins/neuroligins (Jamain et al., 2003; The Autism Genome Project Consortium, 2007), and Ig superfamily contactin proteins (Alarcón et al., 2008; Fernandez et al., 2008; Morrow et al., 2008; Roohi et al., 2008).

Currently, it is unclear whether or not there are localized connectivity defects in ASD. However, based on analyses of mouse mutants, there are many examples for genetic lesions that selectively alter development of specific brain connections, such as the corpus callosum (Paul et al., 2007), or connectivity of axons that comprise the internal capsule (Garel & Rubenstein, 2004; Molyneaux et al., 2007; Price et al., 2006; Uemura et al., 2007).

Localized lesions are exemplified by mutation of genes that are expressed in neurons that share common features, such as the Dlx1&2 homeobox transcription factors, which regulate the development of most forebrain GABAergic neurons, or TBR1, a T-box transcription factor that regulates the development of most early-born cortical glutamatergic neurons (Hevner et al., 2001). Likewise, localized lesions can be generated by mutations of genes that regulate the development of particular parts of the brain, such as Fgf17, which controls the size and character of the frontal cortex and cerebellum (Cholfin & Rubenstein, 2007), or Emx2, which controls the size and character of the occipital cortex (O'Leary et al., 2007). I will discuss some of these examples below, and speculate as to their relevance to some forms of ASD.

FGF Genes–Core Regulators That Pattern the Growth and Nature of the Frontal Cortex and Cerebellum

During evolution of the mammalian brain, perhaps the most salient morphological change has been the increased surface

area of the neocortex with the concomitant increased laminar complexity of the late-born superficial layers (layers II, III, and IV) (Hill & Walsh, 2005; Bystron et al., 2008). The human brain is roughly three times larger than chimpanzee brain. In addition, the prefrontal cortex of humans and greater apes is disproportionately large compared to the rest of the neocortex of lesser apes, monkeys, and less complex mammals (Ongür & Price, 2000; Semendeferi et al., 2002). The prefrontal cortex is the center of cognition and decision-making.

Evolutionarily advantageous innovations can also come with liabilities, particularly if selective pressures have not reduced the frequency of design flaws. Thus, perhaps the benefits of the prefrontal cortex enlargement in humans have come with imperfections that underlie some of the etiologies of neuropsychiatric disorders including ASD. Therefore, insights into some forms of ASD may come from understanding the mechanisms that underlie prefrontal cortex development, including mechanisms that control the size, nature, and connections of its subdivisions.

The brain of ASD patients shows a trend for increased brain volume (and head circumference) apparently due to precocious growth during early postnatal life, followed by a deceleration at later stages (Piven et al., 1995; Carper et al., 2006; Amaral et al., 2008). Enlargements are greatest in the frontal lobes, although increases are also found in the temporal and parietal lobes. Within the frontal lobe, increases are seen in the dorsolateral and medial regions, but not the orbitofrontal cortex. Currently, prenatal and neonatal retrospective studies of ASD head circumference do not report enlargement (Hobbs et al., 2007).

The mechanisms for the postnatal brain enlargement are unknown, although insights may come from understanding the basic mechanisms that regulate cortical growth and patterning.

Over the last decade, fibroblast growth factor (FGF)–signaling has been shown to play a central role in regulating cortical regional properties and growth (Grove & Fukuchi-Shimogori, 2003; Sur & Rubenstein, 2005), and in particular promoting development of the frontal cortex (Garel et al., 2003; Storm et al, 2006; Cholfin & Rubenstein, 2007, 2008). These secreted proteins are produced by patterning centers embedded within the embryonic brain, including at the rostral end of the neural tube (Storm et al., 2006; Cholfin & Rubenstein, 2007, 2008). While Fgf8 has the major role in this process (Garel et al., 2003; Storm et al., 2006), other Fgf genes have smaller but perhaps more interesting roles. For instance Fgf17$^{-/-}$ null mutant mice are viable, but have a subtle reduction in their prefrontal cortex. The defect is selective to the dorsomedial prefrontal cortex, including the anterior cingulate cortex, while apparently not affecting the orbitofrontal cortex (Cholfin & Rubenstein, 2007; Cholfin & Rubenstein, 2008). Like Fgf8, Fgf17 also patterns the regions flanking the midbrain/hindbrain patterning center—including the tectum and the cerebellum (Xu et al., 2000). Thus, Fgf17$^{-/-}$ mice have defects in the prefrontal cortex, inferior colliculus, and cerebellum. In this regard, it is noteworthy that alterations in cerebellar vermis size are seen in ASD (Amaral et al., 2008; Bauman et al., 2006). While there is little

understanding of the mechanism(s) for this, the En2 transcription factor, which lies downstream of FGF-signaling, may contribute to some forms of ASD (Benayed et al., 2005).

The behavior of Fgf17$^{-/-}$ mice shed light on the phenotype of individuals with prefrontal cortex, tectal, and cerebellar defects. They show deficiencies in assays of social recognition and interaction, as well as reductions in neonatal vocalizations (Scearce-Levie et al., 2008). At this point, we can't directly ascribe these phenotypes to specific neuroanatomical lesions, although is seems very likely that the dorsomedial prefrontal hypoplasia strongly contributes to the social deficits. However, given prefrontal-thalamic-cerebellar connectivity (Dum & Strick, 2006), one can not dismiss the behavioral importance of the cerebellar deficit. Furthermore, the hypoplasia of the inferior colliculus could contribute to the vocalization deficits. In any case, the key point is that lesion of a signal gene (Fgf17) disrupts functions of neural systems required for behaviors that are similar to those that are abnormal in ASD.

The analysis of mutations that reduce expression from Fgf8 and Fgf17 show that these genes promote growth of the cortex, and particularly of the dorsomedial frontal cortex—the region that shows the largest increase in size in ASD (Amaral et al., 2008). Thus, perhaps, there is overactivity of the FGF-signaling pathway in some forms of ASD. This could be due to several mechanisms, including increased expression of FGF ligands and/or increased signaling through the receptors and downstream transduction pathway. In this regard, mutation of several components that repress this pathway, including the PTEN phosphatase and TSC1/TSC2, are linked to ASD (see below). Of note, PTEN and TSC1/TSC2 regulate many steps in neural development and function, including synaptic signaling.

Dlx Genes—Gateway to Forebrain Inhibitory Neuron Development and Function

The Dlx homeobox transcription factors are broadly expressed prenatally in progenitors of forebrain GABAergic neurons, as well as postnatally in subsets of mature GABAergic neurons, such as in cortical interneurons (Cobos, Calcagnotto et al., 2005; Cobos et al., 2006). Mutations that simultaneously block the function of pairs of mouse Dlx genes disrupt development (particularly migration and differentiation) of most forebrain GABAergic neurons (including cortical interneurons, and projection neurons of the striatum, pallidum, central nucleus of the amygdala, and the reticular nucleus of the thalamus; Anderson, Eisenstat, Shi, & Rubenstein, 1997; Anderson, Qiu, et al., 1997; Long et al., 2008). Such mutations have the potential to disrupt function within these regions in addition to the communication between the neocortex, basal ganglia, and thalamus with obvious detrimental affects on cognitive and emotional functions (Fanselow & Poulos, 2005; Yin & Knowlton, 2006; LeDoux, 2007).

Whereas mice lacking pairs of Dlx genes die neonatally, mice lacking Dlx1 are viable. However, after ~1 month, there

is a selective degeneration of a subset of cortical interneurons that results in epilepsy (Cobos, Calcagnotto et al., 2005). Thus, Dlx1$^{-/-}$ mutants have an age-dependent onset of seizures analogous to a subset of ASD patients who have late onset of epilepsy (Levisohn, 2007). Furthermore, Dlx genes regulate craniofacial morphogenesis, including the ossicles (Qiu et al., 1995; Jeong et al., 2008). As a result, Dlx1 mutants have reduced hearing acuity (Polley et al., 2006), which has obvious implications for auditory comprehension, but also suggests that analysis of craniofacial morphology may provide important insights into the etiologies of ASD.

While mutations in the Dlx2 and Dlx5 genes have been detected in some autistic individuals, it is unknown whether these contribute to the development of ASD (Hamilton et al., 2005), or comorbid symptoms such as epilepsy. Despite the lack of firm evidence implicating Dlx mutations genes in ASD susceptibility, I suggest that examining the function of the Dlx genes is illustrative of a genetic pathway whose dysfunction could predispose to ASD through defects in forebrain inhibitory neurons (Rubenstein & Merzenich, 2003). This could be through Dlx function in the neocortex and/or basal ganglia (including the amygdala). For instance, in the cortex, reduced Dlx dosage (function) would weaken inhibitory tone in the cortex, thereby increasing the ratio of excitation/inhibition, which would decrease the signal-to-noise ratio, altering neural processing and predisposing to epilepsy. In the basal ganglia, Dlx mutations could alter development of the striatum and pallidum—key components of the cortico–basal ganglia–thalamic circuit that is important in controlling Pavlovian (appetitve) learning, habit learning, and goal directed behaviors (Yin & Knowlton, 2006). Thus, understanding the genetic circuits downstream of the Dlx genes will identify genes required for forebrain inhibitory neuronal function—perhaps many of these, alone or in combination with other genes—are susceptibility factors for ASD.

Currently, the Dlx genes are known to (directly or indirectly) regulate the expression of large numbers of genes that are implicated in GABAergic neuronal development. For example, there is evidence that the Arx transcription factor is downstream of Dlx (Cobos, Broccoli, & Rubenstein, 2005b; Colasante et al., 2008; Long et al., 2009). Mutation of human Arx can cause epilepsy and autism, and in mice results in defects in cortical interneuron development (Colombo et al., 2007). Dlx genes also promote the expression of glutamic acid decarboxylase and vesicular GABA transporter (Stuhmer et al., 2002; Long et al., in press), and thereby will have profound functions in regulating inhibitory tone. Indeed, reduced Dlx dosage is associated with reduced synapse formation and reduced expression of neurexin3, a neuroligin ligand (Cobos, Long, & Rubenstein, unpublished). Dlx repression of the Pak3 kinase is implicated in regulating neurite growth (Cobos et al., 2007); and human Pak3 mutants have mental retardation (van Galen & Ramakers, 2005). Finally, Dlx genes promote the balance of neuronal vs. oligodendrocyte production, and thereby reduced Dlx function can reduce the number of GABAergic neurons, while perhaps altering the extent of myelination (Petryniak et al., 2007).

In sum, the Dlx genes can regulate the development and function of a single generic class of neurons: forebrain inhibitory neurons (e.g., interneurons in the cortex, and projection neurons in the basal ganglia). As such, alterations in the function of the Dlx genes, or of genes downstream of them, can weaken forebrain inhibitory tone, and thereby impact neural systems that underlie cognition. The future will determine to what extent alterations in the Dlx-regulated genetic network contribute to ASD susceptibility.

Detection of Salient Synaptic Information: Signal/Noise Processing

Molecular lesions that alter the development and/or function of excitatory, inhibitory, and neuromodulatory synapses can disrupt neural systems that process cognition and social behaviors. For instance, mutations that alter the balance of excitatory and inhibitory synaptic function may impede the ability to detect salient sensory signals above ambient noise, affect maturation of cortical regions (Hensch, 2005), and have been postulated to contribute to some forms of ASD (Rubenstein & Merzenich, 2003). For instance, selective interneuron apoptosis leads to epilepsy in Dlx1$^{-/-}$ mutants (Cobos, Calcagnotto et al., 2005).

The high prevalence of epilepsy in ASD (compared with its general-population prevalence) suggests an increase in the excitatory/inhibitory balance in ASD. However, current evidence from some mouse models of ASD provides evidence for decreased excitatory/inhibitory balance. For instance, female mice lacking one copy of MeCP2 (the gene responsible for Rett syndrome) show reduced synaptic excitation (Dani et al., 2005). Likewise, mice expressing a human allele of neuroligin3 found in an autistic individual, showed increased synaptic inhibition (Tabuchi et al., 2007). Nevertheless, one would expect a decreased signal-to-noise ratio (reduced signal salience) in the cortical/hippocampal circuits of these mutants. Therefore, there is good reason to continue exploring the model that disruption of excitatory/inhibitory balance, through multiple molecular/cellular mechanisms, contributes to ASD. Whether or not reduced synaptic excitation can evolve into epilepsy remains to be seen.

Male/Female Ratio

One of the great mysteries of ASD, and other neuropsychiatric disorders of childhood, such as attention deficit disorder, is the roughly 4:1 ratio of affected boys to girls. This could arise because maleness may bias cognitive style, emotional response, and instinctual behavior (Baron-Cohen et al., 2005; see Chapter 18 this book). It is this author's unsubstantiated opinion that some males are more likely to have a highly focused cognitive style that is less subject to emotional influences, and that males

are less interested in verbal communication. This idea is akin to the Extreme Male Brain Model of Autism (Baron-Cohen et al., 2005). This bias may sensitize the male brain toward ASD, to the effects of certain alleles, or to environmental factors.

If this conception were correct, how would this male cognitive and behavioral style arise? While there are several ASD-susceptibility genes on the X chromosome (e.g., Arx, Fmr1, MeCP2, Neuroligin3 and 4), this far from accounts for the increased male prevalence of ASD. Thus, other models should be considered. Perhaps the simplest model is that male:female hormonal differences, such as brain concentrations of androgens and estrogens, account for bias (androgens are converted to estrogens in the brain via aromatase; males have higher estrogen concentrations). These hormones are potent regulators of behavior. Furthermore, exposure to them during various stages of brain development has multiple effects, including regulating cell survival (which modulates the number of neurons in particular nuclei: sexually dimorphic nucleus of the preoptic area, and the anteroventral periventricular nucleus), and regulating neuronal connectivity and function (McCarthy, 2008). For instance, estrogens can regulate synapse numbers through controlling the numbers of dendritic spines in some hypothalamic nuclei (ventromedial nucleus and the arcuate nucleus). In addition, estrogens appear to regulate the expression of glutamic acid decarboxylase in the arcuate nucleus of the hypothalamus, and thus can modulate GABA signaling (McCarthy, 2008). Estrogens also can modulate whether GABA is excitatory or inhibitory, via expression of the potassium-chloride cotransporter KCC2 (Galanopoulou, 2005). Finally, androgens can predispose males to GABA-mediated excitoxicity (Nunez & McCarthy, 2008). Therefore, sex steroids could modulate excitatory/inhibitory balance, which could sensitive the male brain to ASD. Perhaps one should consider attempting to devise a therapy for ASD that modulates sex-steroid signaling in males.

Genetic Susceptibility Factors

In the following sections I discuss specific genetic lesions that predispose to ASD, and consider, when feasible, how their functions fit within the developmental models of ASD discussed above. Many of these lesions alter synaptic function and signaling (Zoghbi, 2003; Hong et al., 2005; Walsh, Morrow, & Rubenstein, 2008).

Molecular Pathways Linking Synaptic and Nonsynaptic Signals with Changes in Gene Expression and Protein Synthesis

Tuberous Sclerosis (TSC1&2) and PTEN

Children with TSC (autosomal dominant) have greatly increased rates of autism (25–50%), epilepsy, and mental retardation (Wiznitzer, 2004). TSC1 (hamartin, 9q34) and TSC2 (tuberin, 16p13) encode GTPase-activating proteins that inhibit the activity of the small G-protein Rheb. TSC1/TSC2 are tumor suppressors, because they repress growth responses through reducing activity of mTOR kinase (Inoki et al., 2005). mTOR promotes protein synthesis and other processes that increase cell growth.

TSC1/TSC2 are integral regulators of signal-transduction cascades downstream of signaling pathways for signals that activate receptor tyrosine kinases such as EGFs, FGFs, IGFs, and neurotrophins (Inoki et al., 2005). These signals activate a family of phosphatidylinositol lipid kinases (phosphatidylinositol-3 kinases, PI3K) that in turn activate the serine-threonine kinase AKT, which then represses TSC1/TSC2 (Inoki et al., 2005). TSC1/TSC2 are also regulated by intracellular amino acid concentration and by the ATP/AMP ratio—the end product of this regulation is to promote appropriate levels of protein synthesis and cell size (Inoki et al., 2005).

While TSC patients develop focal CNS lesions (tubers), it is likely that the general function of TSC1&2 in most/all neurons underlies the ASD symptoms. For example, reduced TSC dosage in hippocampal pyramidal neurons results in increased size of the cell body and dendritic spines (Tavazoie et al., 2005)—this is intriguing given the increased size of the brain in some children with autism.

Further clues that implicate this signaling cascade in ASD come from the observation that some patients with mutations in the phosphatidylinositol phosphatase (PTEN; 10q23.31) have ASD with macrocephaly (Butler et al., 2005). PTEN reduces activity of the PI3K pathway through dephosphorylation of phosphatidylinositol-tris-phosphate. Mice lacking CNS function of PTEN have increased signaling through the AKT, TSC, and mTOR pathway (Kwon et al., 2006). These mutants have enlarged brains that are associated with increased dendritic and axonal arbors and increased dendritic spines and synapses. PTEN mutant mice also exhibit abnormal social behavior, further implicating this signaling pathway in autism (Kwon et al., 2006).

Neurofibromatosis Type I (NF1)

Neurofibromin, encoded by the Neurofibromatosis type I (NF1) gene (chr17: 26470278–26670503), regulates many signaling pathways, including those downstream of adenylate cyclase, AKT-mTOR, and Ras-GTPase. As a result, patients can have learning deficits and ASD (Marui et al., 2004). Mouse mutants recapitulate many of these features, and have developmental defects including abnormal patterning of the somatosensory cortex (Lush et al., 2008).

MET

MET encodes a receptor tyrosine kinase (7q31), which is an oncogene that mediates hepatocyte growth factor (HGF)/scatter factor signaling. MET has an important role in neuronal migration in the forebrain and cerebellum, as well as

immune and gastrointestinal function. Mouse mutants have reduced cortical interneurons and a hypoplastic cerebellum. Campbell et al. (2006) identified a common functional allele in the promoter region of the MET gene that is associated with ASD.

Control of Translation and Protein Stability

Fragile X (FRAXA; FMR1)

Mutations that reduce expression (usually through CGG triplet-expansion) of this X-linked gene (Xq27.3) cause mental retardation, and these boys often have ASD (Belmonte & Bourgeron, 2006). Dendrites in FMR1 mutant humans and mice have an immature morphology (too long and thin). This phenotype may result from the observation that FMR1 encodes an RNA-binding protein whose functions includes translation regulation in dendrites. There is evidence that activation of metabotropic glutamate receptors leads to FMR1-regulated protein synthesis in dendrites—including production of proteins, such as PSD-95, that participate in excitatory synaptic transmission (Todd et al., 2003; Bear et al., 2004). Thus, FMR1 may function in part through transducing excitatory synaptic signals into changes in the protein constituents that modify synaptic function and structure. Indeed, reducing mGluR5 dosage partially rescues the phenotype of FMR1 mouse mutants (Dölen et al., 2007).

UBE3A

UBE3A (chr15: 23133489–23204888) is an imprinted gene that encodes an E6-associated protein (E6-AP) that contains an E3 ubiquitin ligase possessing two independent functions: a transcriptional coactivation and an ubiquitin-protein ligase activity, that can regulate the degradation of the transcriptional complexes (Ramamoorthy & Nawaz, 2008). Loss of UBE3A function causes Angelman's syndrome, often characterized by autistic features (Peters et al., 2004). UBE3A is also found at synapses, and maternal deficiency results in abnormal dendritic morphology (Dindot et al., 2008).

Axon and Synapse Formation/Function

Neuroligins (NLGN3 and NLGN4)

Neuroligins encode plasma membrane proteins that are implicated in regulating synapse development through binding neurexin proteins (Varoqueaux et al., 2006). There is evidence that specific combinations and splice forms of neuroligin/neurexin proteins can specify whether an excitatory or an inhibitory synapse will form (Chih et al., 2006). Mutations in two X-linked neuroligins (NLGN3 and NLGN4; Xq13 and Xp22.33, respectively) have been found in rare cases of autism (Jamain et al., 2003). Furthermore, a de novo deletion in neurexin1 (NRX1) has been identified in a pair of affected siblings (Autism Genome Project Consortium, 2007).

Mice with a loss-of-function mutation in the murine NLGN4 ortholog Nlgn4, exhibit deficits in reciprocal social interactions and communication (Jamain et al., 2008). Furthermore, mice engineered to express a neuroligin-3 mutation implicated in ASD have increased inhibitory synaptic transmission (Tabuchi et al., 2007).

Protocadherin 10 (PCDH10)

Protocadherin 10 (OL-Protocadherin) (4q28) encodes a cadherin superfamily protein that is essential for pathfinding of striatal, thalamocortical, and corticothalamic axons through the ventral telencephalon (Uemura et al., 2007). There is a >300 kb deletion near PCDH10 in an individual with ASD from a consanguinous family—the deletion is postulated to alter its expression (Morrow et al., 2008).

Ig-Superfamily Cell Adhesion Proteins: Contactin 3 & 4 (CNTN3 & 4) and CNTNAP2

Genetic variations, including deletions, have been mapped near to the CNTN members of the Immunoglobulin superfamily: CNTN3 (BIG-1; chr3: 74394412–74653033), CNTN4 (chr3: 2908921–3073040), and CNTNAP2 (chr7: 147667553–147745775) (Alarcón et al., 2008; Fernandez et al., 2008; Morrow et al., 2008; Roohi et al., 2008). The encoded axonal plasma membrane proteins are part of a family known to engage in cell adhesion (Yoshihara et al., 1995), and are implicated in axon pathfinding (Kaneko-Goto et al., 2008).

SHANK3 (ProSAP2)

SHANK3 (22q13.3) encodes a protein associated with the postsynaptic density of excitatory synapses, and can promote dendritic spine maturation. Rare mis-sense mutations in SHANK3 have been identified in autistic individuals (Moessner et al., 2007). Furthermore this region of chromosome 22 is a site of recurrent deletions in ASD (Sebat et al., 2007). Bourgeron and colleagues propose that a protein complex that includes SHANK3 and Neuroligins3&4 participates in the assembly of postsynaptic structures.

Neurotransmitters/Neuromodulators

Oxytocin and Vasopressin Receptors (OXTR; AVPR1a)

Oxytocin and vasopressin peptides are neuromodulators expressed by neurons in the hypothalamus and the amygdala. Axons from these neurons selectively ramify within circuits that are implicated in regulating social behaviors; these neuropeptides have demonstrated functions in mediating social behaviors (Young et al., 2005). There is growing evidence that the receptors for oxytocin (OXTR; 3p25–p26) and arginine vasopressin 1a (AVPR1a; 12q14–15) are associated with ASD (Wu et al., 2005; Yirmiya et al., 2006).

Serotonin Transporter (SLC6A4)

Serotonin has potent effects on multiple behavioral dimensions and developmental processes. Serum serotonin levels are increased in a subset of autistic individuals. Although this is not a specific diagnostic finding, it increases the potential importance that some alleles of the serotonin transporter gene (SLC6A4, SERT; 17q11.2) are associated with ASD (Sutcliffe et al., 2005; Brune et al., 2007).

Ion Channels

Calcium Channels (CACNA1C; CACNA1H; SCN1A; SCN2A)

Mis-sense mutations in the L-type (CACNA1C, Cav1.2; 12p13.3) and the T-type (CACNA1H, Cav3.2) calcium channels have been identified in rare cases of ASD (Splawski et al., 2004, 2006).

Sodium Channels (SCN1A; SCN2A)

Rare mis-sense mutations have been identified in two voltage-gated sodium channel genes (SCN1A: 2q24;SCN2A; 2q23–q24.3) (Weiss et al., 2003). A deletion near SCN7A (chr2: 166969785–167051724) has also been identified in a recessive form of ASD (Morrow et al., 2008).

Sodium/Hydrogen Exchanger (NHE9)

NHE9 (also known as SLC9A9; chr3: 144466754–145049979) encodes a $(Na^+, K^+)/H^+$ exchanger disrupted in a pedigree with a developmental neuropsychiatric disorder and mild mental retardation (de Silva et al., 2003). Likewise, a deletion near NHE9 has been identified in a recessive form of ASD (Morrow et al., 2008). Of note, mutations of NHE6, a related transporter, cause X-linked mental retardation and a phenotype mimicking Angelman's syndrome (Gilfillan et al., 2008).

Metabolic Genes

Phenylalanine Hydroxylase (PAH)

Historically, the elucidation that autism can be caused by phenylketonuria (hyperphenylalaninemia), was one of the turning points in establishing the biological etiology of autism (Cohen et al., 2005). There are several hundred alleles of phenylalanine hydroxylase (12q23.2) (www.pahdb.mcgill.ca), many of which, in the homozygous phenotype, can cause phenylketonuria. The rarity of ASD caused by phenylketonuria, may be attributed to the fact that neonatal screening and dietary treatment are now commonplace.

D7-Dehydrocholesterol Reductase
Smith-Lemli-Opitz (SLO)

The SLO gene encodes D7-dehydrocholesterol reductase (DHCR7; 11q12–q13); loss-of-function mutations cause accumulation of D7-dehydrocholesterol. This recessive disorder has broad developmental affects, including ASD in a high proportion of patients (Sikora et al., 2006). While SLO is a rare cause of autism, it demonstrates that disruption of cholesterol metabolism, and related pathways, need to be considered as etiologic mechanisms.

Regulation of Gene Expression

Rett Syndrome (MeCP2)

Girls with Rett syndrome commonly exhibit ASD symptoms; males generally die prenatally. This syndrome is due to loss-of-function mutations of the methyl-CpG-binding protein 2 (MeCP2; Xq28) (Moretti & Zoghbi, 2006). Some mutations result in milder symptoms that include ASD in both boys and girls. MeCP2 is a nuclear protein that binds to methylated CpG dinucleotides. It recruits a corepressor complex that is implicated in transcriptional repression. The brain of mouse MeCP2 mutants shows subtle increases and decreases in the expression of large numbers of genes; there is now evidence that MeCP2 is both a transcriptional activator and repressor (Chahrour et al., 2008). Among the genes that show altered expression include ubiquitin protein ligase E3A (UBE3A) and b3 GABA A receptor (Gabrb3) (LaSalle, 2007); these are imprinted genes in the Angelman's disease locus—inheritance of a maternal duplication of this region (15q11.2–q13) is the most commonly associated chromosomal abnormality found in ASD (Schanen, 2006). There is evidence that MeCP2 mutants also showed increased Dlx5 expression (Horike et al., 2005; Miyano et al., 2008); however, this finding was not replicated by Schüle et al. (2007).

MeCP2's association with ASD alludes to the possibility that epigenetic modifications of chromatin (e.g., cytosine methylation and histone methylation/acetylation) and parent of origin effects (imprinting) may have broader roles in contributing to ASD (Schanen, 2006).

Arx

Arx encodes a homeobox transcription factor (chrX: 24931732–24943986); it is expressed in cortical progenitors and subcortical differentiating GABAergic neurons, including those that become cortical interneurons. Mice lacking this gene have defects in several aspects of telencephalic development, including differentiation of cortical interneurons (Kitamura et al., 2002; Colombo et al., 2007). The Dlx genes promote their expression (Cobos et al., 2005). Affected children often have severe epilepsy (infantile spasms) and severe mental retardation, but mild cases have been identified with ASD (Wallerstein et al., 2008), although Arx mutations are very rare in ASD (Chaste et al., 2007).

RNF8, Encoding a RING Finger Protein

RNF8 (chr6: 37429726–37470492) encodes a RING finger ubiquitin ligase and transcriptional coactivator of RXR-alpha (Takano et al., 2004). Thus, like UBE3A, it can regulate the

activity of nuclear steroid receptors (see above). Furthermore, RNF8 can transduce DNA-damage signals via histone ubiquitylation and checkpoint protein assembly (Huen et al., 2007). Morrow et al. (2008) discovered a deletion near RNF8 in a recessive form of ASD.

Engrailed2 (EN2)

Alleles of the En2 homeobox transcription factor (7q36), which regulates cerebellum development, has been associated with ASD (Benayed et al., 2005). Mouse mutants exhibit social deficits (Cheh et al., 2006). EN2 is downstream of FGF-signaling from the midbrain/hindbrain patterning center (Liu & Joyner, 2001).

Distal-less 2 and 5 (Dlx2 and Dlx5)

Mis-sense mutations of the Dlx2 (2q31.1) and Dlx5 (7q21.3) homeobox transcription factors have been identified in individuals with ASD (Hamilton et al., 2005). As discussed above, these genes regulate development of forebrain GABAergic neurons and may be dysregulated in Rett syndrome (see above).

Genes of Unknown Function

Joubert Syndrome: Abelson's Helper Integration 1 Gene (AHI1)

Joubert syndrome is characterized by partial or complete agenesis of the cerebellar vermis; ~25% of these patients have autistic disorder. In a subset of Joubert patients, mutations have been found in the Abelson's helper integration 1 gene (AHI1; chr6: 135646805–135860596), encoding a protein of unknown function (Alvarez-Retuerto et al., 2008). These patients may also show deficits in axon pathfinding, based on defects in the decussation of the pyramidal tract (Ferland et al., 2004). Of note, AHI1 is also implicated in schizophrenia (Ingason et al., 2007).

Conclusion

The rapidly growing list of genes and alleles that contribute to ASD susceptibility suggests that many more genes will be discovered that are involved in this set of disorders. While this complexity is unsettling in terms of understanding and treating autism spectrum disorders, I hope that this review has been useful in suggesting some of the emerging themes of molecular and neural pathways/systems that underlie ASD.

Challenges and Future Directions

- Identify the mechanisms that promote growth, regional pattern formation, and connectivity of the cerebral cortex, and particularly of the prefrontal cortex, including those mechanisms that underlie the evolution of the human prefrontal cortex.
- Identify the mechanisms that regulate excitatory/inhibitory balance within local cortical circuits, as well as within extended circuited such as the cortical-striatal-thalamic loop.
- Identify mechanisms that underlie the increased ASD susceptibility of males.

Neuropathology of Autism Spectrum Disorders: Postmortem Studies

Points of Interest

- Compared to disorders such as Alzheimer's disease, relatively few autistic brains have been neuropathologically investigated, and even fewer have been subjected to quantitative analysis.
- Lower numbers of neurons have been reported in the amygdala, the fusiform gyrus of the temporal lobe, and the cerebellum.
- One current line of research emphasizes alterations in the basic columnar organization of the neocortex.
- Provocative data signs of ongoing inflammation are observed in the autistic brain.

Considerable progress in understanding the behavioral impairments of autism has been made over the last 65 years since Kanner (1943) first described a group of children with autistic-like disturbances, though the underlying neuropathology of the disorder remains elusive. Autism is a *clinically defined* disorder marked by impairments in reciprocal social interaction, abnormal development and use of language, and repetitive and ritualized behaviors, and a narrow range of interests that manifest by 3 years of age. These behavioral disturbances suggest that certain parts of the brain may be more pathological than others. Regions that constitute the "social brain" for example, might be preferentially impacted by autism. We recently compiled a list of neural systems involved in the functions that could be most affected by the core behavioral features of autism (Figure 31-1) to suggest where one might expect to find neuropathology (Amaral et al., 2008). Several brain regions have been implicated in social behavior through experimental animal studies, lesion studies in human patients, or functional imaging studies (Adolphs, 2001). These include regions of the frontal lobe, the cingulate cortex, the superior temporal cortex, the parietal cortex, and the amygdala. Language function is distributed throughout several cortical and subcortical regions. Foremost for expressive language function is Broca's area in the inferior frontal gyrus and portions of the supplementary motor cortex. Wernicke's area is essential for receptive language function, and the superior temporal sulcus plays a role in both language processing and social attention (Redcay, 2008). Finally, the repetitive or stereotyped behaviors of autism share many similarities with the abnormal of obsessive-compulsive disorder that implicate regions such as the orbitofrontal cortex and caudate nucleus.

Autism is increasingly considered to be a *heterogeneous* disorder with multiple causes and courses. Because there is a great range in the severity of symptoms associated with autism, it is described as a spectrum disorder. Mental retardation is a common correlate of autism representing the "low" end of the spectrum, and there are a number of comorbid symptoms, such as epilepsy, that have neurological underpinnings and affect some, but not all, individuals with autism. The comorbid symptoms of autism must be taken into consideration for the interpretation of the neuropathology of autism. Epilepsy, for example, is associated with pathology of the cerebral cortex, amygdala, cerebellum, and hippocampal formation, all of which have also been implicated in autism. Thus, if one analyzes the brain of an individual who has autism as well as epilepsy, it is not clear whether the observed pathology is related to the core features of autism, to the cause, effects or treatment of epilepsy, or perhaps to some peculiar convergence of the two disorders. Unfortunately, the majority of cases evaluated in earlier postmortem studies of the autistic brain (Table 31-1) involved brains from individuals who had comorbid seizure disorders and mental retardation.

There is also substantial heterogeneity in the onset of autism. Some children have signs of developmental delays within the first 18 months of life. However, 25–40% of children with autism initially demonstrate near-normal development until 18–24 months, when they regress into an autism that is generally indistinguishable from early onset autism (Werner & Dawson, 2005; Hansen et al., 2008; Ozonoff et al., 2008). The possibility that there is early-onset versus regressive phenotypes of autism might have important implications

Figure 31–1. Brain areas that have been implicated in the mediation of the three core behaviors that are impaired in autism: social behavior, language and communication, and repetitive and stereotyped behaviors. *Adapted from* Amaral, D. G., Schumann, C. M., & Nordahl, C. W. (2008). Neuroanatomy of autism. *Trends in Neuroscience, 31*, 137–145, *with permission from Trends in Neurosciences.* (See Color Plate Section for a color version of this figure.)

Table 31–1.

Neuropathological studies of autism using postmortem brain from 1980–2010

Author	Year	Sample Size and Characteristics	Approach and Region of Interest	Major Findings
Williams et al.	1980	4A (3M, 1F; ages 4, 14, 27, 33; 2S; 4MR); no C	qualitative observation—whole brain	Nerve cell loss and replacement gliosis in atrophic orbitofrontal and temporal regions in 2 cases; smaller neurons in CA4; ↓ Purkinje cell density in 1 case
Bauman & Kemper	1985	1A (1M; age 29; no S; 1MR); 1C (1M; age 25)	qualitative observation—whole brain	↑ cell density and ↓ cell size in hippocampus, subiculum, entorhinal cortex, septal nuclei, mammillary body and amygdala. ↓ density of Purkinje cells, neurons small and pale
Coleman et al.	1985	1A (1F; age 21; no S; 1MR); 2C (2F; ages 18, 25)	2D cell counts auditory cortex and Broca's area	No differences, except for ↓ glia in left auditory cortex and ↓ density of pyramidal neurons in right auditory association cortex

(Continued)

Table 31–1. *(Contd.)*

Author	Year	Sample Size and Characteristics	Approach and Region of Interest	Major Findings
Ritvo et al.	1986	4A (4M; ages 10, 19, 19, 22; no S; 3MR); 3C (3M; ages 3, 10, 13)	2D cell counts in cerebellum	↓ Purkinje cell density in cerebellar hemisphere and vermis
Bauman & Kemper	1987	1A (1F; age 11; no S; ?MR); 2C (?M; ?F; age-matched)	qualitative observation—amygdala & hippocampus	↑ cell density in amygdala & hippocampus
Bauman & Kemper	1990	1A (1M; age 12; no S; no MR); 2C (2M; age-matched)	qualitative observation—amygdala, hippocampus & cerebellum	↑ cell density of smaller neurons in limbic system; ↓ density of Purkinje cells; enlarged neurons in deep cerebellar nuclei and inferior olive
Bauman	1991	5A (4M, 1F; ages 9–29; 4S; 4MR)	review of earlier findings	↑ cell density in limbic system (4/5) and ↓ Purkinje cell density in cerebellum (5/5)
Hof et al.	1991	1A (1F; age 24; no S; 1MR)	qualitative observation—cerebral cortex and limbic system	Microcephaly (773 g); neurofibrillary tangles, especially in layer II and III of temporal cortex, probably due to severe head banging
Kemper & Bauman	1993	6A (5M, 1F; ages 9–29; 4S; 5MR); 6C (6M; age- and sex-matched)	qualitative/density measures—limbic system and cerebellum	Small and densely packed neurons in limbic system (6/6); anterior cingulate coarse and poorly laminated in 5/6; ↓ Purkinje cell #s in cerebellum (6/6)
Guerin et al.	1996	1A (1F; age 16; 1S 1MR)	qualitative observations—whole brain	Microcephaly, ↑ ventricular dilation, thin corpus callosum
Raymond et al.	1996	2A (1M; ages 7, 9; no S; 2MR); 2C (?M, ?F; ages 8, 13)	Golgi analysis in hippocampus	Smaller neurons in CA4; less dendritic branching in CA1 and CA4
Rodier et al.	1996	1A (1F; age 21; 1S; 1MR); 1C (1M; age 80)	qualitative observation—pons, medulla and cerebellum	Near-complete absence of facial nucleus and superior olive and shortening of the brainstem
Bailey et al.	1998	6A (6M; ages 4, 20–27 years; 3S; 6MR); 7C (5M, 2F; age-matched)	qualitative/density measures—whole brain	Megalencephaly (4/6); abnormalities in inferior olives (4/6); ↓ Purkinje cells in all adults; cortical dysgenesis in at least 50%
Blatt et al.	2001	4A (4M; ages 19–22; 2S; 4MR); 3C (3M; ages 16, 19, 24)	GABAergic, serotonergic, cholinergic, glutamatergic autoradiography in hippocampus	↓ GABA(A) receptor binding
Perry et al.	2001	7A (6M, 1F; ages ~24; ~4S; ~7MR); 10C (8M, 2F; ages ~32); 9MR (5M, 4F; ages ~32)	cholinergic immunohistochemistry in frontal and parietal cortex and basal forebrain	30% ↓ M1 receptor binding in parietal cortex; 65–73% ↓ α4 nicotinic receptor binding in frontal and parietal cortex; ↑ BDNF in forebrain
Casanova et al.	2002	2AS (2M; ages 22 and 79 years; ?S; no MR); 18C (18M; ages 9–98)	minicolumn analyses Layer III of prefrontal and temporal cortex	Cell columns were more numerous, smaller, and less compact in prefrontal layer III
Casanova et al.	2002	9A (7M, 1F; ages ~12; 5S; 7MR); 9C (?M, ?F; ages ~15)	minicolumn analyses Layer III of prefrontal and temporal cortex	Cell columns more numerous, smaller and less compact in prefrontal layer III
Fatemi et al.	2002	5A (5M; ages ~25; ?S; ?MR); 5C (≥ 4M; ages ~24)	density and size measure of Purkinje cells in cerebellum	24% smaller Purkinje cells in cerebellum; no differences in density

for the types and time courses of neuropathology that one might expect to encounter. Increasingly, researchers refer to "the autisms" rather than a single autism phenotype (Geschwind & Levitt, 2007; Amaral et al., 2008). There is no consistent genetic etiology of autism even though estimates of heritability are as high as 90% (Levitt & Campbell, 2009). The autism spectrum disorders are likely to involve multiple genes and complex interactions between genetic risk and environmental factors. When one takes all of these into consideration, it would be surprising if the neuropathology of autism were identical across all affected individuals. Whether there is a core neuropathology that is common to all, or at least most, individuals with autism remains to be determined.

Magnetic resonance imaging (MRI) studies have provided the greatest contribution to our understanding of how the brains in people with autism deviate from typical development and function. As discussed elsewhere in this book, there is substantial evidence indicating that the brain is undergoing an abnormal developmental time course that appears to include a period of early overgrowth in some individuals with autism, particularly noted in the frontal, temporal, and cingulate cortices and the amygdala (Courchesne et al., 2007; Amaral et al., 2008). Structural MRI is well equipped to deal with the *phenotypically diverse* nature of autism spectrum disorders by providing a reliable method for studying brain growth and function in large numbers of subjects over time. However, if brain size is an indication of aberrant neurological development, what does this really tell us about the neuropathology of autism? If the brain is larger in young children with autism, are there too many neurons, glia, synapses, and so forth? Does the underlying neuropathology differ between brain regions and tissue types? If the difference in brain size does not persist into adulthood, what neuropathological underpinnings account for this phenomenon of an abnormal growth trajectory?

Studies analyzing postmortem brain tissue acquired from individuals with autism provide an approach for understanding the underlying neuropathology. But, due to the limited number of cases and documentation available, these studies are currently not well positioned to deal with the heterogeneity of autism spectrum disorders. It may be obvious, but critical to point out, that postmortem studies are limited to observing the end result of each case's neuropathology due to their particular type of autism, comorbid symptoms, and individualized exposure to environmental factors. Well-designed postmortem studies must control for confounding factors such as age and gender, and excluding or segregating comorbid conditions such as epilepsy. The use of postmortem techniques as a tool for studying the neuropathology of autism is still very much in its infancy. Efforts have historically been hindered by poor tissue quality and small sample sizes, with fewer than *100* autism cases studied to date and a mean sample size of *6* autism cases per study (Table 31-1). In addition, nearly all of the brains studied have been from adults with autism, which is well after the time of peak aberrant neurological growth highlighted by MRI studies. Despite these limitations, with the availability of more abundant, high-quality postmortem tissue and by employing modern neuroanatomical techniques such as stereological methods for counting neurons and in situ hybridization for evaluating expression levels of genes, providing a more complete picture of the neuropathology of the autism spectrum disorders may be possible in the near future.

In this chapter, we first review the studies of the last 30 years that have utilized postmortem tissue and contributed to our current understanding of the neuropathology of autism (Table 31-1). Since autism, at its core, is a disorder of early development, we then review the pre- and postnatal stages of brain development. During this brief review of ontogenesis we speculate about how disruptions in the progressive and regressive events of brain development might result in the known pathology of autism. We next review data indicating that autism may involve ongoing inflammatory processes in the central nervous system. Finally, we discuss our ideas about the future direction of postmortem neuropathological studies, the need for better preparation of brain tissue to maximize the use of each precious case, and how best to serve the needs of multiple research specialties that must accommodate both classical histology and modern molecular approaches.

Historical Perspective

Margaret Bauman and Tom Kemper carried out the initial groundbreaking studies during the mid-1980s to early 1990s to

systematically describe pathology in a sample of postmortem brains from people with autism during life. Before that time, most reports were case studies in which autism was not clearly identified, and in most cases, comorbid pathology such as seizure disorder, environmental insult (e.g., thalidomide exposure), severe mental retardation, self-injurious behavior, or another known neurodevelopmental disorder (e.g., phenylketonuria) was also present (Williams et al., 1980; Bauman & Kemper, 1985, 1990; Coleman et al., 1985; Hof et al., 1991; Guerin et al., 1996; Raymond et al., 1996; Rodier et al., 1996). Concurrently, during the early 1990s, a more consistent clinical definition of autism was beginning to emerge (DSM-IV, American Psychiatric Association, 1994) which enabled Kemper and Bauman (Kemper & Bauman, 1993) to collect and describe six cases of idiopathic autism, five of which had mental retardation and four of which had epilepsy. In a side-by-side comparison of each autism case with an age- and sex-matched control (see Box 31-1), the most consistent finding Kemper and Bauman reported was in the cerebellum. In all six autism cases they examined, there were fewer Purkinje cells in the cerebellar hemispheres. This observation had also been reported by Ritvo and colleagues (Ritvo et al., 1986) in a study in which they examined the brains from four males with autism, three of whom also had mental retardation, compared to three male controls; they found a lower Purkinje cell density in the cerebellar hemispheres and vermis in the autism group. In all six of the cases they studied, Kemper and Bauman (1993) also observed that olivary neurons tended to cluster at the periphery of the nuclear complex. In three of the young autism cases, the neurons in the inferior olive were large, whereas the neurons were small and pale in the adult autism cases. A near absence of the facial nucleus and superior olive was also reported in a female autism case study (Rodier et al., 1996). In addition to the cerebellum, Kemper and Bauman (1993) also observed that neurons in the amygdala and hippocampus of most autism cases appeared unusually small and more densely packed than in age-matched controls. The only area of consistent abnormality in the cerebral cortex of their cases was the anterior cingulate cortex, which appeared unusually coarse and poorly laminated.

In the late 1990s, Anthony Bailey and colleagues (1998) carried out a similar comprehensive qualitative and semi-quantitative study of six cases of autism with mental retardation, four of which had seizures, compared to seven controls. In four of the six autism brains, the brain weights were approximately 20% greater than normal for their age; two of the cases also had indications of macrocephaly in childhood clinical records. Cortical dysgenesis, which is a general term to describe malformation of cortical development, was observed in four of the six autism cases, particularly in the cerebellum and frontal cortex. These observations included increased cortical thickness in the frontal, cingulate, temporal, and parietal cortices; high neuronal density in the hippocampus and frontal and cingulate cortices; neurons present in the molecular layer of the frontal cortex; irregular laminar patterns in the superior frontal gyrus; and poor gray-white matter boundaries in the frontal cortex. Ectopic (misplaced) gray matter and an increased number of neurons were observed in the white matter of the inferior cerebellar peduncle and/or frontal cortex in three of the autism cases. Olivary dysplasia was present in three autism cases, as well as olivary ectopic neurons in two other cases. As described by both Kemper and Bauman (1993) and Ritvo (1986), Bailey et al. (1998) also reported lower numbers of Purkinje cells in the cerebellum in all five of the adult cases with autism, but not in the 4-year-old child with autism and mental retardation.

At the turn of the century, three major factors changed the way postmortem studies of autism were conducted. The first was the widespread adoption of the Autism Diagnostic Interview-Revised (ADI-R; Lord et al., 1994) as a tool to confirm autism in a postmortem case by interviewing the parents or caregivers. Autism became more clearly defined as a clinical disorder in which cases were categorized as autistic disorder or autism spectrum disorder, which includes Pervasive Developmental Disorder Not-Otherwise-Specified (PDD-NOS) and the more loosely defined diagnosis of Asperger's syndrome. Another important change was the establishment of the Autism Tissue Program (ATP) by the National Alliance for Autism Research (NAAR) (now under the direction of Autism Speaks), which supports the collection and distribution of autism brain tissue. The ATP has defined cases of autism by the ADI-R diagnosis thus facilitating modern studies utilizing postmortem autism brain tissue.

The second factor that altered the course of neuropathological studies of autism was that analytic tools, such as modern three-dimensional stereological quantitative techniques, replaced the use of density measures to become the standard for evaluating cellular pathology in postmortem brain tissue. Prior to 2006, reports on the neuropathology of autism (Table 31-1, Box 31-1) were based on two-dimensional observations to describe alterations in neuronal density, or neurons per unit volume, in a given region of brain tissue. However, it had become abundantly clear that density measurements were prone to a number of methodological artifacts, leading to interpretive problems. Haug et al. (1984), for example, found that the process of tissue fixation results in differential shrinkage of brains at different ages; shrinkage was found to be inversely proportional to age. The implication of this finding is that differences in the density of neurons may reflect changes in the volume of the tissue rather than changes in total cell number. Many investigators concluded that the only way to unambiguously interpret pathological changes in neuron number was to actually count a representative sample of neurons in a defined volume (West et al., 1991). This led to the genesis of modern "unbiased" stereological techniques that have now become standard practice for studies to describe cytoarchitectural abnormalities in human brain tissue (Box 31-1). These techniques require larger samples of brain tissue to obtain reliable measures and consequently, with better clinical definition, the sample sizes reported by postmortem autism studies are beginning to increase.

The third major factor influencing the course of neuropathological studies of autism over the last ten years was the dramatic increase in MRI studies reported in the literature that helped to guide postmortem studies on where and when

Box 31–1
Quantitative neuropathological methods then and now

The cellular alterations underlying aberrant brain growth and function in autism have been a focus of study for more than 25 years. However, over time the experimental approaches employed have changed dramatically. Bauman and Kemper (1985; Kemper & Bauman, 1993) carried out the first, groundbreaking systematic postmortem studies of autism, in which histological sections from age-matched autism and control brains, stained for cell bodies, were viewed side-by-side under a dual-headed microscope (Figure 31-A). Increases in neuronal density were observed in the subjects with autism, primarily in the amygdala and hippocampus. However, several studies have raised methodological concerns about the interpretation of density measurements as an accurate representation of neuron number. Concerns have focused on the observation of differential tissue shrinkage during postmortem processing in subjects of different ages (Haug et al., 1984). The potential impact of these confounds on observed cellular density has led many investigators to conclude that the only way to unambiguously interpret pathological changes in neuron number is to actually count a representative sample of neurons in a defined volume (West et al., 1991). Such "unbiased" stereological techniques have therefore increasingly become standard practice in postmortem cytoarchitectural studies. Stereological studies are often carried out on a microscope fitted with a camera and motorized stage controlled via software on a computer (Figure 31-B with permission from MBF Bioscience). In this approach, a representative number of evenly spaced histological sections covering the entirety of the brain region of interest are selected (Figure 31-C, See Color Plate Section for a color version of this figure), the appropriate cellular staining is applied and the region of interest is manually defined on each section. The cell population of interest is then three-dimensionally sampled across the region. An observer, blinded to the condition of the subject from which the tissue was obtained, counts cells at each location in an evenly-spaced grid of "disector counting frames" randomly oriented on each section to produce an estimate of the total number of cells for that brain region. A few experiments employing stereological methodology have now been carried out in subjects with autism, including those by Schumann and Amaral (2006) and Van Kooten et al. (2008), which found decreased neuron numbers in the amygdala and fusiform gyrus, respectively.
in the brain pathology might be present. MRI studies have consistently found increases in brain size in younger children with autism, particularly in frontal and temporal cortices as well as the amygdala and cerebellum, followed by an abnormal growth pattern through adolescence and adulthood (Courchesne et al., 2007; Amaral et al., 2008). Below we discuss the postmortem quantitative studies of the last ten years by the major areas of interest: amygdala, cerebellum, and the frontal, cingulate, and temporal cortices.

Amygdala

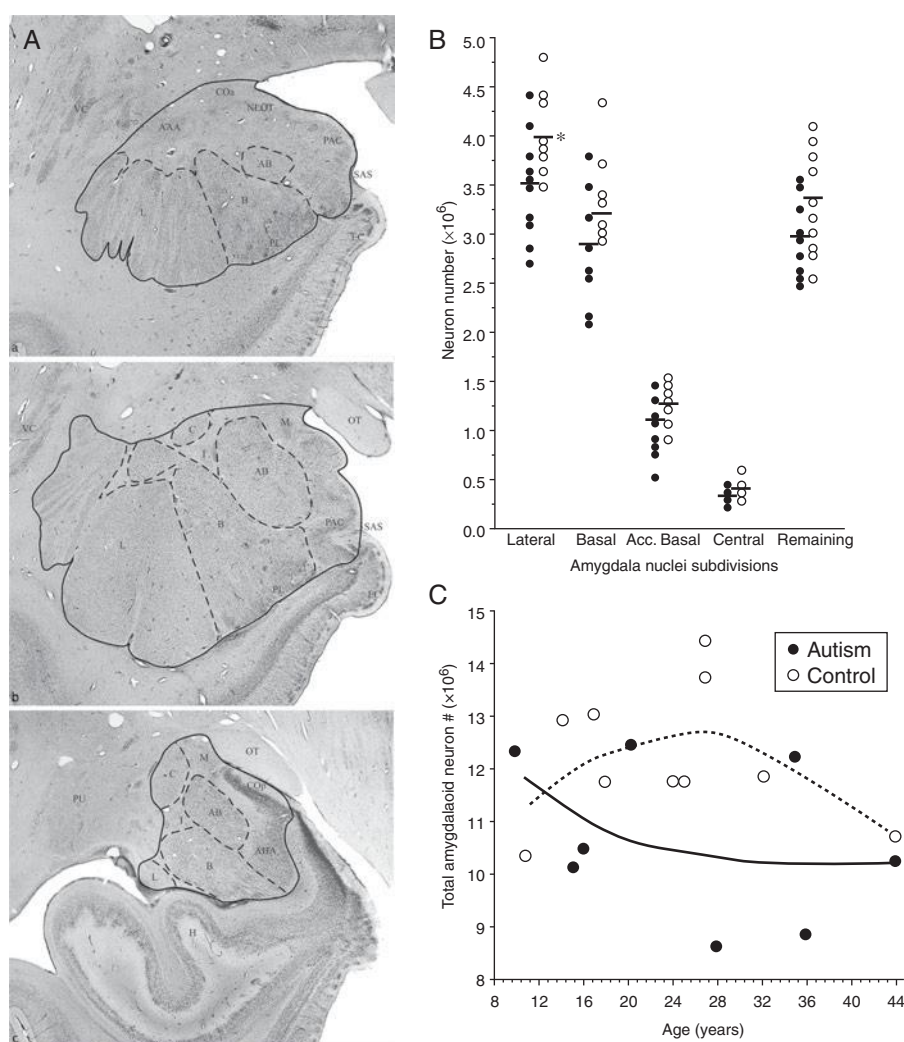
Schumann and Amaral (2006) were the first to carry out a neuropathology study of the brain in individuals with autism using unbiased stereological methods. They measured the number and size of neurons in the entire amygdaloid complex and in individual nuclei in nine male postmortem cases of autism, without seizure disorder, compared to ten typically developing age-matched male controls ranging in age from 10 to 44 years at death. They found that the autism group had significantly fewer neurons in the total amygdala and in the lateral nucleus than the controls (Figure 31-2). Whereas the average number of neurons in the control amygdala was about 12.2 million, the average in the amygdala in the autistic brains was about 10.8 million or about 85% of the total in the control brains. They did not find increased neuronal density or decreased size of neurons as Kemper and Bauman (1993) had initially reported. These findings have yet to be replicated


Figure 31–2. (A) Brightfield photomicrograph of Nissl-stained coronal sections through rostral (*a*), midstrocaudal (*b*), and caudal (*c*) levels of the amygdala. AAA, Anterior amygdaloid area; AB, accessory basal nucleus; AHA, amygdalohippocampal area; B, basal nucleus; C, central nucleus; COa, anterior cortical nucleus; COp, posterior cortical nucleus; EC, entorhinal cortex; H, hippocampus; I, intercalated nuclei; L, lateral nucleus; M, medial nucleus; NLOT, nucleus of the lateral olfactory tract; OT, optic tract; PAC, periamygdaloid cortex; PL, paralaminar nucleus; PU, putamen; SAS, semiannular sulcus; VC, ventral claustrum. Scale bar, 2 mm. (B) Number of neurons in five subdivisions of the amygdala of autism (filled circle) and control (open circle) brains. The asterisk indicates significant difference (*p* < 0.03) in neuron number between autism and control lateral nuclei. (C) Bivariate scattergram of the number of neurons in the total amygdala of autism (solid black line) and control (dotted black line) brains by age. Adapted from Schumann & Amaral (2006), with permission from *Journal of Neuroscience*.

in an independent sample of brains, which is an important step in confirming decreased neuron numbers in the amygdala as a characteristic feature of autism. It is important to emphasize that this is a population difference with both the control brains and the autistic brains demonstrating a wide range of neuronal numbers.

Taken together with the findings from previous magnetic resonance imaging studies, the autistic amygdala shows multiple signs of pathology. It appears to undergo an abnormal pattern of postnatal development that includes precocious enlargement and ultimately a lower number of neurons. It will be important to determine in future studies whether decreased neuronal numbers in the amygdala is a unique characteristic of autism or whether cell loss occurs in other brain regions as well. If the lower number of neurons in the amygdala is found to be a reliable characteristic of autism, what might account for this finding? Two possible hypotheses are: (1) fewer neurons were generated during early development, or (2) a normal or even excessive number of neurons was generated initially, which would be consistent with MRI findings of a larger amygdala in early childhood (Schumann et al., 2004; Schumann, Barnes, Lord, & Courchesne, 2009), but some of these neurons have subsequently been eliminated during adulthood. Unfortunately, there is currently no evidence to support or reject either of these possibilities, and systematic stereological studies on younger autism and control cases are needed.

Cerebellum

Of the 32 postmortem cases of autism reported in the literature in which the cerebellum was studied, 21 (or 66%) showed lower density of Purkinje cells, particularly in the more lateral parts or hemispheres of the structure (Ritvo et al., 1986; Kemper & Bauman, 1993; Bailey et al., 1998, Palmen et al., 2004; Whitney et al., 2008). Even though this is one of the most striking and consistent descriptive findings in neuropathological analyses in the autistic brain, a comprehensive stereological study of the actual number of Purkinje neurons in the whole cerebellum has yet to be carried out.

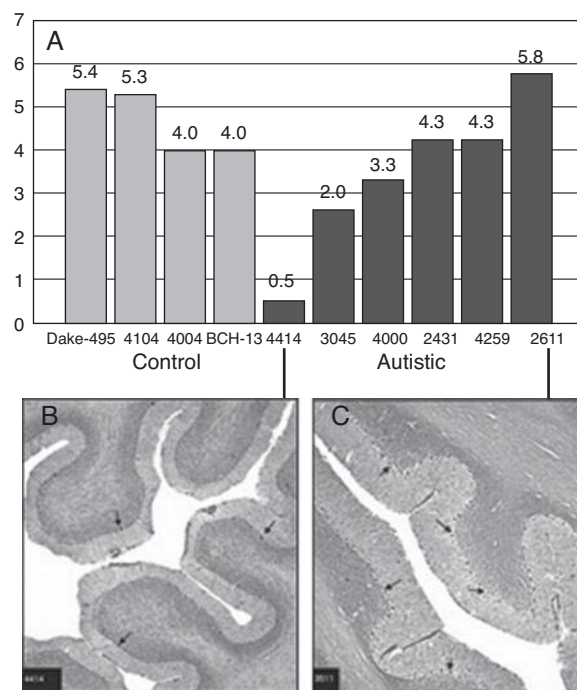
Recent studies from Blatt and colleagues have found that some, but not all, cases of autism show a reduction in the *density* of Purkinje neurons (using immunostaining for calbindin-D28k rather than standard Nissl staining), as well as a decrease in basket and stellate cell densities (Whitney et al., 2008; Whitney et al., 2009) (Figure 31-3). Fatemi and colleagues (2002) reported no differences in the density of Purkinje cells in the cerebellum in five adult cases of autism compared to five adult controls, but found a 24% decrease in the size of Purkinje neurons in the autism group. Blatt and colleagues have also reported substantial alterations in the GABAergic system of the cerebellum, including a 40% reduction in GAD67 mRNA in Purkinje cells, 28% upregulation of GAD67 in basket cells, and decreased levels of GAD65 mRNA in cerebellar dentate nuclei of eight individuals with autism compared to eight controls (Yip, Soghomonian, & Blatt, 2007, 2008, 2009).


Figure 31–3. (A) Number of Purkinje neurons per millimeter in control (light gray bars) and autistic (black bars) cases from calbindin-D28k-immunostained series. Photographs illustrate the variability in Purkinje cell density within autism group in (B) 4414 with reduced Purkinje cell density and (C) 3611 with Purkinje cell density in the normal range. Adapted from Whitney et al., 2008, with kind permission from Springer Science+Business Media. (See Color Plate Section for a color version of this figure.)

The observation of decreased Purkinje cell density appears to be in stark contrast to some reports from MRI studies of an enlarged cerebellum in autism (Courchesne et al., 2007) implying potentially a higher number of neurons. Several factors, however, make it impossible to compare findings from the two methods. At least 20 of the 32 brains examined in postmortem studies came from individuals who also had mental retardation (Ritvo et al., 1986; Kemper & Bauman, 1993; Bailey et al., 1998; Palmen et al., 2004; Whitney et al., 2008). Almost half of the brains were from individuals with epilepsy, and some were from individuals who were taking anticonvulsive medications that might themselves damage Purkinje cells. By contrast, most of the MRI studies were conducted with high-functioning autistic individuals and typically excluded subjects with seizure disorders. So, two very different cohorts of subjects are being studied with these different techniques.

Whether the observations of lower Purkinje cell density actually reflect fewer Purkinje cell numbers in the autistic brain awaits confirmation with unbiased stereological neuron-counting methods. As discussed in detail later in this chapter, an interesting hypothesis has emerged that neuroinflammation in the brain of individuals with autism, indicated by the presence of an increased number of activated microglia, may

be associated with the loss of Purkinje cells in the cerebellum (Vargas et al., 2005).

Frontal Cortex

Although the frontal cortex is one of the most prominent areas of study in the search for potential neuropathology in autism, very little work has been conducted with postmortem brain tissue in this region. Structural MRI studies suggest that the frontal lobe, and in particular, the prefrontal cortex, may show the greatest degree of aberrant development in the brains of children with autism (Carper et al., 2002; Carper & Courchesne, 2005). Yet, no systematic postmortem study to date has explored the underlying neurobiology of the identified aberrant growth in the frontal cortex. Seven recent studies (Table 31-1) have utilized frontocortical tissue; findings include an increased spine density on the apical dendrite of pyramidal neurons in layer II (Hutsler & Zhang, 2010), the presence of ill-defined cortical layers (Mukaetova-Ladinska et al., 2004), and an indistinct boundary between gray and white matter (Avino & Hutsler, 2010) in the dorsolateral prefrontal region. An electron microscopy study of the white matter underlying the orbitofrontal cortex found decreased myelin thickness in 5 autism cases relative to 4 controls (Zikopoulos & Barbas, 2010).

Von Economo (a.k.a. spindle) neurons have been recent focus of interest in autism, although clear evidence of pathology has yet to be found. Von Economo neurons are unique, large cells localized to the anterior cingulate and frontal insular region of great apes and man, and are suspected to play a role in higher order cognitive function and emotional behavior (Allman et al., 2001; Allman et al., 2005). Two recent studies with small sample sizes have failed to find a difference in the number of von Economo neurons in the frontal insular region in autism cases relative to controls (Kennedy et al., 2007; Santos et al., 2010) However, a recent stereological study found a higher ratio of von Economo neurons to pyramidal neurons in layer V of the frontal insula in four autism cases relative to three controls (Santos et al., 2010), suggesting that von Economo neuron pathology may become evident in autism with larger sample sizes.

The frontal cortex has also been the focus of studies of minicolumnar organization of neurons, finding reduced intercolumnar width and increased cell density in dorsolateral prefrontal cortex (Casanova et al., 2002; Buxhoeveden et al., 2006; Casanova et al., 2006; Casanova et al., 2010). These findings are discussed in greater detail later in this chapter.

Anterior Cingulate Cortex

As described above, the anterior cingulate cortex (ACC) was the only region of neocortex noted by Kemper and Bauman (1993) to show abnormalities; they observed the cortex of autism cases to be unusually coarse and poorly laminated compared to controls. Abnormalities in the ACC have since

been reported by Blatt and colleagues, including decreases in cell size in layers I–III and layers V–VI of area 24b and in cell packing density in layers V–VI of area 24c (Simms et al., 2009). The authors also observed irregular lamination in three of nine autism brains and increased density of neurons in the subcortical white matter in the remaining cases. A preliminary study of von Economo (a.k.a. spindle) neuron density was also carried out, but no significant differences in the autism cases were detected (Simms et al., 2009). Instead, the study appeared to uncover two subsets of autism cases, one that displayed an increase in von Economo neuron density and another with reduced density compared to controls. In another study by the same group, decreases in the mean density of GABA(A) and GABA(B) receptors and benzodiazepine binding sites were found in the ACC (Oblak et al., 2009; 2010), suggesting an alteration in GABAergic innervation of the ACC; this could potentially lead to a disturbance of the delicate balance between excitation and inhibition in this cortical area.

Another prominent theory, postulated by Herbert et al. (2004) and Courchesne & Pierce (2005), suggests excessive short-range and diminished long-range connectivity in the white matter underlying the frontal and anterior cingulate cortices. Herbert et al. (2004) reported that increased white matter volume in children with autism is restricted to superficial radiate white matter (i.e., corona radiata and "U" fibers), with no difference reported in deep and bridging white matter (e.g., corpus callosum, internal capsule, etc.). A recent postmortem study of single axons in white matter underlying the anterior cingulate cortex of autism cases found an excessive number of thin axons, which link neighboring areas together, and a decreased number of large axons, that communicate over long distances (Zikopoulos & Barbas, 2010). Interestingly, this study also found an over expression of growth-associated protein (GAP-43 kDa), which is expressed at high levels during rapid axon growth (Benowitz & Routtenberg, 1997), in the white matter underlying the ACC in the autism cases relative to controls. Although this study was carried out in a small sample and included cases with other neurological conditions (i.e. schizophrenia, epilepsy, depression), the findings have important implications for understanding the underlying neurobiology of aberrant connectivity in autism as reported by structural MRI and diffusion tensor imaging (DTI) studies.

Temporal Cortex

In a recent longitudinal MRI study of young children, the temporal cortex was found to undergo an abnormal growth trajectory in children with autism as well as display the greatest degree of aberrant enlargement among the cortical lobes (Schumann et al., 2010). Postmortem studies designed to examine the underlying pathology of this abnormal growth have yet to be carried out. The only study of temporal cortex, and the only other study of stereological neuron number in the autism brain (besides Schumann & Amaral, 2006, on the amygdala) was carried out by Van Kooten, Schmitz, and

colleagues (2008) on the fusiform gyrus, a visual area implicated in processing faces and located midstrocaudal on the inferior surface of the temporal lobe. In seven postmortem brains from patients with autism compared to ten controls, they found that the autism group showed significantly lower neuronal densities within layer III; lower total neuron numbers in layers III, V, and VI; and smaller mean perikaryal volumes of neurons in layers V and VI (Figure 31-4). Although the findings of this study were based on a relatively small sample size, and require replication, the results have implica-

tions for the cellular basis of abnormalities of face perception in people with autism. Pathology may originate from events in the fusiform directly, or from pathology in other brain regions with which the fusiform connects, such as the amygdala, which has also been shown to have a reduction in neuron number in autism patients (Schumann & Amaral, 2006). It will be important to determine in future studies whether decreased neuronal numbers in both the fusiform gyrus and amygdala result in the functional impairments associated with autism or, alternatively, are caused by hypoactivation or underuse during early development.

Blatt and colleagues have proposed widespread abnormalities in the GABAergic system of the brain in individuals with autism, including the fusiform gyrus and hippocampus. Reductions in the mean density of GABA(A) and GABA(B) receptors and benzodiazepine binding sites were recently reported in the fusiform gyrus (Oblak et al., 2010a; 2010b). Decreased GABA(A) receptor binding has also been reported in the hippocampus (Blatt et al., 2001); the decreased binding is likely due to a decrease in the density of binding sites rather than an altered affinity (Guptill et al., 2007). In a recent study, a subpopulation of GABAergic interneurons immunoreactive to calcium binding proteins were found to be decreased in the hippocampus of autism cases relative to controls (Lawrence et al., 2010). However, alterations in the GABAergic system in autism are not specific to the temporal cortex, as Blatt and colleagues have reported similar pathology in the cerebellum and cingulate cortices (Oblak et al., 2009, 2010a, 2010b; Yip et al., 2007, 2008, 2009), but instead appear to be a common feature that may disrupt global inhibitory control in the autistic brain.

Alterations of the Columnar Structure of the Neocortex: The Minicolumn Hypothesis

Increasing interest has been placed on the notion, advanced by Casanova and colleagues (Casanova et al., 2002; Buxhoeveden et al., 2006; Casanova et al., 2006; Casanova et al., 2010), that there are an abnormal number and width of minicolumns (Figure 31-5) in the cortex of individuals with autism. As described in further detail below, minicolumn formation has been associated with early stages of cortical development when postmitotic neurons ascend in linear arrays along a radial glial scaffolding (Rakic, 1988). Within the first year of life, there is a dramatic increase in dendritic growth. By 2 years of age, the minicolumns are spaced further apart with a lower cell density in a given region of cortex. Dendritic bundles and axonal fascicles that extend throughout several layers of the cortex occupy the space between minicolumns (Jones, 2000; Rockland & Ichinohe, 2004). Casanova and colleagues (Casanova et al., 2002; Buxhoeveden et al., 2006; Casanova et al., 2006) have posed the reasonable question of whether there is perturbation in the fundamental organization of minicolumns in the autistic brain.

Sixteen cases of autism (at least 9 with seizures and at least 10 with mental retardation) have been examined for

Figure 31–4. Photomicrographs of 200 μm thick coronal sections of the brain hemispheres through the level of the fusiform gyrus from a control (A, C, E) and a patient with autism (B, D, F), a cross-section of cortex from the fusiform gyrus (C, D; scale bar = 400μm), and layer III of the fusiform gyrus from each subject at high magnification (E, F; scale bar = 50 μm). Adapted with permission from van Kooten et al., 2008.

Figure 31–5. Model of the minicolumnar hypothesis proposed by Casanova et al. (2002, 2006) that there are an abnormal number and width of minicolumns in the cortex of individuals with autism. Each so-called minicolumn contains approximately 80–100 neurons (see schematic of minicolumn formation in Figure 31-8). (A) Model depicts a decreased intercolumnar width in the autism case relative to controls. (B) Nissl images were adapted with permission from Casanova et al. (2006), in which the distance between cell-body defined minicolumns was found to be reduced in layer III of dorsolateral prefrontal cortex (BA 9) in a 4-year-old autism case relative to a 5-year-old control. Given the narrower neuropil area between columns, one would also predict a decrease in the dendritic arborization of BA 9 Neurons (as depicted in the model, A). (See Color Plate Section for a color version of this figure.)

minicolumnar pathology in cortical layer III in three independent studies using varying techniques (Casanova et al., 2002; Buxhoeveden et al., 2006; Casanova et al., 2006). The most consistent finding in these studies is reduced intercolumnar width of the minicolumns in dorsolateral prefrontal cortex (BA 9/46). In a recent follow-up study, Casanova and colleagues (2010) determined that diminished minicolumnar width is not limited to layer III, but instead is present across supra- and infragranular cell layers, most notably in BA 44 (pars opercularis) in the frontal cortex of autism cases. These findings, coupled with increases in neuronal density on the order of 23% noted by Casanova et al. (2006), imply that there should be a greater number of neurons in BA 9 of the autistic cortex. Given the narrower neuropil area between columns, one would also predict a decrease in the dendritic arborization of dorsolateral

prefrontal cortical neurons. These neuropathological questions are ripe for analysis using systematic stereological methods. One would predict an increased number of neurons in the prefrontal cortex in autism cases, given evidence of increased volume at young ages and reduction of minicolumnar spacing; however such a study has yet to be carried out.

Neuroinflammation in Autism

There is emerging evidence that an anomalous immune response during vulnerable periods of brain development could contribute to the neuropathology associated with autism (Ashwood & Van de Water, 2004; Pardo et al., 2005; Ashwood et al., 2006). Interactions between the immune and nervous systems begin early in embryogenesis and persist throughout

an individual's lifetime, with successful neurodevelopment contingent on a normal and balanced immune response (Boulanger & Shatz, 2004; Wrona, 2006). Two cell populations act as directors and effectors of the immune response. Microglia primarily act as the resident phagocytes, constantly eliminating damaged neurons, accumulated debris, and infectious agents. Astroglia, meanwhile, are classically considered to act as directors of the immune response via detection and release of a wide array of cytokines and chemokines. Both microglia and astroglia participate in several additional functions during development, including histogenesis, synaptogenesis, neuronal dendritic arborization, and regulation of neuron numbers (Marin-Teva et al., 2004; Schmitz & Rezaie, 2008). In adulthood, microglia play a dual role; in addition to cytotoxic, phagocytic, and antigen-presenting capabilities, they also demonstrate cytoprotective and neurotrophic functions (for review see Pardo et al., 2005).

Microglia undergo morphological changes based on the current state of the immune response. "Resting" ramified microglia (Figure 31-6), with small cell bodies and long thin processes, are commonly found throughout the typically developing brain across life span for constant surveillance of the local environment to detect inflammatory signals (Nimmerjahn et al., 2005). When infection is presented, microglia may be "activated" by a variety of factors, including pro-inflammatory cytokines, necrotic factors, glutamate receptor agonists, and changes in extracellular potassium concentration. Once the microglial cell is activated, the processes thicken and retract to move rapidly to the site of the insult. The cell body has the appearance of swelling with the uptake of MHC class II proteins and secretes cytotoxic and pro-inflammatory signaling molecules including cytokines and chemokines. These *activated* microglia interact with neurons to fight off infection, typically with minimal damage to healthy brain cells. "Ameboid" microglia in the activated state are commonly observed in the typically developing brain in high concentrations during the prenatal period responding to large amounts of extracellular debris and apoptotic cells that is a consequence of programmed death (Rezaie & Male, 1999).

Although microglial and astroglial activation is often a beneficial response, dysfunction of the immune system
Figure 31–6. (A) Normal appearance of the cerebellum in a control patient; (B–C) Atrophic folia and marked loss of Purkinje and granular cells in the cerebellum of an autistic patient (H&E Stain); (D) Microglia activation seen with anti-MHC class II immunostaining. resulting in a chronic state of neuroinflammation could have detrimental effects on the developing brain and potentially lead to neuronal cell death and alterations in neuronal connectivity (Streit et al., 2005). Ongoing neuroinflammatory processes, as evidenced by the presence of activated microglia and astroglia in cases of autism, was first described by Vargas et al. (2005). They observed excessive microglial activation in the cerebellum and frontal cortex in postmortem brain tissue in a subset of 11 autistic patients (age range 5–44 years) using immunocytochemical staining for MHC class II markers (HLA-DR). The excessive microglial activation was particularly prominent in the granular cell layer of the cerebellum. Vargas and colleagues speculated that the presence of activated microglia near Purkinje neurons in the cerebellum may be related to the commonly noted reduction of Purkinje cells in autism patients, given the regulatory role that microglia play in normal Purkinje neuron death (Marin-Teva et al., 2004) (Figure 31-6). Recently, Morgan and colleagues reported increases in activated microglia number and size in some, but not all, cases of autism in dorsolateral prefrontal cortex and amygdala using an antibody to ionized calcium binding adaptor molecule-1 (Iba-1); a marker that visualizes both resting and activated microglia (Morgan et al., 2010; Morgan et al., personal communication).

At present, the role of microglial activation in autism remains unclear. It is possible that aberrant microglial activity directly contributes to abnormal neurodevelopment, with activation triggered by genetic or environmental factors that otherwise would not be significantly disruptive. Alternately, it may be a largely healthy response to an exogenous insult such as viral infection, or a genetic alteration that, for example, produces an excessively large population of neurons that must be reduced. Interestingly, elevations in pro-inflammatory cytokine and chemokine levels have also been reported in the brain tissue and cerebrospinal fluid of patients with autism (Vargas et al., 2005, Li et al., 2009). An emerging hypothesis is that cytokine levels may be impacted by prenatal maternal infection (see Patterson, 2009, for review). Further evaluation is necessary to define the precise role of the immune response and microglial activation in the pathogenesis of autism. If glial activation in autism is demonstrated to be deleterious, anti-inflammatory agents represent a highly promising future avenue for biotheraputic research.

Future Perspective

Autism is clearly a pathological disorder of neural development, but when and how the pathology occurs remains elusive. Typical brain development is comprised of several stages, including the proliferation and migration of neurons, synaptic growth, and eventually cell death and dendritic pruning. Any deviation at one or more of these stages could produce catastrophic downstream effects. As evident from the previous section, the field of postmortem human brain research in autism is still young and we have few clues to point to a particular stage in which development goes awry. We therefore now ask the reverse question, if a particular stage of development did go awry, what would the resulting pathology look like? Below we describe the normal stages of brain development and speculate, based on the current findings of autistic neuropathology, about the particular stage at which brain development may deviate from normal, leading to autism. However, we would like to reiterate that it is unlikely that a single neuropathological event will account for all autism; future studies will need to be powered and designed to detect various patterns that underlie the "autisms."

Fundamentals of Brain Development

The human central nervous system (CNS) is the most complex organ system in vertebrates and contains a greater variety of cell types than is found in any other organ system. The mature brain is comprised of approximately 100 billion neurons, and perhaps 10 times as many glial cells. Remarkably, the generation of nearly one trillion diverse, complex cell types is accomplished during a brief span of intense proliferation that encompasses approximately 3 months during gestation. Not surprisingly, this period of development is sensitive to genetic abnormalities and/or environmental interference. In fact, it is not surprising that there are occasionally errors of development leading to disorders such as autism; what is surprising given the complexity of the enterprise, is that neurodevelopment is generally successful and results in an individual that is "typically developing."

CNS cells are generated in two proliferative zones that line the ventricular system of the developing brain. Each proliferative zone is home to a distinct class of precursor cell. The primary proliferative zone, the ventricular zone (VZ) is directly adjacent to the lumen of the ventricle. Radial glial cells are the principle precursor cell type in the VZ. The secondary proliferative zone, the subventricular zone (SVZ), appears at the onset of neurogenesis in many CNS regions (Boulder Committee, 1970). SVZ precursor cells are generated by radial glial cells in the VZ, and then migrate radially to establish the SVZ compartment superficial to the VZ (see Figure 31-7). Both VZ and SVZ precursor cells produce neurons in the embryonic forebrain (Noctor et al., 2007). The VZ proliferative zone becomes depleted during development and is not present in the adult brain, but the SVZ remains as a neurogenic compartment in the mature and a similar structure is present in the adult dentate gyrus (Ihrie & Alvarez-Buylla, 2008).

Proliferation in the Developing Brain

Advances in the field of molecular biology have provided exciting new tools that can be applied to investigations of the developing CNS. New molecular tools allow researchers to control the expression of specific genes both regionally and temporally in the CNS. For example, the gene sequence for
Figure 31–7. (A) Scheme depicting precursor cell types in the embryonic brain. After neural tube closure, the embryonic proliferative zone is composed of a single population of neuroepithelial cells which transition into radial glial cells at the onset of neurogenesis in the ventricular zone (VZ). They undergo division at the surface of the lateral ventricle and possess a long thin pial fiber that reaches the pial surface. Radial glial cell divisions produce neurons and intermediate progenitor cells. Intermediate progenitor cell bodies are primarily located in the subventricular zone (SVZ); Divisions occur away from the surface of the lateral ventricle and produce multiple neurons. At the conclusion of neurogenesis radial glial cells begin producing astrocytes, and Translocate to the SVZ, where gliogenesis continues after birth. (B) Micrograph showing an example of a radial glial cell labeled with fluorescent reporter gene. Radial glia are bipolar cells with a single process that contacts the ventricular surface (dotted line) and a single pial process that ascends toward the pial surface (small arrowheads). The cell body (arrow) is located in the VZ. (C) Micrograph showing a radial glial cell (arrow) and a daughter intermediate progenitor cell (large arrowhead) labeled with fluorescent reporter gene. The intermediate progenitor cell maintains contact with the radial glial cell pial fiber (small arrowheads). (See Color Plate Section for a color version of this figure.)

fluorescent reporter proteins has proven invaluable for detailed characterization of specific cell types, such as neural precursor cells in the developing brain. Fluorescent reporter proteins have allowed researchers to visualize neural precursor cells in living tissue. This capability has been used to identify neuronal and glial precursor cells in the developing brain, to characterize their patterns of cell division, cell production potential, and finally to characterize the daughter cells produced by precursor cells.

Glial cells and neurons had long been considered distinct cell types that were produced by separate precursor cell types in the developing brain. However, recent studies have demonstrated that glial functions are much broader, and that astrocytes in particular have much closer functional and lineal relationships with neurons than previously realized. Not only are astrocytes crucial partners with neurons in synaptic communication in the mature brain (Stevens, 2008), but they also generate neurons in several regions of the adult brain including the cortical SVZ (Doetsch et al., 1999), and the dentate gyrus (Seri et al., 2001). Astrocytes are lineally descended from embryonic radial glial cells (Noctor et al., 2004); the two cell types can be considered as representing different generations in the same immediate family. Radial glia are a specialized astroglial cell that is transiently present in the developing brain (Misson et al., 1988). Radial glia are bipolar cells that have a soma in the proliferative ventricular zone, a short descending process that contacts the ventricular lumen, and an ascending process that spans the wall of the developing brain to contact the pial membrane (Figure 31-7). Radial glial pial processes radiate outward from the ventricle to the surface of the brain, a pattern that dominates the appearance of the brain during

early stages of development, and to a degree dictates organization of the mature CNS. Radial glial cells are the principle neuronal precursor cell type in the embryonic CNS (Malatesta et al., 2000; Miyata et al., 2001; Noctor et al., 2001; Noctor et al., 2002; Anthony et al., 2004). Radial glia generate neurons through one of two mechanisms: directly through an asymmetric division that produces a single neuron, or indirectly through a division that produces an SVZ intermediate progenitor cell that subsequently divides symmetrically to produce two neurons (Martínez-Cerdeño et al., 2006b). Most SVZ intermediate progenitor cells appear to undergo a single symmetric division to produce two neurons. But, in some cases they undergo multiple divisions that produce four or more neurons (Haubensak et al., 2004; Miyata et al., 2004; Noctor et al., 2004). A given radial glial cell division can therefore produce either a single neuron or multiple neurons. The exact number of radial glial cells in the embryonic brain has not been determined, nor has the total number of radial glial or intermediate progenitor divisions, but it is likely that billions of cell divisions are required to produce the 20 billion cortical neurons that populate the human cerebral cortex.

Most regions of the adult CNS are organized into discrete functional units. The cerebral cortex is a laminated sheet of tissue that is 2 to 4 mm thick, and organized into six horizontally arranged layers. This elaborate organization is further broken down into functional units that are arranged as radial columns, or cortical columns, that span across the six cortical layers (Mountcastle, 1997) (Figure 31-8). Each cortical column comprises multiple "minicolumns" in which a narrow column of approximately 80–100 radially arranged neurons span the cortical layers (Mountcastle, 1997). Neurons in each cortical
Figure 31–8. Scheme depicting the formation of minicolumn and cortical column functional units in the cerebral cortex. Each minicolumn contains approximately 80–100 neurons. Multiple minicolumns together form a single cortical column. As proposed by Rakic (1988), proliferative units in the ventricular zone (VZ) of the dorsal forebrain produce neurons that are destined for a single mini-column functional unit (dark column) in the cortical plate (CP). Each proliferative unit in the VZ may comprise 5–10 radial glial cells. Each radial glial cell possesses a single pial fiber that stretches across the cortical wall to the pial surface of the brain. The pial fiber guides the migration of newborn neurons from the proliferative zones to their respective minicolumn functional units in the CP. Neighboring proliferative units in the VZ produce neurons that are destined for different minicolumns in the CP (grey columns). Radial glial cells produce both neurons and intermediate progenitor cells, which migrate away from the ventricle along their parental pial fiber. recent work shows that intermediate progenitor cells undergo additional rounds of division in the subventricular zone (SVZ) to produce multiple neurons. Excitatory projection neurons are derived from the VZ of the dorsal forebrain, and migrate radially along radial glial cell fibers. Inhibitory interneurons are derived from the VZ of the medial ganglionic eminence (MGE) in the basal forebrain, and migrate tangentially into the overlying cerebral cortex. Mechanisms that guide migrating interneurons to specific minicolumns remain to be determined. (See Color Plate Section for a color version of this figure.)

column respond to similar stimuli and perform similar functions. The columnar, or radial organization of the cerebral cortex, is thought to derive from the organization of precursor cells in the embryonic ventricular zone. Rakic's Radial Unit Hypothesis proposes that precursor cells in the VZ (radial glia)

are organized into discrete proliferative units that provide a proto-map of cortical columns in the adult cerebral cortex (Rakic, 1988). The Radial Unit Hypothesis predicts that each proliferative unit in the VZ produces the cortical neurons that populate a cortical column; each proliferative radial glial cell produces the cortical neurons that populate a single minicolumn (Figure 31-8). More recent data that shows substantial neurogenesis in the embryonic SVZ (Haubensak et al., 2004; Miyata et al., 2004; Noctor et al., 2004), has lead to modifications of the Radial Unit Hypothesis to account for the contribution of additional proliferative precursor cells in the SVZ (Kriegstein et al., 2006; see Figure 31-8). Subtle changes in the pattern of radial glial division and/or SVZ precursor cell division could produce measurable changes in the total number of neurons in the adult brain. Thus, aberrant regulation of cell proliferation within the VZ or SVZ may contribute to changes in cell number (Schumann et al., 2006; van Kooten et al., 2008), cell density and minicolumnar width (Casanova et al., 2002; Buxhoeveden et al., 2006; Casanova et al., 2006) (Figure 31-5), and ultimately increased brain size (Courchesne et al., 2007; Schumann et al., 2010) as reported in some cases of autism.

Regulation of Precursor Cell Proliferation

Proliferation is tightly regulated during brain development. Precursor cells follow a specific program that generates the proper number of neurons and glia. A wide variety of factors, including neurotransmitter substances, growth factors, and hormones, bind with receptors expressed by embryonic precursor cells and regulate cell division in the developing brain. For example, the classical neurotransmitters GABA and glutamate differentially regulate proliferation in the ventricular and subventricular zones during neocortical development (LoTurco et al., 1995; Haydar et al., 2000). Neurosteroids, such as estradiol, are also present in the embryonic proliferative zones and induce proliferation of precursor cells in the embryonic and adult brain (Martínez-Cerdeño et al., 2006a). Radial glial cells are coupled to one another through connexin gap junction channels that transmit electrical signals (LoTurco & Kriegstein, 1991). New evidence indicates that waves of calcium activity are also transmitted through gap junction channels and regulate radial glial cell proliferation (Weissman et al., 2004). Proteins such as beta-catenin promote proliferation versus differentiation of progenitor cells during cortical development (Chenn & Walsh, 2002). Blood vessels also appear to play an important role in proliferation. Precursor cells are often located in niches along the border of blood vessels in neurogenic regions of the adult brain (Palmer et al., 2000; Seri et al., 2004), as well as in the embryonic brain (Javaherian & Kriegstein, 2009; Stubbs et al., 2009). Furthermore, Temple and colleagues have found that endothelial cells release soluble factors that stimulate self-renewal of embryonic and adult precursor cells (Shen et al., 2004).

These findings indicate that endothelial cells, and perhaps factors circulating in the blood, regulate cell genesis during brain development.

Mutations in specific genes that regulate precursor cell behavior have been identified in Autism Spectrum Disorders. The genes *MCPH1* and *ASPM* are required for proper levels of proliferation during brain growth, and mutations in these genes produce microcephalic brains (Shen et al., 2005). Gene mutations that produce macrocephalic brains have also been identified. For example, mutations in the phosphatase and tensin homologue deleted on the chromosome 10 (PTEN) gene have been associated with large head size and autism (Zori et al., 1998; Goffin et al., 2001). PTEN is a tumor suppressor gene that controls cell size and number (Kwon et al., 2006). PTEN instructs cells to stop dividing, prevents cells from growing too rapidly, and in some cases instructs cells to undergo programmed cell death (Chu & Tarnawski, 2004). Together these functions prevent the formation of tumors and regulate the size of organs during development. Mice in which the PTEN gene has been deleted present with larger brains and hypertrophied neurons with abnormal cellular processes (Kwon et al., 2006). As described above, larger brain size has been reported in autism (Amaral et al., 2008). A recent study identified PTEN mutations in autism spectrum disorders, mentral retardation and developmental delays (Varga et al., 2009; McBride et al., 2010). Additional studies have reported that PTEN mutations are associated with some cases of autism spectrum disorders (Abrahams & Geschwind, 2008; see Chapters by State and colleagues, Lamb, and Morrow & Walsh in this volume). The cause of larger brain size observed in individuals with PTEN mutations has not been determined but may result from dysregulated precursor cell proliferation during development, hypertrophied neurons, decreased cell death, or a combination of the three.

Determination of Cell Fate

The determination of cell fate occurs at regional, local, and cellular levels. The regional expression patterns of different transcription factors along the rostrocaudal axis of the developing nervous system reveals one mechanism by which cortical cells acquire specific identities (Schuurmans & Guillemot, 2002). While all radial glial cells share characteristic morphological features, they nonetheless constitute a heterogeneous population based on protein expression patterns (Kriegstein & Gotz, 2003). This may explain how different regions of the developing telencephalon generate different classes of cortical cells. For example, excitatory pyramidal cells and astrocytes are generated by Pax6 expressing cells in the dorsal telencephalon, while inhibitory interneurons are generated by Dlx-1/2 expressing cells in the ganglionic eminences of the embryonic ventral telencephalon (Anderson et al., 1997; Figure 31-8). The expression of transcription factors such as Dlx-1/2 is likely an early step in the commitment of telencephalic cells to a specific fate. The expression of these factors may even correlate with the phenotype of specific neuronal subtypes. Indeed, new evidence indicates that subregions of the ganglionic eminences express different transcription factors and give rise to interneuron subtypes (Nery et al., 2002). Local environmental factors also play a role in determining the fate of neurons in the developing cortex. Transplantation studies demonstrate that the laminar fate of cortical neurons can be altered when transplantation of cortical precursor cells occurs during specific phases of the cell cycle (McConnell & Kaznowski, 1991). Furthermore, expression of transcription factors is crucial for the normal differentiation of cortical neurons. For example, the absence of the transcription factor Foxg1 during cortical neurogenesis induces deep layer cortical neurons to adopt the phenotype of Cajal-Retzius neurons that are normally found in the superficial layer 1 of the neocortex (Hanashima et al., 2004).

The generation of sufficient numbers of the diverse cell types in the nervous system is accomplished through two basic types of progenitor cell divisions, symmetric and asymmetric (Gotz & Huttner, 2005). Symmetric divisions generate two daughter cells that are similar, while asymmetric divisions generate two daughter cells that differ from one another. Recent evidence indicates that these types of divisions might occur in different proliferative zones, asymmetric divisions occur more frequently at the surface of the ventricular lumen, while symmetric divisions occur more frequently in the SVZ (Noctor et al., 2004). Radial glial cells divide asymmetrically at the ventricular lumen to generate either a single neuron, or a subventricular zone progenitor cell that subsequently generates two neurons. Therefore, each radial glial cell division can generate either one neuron directly, or two neurons indirectly. Thus, determination of daughter cell fate after radial glial divisions impacts the total number of neurons generated at a given time during development. A shift toward production of single neurons would decrease the total numbers of neurons being generated, while a shift toward the production of SVZ progenitor cells would double the neuronal output at a given time. Therefore, regulation of daughter cell fate during neurogenesis impacts the neuronal density for a given neocortical layer or structure. Invertebrate studies have revealed a number of molecules that are differentially segregated in nascent daughter cells during progenitor cell divisions. Some of these fate-determining molecules, such as Notch and Numb, are also expressed in mammalian proliferative zones and research into their role in determining daughter cell fate continues (Pearson & Doe, 2004; Bultje et al., 2009).

Migration in the Developing Brain

Neurons in the adult brain are organized into complex, intricately interconnected groups of nuclei and laminae. One of the remarkable aspects of brain development is that neurons are not born in their adult location, but instead must migrate distances of 7000 μm or more, from the proliferative zones to reach their final destination (Rakic, 1988). To put this into perspective, this is comparable to a person scaling a wall greater in height than Yosemite's 3,000 foot high El Capitan.

Despite the complexity of the task, this feat is achieved with such regularity and precision that there is little variation in the architectonic pattern of brain structures from one person to the next. In the developing neocortex, excitatory cortical neurons are generated in an inside-out sequence such that the deepest layers of the cerebral cortex are generated and migrate into the cortical mantle before the superficial layers. Thus, as development proceeds neurons must migrate progressively longer distances and through an increasing number of cortical cells. The radial glial cells that generate neurons play an important role in the migration of newborn cortical neurons. Radial glia are bipolar cells that have a long pial process that ascends from the cell body in the proliferative VZ, to the pial surface of the developing brain. Newborn excitatory neurons attach themselves to the pial process and migrate toward the cortical plate using the pial process as a directional guide (Rakic, 1971). In fact, many neurons piggy-back along the pial process of their parental radial glial cell (Noctor et al., 2001; Noctor et al., 2004; Noctor et al., 2008), demonstrating the importance of lineage relationships in the developing brain. Newborn cortical neurons extend a leading process toward the overlying cortical plate and migrate radially along the pial fiber of the parent radial glial cell until they reach their destination in the cortical plate, at which point they detach from the pial fiber. This form of migration relies on cell-cell adhesion molecules that interact between radial glial fibers and migrating neurons (Hatten, 1990). Recent data demonstrates that gap junctions play an important role in mediating the adhesion between migrating neurons and radial glial processes (Elias et al., 2007). Neuronal migration is also regulated by a number of extracellular signaling molecules such as neurotransmitter substances acting through the NMDA receptor (Komuro & Rakic, 1993). Migrating neurons depend on additional signaling molecules to reach the correct location in the developing brain. For example, the reelin protein acts through its constituent receptor molecules to guide migrating neurons to the cortical plate, and arrest migration once the neurons have reached their proper location (Tissir & Goffinet, 2003). Reelin may play a distinct role in neuronal functioning in the mature brain. Reductions in reelin protein have been reported in a few select regions of the cerebral cortex and in the cerebellum (Fatemi et al., 2005). Given current understanding of reelin function in the developing mammalian brain, a reduction in reelin protein could be predicted to alter the trajectory of migratory neurons, resulting in the ectopic location of neurons in the forebrain. Examination of the reelin gene (RELN) has detected missense mutations in some cases of autism, but at a very low frequency, leading some to suggest that reelin may not play a major role in the etiology of autism (Bonora et al., 2003). Future studies on the regulation of reelin protein expression may shed light on the role that reelin protein plays in the autistic brain.

Recent experiments employing time-lapse imaging of fluorescently labeled cells in cultured brain tissue have revealed that the patterns of neuronal migration in the neocortex are more complex than originally thought. Experiments in the 1990s discovered that inhibitory cortical neurons are generated in the ventral forebrain and migrate tangentially into the overlying dorsal neocortex (De Carlos et al., 1996; Anderson et al., 1997; Tamamaki et al., 1997; Wichterle et al., 1999). Interneurons do not appear to migrate along radial glial fibers during their journey from the ventral into the dorsal cortex. In fact, they appear to travel perpendicular to the radial glial matrix. It has yet to be determined whether they rely on cellular guides such as developing axonal pathways, or rather are guided solely along gradients of chemoattractive and repulsive factors (Marin & Rubenstein, 2003). Some syndromic forms of autism, for example mutations of CNTNAP2 in an Amish family with epilepsy, MR, and autism, appear to involve disruption of neuronal migration (Strauss et al., 2006), which likely occurs focally in the anterior frontal and temporal lobes (Alarcon et al., 2008). Thus, regional specificity may arise from either differences in protomap related genes, or regional cell adhesion molecules involved in migration.

Recent work in rodents shows that excitatory neurons undergo four distinct stages of migration that can be identified based on the morphology and position of the neurons. After being generated, cortical neurons enter stage one of migration, leaving the ventricular surface and rapidly ascending to the SVZ. During stage two, cortical neurons acquire a multipolar morphology and remain stationary in the SVZ for one day or longer. After sojourning in the SVZ (Bayer & Altman, 1991), many cortical neurons enter stage three, and make a retrograde movement back toward the ventricular lumen. Finally neurons enter stage four, during which they reverse polarity back toward the cortical plate and commence radial migration along the pial fiber (Noctor et al., 2004). Similar ventricular directed movements have been reported for GABAergic interneurons after they have migrated into the dorsal cortex (Nadarajah & Parnavelas, 2002). The ventricle directed movements exhibited by these distinct cell types suggests that both excitatory and inhibitory neurons can respond to some of the same cues during their cortical migrations, and also hints at a potential source of important migration guidance molecules located near the ventricular lumen of the developing brain. Yet another form of migration, termed chain migration, has been identified for olfactory bulb interneurons as they migrate from their birthplace in the cortical subventricular zone along the rostral migratory stream into the olfactory bulb (Lois et al., 1996). Despite differences in the identified forms of migration, all neurons appear to rely on a shared set of intracellular molecules that are involved in extension of the leading process and transport of cellular structures such as the nucleus (Feng & Walsh, 2001; Schaar et al., 2004).

Abnormal Cell Migration

Neuronal migration is thus a complex interplay between the migrating cell and its environment that relies on intracellular machinery as well as extrinsic signaling factors. Given the complexity of this task, it is not surprising that a number of

nervous system malformations have been identified that result from defects in neuronal migration (Feng & Walsh, 2001). Neurons depend on different molecules for the successful progression from one stage of migration to the next. For example, deletion or mutation in the doublecortin gene prevents neurons from transitioning from stage two to stage three. Doublecortin is an X-linked gene, and males with a deletion or mutation in this gene are affected with lissencephaly, i.e., a greatly reduced and smooth cortical surface. Heterozygous females present with a milder form of neuropathology called "double cortex." In this condition, a second band of grey matter is located below the normal location of the cortical laminae (des Portes et al., 1998; Gleeson et al., 1998). This secondary band of tissue consists of neurons that did not progress beyond stage two of migration (LoTurco, 2004). These neurons can fire action potentials, but they do not appear to elaborate the initial axonal process that precedes stage three of migration in the embryonic neocortex (Bai et al., 2003). Another molecule that has been associated with migration failure, Filamin A, is required for leading process extension that precedes transition to stage four of migration. Individuals with a mutation in this gene present with a form of neuropathology termed "periventricular nodular heterotopia," in which large clusters or nodules of cortical neurons are found along the surface of the lateral ventricles. Periventricular nodular heterotopias have also been identified in subjects with fragile X syndrome (Moro et al., 2006), which results from CGG repeat expansion in the *FMR1* gene. The range of neuropathology associated with migration failure varies from severe brain malformations found in lissencephaly, to small ectopic clusters of neurons. In each case, varying proportions of neurons fail to migrate to their proper destination. Afflicted individuals present with mental retardation in severe cases, but even mild malformations are often associated with epilepsy. It is of interest that Bailey and colleagues reported a number of instances of ectopic cortical neuronal clusters in their survey of neuropathology in the autistic brain (Bailey et al., 1998). Recent work identifying alterations in cortical column structure in some autistic brains may also be related (Casanova et al., 2002; Buxhoeveden et al., 2006; Casanova et al., 2006). The etiology of altered minicolumn structure has not been determined, but may result from altered dendritic arborization, increased numbers of proliferative units in the VZ.

Axonal Outgrowth

Neurons are polarized cells that possess a single axon and, typically, multiple dendrites. The proper development of axons and dendrites is crucial for normal functioning, since a single neuron in the adult brain can make thousands of connections with neighboring and distant cells. Neurons begin elaborating processes immediately after being generated. During migration neurons extend and retract multiple leading processes as they migrate through the developing brain tissue toward their destination. These temporary processes serve specific purposes during development but are not retained by the neurons as they differentiate to assume their adult morphology. However, neurons do elaborate some processes during development that are retained as the cells mature, and these processes can determine with which cells a given neuron will communicate. Work in the embryonic cortex shows that sister neurons develop and maintain multiple contacts with one another during migration (Noctor et al., 2001; Noctor et al., 2004; Noctor et al., 2008), and that these contacts presage adults patterns of connectivity (Yu et al., 2009). In the cerebral cortex, most excitatory neurons elaborate an axonal process before initiating radial migration to the cortical plate (Noctor et al., 2004), and these processes can grow substantial distances across the cerebral hemispheres during gestation (Schwartz & Goldman-Rakic, 1991). While migrating cells express and rely on functional neurotransmitter receptors (Komuro & Rakic, 1993; Flint et al., 1998; Komuro & Rakic, 1998), they do not appear to form synaptic connections until after they have reached their destination. Migrating neurons do not have synapses, which precludes the synaptic release of neurotransmitter on these cells, but nonsynaptic release of transmitters before synapse development has been described in the developing brain, including the hippocampus (Demarque et al., 2002). Axon outgrowth can be summarized as occurring in four distinct stages: initial axonal outgrowth, axon pathfinding, pruning, and stabilization (Hedin-Pereira et al., 1999). Numerous molecules that regulate these processes have been identified and are well characterized, including those that guide axon pathfinding such as slit/robo (Dickson & Gilestro, 2006).

A number of MRI studies suggest that there are alterations in connectivity in the autistic brain. Herbert et al. (2003) postulated that the abnormal brain enlargement observed in children with autism is disproportionately accounted for by increased white matter based on their findings of large increases in white matter, but no difference in gray matter, in 7- to 11-year-old boys. Of six studies investigating cerebral gray and white matter volumes in autism, three in very young children (1.5–4 years) have reported findings that are consistent with Herbert's suggestion (Courchesne et al., 2001; Hazlett et al., 2005; Schumann et al., 2010). However, studies carried out with subjects who are in later childhood and adolescence are less consistent with Herbert's hypothesis. Two studies found no difference in white matter in later childhood and adolescence (7–18 years; Lotspeich et al., 2004; Palmen et al., 2005), and one found no difference in adolescence and early adulthood (13–29 years; Hazlett et al., 2006). Herbert et al. examined a narrower age range restricted to preadolescent children (7–11 years) and reported a 13% increase in white matter (Herbert et al., 2003), which is restricted to superficial radiate white matter, with no difference reported in deep and bridging white matter Herbert et al. (2004). As discussed earlier, a recent study of post-mortem human tissue found a decreased number of large axons that project long distances beneath the anterior cingulate cortex, an increased number of thin local projection axons, and increased expression of

GAP-43 (Zikopoulos & Barbas, 2010). While provocative, these observations should be confirmed and extended in studies that include a larger sample size.

Synaptogenesis is initiated at points of axodendritic contact between neurons. Functional synapses can form relatively quickly, in some cases within minutes after required pre- and postsynaptic proteins and material have been transported to the site (McAllister, 2007). Synapse development requires the presence of postsynaptic density, receptors, active zone proteins, synaptic vesicles, and transsynaptic adhesion molecules. Transsynaptic molecules in particular are thought to regulate early stages of synapse formation. Two classes of transsynaptic proteins, neuroligins and β-neurexins, have received considerable attention after the discovery that mutated forms of these proteins are found in some autistic patients (Jamain et al., 2003; Comoletti et al., 2004; Szatmari et al., 2007). Neuroligins are postsynaptic proteins that bind with high affinity to members of the presynaptic β-neurexin family of proteins. The formation of the neuroligin–β-neurexin complex is thought to be sufficient and necessary for synapse formation (McAllister, 2007). Multiple isoforms of neuroligin and neurexin have been identified, and each is associated with different types of synapses. The neuroligin-3 and neuroligin-4 isoforms garnered attention after the discovery that mutations in the genes that code these proteins were identified in some patients with autism (Jamain et al., 2003; Comoletti et al., 2004). The mutated forms of the protein can still induce synapse formation, but bind with their transsynaptic partners at a lower affinity (Jamain et al., 2003), which suggests the possibility that some synapses may be altered in these autistic patients. Mutated genes that code for proteins in the β-neuroexin family have also been identified and are linked to some cases of autism (Szatmari et al., 2007). Furthermore, mutated genes that code for additional proteins required for synaptogenesis, such as shank3 (Durand et al., 2007), and protocadherin 10 (Morrow et al., 2008), have been identified in families with autistic children. These data highlight the importance of proper synaptic formation and point toward the potential etiology of some types of autism.

The Role of Cell Death

Some reports indicate that as many as 50% of all neurons that are generated during the development of the CNS die soon after the formation of synapses. The discovery that neuron–target cell interactions are crucial for cell survival suggested that young neurons receive trophic support from their target cells with which they connect (Levi-Montalcini & Booker, 1960a, 1960b). The subsequent isolation and characterization of nerve growth factor led to the discovery of a large family of survival factors, called neurotrophins, which are secreted by target tissues. Most immature neurons depend on access to neurotrophins for survival; neurons that fail to make proper synaptic connections do not receive sufficient trophic support and do not survive. In addition, some neurons also depend on trophic support from cells that

innervate them (Raff et al., 1993). The neurotrophic theory predicts that the developing nervous system can "correct" for some errors in proliferation or migration by eliminating those cells that do not succeed in making proper connections. Furthermore, the embryonic proliferative zones produce a greater number of cells than is generally required to ensure a higher degree of success during formation of CNS structures. Newborn neurons must therefore compete with one another for access to trophic support from target tissues in much the same way that neighboring trees compete with one another for access to sunlight. Additional signaling pathways also play a role in the programmed cell death of young neurons, such as the caspase family of cysteine proteases (Kuan et al., 2000).

As mentioned above and described in further detail elsewhere in this book, MRI studies have reported increased brain volume in some regions of the frontal lobes in young autistic children, but decreased brain volume in the same areas later in adolescence (for review see Courchesne et al., 2007). Additional groups have weighed in on this issue and generally concur that there is an enlargement of cortical brain volume in young autistic children, but it is not yet clear whether these changes are retained beyond childhood (Amaral et al., 2008). Although the etiology underlying these changes in cortical neuroanatomy has not been determined, the early overgrowth of brain tissue followed by possible degeneration is reminiscent of the neurotrophic theory. This suggests that an alteration in two distinct developmental processes could be associated with some forms of autism. An initial phase of increased proliferation in the ventricular and/or subventricular zone would increase cell numbers and could explain increased volume of grey cortical matter. Failure of these cells to form proper synaptic connections, and thus failure to receive sufficient trophic support, would then reduce cell numbers in affected structures and could explain the reduced brain volume reported for older children and adolescents. Furthermore, some cells in the brain appear to undergo programmed cell death, or apoptosis. Factors that promote and inhibit apoptosis have been identified. Interestingly, expression of the anti-apoptotic factor bcl2 is reduced in some cortical regions of individuals with autism, while the pro-apoptotic factor p53 may be overexpressed in the autistic brain (Fatemi & Halt, 2001). These patterns of expression would both lead to an increase in cell death, which could explain the smaller brain volumes that have been reported in some studies. Neurotrophins can regulate the activity of apoptotic factors such as p53, pointing to specific intracellular signaling pathways that might be activated in the autistic brain.

Establishment and Maintenance of Dendritic and Axonal Arbors

Just as the developing brain produces a greater number of cells than is needed, many neurons initially make an excessive number of synaptic connections (Scheiffele, 2003).

The changes in grey matter volume reported in autistic children discussed above could also result from an exuberant production of neuronal processes and cell-cell interactions, followed by excessive pruning of these processes and synapse retraction. The assembly of mature neural networks relies on tightly controlled cell-cell interactions, and candidate molecules that play crucial roles in these processes have been identified. For example, the α1-chimaerin family of proteins, which are expressed in neurons during differentiation and synaptogenesis (Lim et al., 1992), regulate process growth and pruning along dendritic arbors during brain development (Buttery et al., 2006; Beg et al., 2007). These molecules are crucial for normal development. Neurons, in which expression of α1-chimaerin protein has been decreased, sprout overabundant dendritic processes (Buttery et al., 2006). In contrast neurons in which α1-chimaerin protein is overexpressed have longer dendrites with a greater number of processes. Genes that code for proteins such as α1-chimaerin are candidates for consideration in neurodevelopmental disorders, such as autism, that may result from abnormal patterns of connectivity in the CNS. Indeed, a genomewide screen for linkage with autism conducted in 2001 identified α1-chimaerin as a potential gene of interest (IMGSAC, 2001), which, although speculative, may contribute to diminished long-range connectivity (Courchesne & Pierce, 2005; Geschwind & Levitt, 2007).

Conclusions

Research into the neuropathology of autism is still in its infancy. Progress has been hindered, in part, by the lack of availability of a large number of postmortem brains, particularly from early postnatal periods. Given the inherent heterogeneity in the etiologies and trajectories of the autisms, it is likely that various patterns of neuropathology will be observed if an adequate number of brains become available for analyses. It is fair to say that the technology for sophisticated neuropathological analyses is available once the brains have been obtained. Indications that there are fewer neurons in the fusiform gyrus and amygdala beg the question of whether there were always fewer neurons or whether a neurodegenerative process occurs in autism. While the minicolumn hypothesis is important in focusing future neuropathological efforts, it will be critical to combine this research with estimates of cell number, size, and complexity. Similarly, studies indicating persistent inflammation of the autistic brain are provocative, but must be replicated across multiple brain regions and in larger samples of autistic brains. In the end, the relatively subtle neuropathology observed thus far in the autistic brain provides some hope that the behavioral impairments associated with the syndrome are not due to massive neural alteration, but rather to a more subtle, although pervasive, modulation of brain activity. If so, intervention leading to normalized behavior may be more feasible.

Challenges and Future Directions

- Progress into the neuropathology of autism will require an international collaborative effort to acquire an adequate number of brain specimens for analysis.
- Fundamental studies of neuronal organization using modern quantitative, stereological techniques as well as classical methods (e.g., Golgi) will need to be carried out to understand whether the autistic brain is characterized by abnormal cell proliferation and/or cell loss and if there are fundamental differences in the structure of neurons in the autism brain.
- Sophisticated clinical phenotyping of donors will be essential to account for neuropathology associated with comorbid syndromes and the heterogeneity of the autisms in the neuropathological findings that are obtained from postmortem studies.

Neurotransmitters

Points of Interest

- There is evidence for alterations in many neurotransmitters in autism; the most compelling evidence at this time is for alterations in serotonin and GABA neurotransmission.
- The relationship between neurotransmitters measured in blood and the levels of the transmitter in the central nervous system is not well understood.
- Neurotransmitter changes occur in genetic disorders associated with autism in which the gene mutation does not directly affect a neurotransmitter-related gene (synthetic or degradative enzymes, receptor, transporter, etc.).
- Altered neurotransmitter function during brain development may play a role in altered brain development in autism and provide a mechanism for pharmacological intervention.

Neurotransmitters have been the focus of numerous studies aimed at understanding autism, beginning nearly 50 years ago when Schain and Freedman (1961) first reported elevated serotonin in the blood of autistic subjects. Serotonin still remains the neurotransmitter that has been most studied in autism. There is some evidence for alterations in many transmitters, including GABA, glutamate, dopamine, norepinephrine, acetylcholine, and opioid peptides. This literature has been summarized in great detail recently (Lam et al., 2006). This review will focus on the evidence for two neurotransmitters for which there is the strongest link to autism, serotonin and GABA. For each of these neurotransmitters, the evidence for alterations in autism and the significance for altered neurotransmission on brain development and behavior are discussed.

Serotonin

Serotonin Synthesis and Degradation

Serotonin content in different parts of the body is determined by a vast number of factors. Serotonin is synthesized from the precursor tryptophan (Hamon et al., 1981). Tryptophan is an essential amino acid that must be derived from the diet, and constitutes only 1% of the total amino acid pool. In the blood, the majority of tryptophan is bound to plasma protein. It is the free plasma tryptophan that is available to be transported into the brain. Tryptophan is transported into the brain via the large neutral amino acid carrier (LAT1), where it competes for transport with the other large neutral amino acids (Pardridge et al., 1977; Smith et al., 1987). The first, and rate limiting step, of serotonin synthesis is the formation of 5-hydroxytryptophan catalyzed by the enzyme tryptophan hydroxylase (TPH) (Figure 32-1). Tryptophan hydroxylase is only 50% saturated with tryptophan, resulting in the dependence of brain serotonin levels on the plasma concentration of free tryptophan as well as the plasma levels of the other large neutral amino acids (Fernstrom & Wurtman, 1971).

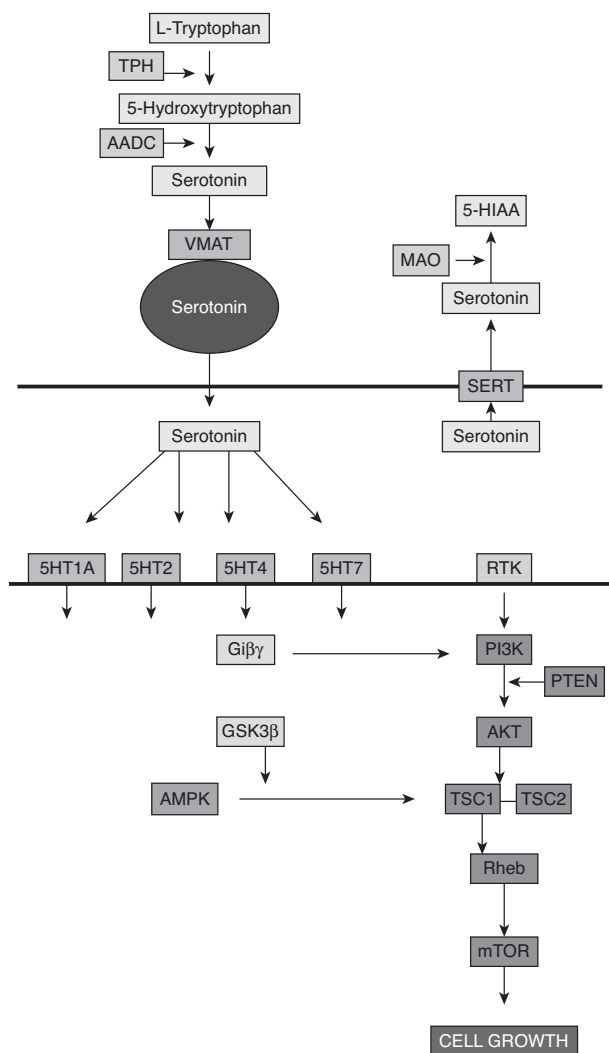
There are 2 genes encoding tryptophan hydroxylase, TPH1 and TPH2 (Sakowski et al., 2006). TPH1 is localized to the pineal gland and throughout the periphery. TPH2 is found in the brain and in the gastrointestinal nervous system (Zhang et al., 2004). The current dogma is that the majority of the serotonin synthesized in the body is generated by the enterochromaffin cells in the gastrointestinal tract (Gershon & Tack, 2007). However, tryptophan hydroxylase is located at many peripheral sites, and the assertion that the majority of serotonin in the body is synthesized in the gastrointestinal tract is not well documented. There is much evidence that serotonin synthetic enzymes are ubiquitously distributed and that serotonin is involved in many different functions throughout the body. Many of these functions might be related to aspects of autism, and its causes. In addition to the gastrointestinal tract and the central nervous system, serotonin is synthesized in bronchial epithelium, taste papillae, thyroid parafollicular cells, ovaries, thymus, pancreas, breast, skin, and arteries (Eddahibi et al., 2006; Ortiz-Alvarado et al, 2006; Matsuda et al., 2004; Stull et al., 2007; Slominski et al., 2002; Ni et al., 2008). TPH and aromatic amino acid decarboxylase (AADC) mRNAs are expressed in the heart, and serotonin is produced and released in cardiomyocytes (Ikeda et al., 2005). TPH-1 mRNA and TPH protein is expressed in trigeminal neurons and is regulated during the estrous cycle (Berman et al., 2006). Serotonin plays an important role in


Figure 32–1. Model demonstrating interaction of serotonergic pathway with the receptor tyrosine kinase (RTK) mediated phosphatidyl inositol 3-kinase/Akt (PI3K) pathway. The synthesis of serotonin from tryptophan catalyzed by tryptophan hydroxylase (TPH) and aromatic amino acid decarboxylase (AADC). Serotonin is stored in synaptic vesicles mediated by the vesicular monoamine transporter (VMAT). Following release from the terminal, serotonin diffuses to both synaptic and extrasynaptic serotonin receptors. Several classes of serotonin receptors have been linked to modulation of the PI3K pathway, including 5HT1A, 5HT2, 5HT4, and 5HT7. Serotonin is taken back up into the terminal by the serotonin transporter (SERT) and metabolized by monamine oxidase (MAO) to 5-hydroxyindole acetic acid (5HIAA). Growth factors such as brain-derived growth factor (BDNF) and insulin-like growth factor (IGF) stimulate cell growth by binding to the receptor tyrosine kinase (RTK) which results in changing the activity of enzymes, causing activation of subsequent components of the pathway. Components of the pathway include phosphatidyl inositol 3-kinase (PI3K), Akt (also known as protein kinase B), tuberous sclerosis complex 1 (TSC1), tuberous sclerosis complex 2 (TSC2), Ras homologue enriched in brain (Rheb), mammalian target of rapamycin complex 1 (mTOR), and PTEN (phosphatase and tensin homologue deleted on chromosome 10). There is evidence that activation of serotonin receptors can change the activity of component of this pathway in part mediated by the G-protein Giβγ and glycogen synthase kinase 3β (GSK3β).

mammary gland function. TPH mRNA is elevated during pregnancy and lactation, and serotonin is present in mammary epithelium and in milk (Matsuda et al., 2004). Elevated plasma serotonin in autism might also be affected by changes in storage and degradation. Plasma serotonin is taken up by platelets through serotonin transporters (Ni & Watts, 2006), and is cleared by liver and lung endothelium (Nocito et al., 2007). Serotonin is metabolized by the enzyme monoamine oxidase to produce its major metabolite 5-hydroxyindoleacetic acid (5HIAA) (for review see Bortolato et al., 2008).

Serotonin Transporter and Receptors

The serotonin transporter (SERT or 5HTT) mediates uptake of serotonin following release at the synapse and at other sites such as the platelet. The gene for the serotonin transporter has two forms, the short and the long form, that are common in the general population. The short variant of the SERT gene has 30–40% lower mRNA expression leading to 50% lower serotonin uptake than transporters produced by the long form (Lesch et al., 1996). To date, 15 receptors for serotonin have been identified, and these are expressed in the brain and throughout the body where they regulate numerous processes (for review see Berger et al., 2009).

Altered Blood Serotonin in Autism

Current evidence now suggests that autism is likely to be caused by dysfunction of many genes (Zhao et al., 2007). Given that many different genes can cause autism, it is striking that 30–50% of autistic individuals show elevated serotonin in the blood (Schain & Freedman, 1961). This result has been replicated by several groups (Hoshino et al., 1984; Anderson et al., 1987; Cook et al., 1990), and extended with the recognition that blood serotonin is also elevated in the first-degree relatives of autistic individuals (Leventhal et al., 1990; Piven et al., 1999; Cook et al., 1994; Leboyer et al., 1999).

Altered Brain Serotonin in Autism

In light of the robust changes observed in blood serotonin, a number of investigators asked whether serotonin in brain was altered by measuring the serotonin metabolite 5HIAA in cerebrospinal fluid. Several studies spanning 20 years of investigation found no difference between autistic and nonautistic control groups in cerebrospinal fluid levels of 5HIAA (for details, see Lam et al., 2006). We used a molecular imaging approach with the tracer alpha[11C]methyl-tryptophan (AMT) imaged with positron emission tomography (PET) (Chugani et al., 1997; Chugani et al., 1999, Chandana et al., 2005). Two fundamentally different types of serotonergic abnormality were found in children with autism. The first is a difference in whole brain serotonin synthesis capacity in autistic children compared to age-matched nonautistic children. Serotonin synthesis capacity was greater than 200% of adult values until the age of 5 years and then declined toward adult values in

nonautistic children. In contrast, serotonin synthesis capacity in autistic children increased gradually between the ages of 2 years and 15 years to values 1.5 times the adult normal values (Chugani et al., 1999). These data suggested that humans undergo a period of high brain serotonin synthesis capacity during early childhood, and that this developmental process is disrupted in autistic children. We also found focal abnormalities in brain serotonin synthesis. Asymmetries of AMT uptake in frontal cortex, thalamus, and cerebellum were visualized in children with autism (Chugani et al., 1997). These results lead to the hypothesis that the dentate-thalamo-cortical pathway may be disrupted in some children with autism. Subsequently, we measured brain serotonin synthesis in a large group of autistic children with AMT PET and related these data to handedness and language function (Chandana et al., 2005). Autistic children demonstrated several patterns of abnormal cortical involvement, including right cortical, left cortical, and absence of abnormal asymmetry. Groups of autistic children defined by presence or absence and side of cortical asymmetry, differed on a measure of language as well as handedness. Autistic children with left cortical AMT decreases showed a higher prevalence of severe language impairment, whereas those with right cortical decreases showed a higher prevalence of left and mixed handedness.

There are several possible explanations for the asymmetries of cortical serotonin synthesis observed in children with autism. First, cortical asymmetry of serotonin synthesis may be normal during early brain development. The presence of abnormal cortical asymmetry in serotonin synthesis observed in approximately one half of the autistic children might represent another manifestation of the abnormality in the developmental regulation of serotonin synthesis. Second, early damage to the dominant left hemisphere leads to compensatory changes in the right hemisphere to support language based on the recognition that damage to the dominant left hemisphere leads to compensatory changes to the right hemisphere to support language (Rasmussen & Milner, 1977; Muller et al., 1999; Curtiss & de Bode, 2003). Evidence for a compensatory change to facilitate language function on the right in autism comes from a study using structural imaging by Herbert et al. (2002), which showed abnormal structural asymmetry in language association cortex in autistic boys. They reported that language-related inferior frontal cortex was 27% larger on the right in the autistic group compared to 17% larger on the left in control subjects.

Genetic Evidence Linking Serotonin to Autism

Blood serotonin levels have been linked to an interaction of the serotonin transporter gene (SLC6A4) and integrin beta3 (ITGB3) (Weiss et al., 2006a,b). This finding was recently replicated and additional interactions between these 2 genes were found, including an additive effect of the HTR5A gene, an interaction of TPH1 and SLC6A4, and an interaction between HTR1D and SLC6A4 for blood serotonin level (Coutinho et al., 2007). As mentioned above, the serotonin transporter has 2 forms. There have been conflicting reports regarding the relative roles of the short and long form in autism (reviewed in

Devlin et al., 2005). More recently, the short allele of the 5HTT receptor was associated with higher gray matter volume in young boys with autism (Wassink et al., 2007). Furthermore, cortical enlargement in autism was reported to be associated with the "low activity" allele of the monamine oxidase A gene (Davis et al., 2008).

Single nucleotide polymorphisms in intron 1 and 4 of TPH2, the brain-specific form of tryptophan hydroxylase, showed an association with autism (Coon et al., 2005). Several recent studies report association of genes that may impact serotonin metabolism in autism. One such study reports the presence of a susceptibility mutation in a promoter variant of the tryptophan 2,3-dioxygenase gene (Nabi et al., 2004). Tryptophan 2,3-dioxygenase is a rate-limiting enzyme in the metabolism of tryptophan (by the kynurenine pathway), the precursor of serotonin. A mutation that results in decreased activity of this enzyme could decrease the metabolism of tryptophan by this pathway and increase the level of whole body serotonin content. Furthermore, tryptophan 2,3-dioxygenase, as well as indoleamine 2,3-dioxygenase (which also catalyses tryptophan metabolism by the kynurenine pathway), are expressed in the placenta and have a role in the prevention of allogeneic rejection of the fetus (Munn et al., 1998; Suzuki et al., 2001). Another recent study investigated the effect of maternal genotypes for monoamine oxidase-A (MAO-A) on the risk of autism in their offspring. Jones et al. (2004) reported that maternal genotypes containing specific polymorphisms at the MAO-A locus show significant negative effects on the intelligence quotient (IQ) in children with autism. These results are consistent with those of a study which found that a low activity MAO-A allele, due to an upstream variable-number tandem repeat region, is associated with both lower IQ and more severe autistic behavior in children, as compared to the high-activity allele (Cohen et al., 2003). The serotonin transporter is highly expressed in the brush border membrane of the human placenta and may mediate transport of serotonin from the maternal circulation to the developing fetus (Balkovetz et al., 1989). Given that there is expression of the serotonin transporter in the placenta, a maternal modifier effect of the serotonin transporter might be a risk factor for autism.

Altered Serotonin in Autism Caused by Genes Not Related to Serotonin

There are several studies showing alterations in serotonergic neurotransmission in Rett syndrome, as well as in the MECP2-null mouse model of Rett syndrome. Decreased levels of the serotonin metabolite 5HIAA were reported in the CSF from 32 patients with Rett syndrome compared to age matched control subjects (Zoghbi et al., 1989). Serotonin concentrations in whole brain from MECP2-null mice showed no difference at birth, but were significantly lower at 42 days of age compared to wild-type mice (Ide et al., 2005). However, these changes were not specific to serotonin, and changes in other transmitters were also reported. Further evidence that the serotonergic system is involved in MECP2, is the report that the selective serotonin uptake inhibitor fluoxetine induced upregulation of MECP2_e1 and MECP2_e2 transcripts in

adult rat brain (Cassel et al., 2005). Conversely, significantly increased brain serotonin content has been reported in a Drosophila FraX model (Zhang et al., 2005). Finally, there is evidence for interaction of the 5HT2C receptor with PTEN (Ji et al., 2006; Muller & Carey, 2006).

Serotonin as a Neurotrophin

Serotonin displays both fast actions as a neurotransmitter and longer-term actions as a neurotrophin. This neurotrophic action may be in part through serotonin regulation of growth factors. For example, serotonin has been reported to stimulate the release of IGF1 and S100b (Lauder, 1993; Lambert & Lauder, 1999). S100b is a trophic factor released from astrocytes by a 5HT1A-mediated mechanism (Whitaker-Azmitia et al., 1996; Azmitia et al., 1996; Ahlemeyer et al., 2000; Eriksen & Druse, 2001). Treatment with selective serotonin reuptake inhibitors has been shown to increase mRNA for BDNF and its receptor trkB (Nibuya et al., 1996; Chen et al., 2001), levels of IGF1 (Khawaja et al., 2004), and FGF2 (Maragnoli et al., 2004) in hippocampus.

Many of these trophic factors are receptor tyrosine kinases that signal through the phosphatidyl inositol 3-kinase/Akt (PI3K) pathway (Figure 32-1). The phosphinositide products of the PI3K recruit Akt and PDK to the membrane resulting in phosphorylation of Akt. There is evidence that serotonin may directly couple to the PI3K pathway. For example, 5HT1A agonists lead to activation of Akt in cultured hippocampal neurons, an action blocked by the 5HT1A antagonist WAY100635 (Cowen et al., 2005; Hsuing et al., 2005). In vivo treatment with agents that increase serotonin resulted in an increase in phosphorylation of GSK-3β, a substrate for Akt (Li et al., 2004). The same results were obtained with the 5HT agonist 8-OH-DPAT and the phosphorylation was inhibited by WAY100635. Alterations in brain growth have long been recognized in autism. Macrocephaly was early recognized in a subset of persons with autism. Recently, mutations in PTEN, a regulator of the PI3K pathway, were shown in cases of autism with extreme macrocephaly (Butler et al., 2005; Varga et al., 2009). Both Akt1 and Akt3 are involved in the attainment of normal brain size (Easton et al., 2005). Thus, serotonin might play a role in brain growth and brain size through PI3K signaling.

Role of Serotonin in Brain Development

Evidence from both pharmacological and gene knockout experiments demonstrates that serotonin plays a role in modulation of synaptogenesis. Immunocytochemistry for serotonin and [^{3}H]citalopram binding to serotonin uptake sites both have demonstrated a transient serotonergic innervation of primary sensory cortex between postnatal days 2 and 14 during the period of synaptogenesis in rat cortex (D'Amato et al., 1987, Cases et al., 1995). Two early studies (Bennett-Clarke et al., 1996, Lebrand et al., 1996) reported that this transient innervation actually represented transient expression of the high-affinity serotonin transporter and vesicular monoamine transporter by glutamatergic thalamocortical neurons.

The serotonin transporter is transiently expressed by glutamatergic thalamocortical afferents (Bennett-Clarke et al., 1996, Lebrand et al., 1996) during the first 2 postnatal weeks in rats. During this period, these thalamocortical neurons take up and store serotonin, although they do not synthesize serotonin. While the role of serotonin in glutamatergic neurons whose cell bodies are located in sensory nuclei of the thalamus is not yet known, there is evidence that the serotonin concentration must be neither too high nor too low during this period. Thus, depletion of serotonin delays the development of the barrel fields of the rat somatosensory cortex (Blue et al., 1991; Osterheld-Haas & Hornung, 1996) and decreases the size of the barrel fields (Bennett-Clarke et al., 1994). Conve-rsely, increased serotonin during this critical period, as in the MAO-A knockout mouse, results in increased tangential arborization of these axons, resulting in blurring of the boundaries of the cortical barrels (Cases et al., 1996). Decreased or increased brain serotonin during this period of development results in disruption of synaptic connectivity in sensory cortices (Cases et al., 1995; Bennett-Clarke et al., 1994; Cases et al., 1996). Furthermore, disruption of serotonin transporter functions impairs the cerebral glucose metabolism response to whisker stimulation (Esaki et al., 2005). The effect of serotonin on synaptogenesis and synaptic function is not limited to the sensory cortices. For example, Yan et al. (1997) have reported that depletion of serotonin with PCA or 5,7-dihydroxytryptamine in neonatal rat pups resulted in large decreases in the numbers of dendritic spines in hippocampus. Finally, alterations of serotonergic function during development have lasting functional changes into adulthood (Ansorge et al., 2004; Gross et al., 2002).

Gamma-Aminobutyric Acid (GABA)

Gamma-aminobutyric acid (GABA) is synthesized from glutamate catalyzed by the enzyme glutamic acid decarboxylase (GAD), of which there are two forms identified: GAD_{65} and GAD_{67} (Kaufman et al., 1991). There are three types of GABA receptors, $GABA_A$ and $GABA_C$ are ligand-gated ion channels, and $GABA_B$ is a G protein coupled receptor (Bowery, 1993). Gamma-aminobutyric acid (GABA) induces fast inhibition by acting on $GABA_A$ receptors in the mature brain, while activation of $GABA_A$ receptors in neonatal brain produces depolarization due to the high intracellular chloride concentration in immature neurons (Yuste & Katz, 1991; Owens et al., 1996; Rivera et al., 1999). The $GABA_A$ receptor complex is composed of 5 polypeptide subunits to form a chloride channel (Nayeem et al., 1994). These polypeptide subunits have been classified based on sequence, and subunit classes have been designated $\alpha, \beta, \gamma, \delta, \varepsilon, \pi, \rho$ (Barnard et al., 1998), and θ (Whiting, 1999). The $GABA_A$ receptor complex incorporates binding sites not only for GABA, but also for benzodiazepines, barbiturates, steroid anesthetics (Olsen et al., 1991; MacDonald & Olsen, 1994; Olsen & Sapp, 1995), volatile general anesthetics (Olsen et al., 1991; Harrison et al., 1993), and possibly alcohols (Mahmoudi et al., 1997).

Pathological Evidence for Altered GABA Neurotransmission in Autism

A number of studies have addressed GAD and GABA receptors in postmortem autism brain and body fluids, by biochemical, receptor binding, western blotting, and mRNA expression methods. Abnormalities of GABA have been detected in blood and platelets of subjects with autism (Rolf et al., 1993). Fatemi et al. (2002) reported reduced GAD_{65} and GAD_{67} protein expression using western blotting in parietal and cerebellar cortices in 9 specimens from autistic adults aged 19–30 years compared to 7 age-matched controls. Blatt and colleagues have studied expression of GAD_{65} and GAD_{67} expression in different cerebellar cell groups. This group has reported decreased GAD_{67} mRNA levels in cerebellar Purkinje cells in autistic subjects (Yip et al., 2007), whereas GAD_{67} was increased in cerebellar interneurons (Yip et al., 2008). Finally, Yip et al. (2009) found decreased GAD_{65} mRNA levels in a subpopulation of cells in cerebellar dentate nuclei. Oblak et al. (2009) measured GABA receptor binding with $[^3H]$muscimol and benzodiazepine binding site with $[^3H]$flunitrazepam in anterior cingulate cortex in specimens from 7 autism subjects aged 19–30 years, compared with control subjects aged 16–43. They found large decreases in the maximum number of binding sites in both ligands in supragranular and infragranular layers of the anterior cingulate cortex. Fatemi, Reutiman, Folsom, and Thuras (2009) examined expression of four $GABA_A$ receptor subunits in using western blotting and found significantly decreased GABRA1, GABRA2, GABRA3, and GABAB3 subunit expression in parietal cortex, GABRA1 and GABRB3 in cerebellum and GABRA1 in superior frontal cortex in specimens from autistic subjects compared to controls. The same group also found decreased GABAB subunit expression in the same three brain regions (Fatemi, Folsom, Reutiman, and Thuras, 2009). These studies suggest widespread decreases in expression of the GABA synthetic enzymes as well as $GABA_A$ and $GABA_B$ receptors.

Genetic and Imaging Evidence for a Role of GABA in Autism

Cytogenetic studies have reported abnormalities in chromosome 15 in autism, specifically 15q11-13, the region that encodes several $GABA_A$ receptor subunit genes (GABRB3, GABRA5, and GABRG3; Silva et al., 2002; Menold et al., 2001; Buxbaum et al., 2002). Menold et al. (2001) reported two single nucleotide polymorphisms located within the GABRB3 gene in autism. Moreover, symptoms of autism can be associated with both Prader-Willi and Angelman's syndromes, both of which involve alterations in the chromosome 15q11-13 region (for a review, Nicholls & Knepper, 2001). Although autism and Angelman's syndrome are distinct disorders, there is considerable overlap among them, with both conditions characterized by language deficit, seizures, mental impairment, behavioral abnormalities, and sleep disturbances. The region 15q11-13 contains the disease loci for Angelman's syndrome (UBE3A) resulting from deletion or mutation within maternal chromosome 15q11-13 (Kishino et al., 1997).

Based on investigations of a GABRB3 gene knockout mouse (Homanics, 1997; DeLorey, 1998), it was suggested that the lack of GABRB3 gene could contribute to most of the clinical symptoms in Angelman's syndrome. Interestingly, Angelman's patients with a maternal deletion of 15q11-13 leading to the loss of β3 subunit of GABA receptor showed significantly decreased binding of $[^{11}C]$flumazenil in frontal, parietal, hippocampal, and cerebellar regions in a PET study (Holopainen et al., 2001). Lucignani et al. (2004) studied 6 adults with Prader-Willi syndrome and found decreased $[^{11}C]$flumazenil binding in insula and cingulate, frontal, and temporal neocortices compared to normal control subjects. These studies demonstrate the utility of PET in elucidating the functional consequence of specific genetic abnormalities. Similarly, $GABA_A$ receptor binding, measured with $GABA_A$ receptor channel ligand ($[(35)S]$t-butylbicyclophosphorothionate) and benzodiazepine ligand ($[(3)H]Ro$ 15-4513), was decreased in a GABAB3 knockout mouse but not in a UBE3A knockout mouse (Sinkkonen et al., 2003). The same 15q11-13 region has been implicated in autism based on several observations showing chromosomal duplications in autistic individuals and evidence of linkage disequilibrium in autistic families (Cook, 1997; Bass, 2000). Specifically, linkage disequilibrium was identified in GABRB3 and GABRA5, as well as at the Angelman's syndrome gene UBE3A in autism families (Cook, 1998; Martin, 2000; Nurmi, 2001). Expression of nonimprinted 15q11-13 GABA receptor subunit genes was significantly reduced specifically in the female 15q11-13 duplication (Hogart et al., 2008).

Role of GABA in Brain Development

It is well demonstrated that GABA mechanisms are involved in the refinement of ocular dominance columns. Treatment with GABAergic drugs during a critical period alters the time course of this development (Hensch et al., 1998). There is abundant evidence that developmental changes in GABA neurotransmission are related to critical periods of activity-dependent synaptic plasticity in response to sensory experience in animals (Wolf et al., 1986; Ramoa et al., 1988, Reiter & Stryker, 1988). Furthermore, there are dramatic changes in $GABA_A$ receptor subunit composition in developing brain, for example in visual cortex (Huntsman et al., 1994; Huang et al., 1999), somatosensory cortex (Golshani et al., 1997; Huntsman et al., 1995), and cerebellum (Carlson et al., 1998). A specific role for benzodiazepine-sensitive $GABA_A$ receptors in the critical period for establishing ocular dominance has been suggested by investigators, who have demonstrated that infusion of diazepam can restore visual cortex plasticity in mice with gene-targeted disruption of the 65-kD isoform of the GABA synthetic enzyme glutamic acid decarboxylase (GAD_{65}) (Hensch et al., 1998). GAD_{65} knockout mice showed no shift in ocular dominance with eye closure during the critical period. However, ocular dominance shift in response to eye closure did occur in these mice if diazepam was infused in the visual cortex during the critical period.

Conclusion

There is abundant evidence for changes in neurotransmitters in autism. These changes in some cases might be directly caused by changes in genes directly relevant to the transmitter, such as enzymes involved in syntheses and degradation, transporters, or receptors. In other cases, the changes in the neurotransmitter might result from altered brain development due to mutation in a trophic factor or signaling pathway, infection, or other environmental event. As illustrated for both serotonin and GABA, neurotransmitters themselves affect brain development, and alterations in neurotransmitters at critical periods of brain development can lead to long-lasting changes in brain connectivity, affecting behavior. Although human pathology studies can provide distinct anatomical detail for localization of neurotransmitters and proteins relevant to their function, postmortem measures are limited to a snapshot in time at the age and condition of death. Such studies will not be able to provide a definition of neurotransmitter changes through development for the many different causes of autism. Animal studies based on particular genes or environmental factors leading to autism can be used to understand the effects of these factors on brain development and be used for preclinical testing of therapeutic agents. Ultimately, however, longitudinal molecular imaging studies aimed at relevant neurotransmitters would be needed to define development changes in a particular neurotransmitter in cases in which the cause of autism is known.

Challenges and Future Directions

Although neurotransmitters in autism has been a subject of study for nearly 50 years, knowledge of the role of the multitude of transmitters and their associated signaling partners in autism is limited. New tools are now available to allow a greater depth of understanding of how neurotransmitters might be altered by different causes of autism at different stages of development over the lifespan.

- Use of animal genetic models of human genetic or environmental causes of autism with microarray techniques to determine the expression of mRNAs for all neurotransmitter related genes, including enzymes mediating synthesis and degradation, transporters, receptors, signaling pathways.
- Use of molecular imaging techniques in humans with known genetic or environmental causes of autism to follow up on discoveries from animal models.
- Employ pharmacological treatment strategies aimed at correcting neurotransmitter abnormalities during development to correct developmental errors.

Brain Chemistry: Magnetic Resonance Spectroscopy

Points of Interest

- ^{1}H MRS is FDA-approved and uses the same equipment as MRI to noninvasively measure hydrogen-containing brain chemicals.
- The areas under the curve of individual peaks in a ^{1}H MRS spectrum used to calculate chemical concentrations also are influenced by pulse sequence and acquisition parameters (e.g., echo time) used to acquire the spectrum.
- The concurrent measurement of multiple chemicals by ^{1}H MRS provides relational information that can reveal patterns of chemical alterations associated with a specific pathophysiology.
- ^{1}H MRS can assess interactions between glutamate and GABA levels, the most abundant excitatory and inhibitory neurotransmitters, respectively, as well as other chemicals, such as choline, creatine, myoinositol and N-acetyl-aspartate, that provide information on the functionality or "health" of neuronal and glial cells.
- Among the more consistently observed chemical alterations associated with ASD, particularly in younger children, are reduced levels of chemicals, such as N-acetyl-aspartate and choline, that are consistent with emerging theories of decreased brain packing density or inflammatory processes early in the developmental course of ASD.

Background

The diagnosis of ASD, typically made in early childhood, is based on rigorous behavioral assessment (APA, 1994). With improvements in diagnostic instruments, the earliest age for reliable clinical diagnosis of ASD has been progressively pushed back to the range of 18 to 36 months of age (Dawson et al., 2002; Dawson et al., 2004; Lord et al., 2006; Zwaigenbaum et al., 2005; Watson et al., 2006; Bryson, McDermott, Rombough, & Zwaigenbaum, 2008; Landa & Garrett-Mayer, 2006). During this time frame, the brain reaches 80–90% of its adult volume, with the overall adult pattern of myelination, and elaboration of new synapses, well underway (Pfefferbaum et al, 1994; Sampaio & Truwit, 2001; Huttenlocher & Dabholkar, 1997). Concurrent with this period of rapid brain development is the development of a wide range of cognitive, social, and language abilities (Kagan, Herschkowitz, & Herschkowitz, 2005).

The pathogenesis of ASD remains little understood but is generally thought to reflect an alteration in the underlying complex interaction of genetic and environmental influences on normal brain development during the postnatal period (DiCicco-Bloom et al., 2006). Earlier imaging studies seeking to identify specific anatomical correlates to ASD have reported a wide array of structural findings that have been often inconsistently replicated, as reviewed elsewhere (Lyon & Rumsey, 1996; Williams & Minshew, 2007). Often reflecting pragmatic considerations of clinical feasibility, imaging studies of ASD typically have concentrated on small samples of older, high-functioning individuals who can cooperate with the imaging procedure. One limitation with this approach of studying only cooperative individuals is that those with mental retardation and seizures, a clinically important and very prevalent subgroup of individuals with ASD, have often gone unstudied. Additionally, a particular difficulty with interpreting brain imaging findings from studies of ASD, beyond such considerations as imaging or analytic techniques used and the sample power, is that a broad range of subject ages are frequently grouped together in individual studies. Wide age ranges within a sample can inadvertently obscure brain developmental alterations that may be present only at distinct age points in ASD, making interpretation of the imaging literature difficult.

More recently, there have been several MRI studies of young children with ASD having samples that comprise a relatively narrow age range of between 2 and 4 years of age. These studies have consistently found on average 10–15% cerebral enlargement after exclusion of cerebrospinal fluid (Courchesne et al., 2001; Sparks et al., 2002; Hazlett et al., 2005). Retrospective and prospective studies of the trajectory of head circumference growth in infants subsequently diagnosed with ASD also suggest normal head size at birth but more rapid increases in size than for typically developing children between 6 and 12 to 18 months of age (Courchesne et al., 2001; Hazlett et al., 2005; Davidovitch, Patterson, & Gartside, 1996; Lainhart et al., 1997; Dawson et al., 2007). Clinically defining features of ASD, such as social deficits, are generally not observed at 6 months of age in children subsequently diagnosed with ASD. Rather, symptom onset occurs sometime after the second half of the first year. Although there are variable patterns of symptom onset, most children diagnosed with an ASD demonstrate symptoms between 12 and 24 months (Dawson et al., 2002; Dawson et al., 2004; Lord et al., 2006; Zwaigenbaum et al., 2005; Watson et al., 2006; Bryson et al., 2008; Landa et al., 2006). Thus, the onset of cerebral enlargement in ASD appears to be a postnatal phenomenon that has an initial time course that converges with the time course for symptom onset (Hazlett et al., 2005; Dawson et al., 2007).

Whether or not cerebral enlargement has a primary role in the pathogenesis of ASD, characterizing the nature of this phenomenon has the potential to provide important insights toward understanding the pathogenesis of ASD. In this regard, it has been proposed that mechanisms underlying cerebral enlargement may also alter brain cytoarchitecture in ASD, with secondary disturbances of white matter tract development and resultant abnormalities of connectivity (Casanova & Tillquist, 2008). Specific components of the white matter circuitry, which predominantly involves short- and medium-range intrahemispheric association fibers rather than longer-range white matter tracts, may be differentially impacted by early overgrowth of the cerebrum (Herbert et al., 2004). In keeping with this consideration, MRI investigations of the corpus callosum in ASD, which connects the right and left cerebral hemispheres, variably find decreases in absolute size but, more consistently, demonstrate a disproportionate reduction in corpus callosum size when total cerebral volume is taken into account (Piven, Bailey, Ranson, & Arndt, 1997; Boger-Megiddo et al., 2006). If optimalization of synaptic organization during the early postnatal period fails to occur, this could result in disruption of vulnerable neural structures and circuits implicated in ASD (Sampaio et al., 2001; Huttenlocher et al., 1997; Belmonte et al., 2004). It has been further suggested that other neurodevelopmental disorders that also manifest during this period, and may have phenotypic overlap with ASD (e.g., Rett syndrome, Fragile X syndrome [FXS]), could also involve alterations of synaptic maturation in common with ASD (Zoghbi, 2003; Bagni & Greenough, 2005). That white matter alterations might be secondary to alterations of gray matter development, which are in turn due to

some other process such as inflammation at earlier stages of brain development, has been suggested though not yet established (Petropoulos et al., 2006).

Research applications of highly resolved 2-D and 3-D structural MRI have demonstrated intriguing clinical relationships between brain anatomical alterations and ASD. For example, an inverse relationship between amygdalar volume at 3 years of age and the trajectory for social skills development between 3 and 6 years of age in children with ASD has been reported (Munson et al., 2006). These structural observations can help to focus research efforts, but do not directly address pathological mechanisms underlying those relationships. The factors that influence image intensity in conventional MRI are complex, and image intensity changes alone do not allow underlying pathological processes to be identified. Furthermore, although MRI is sensitive to changes in tissue water characteristics used to define anatomy at a macroscopic level, it is less sensitive to what is occurring at a cellular level (Petropoulos et al., 2006). In this regard, magnetic resonance spectroscopy (MRS), a complementary imaging technique, can provide useful insights into mechanisms that may account for brain structural alternations in ASD (Dager, Friedman, Petropoulos, & Shaw, 2008; Dager, Corrigan, Richards, & Posse, 2008).

Magnetic Resonance Spectroscopy

MRS was first described in the 1940s and thereafter rapidly applied to characterize chemical samples, in vitro (Purcell, Torrey, & Pound, 1946; Bloch, Hansen, & Packard, 1946; Proctor & Yu, 1950). There are comprehensive reference works available that describe the basic principles of MRS (Gadian, 1982; De Graaf, 2007). As a brief overview, certain atomic nuclei, which include hydrogen (^{1}H), lithium (^{7}Li), carbon (^{13}C), fluorine (^{19}F), sodium (^{23}Na), and phosphorus (^{31}P), have magnetic properties due to the presence of unpaired nucleons (protons or neutrons) that result in a dipole or magnetic orientation to the nuclei. These nuclei are not radioactive and are naturally occurring, although often in small physiologic concentrations. Innovative adaptation of existing in vitro MRS technology, primarily in vivo detection of the spatial distribution of hydrogen atoms (protons) incorporated into the structure of water and lipid, is what made MRI clinically feasible long before MRS was first applied to living systems (Lauterbur, 1973; Mansfield & Grannell, 1973).

Magnetic Resonance Spectroscopy (MRS): At one time referred to as nuclear magnetic resonance (NMR) imaging, this imaging technique is now called MRI in recognition of its noninvasive and nonionizing (nonradioactive) properties. As with MRI, MRS data is produced by perturbing hydrogen nuclei that are aligned with the scanner magnetic field by transmission of a radiofrequency (RF) pulse, which causes

them to absorb and reemit energy. The hydrogen nuclei change orientation ("flip") during the absorption process and subsequently realign with the magnetic field. The signal emitted during realignment is termed the free-induction decay (FID), and is detected up by a receiver coil, digitized, and Fourier transformed to produce a frequency domain MRS spectrum.

MRS can be used in vivo to noninvasively measure brain chemical composition, characterize certain cellular features, and characterize tissue metabolic processes (for a recent review of psychiatric clinical applications, see Dager, Corrigan et al., 2008). Detection of tissue-based abnormalities in brain regions that appear normal by MRI, as well as elucidation of pathology underlying MRI-visible abnormalities, is possible with MRS (Friedman et al., 1999). Although numerous studies have utilized MRI to detect brain structural abnormalities associated with ASD, there have been relatively few studies using MRS to investigate ASD. Several MRS studies of ASD have used nuclei other than ^{1}H, such as ^{31}P to investigate cell membrane turnover (Minshew, Goldstein, Dombrowski, Panchalingam, & Pettegrew, 1993) or ^{19}F MRS to study the brain uptake, steady-state concentration, and elimination half-life of fluorine-containing psychotropic drugs (e.g., fluoxetine and fluvoxamine) used clinically to treat children with ASD (Strauss, Unis, Cowan, Dawson, & Dager, 2002). However, as most MRS research investigating ASD has employed ^{1}H MRS, this is the focus of the chapter.

^{1}H MRS utilizes the same scanner equipment as MRI and can noninvasively detect and quantify low-molecular-weight brain chemicals other than water that also contain hydrogen as part of their molecular structure. To obtain a usable ^{1}H MRS signal, suppression of the water signal, which otherwise would overwhelm the signal from these other hydrogen-containing chemicals, is required first. The ^{1}H spins of chemicals at equilibrium in the scanner's static magnetic field (typically 1.5 Tesla or 3 Tesla) are perturbed by transmitting a radiofrequency (RF) pulse at a specific frequency. This causes the ^{1}H spins to absorb energy by putting more of the spins into a higher energy state and then reemit energy (resonate) as those spins drop back into the parallel state. This reemission of energy varies in strength depending on the properties of the particular electron cloud shielding each chemical bond. Since the electron cloud that shields each nuclei is different due to unique molecular bond configurations of the chemical, each proton experiences a slightly different local magnetic field and, as a result, resonates at a slightly different frequency, referred to as its "chemical shift."

Chemical Shift: The shift in resonance frequency of the hydrogen nucleus of a given chemical as compared to the resonance frequency of a hydrogen nucleus in a water molecule. The chemical shift of the hydrogen nucleus in a chemical dictates the location of the peaks for that chemical on an MRS spectrum and is what makes ^{1}H MRS a useful investigative tool, as specific chemicals can be identified and measured.

The chemical shift for a given chemical is directly proportional to the magnitude of the magnetic field strength used for data acquisition. Frequency measurements for a given chemical are expressed as a dimensionless quantity, by convention given in units of parts per million (PPM), to allow standardization between scanners having different field strengths. This chemical shift measure allows for identification and quantification of specific chemicals that are further described below, In addition, the rate at which spins realign with the static magnetic field following perturbation by the RF pulse, termed T_1 relaxation, and the rate by which the spins lose coherence, termed T_2 relaxation, can also be measured. These measurements, typically of water but also other brain chemicals, can help to characterize features of the microenvironment, or cytoarchitecture, which has been found to be altered in ASD (Dager, Friedman, et al., 2008; Petropoulos et al., 2006; Friedman et al., 2003).

T1 and T2 Relaxation: T1 relaxation (longitudinal or spin-lattice relaxation) is the rate at which hydrogen nuclei realign with the static magnetic field after perturbation by an RF pulse. For a given chemical, the T1 relaxation rate is governed by the magnetic field strength and the composition of the surrounding cellular matrix. T2 relaxation (transverse or spin-spin relaxation) reflects the loss of signal following the RF pulse that is caused by interactions with hydrogen nuclei from nearby tissues, The T1 and T2 relaxation rates of tissues can provide information on many tissue properties, including neuronal maturation and myelination in the brain.

MRS chemical levels are determined by measuring the area under each spectral peak using commercially available MRS software fitting packages (e.g., Provencher, 1993; Provencher, 2009). Often, these chemical peak areas are referenced, or normalized, by the computation of ratios between peak areas from two chemical peaks simultaneously acquired. Reporting chemical ratios for ^{1}H MRS findings (e.g., NAA/Cre) can reduce the effect of individual acquisition differences on chemical measurements across studies. This approach also has the advantage of compensating for partial volume differences in individual voxels. Partial volume primarily reflects the variable inclusion of CSF in the voxel, as well as differences in gray-white tissue composition, as this also can influence the relative chemical proportions. A substantial drawback to using chemical ratios is the requirement that the denominator (often Cre but other chemicals, such as NAA or Cho, may instead be used) not be affected by the pathological process under investigation. This requirement is often not met.

More recent quantification approaches have utilized measurements from a separate water scan, using the unsuppressed water peak as an internal reference standard to control for SNR differences across studies. "Absolute" quantification approaches reference the chemical of interest to an internal reference (e.g., brain water measured from a separately acquired ^{1}H MRS scan) or external phantom (e.g., test-tube placed next to the head) in order to follow or compare chemical levels within and

between individuals. However, if this quantification approach requires the acquisition of an additional scan, there can be problems when scanning under time constraints, as occurs in the study of sleeping children. Quantification techniques also are more difficult to implement and entail many assumptions, such as the stability or full visibility of brain water, but are generally the preferred approach for reporting MRS data. Using the water peak as an internal standard does necessitate a correction for partial volume effects, frequently not performed in published studies.

Reliability for brain chemical measurements using ^{1}H MRS has been clearly established, but due diligence is critical when applying this methodology, as numerous potential pitfalls exist, both in data acquisition and analysis (Dager & Steen, 1992; Brooks, Friedman, & Stidley, 1999). In practical terms, there are limitations in detecting chemicals at low concentrations, generally in the millimolar range, for in vivo ^{1}H MRS (Dager, Corrigan, et al., 2008; De Graaf, 2007; Ross & Michaelis, 1994; Gadian, 1982). Chemicals in the brain that can be detected and quantified by ^{1}H MRS include N-acetyl aspartate (NAA), most often measured as the total of NAA + N-acetyl aspartyl glutamate (NAAG); creatine (Cre), composed of creatine and phosphocreatine; choline (Cho), which has multiple resonances reflecting signal from four membrane/myelin related chemicals: phosphorylethanolamine (PE), phosphorylcholine (PC), glycerophosphorylethanolamine (GPE), and glycerophosphorylcholine (GPC); myoinositol (mI); and lactate, which is difficult to detect at rest in the normal brain. Glutamate (Glu), gamma-aminobutyric acid (GABA), and glutamine (Gln) have complicated peak shapes and resonate at overlapping spectral locations, resulting in the use of the term GLX as a common description of the combined peaks, although at higher field strength individual peaks can be resolved and quantified, as described further below (Dager, Corrigan et al., 2008; Posse et al., 2007; Lin et al., 2007; Schubert, Gallinat, Seifert, & Rinneberg, 2004; Hurd, Gurr, & Sailasuta, 1998; Behar & Ogino, 1991; Ryner, Sorenson, & Thomas, 1995).

Turning to some of the specific chemicals that have been studied in ASD, NAA is an amino acid that is found only in the nervous system, and primarily in neurons and axons (Tallan, Moore, & Stein, 1956). A complex NAA shuttle between neurons and oligodendrocytes suggests important roles for NAA in regulating synaptogenesis and synaptic maintenance, as well as myelination, cellular osmolarity, and neuronal metabolism (Coyle et al., 2000; Neale et al., 2000; Tsacopoulos & Magistretti, 1996; Baslow, 2000). During normal development, NAA levels increase dramatically over the first year of life, then variably increases across different brain regions, gradually plateauing in early adulthood (Kreis & Ross, 1993; van der Knaap et al., 1990; Huppi et al., 1991). Increases in NAA parallel myelination, and are thought to reflect neuronal maturation as a result of increasing synaptic complexity, as well as increased axonal projections. Available data further support a role for NAA as a sensitive marker of both neuronal integrity and neuronal-glial homeostasis (Birken & Oldendorf, 1989; Coyle & Schwarcz, 2000; Neale,

Bzdega, & Wroblewska, 2000). For example, a ^{1}H MRS study of traumatic brain injury found that NAA brain levels were reduced in relation to severity of head trauma and higher NAA levels were predictive of improved clinical outcome (Friedman et al., 1999). NAA alterations characterized by ^{1}H MRS also have been reported to be useful for predicting clinical outcome in pediatric studies of developmental disorders. As shown in a study of neurologically at-risk children, those who subsequently manifested developmental disorders (DD) clinically had reduced NAA measures, reported as NAA/Cho or NAA/Cre ratios (Kimura, Fujii, & Itoh, 1995). These chemical alterations also were found to be a better outcome predictor than structural MRI features.

Chemical Ratios: Meaningful comparison of chemical differences using a ratio (e.g. NAA/Cho in the example of at-risk DD children) requires that the concentration of the chemical in the denominator be equivalent across diagnostic groups. As Cho might be expected to be altered in a direction opposite that of NAA in DD children, its use as the denominator in assessing NAA could amplify any NAA differences between groups. Because neurodevelopmental disorders, such as ASD, are likely to affect the concentrations of multiple brain chemicals, the use of ratios may obscure specific chemical abnormalities.

The Cho spectral peak reflects only the mobile fraction of choline-containing compounds present in tissue, with the larger fraction of Cho being incorporated into molecules in cell membranes and myelin, rendering them MR-invisible (Gadian, 1982; Ross et al., 1994). In contrast to NAA, Cho levels decrease rapidly over the first year of life, also paralleling myelination, and reflect decreases in the PE and PC components of the Cho peak; in contrast, smaller magnitude increases of GPE and GPC also occur (Kreis et al., 1993; van der Knaap et al., 1990). In many individuals with traumatic brain injury, Cho is increased in relation to severity of neuronal injury as a result of the addition of membrane and myelin breakdown products to the ^{1}H MRS signal (Friedman et al., 1999). Furthermore, in contrast to NAA reductions, ^{1}H MRS visible Cho is elevated, at least acutely, in most pathological CNS disease states with cellular disruption.

Bulk Cre in the ^{1}H spectrum provides some indication of energy metabolism and high energy phosphate storage, although ^{31}P MRS provides an unambiguous measure of phosphocreatine, a more straightforward measure of high-energy phosphate levels (Gadian, 1982; Ross et al., 1994). Cre levels also change during normal brain development, with ^{1}H MRS measures of Cre increasing from birth until around 2 years of age, in a direction opposite that of Cho (Kreis et al., 1993; van der Knaap et al., 1990; Huppi et al., 1991). Similarly to NAA, Cre is decreased in response to traumatic brain injury or in the setting of neuronal injury associated with many CNS disease states (Friedman, 1999).

An important regulator of brain osmotic balance, mI is also a putative marker for glial cells, in particular astrocytes, and a

precursor for the phosphoinositides that are involved in the cell membrane second messenger system (Moore et al., 1999). In the setting of inflammatory processes, or acute stroke with associated cytotoxic edema, mI levels may be acutely altered as a measure of glial swelling (Rumpel, Lim, Chang, et al., 2003).

Lactate, at one time thought to be solely a by-product of cellular metabolism, has been found to have an important role in brain bioenergetics, including as an energy substrate for neuronal metabolism (Schurr, West, & Rigor, 1988). Elevated resting brain Lactate levels, often in conjunction with other chemical alterations such as elevated GLX or reduced NAA, may also reflect alterations of brain energy metabolism, such as a shift in redox state from oxidative metabolism toward glycolysis, and provide a potential marker for mitochondrial compromise, as has been observed in medication-free subjects with bipolar disorder (Dager et al., 2004) or individuals with mitochondrial genetic diseases (Dinopoulos et al., 2005; Kaufmann et al., 2004). However, it is important to recognize that moderate reductions in cerebral blood flow and/or increased brain metabolism, as occurs with hyperventilation (Dager et al., 1995) or caffeine ingestion (Dager et al., 1999), also can acutely increase brain lactate levels.

Brain levels of Glu and GABA, the major excitatory and inhibitory neurotransmitter, respectively, are of substantial interest in many neuropsychiatric conditions, including ASD. It is now quite feasible to separate and accurately measure these chemicals at scanner field strengths of 3 Tesla and higher. Whereas Glu can be accurately identified and measured at 3 Tesla using standard pulse sequences with specific acquisition parameters (Schubert, Gallinat, Seifert, et al., 2004), measurement of GABA requires the use of newer, specialized ^{1}H MRS acquisition and analytic techniques, as briefly described below.

Advances in Magnetic Resonance Spectroscopy

Recent technical advances in ^{1}H MRS have led to substantial improvements in spectral, spatial, and temporal resolution. Spectral resolution, the degree of separation or isolation of individual chemical peaks, improves as scanner field strength increases (Vaughan, et al., 2006; Otazo, Mueller, Ugurbil, Wald, Posse, et al., 2006). Better acquisition methods (pulse sequences) and analytic approaches, to be further discussed below, also can further enhance spectral resolution. There is generally a trade-off between spatial and temporal resolution, with increased spatial resolution achieved at the expense of temporal resolution, or vice versa. Spatial resolution and temporal resolution are both functions of the signal-to-noise ratio (SNR), which is also a function of scanner field strength and coil sensitivity, chemical concentration, acquisition parameters (e.g., echo time), and magnetic resonance characteristics of the chemicals of interest. Pragmatically, the most practical approach for enhancing SNR is through increasing signal averaging or number of acquisitions, but the improvement is proportional only to the square root of the number of acquisitions (i.e., in order to double the SNR ratio, there must be 4-times the signal averaging). Although in practical terms, there are technical problems that mount as magnetic field strength increases, the SNR of singlet resonances increases linearly with increases with field strength (Vaughan et al., 2006; Otazo et al., 2006). Improvements in SNR also can be achieved with the use of a shorter echo time (TE) (Posse, Schuknecht, Smith, van Zijl, & Herschkowitz, 1993) and with improved head coil designs (Wald, Moyher, Day, Nelson, & Vigneron, 1995).

Initial MRS studies were limited to measuring chemicals within a single large volume of tissue, referred to as single-voxel techniques. With earlier ^{1}H MRS single-voxel techniques performed at 1.5 Tesla, in order to acquire a scan in a relatively short duration of time (e.g., 5 minutes) while at the same time allowing for measurement of chemicals at low natural abundance, such as lactate, voxel sizes as large as 27cc were required to achieve adequate SNR (Dager et al., 1995). Most ^{1}H MRS studies of ASD populations have employed single-voxel techniques that provide chemical information for only a single brain area and, due to large voxel sizes, there can be quite variable anatomical placement of the voxel. With technical advances, particularly in scanner and head coil hardware, voxel sizes can be substantially reduced. Thus, ^{1}H MRS with a voxel size of 0.18 cc (3.4 x 3.4 x 15 mm^3), or smaller, can be acquired at 3 Tesla field strength, albeit with a lower SNR that requires more signal averaging (Dager, Corrigan, et al., 2008; Lin et al., 2007).

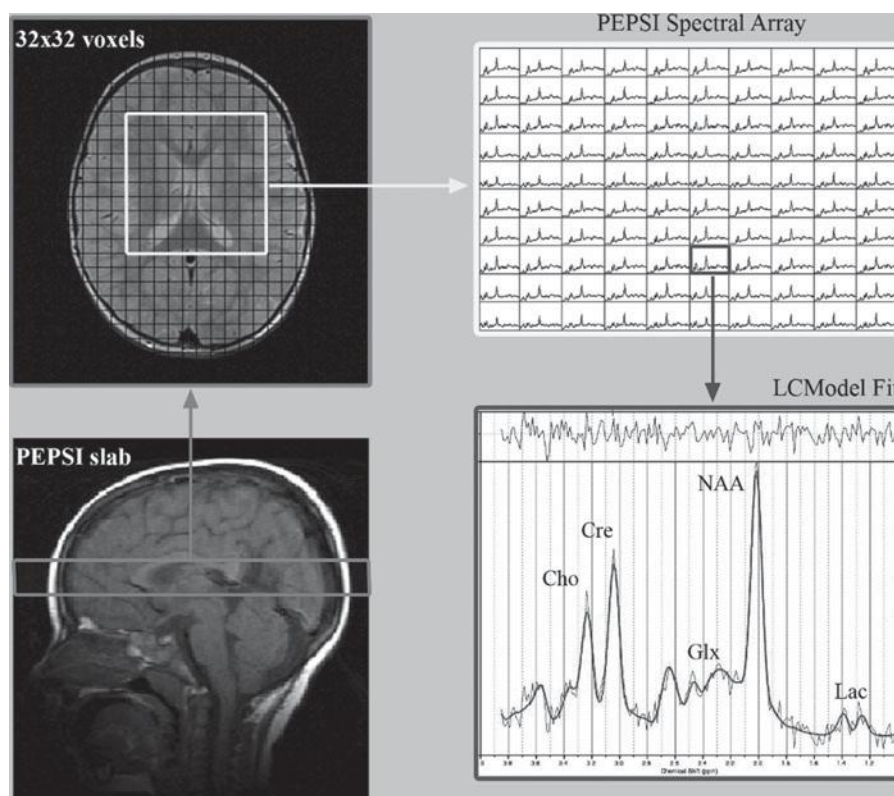
A substantial advance in ^{1}H MRS research applications has been the implementation of rapid 2-D and 3-D ^{1}H MRS imaging techniques (^{1}H MRSI). ^{1}H MRSI allows for the mapping of anatomical distributions of chemical concentrations, similar to the mapping of anatomical distributions of ^{1}H water signal obtainable with MRI (Posse et al., 1997). In contrast to the substantial time required for performing repeated single-voxel ^{1}H MRS acquisitions to sample multiple individual regions, ^{1}H MRSI techniques, such as proton echo-planar spectroscopic imaging (PEPSI), use very rapid spectral-spatial encoding techniques for simultaneous spectral acquisitions across many anatomical voxels. For example, instead of a single 27cc voxel, a 32 x 32 spatial matrix [1024 voxels, individual voxel resolution = 1cc] can be acquired in the same 4–5 minute time frame across a single tissue slice at 1.5 Tesla (Posse et al., 1997). In Figure 33-1, a representative MRI axial slice (20 mm thick) is shown overlaid with a 32 x 32 2-D PEPSI voxel matrix (voxel resolution =1.0 cc). A subset of acquired spectra and the fitting of an individual spectrum are illustrated in Figure 33-2. More recently developed 3-D ^{1}H MRSI techniques can allow the simultaneous acquisition of multiple contiguous anatomical slices (e.g., 8192 voxels over 8 slices with 0.3 cc voxel resolution) within the same 4- to 5-minute time frame using a 3 Tesla scanner (Lin et al., 2007; Dager, Corrigan, et al., 2008). In Figure 33-3, example 3-D PEPSI acquisitions from a standard 3 Tesla clinical scanner are shown for a sleeping 6-month-old without a family history of ASD and for a 12-month-old at high risk for an ASD due to an older affected sibling.


Figure 33–1. A ¹H magnetic resonance spectroscopy imaging (¹H MRSI) axial slab location (20 mm thick) overlaid with a 32 x 32 2-D MRSI voxel matrix. A subset of the acquired MRSI voxels is shown on the upper right-hand corner. An individual voxel with identified chemical peaks is shown in the lower right-hand corner.
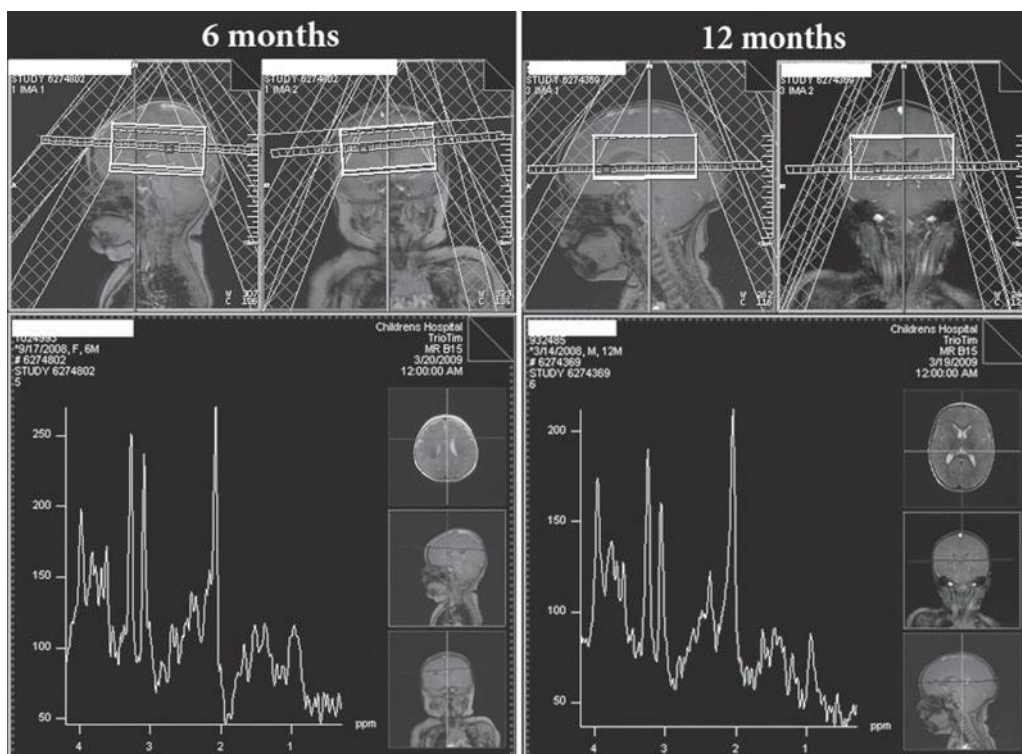
Figure 33–2. LC Model fitting results for an individual spectrum acquired from the left frontal lobe. Shown are the raw absorption mode spectrum (lighter line) and corresponding LC Model fit based on a priori knowledge (darker line). The residuals, calculated as a subtraction of the fit from the spectrum, are plotted at the top. The table of chemical concentrations calculated from the fit is to the right. Cramer-Rao lower bound (%SD) also is shown on the right-hand side for each chemical concentration map. Cramer-Rao lower bounds provide information on the "goodness of fit" and can be used as an objective method for filtering out poor quality spectra.


Figure 33–3. Example 3-D PEPSI spectra, acquired over 4.5 minutes on a clinical 3 Tesla scanner, showing the 3-D anatomical volume, individual voxel placement (blue box) and outer volume sat band positioning for a 6m infant without a family history of ASD and for a 12m infant at high risk for an ASD due to an older affected sibling. Each example shows one 0.3 cc voxel out of the 8,192 collected concurrently. (See Color Plate Section for a color version of this figure.)

Magnetic Resonance Spectroscopic Imaging (MRSI): MRSI represents an important advancement in MRS technology by acquiring spectra from multiple voxels simultaneously. This dramatically increases the number of brain regions that can be sampled in a single scan and allows for the creation of spatial maps of chemical distributions across brain regions or for gray/white matter.

^{1}H MRSI approaches have obvious clinical advantages for the study of populations that are difficult to image, such as agitated or sleeping subjects (such as young children), or for measuring anatomical relationship to changing metabolic states, such as in response to brain metabolic challenges (Dager et al., 1999). Coupled with volumetric MRI using regression analysis, one also can take advantage of the large number of voxel samples obtained with ^{1}H MRSI to calculate estimates of "pure" gray or white matter neurochemistry in studies of ASD (Friedman et al., 2006; DeVito et al., 2007). One substantial challenge associated with using ^{1}H MRSI techniques, however, is the necessity of an adequately uniform magnetic field over the anatomical volume scanned. This requirement of field uniformity, which can be partially compensated for with higher-order shimming, is much more stringent than that required for acquisition of structural MRI.

Shimming: Magnetic resonance data acquisition requires a uniform static magnetic field, which is provided by the main scanner magnet. Imperfections in scanner electronics and the introduction of a person's head inside the scanner can cause alterations in the static magnetic field. Shimming is a method by which scanner hardware is used to detect and compensate for magnetic field variations to make the static magnetic field as uniform as possible during data acquisition.

The use of the pulse sequences utilizing the most up-to-date technology, or optimization of existing product pulse sequences by using improved acquisition parameters (e.g., short echo times that maximize signal by reducing the effects of T2 decay), can substantially improve data quality. For example, very short echo times (e.g., 11 ms) can be used for some ^{1}H MRSI acquisitions to increase SNR and improve detection of chemicals with short T2s, such as mI or GLX, as well as alleviate some of the confounds associated with chemical quantification (Dager, Corrigan, et al., 2008; Friedman et al., 2003; Posse et al., 1993). Furthermore, acquisition of both short and long echo time chemical measurements can allow for estimation of chemical T2 relaxation, shown to be abnormal in ASD (Friedman et al., 2003).

Echo Time: The echo time, or TE, is the time following the RF pulse when acquisition of the FID signal is initiated.

Although ^{1}H MRS can detect a number of chemical signals, the spectra also contain a "forest" of multiple overlapping resonances that can substantially hinder the quantification of many of these chemicals (Dager, Corrigan, et al., 2008). Spectral editing techniques are increasingly being used to provide more specific information about chemical bond structure and to individually measure some chemicals that are not otherwise separable, such as Gln and GABA (Lin et al., 2007; Jensen, Frederick, & Renshaw, 2005; Jensen, Frederick, Wang, Brown, & Renshaw, 2005; Behar & Ogino, 1991; Ryner et al., 1995; Hurd et al., 1998; Hurd et al., 2004; Mescher, Merkle, Kirsch, Garwood, & Gruetter, 1998). An example two-dimensional spectral plot from a typical adult male acquired using J-resolved spectral editing is shown in Figure 33-4. Identification of chemical spectra that were acquired simultaneously demonstrates the separation of the coupled resonances of brain glutamine and glutamate, in addition to other typically measured chemicals. In Figure 33-5, results are shown using a MEGA-PRESS acquisition to isolate and identify the GABA resonance that would otherwise be obscured by the overlapping spectral peaks of other chemicals.

Spectral Editing Techniques: Spectral editing techniques are acquisition methods that vary the timing of specific data acquisition parameters to allow for measurement of chemicals that are difficult to distinguish due to overlapping peaks. MEGA-PRESS is a ^{1}H MRS spectral editing technique designed to measure chemicals such as GABA, glutamate, and glutamine. This technique requires separate acquisitions for measurement of each chemical of interest. Two-dimensional J-resolved ^{1}HMRS spectral editing techniques are designed to measure multiple chemicals during a single acquisition, allowing for simultaneous measurement of multiple chemicals, although separating some chemicals, such as GABA, can be analytically challenging.

Imaging research centers are increasingly utilizing higher field scanners (up to 9.4 Tesla), although scanner strengths beyond 3 Tesla are not yet approved for clinical use by the Food and Drug Administration. The use of high field scanners (3 Tesla and higher), in conjunction with advancing RF coil array technology, allows substantially improved measurement sensitivity and enhanced ability to resolve specific brain chemicals of particular importance in ASD investigations. By combining MRSI approaches with recent advances in parallel imaging, ^{1}H MRSI data acquisition times can be drastically reduced to under a minute for some applications, depending on the scanner field strength, to obtain single-average images of chemicals such as Cho, Cre, and NAA, as well as Glu, with acceptable spectral quality and localization (Lin et al., 2007; Posse, Otazo, Tsai, Yoshimoto, & Lin, 2008; Otazo, Tsai, Lin, & Posse, 2007; Tsai et al., 2008; Dager, Corrigan, et al., 2009). A further area of technical advancement, the development of ^{1}H MRS approaches for acquiring spectra from brain areas typically difficult to study due to susceptibility artifacts, will be useful for investigating brain regions important for understanding ASD, such as the amygdala (Josey, Al Sayyari, Buckley, & Coulthard, 2009).

MRS Findings in ASD

A substantial proportion of the available literature using ^{1}H MRS to investigate ASD must be considered descriptive since findings are based on only a limited number of cases. Also, as described above, the manner by which methodological factors have been handled, such as patient and control group selection criteria, including differences in diagnostic criteria, age ranges, autistic subtypes, and IQ inclusion parameters, has varied widely across studies. Comparison between studies can also be difficult due to differences in ^{1}H MRS data acquisition protocols, particularly since the field is continuously developing newer acquisition techniques and more powerful scanners are becoming increasingly available. ^{1}H MRS studies of ASD
Figure 33–4. A 2-D J-resolved spectral image acquired over 20 minutes from a 64 cc volume at 3 Tesla. Spectral resonances for glutamine, glutamate, Glu/Gln complex, lactate, as well as myoinositol, choline, creatine, and NAA are shown. Data were acquired as a function of echo time, using progressively increasing echo times to record signal change that can differentiate between chemicals. (See Color Plate Section for a color version of this figure.)
Figure 33–5. Separation and identification of the GABA resonance from the overlapping resonances of other chemicals using MEGAPRESS. These data were acquired over 13 minutes from a 18 cc voxel at 3 Tesla, using the interaction of neighboring ^{1}H within the GABA molecule to subtract out signal from other overlapping chemicals. A specific RF pulse is required for GABA signal acquisition with MEGAPRESS.

generally have been conducted using single-voxel techniques that typically involve the acquisition of data from only a few anatomical regions of relatively large volume (on the order of 2 x 2 x 2 = 8 cm³). Importantly, the regions of interest chosen for study, and anatomical specificity, often vary substantially between studies. The analytic approaches used for quantification of chemical measures also are not well standardized and can substantially influence results. Moreover, MRS and MRSI are intrinsically low-resolution techniques that rely heavily on MRI-based partial volume correction of the different tissue types and relaxation time constants of water and chemicals with any propagation of small errors producing significant downstream effects on chemical quantification (Friedman et al., 2003).

Comparison of ^{1}H MRS findings in ASD across published studies, despite the challenges in summarizing these varied data, does reveal interesting patterns of chemical alterations. Abnormal ^{1}H MRS chemical patterns, most consistently reductions in NAA, found in many, though not all, studies of ASD suggest differences in tissue chemical composition or neuronal integrity (Dager, Friedman, et al., 2008; Friedman et al., 2003; Friedman et al., 2006; DeVito et al., 2007; Hashimoto et al., 1997; Chugani, Sundram, Behen, Lee, & Moore, 1999; Otsuka, Harada, Mori, Hisaoka, & Nishitani, 1999; Hisaoka, Harada, & Nishitani, 2001; Murphy et al., 2002; Page et al., 2006; Kleinhans, Schweinsburg, Cohen, Muller, & Courchesne, 2007; Endo et al., 2007; Zeegers, van der Grond, van Daalen, Buitelaar, & van Engeland, 2006; Vasconcelos et al., 2008; Gabis et al., 2008; Levitt et al., 2003; Oner et al., 2007; Hardan

et al., 2008). Although findings have been more variable, perhaps reflecting greater regional specificity, reduced Cho found in some studies may reflect decreased membrane turnover, in a direction opposite to what would be expected due to neuronal injury from membrane or myelin breakdown. There is also some suggestion of age-related effects on ^{1}H MRS differences. For example, evidence for reduced NAA levels tend to be more consistently found in younger populations with ASD, although one study of adults with ASD also reports regional reductions of NAA (Kleinhans et al., 2007). A summary of published single-voxel ^{1}H MRS findings (Hashimoto et al., 1997; Chugani et al., 1999; Otsuka et al., 1999; Hisaoka et al., 2001; Murphy et al., 2002; Page et al., 2006; Kleinhans et al., 2007; Endo et al., 2007; Zeegers et al., 2006; Vasconcelos et al., 2008; Gabis et al., 2008) is shown in Table 33-1.

As illustrated in Table 33-2, there have been only a few published ^{1}H MRSI investigations of ASD (Friedman et al., 2003; Friedman et al., 2006; DeVito et al., 2007; Levitt et al., 2003; Oner et al., 2007; Hardan et al., 2008). Findings from these studies are generally consistent with ^{1}H MRS single-voxel evidence for widespread alterations of tissue chemical composition. Importantly, the integration of ^{1}H MRSI measurements and MRI anatomical findings can lead to a better understanding of mechanisms underlying specific brain structural alterations associated with ASD. For example, to explain the approximately 10% cerebral enlargement observed from structural MRI studies of ASD children at 3 to 4 years of age, we tested an exploratory hypothesis of regionally increased NAA concentrations posited to reflect increased numbers of neurons or more dense connections arising from a disturbance of normal neuronal apoptosis or synaptic pruning processes during early development in children with autism (Friedman et al., 2003). In this model, regional chemical concentrations were predicted to be increased, and chemical T2 relaxation times, estimated from acquisition of ^{1}H MRSI using two TE (20 ms and 272 ms), were predicted to be shortened as a result of densely packed molecules having increased interaction over time following excitation by the RF pulse. Results from this study instead revealed a pattern of widely distributed regional reductions in NAA, Cre, and mI concentrations (and Cho in gray matter), and prolonged chemical T2 relaxation, all in a direction opposite to what was initially predicted. Overall, these ^{1}H MRSI findings were not consistent with increased cellular packing density among the 3- to 4-year-old children with ASD and, thus, do not support models of abnormally reduced apoptosis and/or delayed synaptic pruning, nor provide evidence for neuronal "overgrowth" during the preschool years (Dager, Friedman, et al., 2008; Friedman et al., 2003). In further analyses of these data, MRSI images were coregistered to segmented tissue maps produced from MRI acquired at the same session, and regression analytic techniques were used to characterize the compartmental distribution of chemical alterations between white and gray matter (Friedman et al., 2006). Chemical abnormalities were predominantly observed in gray matter, supporting an altered gray matter cytoarchitecture for the 3- to 4-year-old ASD

Table 33–1.
Single voxel ¹H spectroscopy studies of autism spectrum disorders

Investigator	N	Age in years (mean±SD)	Population	Echo Time (ms)	Brain Region	Finding
Hashimoto, 1997	28 (20M,8F)	2–12 (5.6±2.2)	AD	270	Right parietal lobe	No differences in NAA/Cho, NAA/Cre, Cho/Cre
Chugani, 1999	9 (8M,1F)	3–12 (5.7±2.5)	AD	30	Frontal and temporal lobes, cerebellum	Reduced cerebellar NAA Increased frontal lobe lactate in 1 child
Otsuka, 1999	27 (21M,6F)	2–18	AD	18	Right hippocampus/amygdala, left cerebellum	Reduced hippocampus/amygdala and left cerebellar NAA
Hisaoka, 2001	55 (47M,8F)	2–21 (5.8)	AD	135	Bilateral frontal, parietal, and temporal lobes, cingulate, brain stem	Reduced bilateral temporal lobe NAA
Murphy, 2002	14 (all M)	(30±9)	ASP	136	Right medial prefrontal and parietal lobes	Increased right medial prefrontal NAA, Cho and Cre
Page, 2006	25 (20 M,5F)	(35.6±11.5)	ASD	35	Right hippocampus/amygdala, right parietal lobe	Increased right hippocampus/amygdala Glu+Gln and Cre
Kleinhans, 2007	13 (all M)	15–44 (24.5±9.5)	ASD	35	Left middle frontal and superior parietal cortex, occipital cortex at calcarine fissure, cerebellum	Reduced left middle frontal cortex NAA Reduced NAA in combined brain regions
Endo, 2007	38 (32M,6F)	6–20 (12.9±3.8)	ASD	35	Right medial temporal and prefrontal lobes, cerebellar vermis	Reduced right medial temporal NAA/Cre
Zeegers, 2006	25 (all M)	AD: (3.6±0.6) PDD-NOS: (3.8±1.3)	ASD	144	Left frontal subcortical white matter, left hippocampus/amygdala	No differences in NAA, Cho, Cre, NAA/Cre, NAA/Cho between children with ASD and developmentally delayed children without ASD
Vasconcelos, 2008	10 (all M)	median age 9.53±1.8	AD	30	Bilateral anterior cingulate, left striatum, cerebellum and frontal lobe	Increased anterior cingulate mI and Cho Increased anterior cingulate and left striatum mI/Cre
Gabis, 2008	13 (10M,3F)	7–16 (10±2.5)	ASD	40	Bilateral hippocampus/amygdala and cerebellum	Reduced bilateral hippocampus/amygdala NAA/Cre Increased bilateral hippocampus/amygdala and cerebellar mI/Cre Increased left hippocampus/amygdala and cerebellar Cho/Cre

children compared to age-matched typically developing and developmentally delayed children. A subsequent ¹H MRSI study of preadolescent children with ASD, which used different acquisition techniques but similar regression analytic approaches, also observed reduced NAA in gray matter, but not white matter, compared to typically developing controls (DeVito et al., 2007).

Overall, the direction and widespread anatomical distribution of chemical alterations observed from these ¹H MRSI studies, which primarily demonstrate reduced brain chemical concentrations per unit brain tissue volume, were not consistent with our a priori theoretical model of diffusely increased neuronal packing density in the children with ASD

(Friedman et al., 2003). Furthermore, evidence from quantitative T2 relaxation measures of brain water, used as a temporal marker for brain maturational stage, does not support accelerated "normal" brain growth early in the developmental course of ASD (Petropoulos et al., 2006). Instead, evidence to date suggests a revised model characterized most simply as altered gray matter cytoarchitecture having a reduced unit density, at least at the 3- to 4-year-old age range in ASD (Dager, Friedman, et al., 2008).

In the postnatal developing brain, increased levels of whole blood and platelet serotonin, reported in an estimated 30% of affected individuals with ASD, may lead to abnormal development of serotonergic fibers with decreased numbers of

Table 33–2.
2-D ¹H spectroscopic imaging studies of ASD

Investigator	N	Age in years (mean±SD)	Population	Echo Time (ms)	Brain Region	Finding
Friedman, 2003	45 (38M,7F)	3–4 (4.0±0.4)	ASD	20/272	21 brain regions	Widespread regional reductions of NAA, Cre and mI Prolonged NAA T2 relaxation
Levitt, 2003	22 (18M,4F)	5–16 (10.4±3.4)	ASD	272	22 brain regions	Reduced left anterior cingulate Cho Reduced left caudate and right occipital cortex Cre Increased right caudate Cho and Cre
Friedman, 2006	45 (38M,7F) [same sample as Friedman, 2003]	3–4 (4.0±0.4)	ASD	20/272	21 brain regions	Gray matter reductions predominate over white matter reductions of NAA, Cho, Cre, and mI Prolonged gray matter Cho T2 relaxation
DeVito, 2007	26 (all M)	6–17 (9.8±3.2)	AD	135	Frontal, temporal, and occipital gray matter, cerebral white matter, cerebellum	Widespread reductions of NAA and Glx in cerebral gray matter and cerebellum
Oner, 2007	14 (all M)	17–38 (24.3±7.1)	ASP	270	Right dorsolateral prefrontal cortex, right anterior cingulate cortex [data from additional regions not reported]	Increased right anterior cingulate NAA/Cho
Hardan, 2008	18 (all M)	(11.9±2.2)	AD	20	Bilateral thalamus [data from additional regions not reported]	Reduced left thalamus NAA, Cre, and Cho

serotonin terminals, decreased synaptogenesis, and reduced synaptic density (Whitaker-Azmitia, 2005). This mechanism also has been implicated in aberrations in cortical columnar development and connectivity (Casanova et al., 2008; Chugani, 2004). As a possible mediator or alternative consideration, there is emerging evidence to suggest the possibility of early inflammatory processes in autism that, if present, might also contribute to findings of reduced tissue density. For example, microglial activity and elevated cytokines in various brain regions have been reported across a broad age range of individuals with autism (Vargas, Nascimbene, Krishnan, Zimmerman, & Pardo, 2005). Additionally, increased glial fibrillary acidic protein found in postmortem samples of frontal and parietal cerebral cortex and cerebellum from older (> 18 years old) individuals with autism also suggests abnormal CNS immune activity persisting from an earlier age-point (Laurence & Fatemi, 2005). These findings are intriguing, but any related model that might account for abnormal cortical development in ASD, perhaps reflecting altered serotonergic function and/or early inflammatory processes, awaits systematic investigation. Thus, ¹H MRSI findings for altered brain tissue cytoarchitecture point toward a substantially different explanatory model than cerebral overgrowth or abnormal apoptotic or synaptic pruning regulatory mechanisms for structural MRI findings of cerebral enlargement in very young children with ASD. However, newer explanatory models that

potentially could address MRI and ¹H MRS findings at this time remain speculative (Dager, Friedman, et al., 2008).

¹H MRS studies of ASD at lower magnetic field strength scanners (1.5 Tesla) have not been able to satisfactorily resolve the Glx complex to separately quantify Glu, Gln, and GABA. The capability to individually measure these chemicals, now feasible with the availability of advanced spectral editing techniques at higher field strength, provides new opportunities to address specific hypothesis-driven theories such as competing theories of hypoglutamatergic (Carlsson, 1998) or reduced inhibitory balance (Belmonte et al., 2004) mechanisms in ASD. These theories could support alterations of either decreased or elevated Glu, Gln, and GABA, conceivably for different brain regions concurrently (Polleux & Lauder, 2004). Although ¹H MRS studies of children with ASD have found either no differences or lower levels of Glx, the possibility remains that diagnostic differences in individual constituent chemicals are lost in the overall GLX measurement, regional differences exist, or there are age-related differences. Keeping in mind the inherent difficulties in accurately measuring the large and broad Glx peak that comprises the overlapping resonances of Glu, Gln, and GABA at 1.5 Tesla, a single-voxel ¹H MRS study of a small sample of medication-naïve adults with ASD found regional elevations of GLX in the right amygdala-hippocampal region compared to a control brain region in the parietal lobe (Page et al., 2006). In consideration of this

finding, a ^{13}C MRS study that evaluated glutamate-glutamine cycling in patients with intractable temporal lobe epilepsy found significant slowing of the cycle and elevated hippocampal Glu levels (Petroff, Errante, Rothman, Kim, & Spencer, 2002). As proposed by those authors and others (During & Spencer, 1993; Maragakis & Rothstein, 2001), regionally increased Glu release, or impaired clearance, could contribute to an ongoing state of increased cerebral excitability/excitotoxicity that could potentially create conditions suitable for seizure generation. This model is of potential clinical relevance to ASD, as there is a substantial risk of seizures that has a bimodal pattern of onset either in the first 2 years of life or, more typically, as the child enters adolescence, with estimates of prevalence rates ranging between 15 and 38% (Volkmar & Nelson, 1990; Giovanardi, Posar, & Parmeggiani, 2000; Tuchman & Rapin, 2002). Although the finding of elevated GLX in older individuals with ASD remains to be replicated, in conjunction with a recent report that GLX levels in preadolescents with ASD were lower (DeVito et al., 2007), the possibility of GLX levels increasing as these children grow older has potential implications for seizure onset in adolescents with ASD and for new targeted treatment approaches as well (Niederhofer, 2007).

More recently, speculation has focused on the possible role of mitochondrial compromise in ASD (NIH, 2008). This interest, in part, has been stimulated by recent clinical reports of adverse reactions temporally related to vaccination that implicated mitochondrial deficits as the mediating factor. There also are important treatment considerations if evidence for a mitochondrial contribution to vulnerability or symptom expression in ASD were to be established. For example, therapeutic properties of lithium carbonate are hypothesized to be mediated via elevations of bcl-2, a neuroprotective protein that also has mitochondrial membrane-stabilizing effects (Manji et al., 2003).

To date, a standardized approach for medical assessment of mitochondrial abnormalities and objective criteria for diagnosis of mild mitochondrial dysfunction have yet to be established (NIH, 2008). As mitochondrial DNA is distinct from nuclear DNA, much less stable and with substantially different patterns of heritability, different genetic models are required to test for relationships to ASD (Pons et al., 2004). The wide variability of clinical and metabolic manifestations of mitochondrial dysfunction could reflect variable loading of mitochondrial DNA polymorphisms, and across tissue types, that exhibit differing threshold response to oxidative stress (Calabrese et al., 2001). Elevated brain lactate determined by ^{1}H MRS is considered to be a sensitive biomarker, and substantially more specific than blood lactate elevations, for establishing the presence of mitochondrial dysfunction (Dinopoulos et al., 2005; Kaufmann et al., 2004; NIH, 2008). However, the substantial brain lactate elevations that occur in healthy subjects in response to mild, event-dependent physiological alterations, such as hyperventilation or caffeine ingestion, illustrate the difficulties attributing specificity to increased brain lactate as a biomarker for mitochondrial compromise (Dager et al., 1995; Dager et al., 1999).

^{1}H MRS investigations of subtle evidence for brain mitochondrial abnormalities in other psychiatric disease processes, such as bipolar disorder, have sought to evaluate brain lactate elevations in conjunction with other brain chemical alterations, such as NAA reductions or GLX elevations (Dager et al., 2004). To date, there has been only a single ^{1}H MRS report of regional brain lactate elevations associated with ASD, for one individual within a case series of older children with ASD, who also had elevated blood lactate levels (Chugani et al., 1999). Furthermore, although a number of ^{1}H MRS studies of ASD have found reduced NAA, only one study has reported regionally elevated GLX in adults with ASD (Page et al., 2006). In contrast, a ^{1}H MRSI study of 3- to 4-year-old children with ASD (N = 45), that used acquisition parameters and a 1.5T scanner platform identical to that employed for a study that detected a generalized pattern of gray matter lactate and GLX elevations in medication-free bipolar subjects (Dager et al., 2004), found no such evidence for either lactate or GLX regional or gray matter elevations (Friedman et al., 2003; Friedman et al., 2006). For this later work, confounding effects of anxiety or hyperventilation that could have artificially elevated brain lactate were eliminated through the use of propofol anesthesia to conduct the study. It is conceivable that use of propofol in the ASD group could have obscured possible lactate differences between diagnostic groups, as the typically developing control group were not sedated but instead scanned late at night during natural sleep. The alternative consideration, that use of propofol might produce regional lactate elevations in conjunction with any compromise of cerebral blood flow, was evaluated for but not found (Amundsen et al., 2005).

Brain lactate can be difficult to detect or accurately measure under basal conditions. Increasing scanner magnetic field strength and improved spectral analytic methods offer the possibility of enhanced sensitivity for detecting subtle metabolic alterations (Dager, Corrigan, et al., 2010). It is also possible that physiological challenge approaches designed to "unmask" subtle metabolic alterations, as has been demonstrated for panic disorder subjects in response to regulated hyperventilation (Dager et al., 1995), could more fully address the potential occurrence of subtle mitochondrial dysfunction in ASD.

It is important to recognize that ^{1}H MRS or ^{1}H MRSI findings most frequently reported in association with ASD (e.g., reduced NAA) are not diagnostic of ASD or specific to symptom expression. Other disorders that have overlapping phenotypic expression as ASD, such as Rett syndrome, may also exhibit a similar ^{1}H MRS pattern of altered brain chemistry. For example, the majority of published ^{1}H MRS studies of Rett syndrome, albeit usually with very small sample sizes, also find reduced NAA or NAA/Cre (Nielsen et al., 1993; Hanefeld et al., 1995; Hashimoto et al., 1998; Pan, Lane, Hetherington, & Percy, 1999; Gokcay, Kitis, Ekmekci, Karasoy, & Sener, 2002; Khong, Lam, Ooi, Ko, & Wong, 2002; Horska et al., 2000). Also, reduced NAA is one of the more consistent ^{1}H MRS alterations associated with idiopathic developmental

delay (Kimura et al., 1995). Other psychiatric disorders also may exhibit overlapping patterns of brain tissue chemical alterations as ASD. For example, the most robust ^{1}H MRS findings in adults with schizophrenia are substantial NAA reductions in frontal lobe, parietal lobe, and medial temporal lobe gray and white matter, along with a similar magnitude of reduced NAA in the cerebellum (Steen, Hamer, & Lieberman, 2005). As NAA increases are observed following both short-term and longer duration antipsychotic treatment of schizophrenia (Bertolino, Callicott, Mattay, Weidenhammer, Rakow, et al., 2001), it is unlikely that reduced baseline NAA levels in schizophrenia primarily reflects reduced neuronal density. These observations may instead reflect the effects of medication on NAA's role in synaptic maintenance, myelination, regulation of cellular osmolarity, and neuronal metabolism (Birken et al., 1989; Coyle et al., 2000; Neale et al., 2000).

Conclusions

^{1}H MRS is advancing our understanding of basic mechanisms underlying brain developmental abnormalities associated with ASD, such as the early cerebral enlargement observed by MRI. ^{1}H MRS findings, to date, from studies of ASD do not appear to be of diagnostic specificity but can be used to interrogate brain structural alterations in ASD and relationships to specific developmental time points. Studies of young children with ASD provide evidence for widespread reductions in NAA and other brain chemical levels, and alterations in the mobility of these chemicals (T2 relaxation), suggest early alterations in brain tissue development. This altered brain tissue cytoarchitecture is posited to reflect generalized reductions in neuronal density and/or alterations in neuronal and synaptic maintenance, and is found to primarily affect gray matter at earlier ages. Applications of ^{1}H MRS and quantitative T2 relaxation to test specific models hypothesized to account for early cerebral enlargement do not support accelerated cerebral overgrowth or abnormal apoptotic or synaptic pruning mechanisms. Instead, insights gained from ^{1}H MRS findings are contributing to the formulation of new explanatory models to account for multimodal imaging and related histopathological findings in ASD.

Challenges and Future Directions

- Current, widely available ^{1}H MRS/I methods can be used to characterize:
  - the timing of chemical changes in relationship to developmental course
  - anatomical localization of chemical alterations
  - relationships between chemical alterations and structural abnormalities
  - relationships between chemical alterations, clinical prognosis, and treatment response
- Advances in the field are improving:
  - isolation and quantification of chemicals of particular interest to ASD.
  - temporal resolution for better evaluation of active metabolic processes
  - spatial resolution and magnetic field homogeneity to allow for more precise interrogation of particular brain regions of interest in ASD, such as the amygdala, and even amygdalar subregions.
- Current methodological limitations include:
  - difficulties with between-site standardization of MRS measurements
  - lack of a standardized analytic methodology that avoids common pitfalls and yields accurate and reproducible MRS measurements.

Oxytocin, Vasopressin, and Social Behavior: Implications for Autism Spectrum Disorders

Points of Interest

- Oxytocin and vasopressin are highly evolutionarily conserved modulators of reproductive and social behavior.
- Oxytocin and vasopressin modulate social motivation, social information processing, and social bonding in a variety of rodent species.
- Individual variation in the neuropeptide receptor systems has been associated with variation in social behavior in rodents.
- Oxytocin has been shown to modulate a variety of complex social behaviors in humans, such as trust, emotional perception, and face processing.
- Disregulation of peripheral peptide levels and polymorphisms in oxytocin, vasopressin, and their receptor genes have been associated with ASD.

Elucidation of the basic neurobiological mechanisms underlying social cognition and social behavior is pivotal for understanding the biology mediating normal human social behavior and may also provide valuable insights into the pathophysiology and potential treatment of disorders of social behavior. An extensive literature has implicated the neuropeptides oxytocin and vasopressin as being key modulators of species-typical social behavior. This chapter will review the evidence from animal and human research demonstrating that these neuropeptides modulate several aspects of social cognition and behavior, including social motivation, social information processing, and social attachment.

Oxytocin (OT) and arginine vasopressin (AVP) are evolutionarily conserved molecular modulators of complex social behavior (Donaldson & Young, 2008). These nine–amino acid peptides have been implicated in the regulation of many different aspects of affiliative behavior including social recognition and social memory in rodents, communication, parental care, and social bonding (Insel & Young, 2001).

Variations in the OT and AVP systems have been linked with both interspecies and individual variation of sociality in animal models, which has inspired researchers to look for parallel relationships in human populations. Despite the complexity of human social behavior, OT and AVP have also been linked to trust, altruism, emotional expression and perception, and social bonding.

Due to their involvement in social behavior, it has been suggested that disregulation of these systems may contribute to the disruptions in the social domain in autism spectrum disorder (ASD) and other psychiatric disorders characterized by social impairment (Hammock & Young, 2006). Even if alterations in the OT and AVP systems are not involved in the etiology of ASD, pharmacological manipulation of these systems may be a viable strategy for enhancing social cognition and interpersonal relationships in this disorder (Bartz & Hollander, 2006). Social impairments are the most defining characteristic of ASD. In clinical populations, social impairments are seen as gaze aversion, limited affective expression, improper coordination of gestures with speech and impairment in interpreting these nonverbal cues in others (Bartz & Hollander, 2006). Animal models have shown that inhibition of the OT and AVP systems, either through genetic or pharmacological manipulation, results in impairments of social investigation, recognition, and motivation that are analogous to the deficits seen in individuals with autism. To understand the nature of the complex relationship between these neuropeptides and social behaviors, numerous studies have looked at their effect on three facets of affiliative behavior: social motivation, social information processing, and social attachment.

This chapter will examine the role that OT, AVP, and their related systems play in mediating the core components of social behavior. Their involvement in both normal social behavior and how their disregulation leads to disturbances in behavior will be discussed. Parallels will be drawn between the neurobiological findings in animal models and the genetic and

imaging studies done in both typical and clinical human populations. Finally, the direct evidence implicating a role for these neuropeptide systems in autism spectrum disorders will be presented with a discussion of how these findings may shape the development of novel pharmacological therapies for treating social impairment.

Oxytocin and Vasopressin: The Social Peptides

Oxytocin

OT is a nine–amino acid peptide (nonapeptide) that is synthesized in the magnocellular neurons of the paraventricular nucleus (PVN) and the supraoptic nucleus (SON) of the hypothalamus and transported to the posterior pituitary, where it is stored and secreted into systemic circulation (Gimpl & Fahrenholz, 2001). Peripherally, OT acts as a reproductive hormone to facilitate uterine contractions during parturition and milk letdown during lactation. OT is released during orgasm and ejaculation in humans (Carmichael et al., 1987). OT functions centrally as a neuromodulator, acting at discrete receptor sites throughout the brain on a relatively slow time scale, mediating sociosexual behaviors (Landgraf & Neumann, 2004). In the brain, oxytocin is released both axonally and dendritically from the hypothalamic oxytocinergic neurons targeting a number of distant regions, including the septal region, nucleus accumbens, hippocampus, amygdala, medio-basal hypothalamus, and even the brain stem and spinal cord in rodents (see Figure 34-1) (Ross & Young, 2009) While the innervation of oxytocin fibers is conserved among species, OT receptor (OTR) distribution is highly species-specific, with significant inter- and intraspecies variation that may contribute to the variation in social behavior (Ross et al., 2009).

Vasopressin

Arginine vasopressin (AVP) is an evolutionarily homologous molecule that differs from the structure of OT at only two amino acid positions (See Figure 34-2). Like OT, AVP is also a neurohypophyseal peptide that is synthesized in the magnocellular neurons of the PVN and SON and is released from the posterior pituitary into peripheral circulation. Vasopressin is also released within the brain from neuronal projections arising from the parvocellular neurons of the PVN, the superchiasmatic nucleus, the bed nucleus of the stria terminalis (BNST), and the medial amygdala (MeA; see Figure 34-1; De Vries & Miller, 1998). The vasopressinergic neurons in the BNST and MeA are regulated by androgens, making the AVP system one of the most sexually dimorphic neurotransmitter systems (De Vries & Miller, 1998). Within specific brain regions, like the BNST and MeA, males have significantly more AVP than do females (Van Leeuwn, Caffe, & De Vries, 1985). Peripherally,
Figure 34–1. Localization of the oxytocin and vasopressin systems. In the prairie vole (*Microtus orchogaster*), oxytocin and vasopressin are synthesized in the paraventricular (PVN) and supraoptic nuclei (SON) of the hypothalamus. These neurons project directly to the pituitary gland for storage and release into the blood stream. In addition, the hypothalamic neurons also project both axonally and dendritically to discrete regions throughout the brain for local release. Oxytocin projections from the PVN and SON target OT receptors in a number of brain regions including the nucleus accumbens (NAcc), hippocampus (Hipp), and amygdala (Amy). Vasopressin from the PVN, the superchiasmatic nucleus of the hypothalamus, Amy, and the bed nucleus of the stria terminalis (BST) is released throughout the brain, primarily targeting V1a and V1b receptors.

AVP plays an important role in maintaining fluid homeostasis and blood pressure. AVP acts at three different receptor subtypes: vasopressin receptor 1a (V1aR), vasopressin receptor 1b (V1bR), and vasopressin receptor 2 (V2R). While all three receptors types are expressed in varying densities in both the brain and the periphery, V1aR is the most widely distributed AVP receptor in the brain and is thought to be the most behaviorally relevant. The V1b receptor is expressed primarily in the pituitary and some restricted brain regions, and the V2 receptor is expressed primarily in the kidney, where it regulates water balance (Caldwell, Wersinger, & Young, 2008). The similarity in structure of the AVP and OT molecules enables each to bind and activate the other's receptor, creating a degree of redundancy in these systems, which complicates the interpretation of experiments using these peptides (Figure 34-2).

Evolutionary Conservation of Neuropeptide Structure and Social Function

The OT and AVP family of neuropeptides have been inextricably linked with social behaviors throughout evolutionary history. Homologues of these peptides have been identified in animals as diverse as hydra, worms, insects, fish, amphibians, birds, and mammals and have been shown to

OT: Cys-Tyr-**Ile**-Gln-Asn-Cys-Pro-**Leu**-Gly-NH$_2$
AVP: Cys-Tyr-**Phe**-Gln-Asn-Cys-Pro-**Arg**-Gly-NH$_2$
Figure 34–2. Oxytocin and Vasopressin. OT (oxytocin) and AVP (vasopressin) are closely related nine–amino acid peptides. OT has only one known receptor, while AVP binds to three known receptors: AVP-R1a, AVP-R1b, and AVP-R2. However, as the peptides differ at only two amino acids, there is some binding of each peptide at the other's receptor(s). Thus there is some degree of cross-reactivity of both endogenous peptides and in pharmacological studies.

regulate social and reproductive behaviors (Donaldson & Young, 2008). The genes encoding these two molecules are thought to be originally derived from a single common ancestral gene through a gene duplication event early in vertebrate evolution. Arginine vasotocin (AVT), an evolutionary antecedent of AVP, is present in all nonmammalian vertebrates examined to date, and may have been modulating social and reproductive behaviors as early as the Precambrian era, almost 600 million years ago (Acher, 1995). It is thought that the gene encoding AVT underwent duplication in the evolution of early fish approximately 450 million years ago, resulting in a second oxytocin-like peptide, isotocin, that is still present in bony fish. In male goldfish (*Carassius auratus*), both isotocin and vasotocin modulate social approach, and levels of these peptides have been associated with levels of sociality (Thompson & Walton, 2004). Isotocin was replaced by mesotocin during the water-to-land transition and is currently present in amphibians, reptiles, and birds. Mesotocin has been shown to regulate aggression differentially in songbirds, based on the social organization of the species (Goodson, 1998). OT is present in all utherian and protherian mammals and, despite the evolutionary divergence, still only differs from AVT by one amino acid. AVP also arose from a single peptide substitution in AVT in placental mammals. The conservation of the structure and function of these neuropeptides throughout evolution is quite remarkable, and the conservation of regulation of sociosexual behaviors in animals from goldfish to rodents suggests that OT and AVP may also play a role in regulating human social behavior.

Neuropeptides and Their Role in Mammalian Social Behavior

"Social behavior" is a complex term encompassing several different aspects of interaction between conspecifics. To better understand the complexities of social behavior, the social domain can be parsed into discrete, identifiable, and most importantly, analytical components. To be useful for scientific research, each of these components must consist of a specific behavioral phenotype that can be measured in a controlled laboratory setting, and must provide a reflection of the organism's total social repertoire. In both animals and humans, social motivation, social information processing, and social attachment have been indentified as subdomains contributing to the complexity of social behavior (Figure 34-3). The study of each of these components independently simplifies the examination of the biological underpinning of complex social behavior. Here we will examine each of these subdomains separately.

Social Motivation

The motivation to interact with conspecifics is the first step needed to engage in a successful social relationship. Inherent in every social encounter is the possibility of a negative outcome, such as indifference or aggression. Thus, there are strong pressures limiting engagement in social interactions. Social motivation is a measure of desire to overcome these
Figure 34–3. A conceptual model of complex social behavior. "Social behavior" is a broad term that encompasses any interaction between two conspecifics. To be able to study the biological mechanisms governing this behavior, it must be broken down into discrete subgroups of behavior that can be measured in a laboratory. Affiliative social behavior is comprised of three subdomains: social motivation, social information processing, and social attachment. Each of these domains contributes to the complexity of social behavior through separate but converging systems. The study of each of these components independently allows for the design and implementation of experiments that can more directly address the mechanisms. Social motivation can be studied through experiments of maternal motivation, social information processing through social recognition paradigms, and social attachment through pair bonding or maternal bonding.

negative factors to actively engage in a social interaction. OT is thought to play a role in enhancing social motivation. One potential mechanism for this is related to its anxiolytic actions. OT has been shown to reduce the behavioral and neuroendocrine responses to social stress enabling an animal to approach and interact with conspecifics. Alternatively, OT may alter the valence of social interactions, making them more rewarding and ultimately promoting social interaction.

In Rodents

In animal models, social motivation can be assessed by measuring behaviors that promote social contact, the latency of the subject to approach another individual and the amount of time spent in social contact with the individual. Social motivation can be measured in adult conspecific, offspring-parent, and parent-offspring interactions. For example, rodent pups emit ultrasonic vocalizations when separated from their nest or mother to protest social isolation. The role of OT in social motivation was examined using this offspring-parent paradigm through the comparison of vocalizations produced by wild type mice and OT knockout (OTKO) mice after separation. OTKO mice emit significantly fewer distress vocalizations than their wild type litter mates (Winslow et al., 2000). In a similar reunion task, where pups are separated from their mothers by a divider with small holes that allow the pups cross though but

not the mothers, wild type mice quickly learn to cross through holes to reunite with their mothers while the OTKO mice do not. As both the mutant strain and the wild type strain are able to emit normal vocalizations and show similar locomotor activity, the data suggest that the knockout pups may not find social isolation as distressing or may lack the social motivation to engage in these behaviors.

Initiation of parental behavior, though, represents one of the most dramatic shifts in social motivation, as in many rodent species the female shifts from an aversion to an attraction to infants. Thus, maternal nurturing behavior may be a useful assay for understanding the neurobiology of social motivation. Maternal behavior, which for rodents includes nest building, licking and grooming of pups, and crouching over pups, is induced at the time of labor and parturition (see Figure 34-4). Virgin female rats find pups highly aversive and will avoid or attack them if encountered. Only after the birth of a female's first litter will she be motivated to interact with pups. Though after that moment, for the rest of her life, regardless of reproductive status, she will find all pups highly rewarding and can even be trained to lever press for access to the pups in the same way rats can be trained to work for drugs of abuse (Fleming & Anderson, 1987; Lee, Clancy, & Fleming, 1999). The switch from indifferent to nurturing behavior toward pups is thought to be mediated in part by OT. Lesions of the hypothalamic PVN prior to parturition, which effectively eliminates the brain oxytocin system, prevents the initiation of maternal behavior (Insel & Harbaugh, 1989). Correspondingly, infusion of OTR antagonists into the ventricles of psuedopregnant female rats, attenuates the expression of maternal behavior (Fahrbach, Morrell, & Pfaff, 1985). Specific infusions of the antagonist directly into the medial preoptic area (MPOA) and ventral tegmental area (VTA) also inhibit maternal behavior, indicating that OT in these regions is necessary for the normal expression of maternal behavior (Pedersen, Caldwell, Walkder, Ayers, & Mason, 1994). It was also shown that not only is OT necessary to promote maternal behavior in virgin rodents, but it is sufficient for inducing it. Ventricular injections of OT stimulates maternal behavior in females rats and mice independent of their sexual experience or hormonal state (McCarthy, 1990; Pedersen, Ascher, Monroe, & Prange, 1982).

The hormones of pregnancy are thought to prime the brain's ability to respond to the OT surge experienced at parturition, thus enabling OT to initiate the onset of maternal behavior. OTR expression is increased by changes in estrogen, such that during pregnancy when estrogen levels increase, OTR expression increases in the hypothalamus and preoptic area (Meddle, Bishop, Gkoumassi, Van Leeuwen, & Douglas, 2007). Individual variation in levels of OTR expression in brain regions such as the bed nucleus of the stria terminalis, the amygdala, and the MPOA have been correlated with variation in maternal care (Champagne, Diorio, Sharma, & Meaney, 2001; Francis, Champagne, & Meaney, 2000; Francis, Young, Meaney, & Insel, 2002).

While the switch to maternal care is based on the hormonal changes associated with pregnancy in mice and rats,

Figure 34–4. Maternal Behavior as a Model for Social Motivation. Maternal behavior for rodents, including rats, consists of nest-building (upper left panel), pup retrieval (upper right panel), crouched nursing (lower left panel), and licking and grooming (lower right panel). Female rats only express maternal behavior after giving birth to their first litter of pups; prior to this experience female rats are indifferent toward pups. This switch in behavior demonstrates the extremes of social motivation.

spontaneous parental behavior exists in other species like the prairie vole (*Microtus ochrogaster*). Prairie voles are highly social, monogamous rodents that display both biparental and alloparental behavior. Female prairie voles display spontaneous juvenile parental behavior in which nonreproductively active adolescent voles provide care for successive sibling litters (Solomon, 1991). This parental behavior recedes in approximately 50% of females once they reach sexual maturity. Spontaneous alloparental behavior is also thought to be OT dependent, as injections of OTR antagonist directly into the nucleus accumbens, an area of the brain that mediates reward and reinforcement, blocks the expression in adult nulliparious females (Olazabal & Young, 2006a). The expression of spontaneous alloparental behavior in both juvenile and adult prairie voles is positively correlated with the density of OTR binding in the nucleus accumbens (See Figure 34-5) (Olazabal & Young, 2006a, 2006b). Juvenile females with high levels of OTR binding show more time spent crouching over pups than those with low levels (Olazabal & Young, 2006b). Viral vector upregulation of OTR in the nucleus accumbens of adult female prairie voles, though, is not sufficient to increase the expression of spontaneous care, however it is sufficient to accelerate social bond formation (Ross et al., 2009). This suggests that the developmental influence of OTR in the nucleus accumbens,

as opposed to simply receptor number in adulthood, may regulate this behavior.

As a biparental species, male prairie voles are also highly motivated to care for pups, unlike mice, rats, and nonmonogamous meadow voles. In males, it is thought that parental behavior is mediated by the AVP system. Injection of a V1aR antagonist prevents the expression of paternal care. Infusions of AVP into the lateral septum of male prairie voles increases time spent crouching over and licking and grooming pups (Wang, Ferris, & De Vries, 1994). Similar to the relationship between OTR levels in females and maternal behavior patterns, expression patterns of the V1aR corresponds to paternal behavior, in the form of licking and grooming of pups (Hammock & Young, 2006).

In Humans

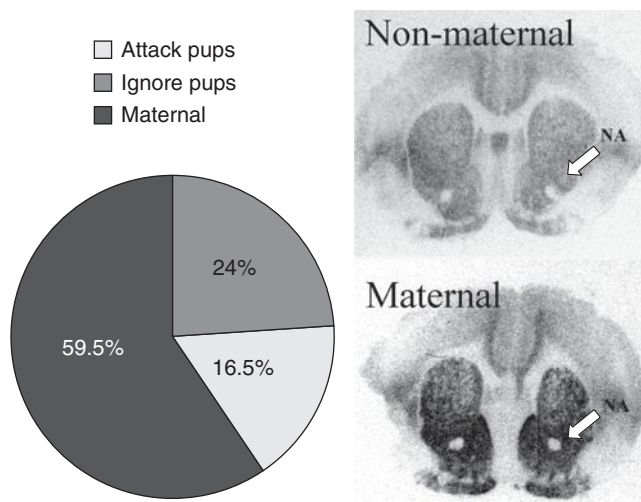
Reduced social motivation is one of the defining and most debilitating features of ASD. The expression of social withdrawal is a dimension of diagnostic instruments, like the Aberrant Behavior Checklist. This makes characterization of the neurobiological mechanisms underlying this behavior central to developing novel treatment strategies for autism. Normal social motivation in humans, like in rodents, has been


Figure 34–5. Variation in Maternal Behavior in Prairie Voles. Unlike mice or rats, about half of all virgin female prairie voles show spontaneous alloparental behavior. The expression of this behavior is positively correlated with the density of OTR in the nucleus accumbens (NA). Autoradiographic binding of brain sections shows high levels of receptors in maternal animals (lower panel). Adapted with permission from Olazabal, D. E., & Young, L. J. (2006a). Oxytocin receptors in the nucleus accumbens facilitate "spontaneous" maternal behavior in adult female prairie voles. *Neuroscience*, *141*(2), 559–568.

studied in mother-infant interactions. It has been suggested, though not directly shown, that OT influences some aspects of human maternal behavior. OT is released peripherally during the initiation of labor, the early postpartum period, and breastfeeding in human mothers (Carmichael et al., 1987; McNeilly, Robinson, Houston, & Howie, 1983; Nissen, Lilja, Widstrom, & Unvas-Moberg, 1995; Vasicka, Kumaresan, Han, & Kumaresan, 1978). About one third of women also see a spike in peripheral OT levels late in their third trimester of pregnancy, which interestingly has been correlated with higher ratings of maternal-infant bonding (Levine, Zagoory-Sharon, Feldman, & Weller, 2007). Maternal behavior in humans, though, is not entirely mediated by hormonal changes, as spontaneous parental behavior can be seen in families with adopted children. Despite this correlational evidence, precise role of OT in modulating maternal responsiveness in humans remains unknown.

Social Information Processing

After the initiation of interaction, social recognition and social memory are critical for stable functioning in social groups. Social memory, which enables an individual to distinguish between family, friends, and foes, and behave accordingly, is dependent on the processing of social information. The social impairments of autism are associated with deficits in face identity recognition and facial expression perception (Schultz, 2005). The ability to recognize individuals in animal models, referred to as social recognition, has been used to examine the neural mechanisms underlying social memory and social information processing.

In Rodents

Humans and other nonhuman primates primarily depend on visual and auditory cues to recognize conspecifics. Rodents, however, while employing similar mechanisms for discrimination, use an alternative modality; relying on olfactory and pheromonal cues to detect and recognize familiar individuals. Research into this field has shown that both OT and AVP are involved in the encoding and recall of olfactory-cued social memories. Social recognition can be modeled experimentally in rodents by utilizing their natural interest in novelty. Rats and mice will generally spend more time investigating a novel object or animal than a familiar one. To experimentally assay social recognition, an animal is allowed to investigate a conspecific for a period of time, thus becoming familiar with the animal. The animal is then reexposed to either the same familiar animal or a novel animal, and the amount of time the test animal spends sniffing the stimulus animal is measured (Ferguson, Young, Hearn, Insel, & Winslow, 2000). Typically, over multiple exposures to the same animal the amount of investigatory time will decrease and this is interpreted as recognition of the stimulus animal. If a novel animal is then introduced, the test animal should return to their original levels of investigation. Manipulations that disrupt social recognition will be reflected in a constant investigation time over multiple trials. OT enhances social recognition. OT infused into the olfactory bulbs (OB), lateral septum (LS) and medial preoptic area (MPOA) of male rats prolongs the duration of the social recognition response (Dluzen, Muraoka, Engelmann, & Landgraf, 1998). The generation of oxytocin knockout (OTKO) mice has provided an eloquent model for assessing the role of OT in social memory. Male OTKO mice are unable to recognize familiar conspecifics following a prolonged encounter (Ferguson et al., 2000). In OTKO mice, a novel female stimulus mouse elicits the same amount of olfactory investigatory behavior, as does a familiar mouse after multiple exposures, whereas control mice show a decrease in olfactory investigation of familiar individuals (See Figure 34-6). This deficit does not represent an impairment in either nonsocial sensory or memory processes, as the OTKO mice are able to discriminate between nonsocial scents. This suggests that the impairments of OTKO mice are specific to the recognition of socially important cues (Ferguson et al., 2000). Anatomical studies of c-Fos expression, a marker of neuronal activity, show that OTKO mice have decreased activation in the medial amygdala following a social encounter (see Figure 34-7). Furthermore, OT injection into the medial amygdala (MeA), but not into the olfactory bulb of OTKO mice restores social recognition. Complementarily, application of an OTR antagonist only to the MeA inhibits social recognition in wild type mice (Ferguson, Aldagm, Insel, & Young, 2001). The rescue effect of OT in OTKO mice is only effective if it is injected

prior to initial encounter. This suggests OT may function in the processing of social information or memory acquisition rather than in social memory recall.

The AVP system has also been shown to play a significant role in mediating social recognition. Intracerebroventricular injection of AVP prolongs social recognition by activating the V1aR in the LS and in the OB. Site-specific injection of AVP into the LS enhances social recognition, while V1aR antagonist administration inhibits social recognition (Dantzer, Koob, Bluthe, & Moal, 1988). Downregulation of the V1aR through the use of antisense oligonucleotides reduces social recognition in normal rats (Landgraf et al., 1995). Conversely, upregulation of the V1aR using viral vector gene transfer enhances the duration of the animals' social recognition memory. Recently, the V1b receptors have also been implicated in mediating social recognition. Both V1aR and V1bR knockout mice show impairments in social memory. Characterization of the deficits in social recognition of V1bRKO mice, though, suggests they are more mild than in the V1aRKO and may be primarily due to deficits of social motivation. The mice can differentiate between male and female urine, but do not spend more time investigating the scent of the opposite sexed animal, thus behaving in a highly
Figure 34–6. Social Amnesia in OTKO Mice. In Wild-Type Mice, Repeated Exposure to the Same Stimulus Animal Results in Decreased Duration of Olfactory Investigation. When Presented with a Novel Stimulus Animal, the Amount of Olfactory Investigation Returns to the Same Levels as Seen During the First Trial of Investigation of the Original Animal. In the OTKO Mice there is No Decrease in Investigation of the Stimulus Animal Over Multiple Trials. In Olfactory Investigation of a Nonsocial, Citrus Scent, though, both the Wild-Type and the OTKO Mice Both Show Decreased Investigation of the Odor, Indicating that the Deficits of the OTKO Mice are Specific to the Processing of Social Stimuli. species atypical fashion. Thus, they can discriminate the odors but are not motivated to further investigate scents of sociosexual importance (Caldwell et al., 2008).

In Humans

The significant body of evidence linking OT with social recognition in rodents has spurred a number of studies looking at the effects of OT on face-processing in humans. A number of caveats exist in translating research on social behavior in rodents to humans, primarily related to how social information is differentially processed between the species. Social cognition in humans involves far more cortical processes than in rodents. Human social behavior is based on an integration of the visual and auditory systems with executive cortical regions, while in rodents the sensory systems are primarily connected to the limbic system. It is possible that the neuropeptides play a strong modulatory role in mediating olfactory or limbic responses and consequently may have less of an effect on human social behavior (Hammock & Young, 2006). However, it is likely that OT and AVP modulate the circuitry involved in processing of visual and auditory social information in humans analogously to its role in rodents (Domes, Heinrichs, Michel, Berger, & Herpertz, 2007; Guastella, Mitchell, & Dadds, 2008; Meyer-Lindenberg, 2008).

Research into the function of OT and AVP in the brains of humans is in its infancy and is limited in the types of experiments that can be undertaken. As a result, scientists are just coming to understand the role of neuropeptides in human social cognition. Currently, the most effective technique for studying the direct functional effects of the neuropeptides in the brain is through intranasal administration of the peptides. OT and AVP have low penetrance across the blood-brain barrier and consequently have limited efficacy when administered peripherally. However, it is thought that intranasally administered peptides are transported directly across the nasal mucosa to the cerebrospinal fluid, into the brain parenchyma thus allowing them to have central effects (Bartz & Hollander, 2008). To date, only one study has physiologically demonstrated the efficacy of this route of administration. In humans, AVP was shown to increase in CSF within 10 minutes after intranasal administration and remain elevated for at least 80 minutes (Born et al., 2002). Thus far, the equivalent study has not been done for OT.

Several recent studies have linked the functional effects of the neuropeptides with cognitive processes associated with social recognition and social information processing. Intranasal OT has been shown to enhance face recognition and interpretation of facial expression (Domes et al., 2007; Rimmele, Hediger, Heinrichs, & Klaver, 2009). OT administration preferentially enhanced memory of faces over memory of nonsocial stimuli (Rimmele et al., 2009). OT may also play a role in social memory consolidation as it has been shown to enhance memory for previously seen faces when administered after viewing the faces (Savaskan, Ernhardt, Schulz, Walter, & Schachinger, 2008). OT has even been shown to enhance emotional perception as seen in a test of "mind reading," a paradigm that requires individuals to infer the emotion of stimulus faces, by viewing images of only the eye regions (Domes et al., 2007). These findings are likely due to OT's ability to enhance facial and emotional recognition by increasing the amount of time an individual spends looking at the eye region of a conspecific (Guastella, Mitchell, & Mathews, 2008). OT also regulates social stimuli perception by modulating amygdala function in humans. Functional imaging studies have shown that strong amygdala activation is induced by fear-inducing visual stimuli. Administration of intranasal OT potently reduces the activation of the amygdala in response to these stimuli (Kirsch et al., 2005). Interestingly, fMRI studies have shown that application of intranasal OT specifically decreases the activation of the right amygdala typically associated with emotional facial recognition (Domes et al., 2007).

Individuals with ASD appear to have deficits in social recognition that are reminiscent of those seen in OTKO mice. Individuals with autism can identify faces in relation to basic objects; however, they do show impairments when asked to match unfamiliar faces on tests like the Benton Face Recognition Test (Barton, 2003; Davies, Bishop, Manstead, & Tantam, 1994). They also show deficits in perceiving facial expression, age, and sex (Hobson, 1987; Tantam, Monaghan, Nicholson, & Stirling, 1989). Patients with Turner's syndrome, which has a high comorbidity with autism, also show deficits in recognizing faces and facial expressions (Lawrence et al., 2003). This deficit may, in part, be attributed to decreased activation in the amygdala and the fusiform face area, the areas typically involved in face recognition, and increased activation of cortical regions when viewing images of human faces compared to normal subjects (Critchley et al., 2000; Pierce, Müller, Ambrose, Allen, & Courchesne, 2001; Schultz et al., 2000). Individuals with autism also fail to show amygdala activation typically seen in control subjects, when asked to interpret the expressions of face stimuli while viewing human eye regions (Baron-Cohen et al., 1999). Interestingly, OTKO mice show a similar pattern of decreased amygdala activation and increased cortical recruitment in social recognition tasks (Ferguson et al., 2001).

Currently only a limited number of studies have looked at the effects of AVP on human social information processing. Intranasal AVP modulates the perception of facial expression in a sexually dimorphic fashion. In animals, AVP modulates social communication, particularly the production of social signals involved in courtship and aggression. In human males, intranasal AVP modulates facial expressions in response to social stimuli. AVP administration in men decreases the perception of friendliness in unfamiliar male faces and stimulates the production of antagonistic facial expressions. However in females, the opposite effect is observed; AVP increases the perception of friendliness in female faces and stimulates affiliative facial motor patterns in response to those faces (Thompson, George, Walton, Orr, & Benson, 2006). It is possible that this dimorphic effect is due to the opposing strategies adopted by men and women to handle stressful social situations.

Social Attachment

Social bonding is a complex social behavior that requires social motivation and social information processing to develop an enduring attachment. A social bond is apparent when individuals demonstrate a preference for interaction with a specific conspecific. Impairments in social motivation and social information processing in individuals with autism likely contribute to difficulty in forming normal social relationships. The study of social attachment in animal models allows for the investigation of the neurobiological mechanisms underlying the attachment process and may be relevant to many types of social relationships. Two animal models have contributed significantly to our understanding of the neurobiological mechanisms underlying attachment, pair bonding in the prairie vole and maternal-infant bonding in sheep. Each of these models is discussed in detail below.

In Voles

The genus *Microtus* (voles) is an ideal model for the comparative study of social attachment as it contains both monogamous (prairie and pine voles) and polygamous (meadow and montane

voles) species. Prairie and pine voles are highly social, monogamous animals that form long-lasting social bonds with a specific partner. In contrast, meadow and montane voles are asocial and polygamous, with males and females coming together only to mate. One difference between these species that contributes to their highly divergent social systems is the organization of their OT and AVP systems.

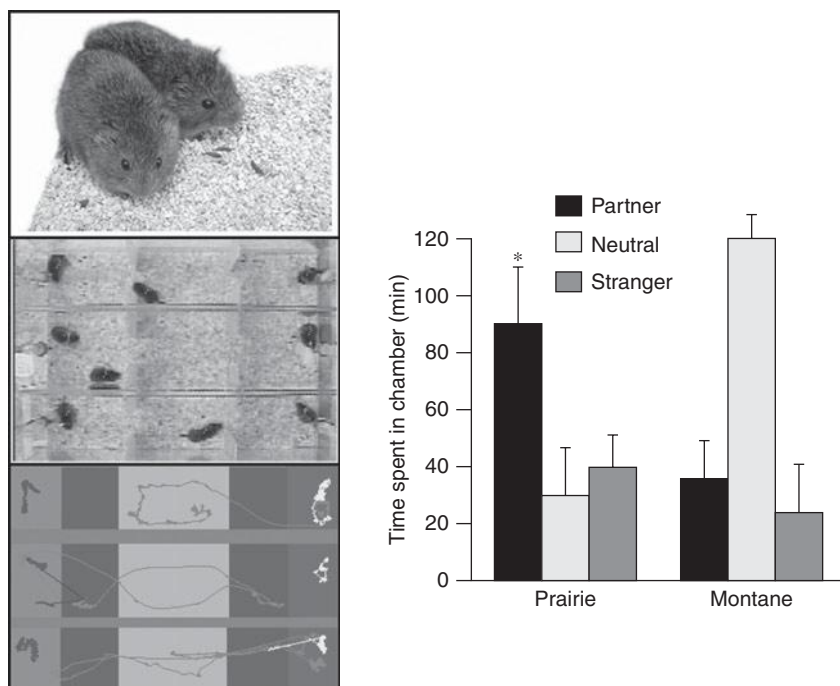
Because of the important role that OT plays in mother-infant relationships, the peptide was hypothesized to mediate pair bonding in prairie voles. OT infusions into the brains of female prairie voles induce pair bonds as measured by the development of a partner preference (See Figure 34-8) under conditions nonconducive to bond formation (Williams, Harbough, & Carter, 1994). Complementarily, application of an OTR antagonist intracerebroventricularly prevents the formation of social bonds even after long cohabitation periods with mating (Williams et al., 1994). Central OT receptor manipulation was able to directionally modulate social bond formation without having any impact on sexual behavior. These data suggest that the species differences in the ability to form a social bond between mates may be attributed to differences in the OT system. The distribution of OT fibers throughout the brain is well conserved throughout mammalian


Figure 34–8. Partner Preference Test. Social attachment in prairie voles is measured using the partner preference test. In this behavioral test a male is paired with an unfamiliar female vole and allowed to cohabitate for a period of time (Upper Panel). The pair is then separated, and the partner female is tethered in the partner preference apparatus along with a stranger female. The male is then placed in the apparatus and allowed to wander freely for 3 hours (Middle Panel). The amount of time the male spends with either the partner female or the stranger female is recorded and analyzed using behavior analysis software (Lower Panel). If the male is shown to have spent twice as much time with the partner female than with the stranger female, he is said to have formed a partner preference. Partner preference is a marker of social attachment. Prairie voles easily form a partner preference after about 24 hours of cohabitation. Montane voles, however, fail to show a preference for their partner after as much as 2 weeks of cohabitation. (See Color Plate Section for a color version of this figure.)

species and both prairie and meadow voles have similar patterns of OT in the brain. There is, however, striking variation in the distribution of the OTR between the prairie and the meadow vole. Prairie voles have a significantly higher density of OTR in the caudate putamen and the nucleus accumbens than do the polygamous species. Application of OTR antagonists directly to the nucleus accumbens inhibits mating induced partner preference, implicating the accumbens particularly as a site necessary for pair bonding (Young, Lim, Gingrich, & Insel, 2001).

In males, OT plays a lesser role in pair bond formation (Liu, Curtis, & Wang, 2001). Instead AVP has primarily been implicated in mediating pair bonding. AVP's effect on male pair bonding parallels the role of OT in females, in that centrally infused AVP facilitates partner preference (without mating) while a V1aR antagonist inhibits mating-induced partner preference (Winslow, Hastings, Carter, Harbaugh, & Insel, 1993). Like OT, vasopressin innervation is consistent across mammalian species with dramatic differences in receptor densities apparently mediating inter and intraspecies variation (Wang, Zhou, Hulihan, & Insel, 1996). Considerable variation in the distribution of V1aR in the brain is seen between prairie and meadow voles, with higher densities of the receptor in the ventral pallidum in the monogamous voles. The ventral pallidum is a major efferent of the nucleus accumbens, and like the accumbens, mediates reward and reinforcement. Interestingly, the difference in receptor distribution between monogamous and polygamous species of

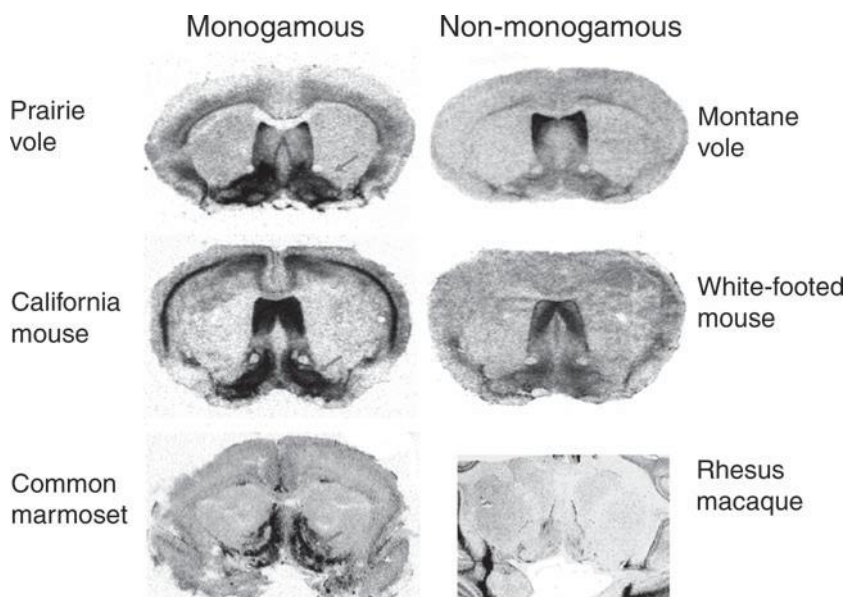
voles is mirrored in other closely related species that have similar social organizations of other species of rodents and even in some nonhuman primates. For example, the monogamous marmoset has higher densities of V1aR in the ventral forebrain reward areas than do nonmonogamous rhesus macaques (see Figure 34-9) (Young, 1999). Despite the variation in receptor densities between the two microtine species, there are no species differences in the functional mechanics of the V1aR between the montane and prairie voles, and the protein coding region of the V1aR gene (*avpr1a*) is 99% genetically identical (Insel, Wang, & Ferris, 1994; Young, Nilsen, Waymire, MacGregor, & Insel, 1999). This implicated the promoter region of the gene encoding the V1aR (*avpr1a*) in the differential expression of the receptor and the subsequent differences in both paternal care and social bonding. Transgenic mice containing the regulatory region of prairie vole *avpr1* gene show a receptor expression profile very similar to that of prairie voles (Young et al., 1999). Furthermore, if these mice are given an injection of AVP they showed an increase in affiliative behavior. This led to comparison of the regulatory regions between prairie voles and montane voles. The prairie vole promoter region at the *avpr1a* locus contains a microsatellite element that consists of a repetitive sequence upstream of the transcription start site that is largely absent from the meadow vole. The differences in the microsatellite region, therefore, may in part regulate the species differences in receptor expression. Within prairie voles there is also great degree of variation in the density of V1aR expression in specific


Figure 34–9. Distribution of V1aR in Monogamous and Nonmonogamous Species. The pattern of higher V1aR expression in the ventral pallidum of the prairie vole than in the montane vole is mirrored in several other species, including the monogamous California mouse and the closely related promiscuous white-footed mouse. This pattern is even seen in some primate species, with the monogamous marmoset showing higher levels of V1aR in the ventral forebrain than the nonmonogamous rhesus macaque. Reprinted with permission from Young, L. J. (1999). Frank A. Beach Award. Oxytocin and vasopressin receptors and species typical social behaviors. *Hormones and Behavior, 36*(3), 212–221.

brains regions, including the olfactory bulb, extended amygdala, thalamus, cingulate cortex, and the ventral pallidum. Furthermore, there is significant variation in the length of the repetitive microsatellite among individual prairie voles. To determine whether variation in the length of the microsatellite contributed to variation in V1aR expression and social behavior, two lines of prairie voles were generated, one with a long microsatellite repeat and one with the short repeat (Hammock & Young, 2005). The resulting animals had robust differences in V1aR expression in the brain, with the long-alleled animals showing greater expression in olfactory bulb and the lateral septum but with lower levels in the amygdala and the hippocampus than the short-alleled animals. Long-alleled male prairie voles also displayed a shorter latency to approach and investigate a novel juvenile male and developed partner preferences more quickly than short-alleled animals (Hammock & Young, 2005). These data suggest that the microsatellite polymorphism in the 5' regulatory region of the *avpr1a* gene alters the expression of the receptor throughout the brain and that the distribution of the receptor influences social behavior. The relationship between receptor density in specific brain regions and prosocial behavior was further tested by overexpressing the V1aR in the ventral pallidum of nonmonogamous meadow voles. Upregulation of the V1aR in the ventral pallidum enhances partner preference in prairie voles and can even induce partner preferences in nonmonogamous meadow voles (see Figure 34-10; Lim et al., 2004). Thus demonstrating that simply by increasing the density of receptors in a single brain region, social behavior can be radically changed.

In Sheep

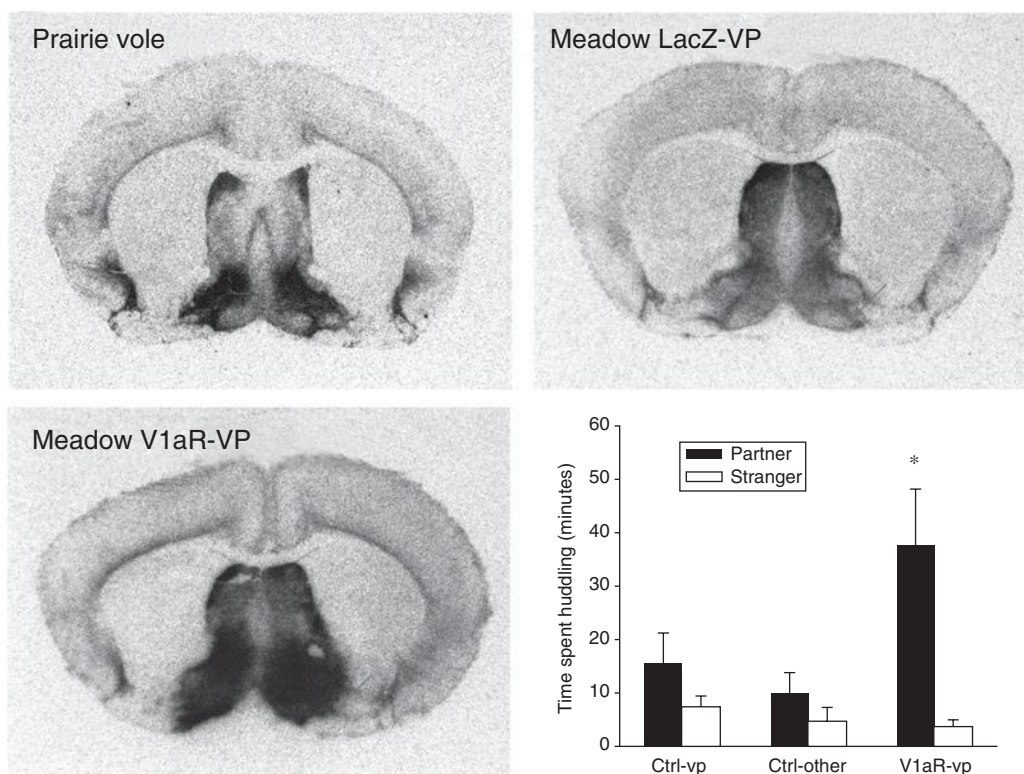
Maternal-infant bonding in sheep has been used as a model to identify the mechanisms involved in social attachment as well. Unlike rodents, which are typically promiscuously maternal, ewes form a strong selective bond for their own lamb. Sheep live in large social groups and are constantly moving while they graze. They are synchronous breeders, which means many young are born in the herd at the same time, and they birth precocial young who are able to stand and run shortly after birth. These features require that ewes form a strong


Figure 34–10. V1aR Gene Transfer in Meadow Voles. The monogamous male prairie vole shows high expression of the V1aR in the ventral pallidum (Upper Left Panel), which corresponds to high levels of partner preference. To induce the ability to form social attachments in the polygamous male meadow vole the V1aR was upregulated by the injection of a viral vector containing the *avpr1a* gene. When injected into a specific brain region the viral vector induces the production of its gene product, in this case causing the increased expression of the V1aR (Lower Left Panel). Upregulation of the V1aR but not a control molecule, LacZ (Upper Right Panel), induced partner preference in the male meadow vole (Lower Right Panel). Reprinted with permission from Lim, M. M., Wang, Z., Olazabal, D. E., Ren, X., Terwilliger, E. F., & Young, L. J. (2004). Enhanced partner preference in a promiscuous species by manipulating the expression of a single gene. *Nature, 429*(6993), 754–757.

selective bond shortly after birth to prevent the lamb from being lost (see Figure 34-11; Kendrick et al., 1997). Bond formation, like maternal behavior, in ewes is induced by the hormonal changes associated with pregnancy and the physiological feedback associated with labor and delivery. Ewes become maternal immediately after birth, and within a couple of hours postpartum they become selectively maternal toward one lamb and will allow only their own lamb to nurse. Vagino-cervical stimulation (VCS) can induce a ewe to accept an unfamiliar lamb even after she has bonded with her own lamb. Epidural anesthesia prevents VCS from inducing maternal bonding (Levy, Kendrick, Keverne, Piketty, & Poindron, 1992). OT infusion alone induces acceptance of an unfamiliar lamb even in a nonpregnant ewe (Kendrick, Keverne, & Baldwin, 1987). It is thought that in sheep VCS, which occurs naturally during parturition, sends sensory signals through the spinal cord to the PVN, which then releases large amounts of OT into the circulation and throughout the brain. OT release in limbic structures facilitates the onset of maternal nurturing behavior, while OT infusion in the olfactory bulb induces a reorganization resulting in selective responsiveness to their own lamb's odor. The specific odor of the lamb is encoded through plastic changes in the olfactory bulb that are permitted by OT and mediated by the neurotransmitters

GABA and glutamate (Kendrick et al., 1997). In humans, selective kin recognition is primarily mediated by visual input, but remarkably it has also been reported that women are able to recognize the smell of their infant within hours of giving birth, suggesting a potentially conserved mechanism (Porter, Cernock, & McLaughlin, 1983).

In Humans

Preliminary research in humans is consistent with the animal studies mentioned above and suggests that the OT and AVP systems may also be involved in human social attachments. Functional magnetic resonance imaging has shown there is a high degree of overlap between the distribution of OT receptors in the human brain and the regions of brain activation when viewing images of romantic partners or mothers viewing images of their infants (Bartels & Zeki, 2004). Plasma levels of OT have also been shown to increase in both males and females during sexual activity and intercourse (Blaicher et al., 1999; Carmichael et al., 1987; Uvnas-Moberg, 1998). As the most intense form of social contact, sexual intercourse is also likely to be the stimulus for OT release in the brain (Neumann, 2008). Women with high levels of OT report the occurrence of nonsexual tactile interaction between partners, like massage or hugging, at greater frequency than those with lower levels (Light, Grewen, & Amico, 2005). Perceived partner support has also been associated with higher levels of OT in both men and women (Grewen, Girdler, Amico, & Light, 2005). Conversely, negative social experiences, like early life abuse or neglect, result in decreased levels of OT in the CSF. OT levels are negatively correlated with the number and duration of abuses (Heim et al., 2008).

The opposite relationship was seen though, in associations between reports on relationship quality and levels of OT. Basal plasma levels of OT were negatively correlated with living situations, marriage quality, physical affection, and communication (Taylor et al., 2006; Turner, Altemus, Enos, Cooper, & McGuinness, 1999). However, it should be noted that plasma levels of neuropeptide should be interpreted with caution since peptides are released into the periphery and into the brain independently, and circulating peptides do not cross the blood-brain barrier.

A recent study demonstrated an association between a microsatellite element in the 5' flanking region of the human *avpr1a* gene, similar to the microsatellite seen in prairie voles, and several traits indicative of pair bonding behavior in men. One particular allele was associated with marital status, perceived marital problems, and even marital quality as perceived by their spouses. As would be predicted by the animal research, no association was found between women and this locus (Walum et al., 2008). This study provides remarkable evidence of a conserved mechanism regulating social cognition in rodents and man.

In humans, both neuropeptides may also promote interpersonal relationships by increasing perceptions of trust and altruism. The aforementioned microsatellite polymorphism of

Figure 34–11. Maternal Infant Bonding in Sheep. Maternal bonding in sheep is a model of social attachment. Ewes form a strong selective bond specific for their own lamb soon after parturition. It is particularly important that the ewe learn to recognize their lamb, as sheep are synchronous breeders that give birth to precocial young, which prevents kin identification by proximity. The formation of this selective bond is dependent on OT. Photo courtesy of Keith Kendricks.

the human *avpr1a* gene has also been linked to prosocial behavior. Individuals with the short allele (308–325bp) are less generous in the Dictator game, an economic game of altruistic decision making, than those with the long allele (Knafo et al., 2008). In a similar game, intranasal OT was found to promote trust behavior, in that subjects that had received the peptide shared more money with their social partner than those that had not, even after being cheated by their social partner (Kosfeld, Heinrichs, Zak, Fischbacher, & Fehr, 2005).

Evidence for Disregulation of Neuropeptides Systems in Autism Spectrum Disorders

Genetic Evidence

It is clear that OT and AVP play a central role in the regulation of complex social behaviors. This, coupled with the high heritability of autism, has led many researchers to look at the possible link between mutations of the neuropeptides systems and ASD. To date several genetic association studies have implicated the OTR and V1aR in the etiology of autism. The human OTR is encoded by a 19 kbp gene located on chromosome 3p25 containing three introns and four exons (Inoue et al., 1994). Two genomewide scans have highlighted the 3p25 region as a linkage site for ASD (Lauritsen et al., 2006; McCauley et al., 2005). Four studies to date have found a positive association of the OTR gene with autism in three distinct populations. A study of the Chinese Han trios demonstrated an association between ASD and two single nucleotide polymorphisms (rs2254298 and rs53576) and several haplotypes involving one of the sites (Wu et al., 2005). A second study by Jacob et al. (2007) looked at whether these associations replicated in a Caucasian population and verified the association at the rs2254298 site. The two studies found overtransmission of opposing alleles in the affected population, the G allele in the Caucasian population and the A allele in the Chinese population. A third comprehensive association study was undertaken by Israel et al. (2008) of an Israeli population looking at all of the known labeled SNPs across the OTR gene region and found a strong association between a five locus haplotype block including the site found in both previous studies and ASD. This group also showed an association with IQ and daily living skills with SNPs in the OTR gene, suggesting this gene may play a role in other disorders and nonclinical populations (Israel et al., 2008). These findings reinforced the work done by Lerer et al. (2008), which showed similar association of ASD with specific loci in the OXTR gene in the Israeli population, as well as associations with IQ and the Vineland Adaptive Behavior Scales, a clinical measure of personal and social skills. The association of the OXTR gene with ASD found in the aforementioned targeted studies was also seen by Yrigollen et al. in a study of genes associated with affiliative behavior as candidate genes for autism (Yrigollen et al., 2008).

Single-subject cases have also implicated the OTR gene in the etiology of autism. A unique case study of a 9-year-old boy with pervasive developmental disorder was found to have a duplication of the chromosome region containing the OTR gene resulting in a 2- to 3-fold increase of OTR expression compared to control subjects (Bittel, Kibiryeva, Dasouki, Knoll, & Butler, 2006). The oxytocin gene has also been implicated in autism in a case study in which a child with Asperger's syndrome was found to have a 1.1Mb deletion of 20p13 a region with involves ~27 genes including the OT peptide gene (Bittel et al., 2006; Sebat et al., 2007).

Associations have also been made between the *avpr1a* gene and autism. In humans, the *avpr1a* gene located on chromosome 12q14-15, contains three microsatellite regions in the 5' flanking and one in the single intron, analogous to but different from the vole polymorphisms. Two microsatellites, RS1 and RS3, have been the focus of much investigation due to their highly polymorphic number of repeats. Three independent groups have found a possible link between polymorphisms in the *avpr1a* gene and autism. Studies have shown linkage disequilibrium between autism and the RS3 microsatellite in the *avpr1a* gene (Kim, 2001; Wassink et al., 2004; Yirmiya et al., 2006). The microsatellites in humans, as in voles, have been shown to have functional consequences. The number of microsatellite repeats in both the RS1 and RS3 sites is shown to have an effect on amygdala activity in response to fear stimuli. The long allele of the RS3 site is associated with extremely high levels of amygdala activation in response to the stimuli (Meyer-Lindenberg et al., 2008), which is particularly interesting as autistic individuals have been shown to have abnormal amygdala activation in fMRI studies (Dalton et al., 2005). The long RS3 allele has also been associated with higher levels of the *avpr1a* mRNA in human postmortem hippocampal tissue than the short RS3 allele, similar to what is seen in the vole literature (Knafo et al., 2008). Despite these numerous studies, there is no evidence that genetic variation in the OTR or V1aR genes are a major contributor to ASD. Rather, they suggest that variation in these genes may be one of many contributing factors in some small fraction of ASD cases.

Peripheral Evidence

Children with autism have been observed to have lower levels of peripheral OT in plasma than age-matched controls. Within the control group, levels of OT were found to be positively correlated with measures of social behavior including socialization, social coping, and interpersonal relationships. Unexpectedly, in the autistic group the lower baseline levels of OT were negatively correlated with these same measures of social behavior (Modahl et al., 1998). This difference could be the result of differential processing of OT in the brains of children with autism, as plasma samples of autistic children were also found to have higher levels of OT precursors as well as a higher ratio of OT precursor to OT (Green et al., 2001). These findings were replicated in a second independent study that also found autistic children to have lower peripheral levels of

vasopressin (Al-Ayadhi, 2005). In adults the findings appear to be reversed, as individuals with ASD have higher plasma levels of OT compared to controls (Jansen et al., 2006). There is no apparent reason to account for the discrepancy in findings between the groups, suggesting there may be a developmental compensatory mechanism. However, it is important to note that peripheral levels of oxytocin and vasopressin do not necessarily reflect central levels (Bartz & Hollander, 2006).

Implications for Developing Pharmacological Therapies

Given the role of OT and AVP in modulating social motivation, social information processing, and social attachment, these systems may be viable targets for treating the social deficits associated with ASD. Indeed, some very preliminary studies have suggested that OT infusion may have positive effects in ASD patients, but more work is needed to draw any conclusions. Hollander et al. (2003) investigated the role of intravenous OT administration on the inhibition of repetitive behavior, one of the other core symptoms of ASD. A continuous 4-hour treatment with the Pitocin, a synthetic oxytocin, was found to significantly decrease repetitive behaviors over time as compared to placebo. A similar procedure was then used to look at the effect of OT on social cognition as assayed by a test of affective speech comprehension. Subjects who received the peptide prior to the first trial were shown to have enhanced retention of speech comprehension 2 weeks later compared to those who received it prior to the second trial. The study did, however, fail to observe a direct effect of OT on performance. Collectively these studies suggest that OT may have a therapeutic value for treating two of the three primary deficits of autism. One point of concern, though, is the issue of peripheral administration and brain penetration. Endogenous plasma OT is unable to efficiently cross the blood brain barrier (Landgraf & Neumann, 2004), which calls into question how intravenously administered OT can have a direct effect on behavior. It is hypothesized that high levels of exogenous administration allows for low levels of OT to be transported across the blood-brain barrier. As an alternative, intranasal OT has been proposed as a route of administration, as it has been used in many of the human behavioral studies. However, due to the relative inefficiency in the transmission of peripherally administered OT and the unknown efficacy of intranasally delivered OT, the development of small molecule OTR agonists that more easily cross the blood brain barrier is needed to explore the viability of peripherally administered OT drugs for the treatment of social deficits in autism.

Conclusion

OT and AVP are important regulators of complex social behaviors. These neuropeptides modulate three major components of social interaction: social motivation, social information processing, and social attachment. Individuals with ASD show impairments in each of these three subdomains, with reduced social interest, reduced perception of nonverbal social cues and reduced ability to form reciprocal social relationships. Social motivation to care for infants in many species is dependent on central release of OT. The proper processing of social information necessary for social recognition requires OT and AVP neurotransmission. Social attachment in monogamous species and the mother-infant bond are modulated by these neuropeptides. Even in humans it appears that OT systems may play some role in complex social behaviors such as attachment and interpersonal trust. Regardless of whether disregulation of these neuropeptide systems contributes to the etiology of social deficits in ASD, the OT and AVP systems may prove to be viable targets for novel pharmacotherapies to enhance social cognition in psychiatric disorders characterized by social deficits.

Challenges and Future Directions

- Animal models have already provided a great deal of insights into the role of OT and AVP in the regulation of social behavior and social cognition. A major challenge is to develop behavioral paradigms in animal models with face, construct, and predictive validity relevant to ASD to facilitate further studies on the potential of drugs that modulate the OT and AVP systems as therapies to treat the social cognitive deficits in ASD.
- Several studies have reported genetic associations between ASD phenotypes and polymorphisms in the OT and AVP systems. However, it will be important to explore in more detail the impact of early social experience on OT and AVP systems. For example, can social enrichment enhance these peptide systems?
- Animal studies have revealed relationships between OTR and V1aR densities in particular brain regions and social behavior. However, the examination of these receptor systems has been difficult in human tissue. It will be important to develop technologies, such as positron emission tomography (PET), that will allow visualization of these peptide receptors in living individuals to determine whether alterations in receptor systems in the brain are associated with social deficits in ASD.
- ASD is a multigenic disorder, and disruptions in OT and AVP related genes are clearly not a major risk factor for the disorder. However, it will be important to consider whether diverse etiologies may have a common impact on social cognition through disregulation of some aspect of the OT and AVP system. Regardless as to whether disregulation of OT and AVP are involved in the social deficits in ASD, these systems should be considered when developing pharmacotherapies to enhance social function in ASD.

From Toddlers to Adults: The Changing Landscape of the Brain in Autism

Points of Interest

- Autism is due to abnormal brain development beginning early in life. The signature(s) of this early neural maldevelopment is far more likely to be detectable at the developmental time when behavioral symptoms first appear.
- Autism involves early brain overgrowth prior to 3 years of age followed by arrested growth and degeneration. This atypical neural development is pronounced in key structures such as the frontal lobe, temporal lobe, and amygdala; hypoplasia of subregions of cerebellar vermis also occurs during this early period of life in individuals with autism.
- Abnormal neural connectivity is hypothesized to be a downstream consequence of an earlier neural defect.

The behavioral signs and symptoms of autistic disorder and pervasive developmental disorder begin during later infancy and the toddler period in the majority of cases. Before 6–12 months of age, such signs are typically absent or, at most, very subtle, according to recent prospective studies (Wetherby, et al., 2004; Zwaigenbaum, et al., 2005; Ozonoff, Heung, et al., 2008; Pierce, Glatt, et al., 2009). The first red flags in older infants and toddlers include deficits in the development of higher-order social, language, communication, and emotion functions. Ritualistic and/or repetitive behaviors and cognitive deficits are not as consistently present but do occur in some individuals even at an early age. These behavioral deficits must necessarily be due to abnormal development of the brain at or before this early age period.

In humans, this very period from roughly 6–12 months to 3 years is a time of major cell growth, synaptogenesis, and circuit formation for the neural systems that mediate these higher-order functions. No other period in human development is its equal: Circuit formation and functional organization in these systems at this time create the single most astonishing expansion of human higher-order processing capacity of any age period in human life. Therefore, abnormal development of processes in these systems during this age period almost certainly underlies the emergence of autistic behavioral signs and symptoms in infants and toddlers. However, a major unknown is whether such maldevelopment began *before* this period or, instead, occurs for the very first time *during* this period. This gap in knowledge exists because these higher-order neural systems are not developed sufficiently before this period, even in the completely neurotypical infant, and so, behavioral indices of deviation from normal capacity in these systems can only be readily behaviorally detected after the age when these functions typically develop. Behavioral methodologies alone, therefore, cannot address this key gap in knowledge in the biological time of onset of autism. From the perspective of elucidating the causes of autism, identifying early markers will allow effective interventions to begin earlier or even the identification of plausible paths to preventing autism. There are few questions in the field of autism that are more important to answer.

Since autism is undeniably due to abnormal brain development beginning in early life, knowledge of this early brain abnormality is paramount. Clearly, the signature of this early maldevelopment is far more likely to be detectable, perhaps even vivid, at the developmental time when behavioral symptoms first appear. However, there is a lack of a clear developmental perspective in the literature. As highlighted in a recent review, more than 90% of all studies of neuroanatomy in autism have been on 10-, 20-, or 40-year-olds with autism, not on 1- to 3-year-olds (Courchesne, Pierce, et al., 2007). In the past, most but not all (Courchesne, Pierce, et al., 2007; Amaral et al., 2008) reviews of the neuroanatomy of autism have not considered age-related effects when seeking a coherent picture of the neuroanatomic defects that underlie the emergence of autism.

In the recent research of a few laboratories, however, early brain development in autism has been a focus of investigations (Courchesne, Karns, et al., 2001; Courchesne, Carper, et al., 2003;

Hazlett, Poe, et al., 2005; Dawson, Munson, et al., 2007; Mosconi, Cody-Hazlett, et al., 2009; Schumann, Barnes, et al., 2009; Schumann, Bloss, et al., 2010). Findings led to the theory that autism involves early brain overgrowth followed by arrested growth and potential degeneration (Courchesne & Pierce, 2005; Courchesne, Pierce, et al., 2007; see Figure 35-1), Support for this theory of an unusual brain growth trajectory across the lifespan in autism comes from a new longitudinal and cross-sectional MRI study of 586 autistic and typically subjects 1 to 50 years of age (Courchesne Campbell, 2010). This theory (Courchesne, Pierce, et al., 2007) argues that early brain growth pathology begins *before* the first detected signs of autism. If the early brain overgrowth theory of autism is valid, then it would provide a central organizing principle for a host of research into genetic and nongenetic causes, avenues for treatment, animal models, and early identification. In this chapter, we review the head circumference and MRI evidence relevant to this theory and highlight areas of evidence that remain to be gathered to refine or refute it. In addition, new information from functional neuroimaging and postmortem studies that speak to this theory are also discussed. Future directions in research into the early developmental neuroanatomical bases of autism are suggested, including research that aims to define relationships between brain growth abnormality in autism spectrum disorders (ASD) and clinical, treatment, and etiological factors.

Discovery of Early Brain Overgrowth in Autism and Replication Studies

Head Circumference Evidence of Early Overgrowth in Autism

Abnormal brain enlargement in 2- to 3-year-old toddlers diagnosed with autism was first discovered using quantitative MRI a number of years ago (Courchesne, Karns, et al., 2001). Since autism begins before that age, the question remained as to whether this enlargement preceded or followed the onset of the first signs of autism. However, this same study also reported that autistic children with brain enlargement had normal to slightly smaller than normal head circumference (HC) at birth. That suggested the hypothesis that early brain overgrowth in autism begins sometime during the first 2 years of life.

To test that possibility, Courchesne et al. (2003) analyzed cross-sectional and longitudinal HC data using retrospective records from birth to 2 years of age in patients with autism from the Courchesne et al. (2001) study. To determine whether HC is a good retrospective index of brain size, Courchesne and colleagues additionally conducted a separate MRI-HC correlation study in autistic and typically developing toddlers and children (Bartholomeusz, Courchesne, et al., 2002). They found that HC at that early age (but not in adolescents or adults) is an excellent predictor of overall brain volume.

Courchesne et al. (2003) found that at birth, HC in infants who later went on to develop autism was typically near normal

A Three phases of growth pathology in autism
Figure 35–1. Three phases of growth pathology in ASD.
(A) Model of early brain overgrowth that is followed by arrest of growth. Red line represents ASD, while blue line represents age-matched typically developing individuals. In some regions and individuals, the arrest of growth may be followed by degeneration, indicated by the red dashes that slope slightly downward. (B) Sites of regional overgrowth in ASD include frontal and temporal cortices, and amygdala. From Courchesne, E., Pierce, K., et al. (2007). Mapping early brain development in autism. *Neuron, 56*(2), 399–413. (See Color Plate Section for a color version of this figure.)

(by World Health Organization norms) or slightly below normal average (by Centers for Disease Control norms) with a mean of 34.6 cm; only about 6% of these newborns had excessively enlarged HC at birth (Figure 35-2A including Webb, Nalty, et al., 2007; Figure 35-2B Dementieva et al., 2005). However, by 6–14 months of age, HC had become enlarged, with 76% of infants across different studies (Courchesne et al., 2003; Dementieva et al., 2005; Webb et al., 2007) exceeding +1 standard deviation above normal average (Figure 35-2C). This finding of early overgrowth during the first years of life in autism based on HC has now been replicated by several independent research groups (Dementieva, Vance, et al., 2005; Hazlett, Poe, et al., 2005; Dissanayake, Bui, et al., 2005; Dawson et al., 2007; Webb et al., 2007). Further, Elder et al. (Elder, Dawson, et al., 2008) found that toddler siblings of children with ASD who had more rapid growth from birth to 12 months and showed a deceleration in head circumference growth from 12 to 24 months had more parent reported difficulties in social and communication behaviors.

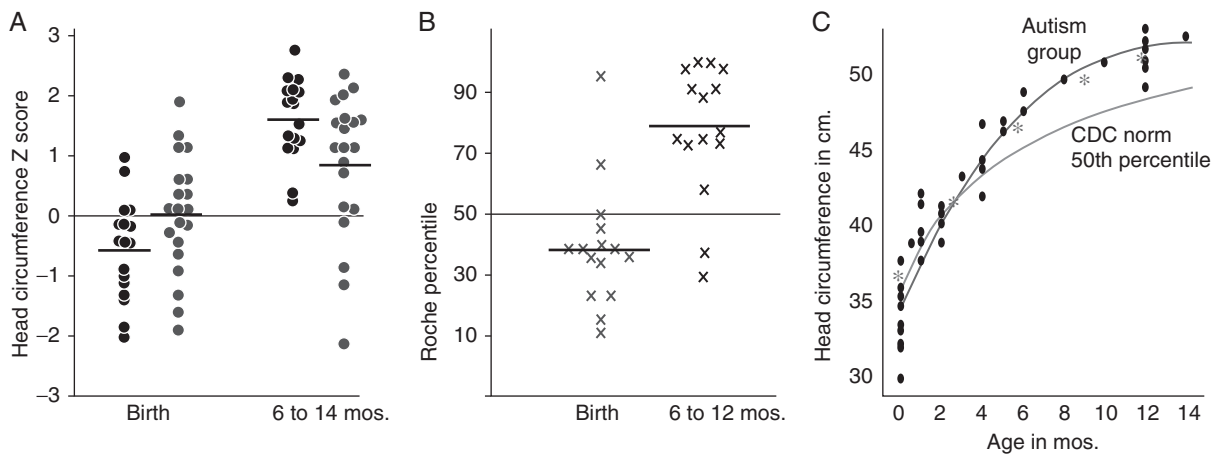
In addition to these longitudinal and cross-sectional studies of HC across the first 2 years of life in autism, several older studies reported only on birth HC. Figure 35-3 showed that in every


Figure 35–2. Abnormal growth of head circumference during infancy and the toddler years in autism. (A) Z scores from Courchesne et al. (2003) (in black circles) and Webb et al. (2007) (in gray circles) showing individual data points at birth and a second point between 6 and 14 months. Means represented by black lines. (B) Percentiles from Dementieva et al. (2005) showing mean and individual data points at birth and a second point between 6 and 12 months. Means represented by black lines. (C) Longitudinal data from N=14 babies who developed autism (black circles) and growth curve based on their data (darker top line) from Courchesne et al. (2003) and mean data from Webb et al. (2007) (in gray asterisks).

report of HC at birth in newborns who later go on to develop autism, it is typically near normal or slightly below normal average. What is remarkable about this evidence is the consistency of the absolute HC at birth in autism across studies and decades. Some previous reviews of the HC literature have failed to note this consistency; "differences" between studies have been due to the norms used and not to the actual size of the HC and therefore the brain at birth. Importantly, among the studies that provided individual subject HC data (Courchesne, Carper, et al., 2003; Dementieva, Vance, et al., 2005), only about 5–10% had excessively large HC at birth (Figure 35-2A and 35-2B).

Other major questions are whether HC growth patterns differ between domains of the autism spectrum (e.g., autistic disorder, PDD-NOS, and Asperger's syndrome) or vary in some other way in relation to symptom severity. Courchesne et al. (2003) reported that more abnormally accelerated HC growth at young ages was associated with more severe stereotyped and repetitive behaviors, later onset of first words, and greater likelihood of an autistic disorder rather than PDD-NOS diagnosis. In contrast, accelerated HC growth in early life in autism has been associated with higher levels of adaptive functioning (Dementieva, Vance, et al., 2005). Webb et al. (2007) did not find any association between a diagnosis of PDD-NOS versus autistic disorder or with history of regression. In one study, small and nonsignificant differences between autistic disorder and Asperger's groups in HC growth rates in the first years of life were detected, but sample sizes may have been too small to detect differences (Dissanayake, Bui, et al., 2006).

Perhaps less valuable are HC studies of older children, adolescents, and adults with ASD because with increasing age, HC becomes a progressively poorer index of the size of the brain (Aylward, Minshew, et al., 2002; Bartholomeusz, Courchesne, et al., 2002). MRI would clearly be the measure of choice at those ages, and results from such studies are reviewed

below. Similarly, MRI will eventually become the measure of choice for even infants and toddlers at-risk for autism because of its greater accuracy and unparalleled resolution of living human brain anatomy.

Nonetheless, important gaps and ambiguity in information remain. While CDC or WHO norms remain the largest normative database against which to compare autism HC in early life, it is important to be able to additionally show effects in large samples of comparably recruited autistic and healthy, typically developing (nonpediatric patient) infants and toddlers. By doing so, it will be possible to test more complex and
Figure 35–3. Summary of 10 reports of birth head circumference in neonates who were later diagnosed as having autism. Graph adapted from Courchesne, E., Pierce, K., et al. (2007). Mapping early brain development in autism. *Neuron, 56*(2), 399–413, and includes data means from Mason-Brothers et al., 1990; Lainhart et al., 1997; Stevenson et al., 1997; Courchesne et al., 2001; Gillberg & De Souza, 2002; Courchesne et al., 2003; Dementieva et al., 2005; Hazlett et al., 2005; Dissanayake et al., 2006; Webb et al., 2007.

clinically useful relations between growth rates of HC in early life and a variety of important biological and behavioral measures including genotype, diagnostic, prognostic, in vivo MRI and fMRI, blood biomarkers, treatment responsiveness, and so forth. To this end, a new study has developed a procedure that identifies in the general population (not just in younger siblings of autistic children) infants and toddlers who are at risk for ASD and then obtains at that early stage diagnostic, psychometric, biomarker, DNA, blood-based RNA, MRI, and fMRI measures along with HC (Pierce, Glatt et al., 2009).

The results raise the possibility that early brain overgrowth could be common across the autism spectrum, and as such may point to a common set of biological pathways that cause an ASD. Courchesne et al. (Courchesne, Pierce, et al., 2007) concluded that there was evidence that brain overgrowth occurs in the first 2-3 years of life in autism and that in many cases this growth pathology precedes the first clinical signs of the disorder (also see Courchesne, Carper, et al., 2003; Dementieva, Vance, et al., 2005; Dawson et al., 2007; Webb et al., 2007). This suggests that the neural defects that cause autism are present *before* the critical peak period of circuit formation and functional organization in higher-order social, communication, emotion, and language systems and as such cause circuit formation and function to proceed abnormally. Thus, abnormal connectivity and function was theorized to be the downstream consequence of an earlier neural defect. Finally, the authors pointed out that while a number of different cellular and molecular factors could underlie early brain overgrowth, the most obvious and likely candidates include excess neuron numbers due to dysregulation of neurogenesis and/or naturally occurring cell death and excess glial numbers (see Courchesne, Carper, et al., 2003; Courchesne & Pierce, 2005; Courchesne, Pierce, et al., 2007). The discovery of the common underlying neuropathology could be key to identification of the upstream causes of ASD. Equally important then, would be the question of whether clinical outcome differences along the spectrum (from low functioning to high) might reflect individual genetic or experiential differences that modify the impact of a common triggering neuropathology. While interesting, these possibilities remain largely conjectural, and much additional information is needed from future studies. For instance, are there clinical and/or biological differences related to age of onset, rate, duration, and magnitude of early brain overgrowth?

There is additional interest in how the accelerated postnatal HC growth in autism compares to other disorders that involve head and brain enlargement. Table 1 in Courchesne and Pierce (2005) summarizes a variety of neuroanatomical, physical, metabolic, behavioral, and/or other clinical characteristics that distinguish other disorders from autism. For example, autism does not typically involve pronounced ventricular enlargement, craniofacial abnormalities, or excessive head enlargement in utero and/or at birth, but one or another of these are common features of several other disorders presenting with excessive head size at birth as well as during infancy, such as Sotos syndrome, hydrocephaly, and macrocephaly-Cutis marmorata

telangiectatica congenita (M-CMTC). Also presenting with HC enlargement at birth is familial macrocephaly (defined as absence of a clinical syndrome, normal radiographic brain development, parent or sibling with macrocephaly and/or macrocephaly traced through several generations; DeMyer, 1986). There are 164 conditions that are associated with macrocephaly (Williams, Dagli, & Battaglia, 2008). Most are extremely rare, with some having as few as 30 total cases worldwide. Thus, ASD, which occurs in 1 in 150 individuals, is the single most common condition associated with excessive head and brain size at young ages. On the other hand, unlike these other conditions—including familial macrocephaly, brain enlargement in the great majority of ASD individuals is developmentally restricted to the first several years of life, and, as discussed below, eventually most ASD individuals do *not* have excessive brain size by adolescent and adult years. Studies that have compared rates of macrocephaly in ASD to other types of mild developmental disorder (e.g., ADHD; see e.g., Rodier, Bryson, et al., 1997; Ghaziuddin, Zaccagnini, et al., 1999; Fidler, Bailey, et al., 2000) or to relatives of ASD individuals (Fidler, Bailey, et al., 2000; Miles, Hadden, et al., 2000) and have not found large differences, have not taken into account the latter fact that brain enlargement in autism is unusual in being relatively restricted to younger developmental age periods. This is reviewed further below.

MRI Evidence of Early Brain Overgrowth, Arrest, and Decline in Autism

As noted above, abnormal early brain overgrowth in autism was initially discovered in 2- to 3-year-olds with quantitative MRI nearly a decade ago (Courchesne, Karns, et al., 2001); overall brain size in the autistic toddlers was 10% larger than in typically developing toddlers (see Figure 35-4). In that study, abnormal enlargement in these very young autistic toddlers was also present for whole cerebral volume, cerebral gray matter volume, and cerebral white matter volume. This new phenomenon of pathological early brain and cerebrum overgrowth in autism has since been replicated in a number of other studies. First, in 3- to 4-year-olds, Sparks et al. (Sparks, Friedman, et al., 2002) reported a 9% larger cerebrum volume in autistic as compared to typically developing and developmentally delayed children. Then, in 2-year-olds, Hazlett et al. (Hazlett, Poe, et al., 2005) reported a significantly larger cerebrum, including cerebral gray and white matter in autism as compared to typically developing and developmentally delayed children. In the first MRI study of very young autistic girls, Bloss and Courchesne (2007) found abnormal enlargement of the brain and cerebrum volume in 2- to 5-year-old autistic girls compared to typical girls. Interestingly, this abnormal increase in brain and cerebrum size in the autistic girls was somewhat greater than that seen in age-, IQ-, and autism severity–matched autistic 2- to 5-year-old boys. Most recently, we have also found enlargement of cerebral, cerebral gray, and cerebral white volumes in 2- to 5-year-old autistic boys and girls (Schumann, Bloss, et al., 2010). As discussed below, Bloss
Figure 35–4. Studies showing abnormal brain or cerebral overgrowth in autism by age 2 to 4 years. Data plot shows individual MRI-based brain volumes in autistic 2- to 4-year-old males (black dots) as compared to the average volume of 1179 ml in typical 2- to 4-year-old males (from Courchesne et al., 2001). On the right, 3D reconstructions shown of a 3-year-old autistic boy with a brain volume of 1810 cc as compared to the brain of a typically developing 3-year-old boy with an average brain size. Adapted from Courchesne, E., Karns, C., et al. (2001). Unusual brain growth patterns in early life in patients with autistic disorder: An MRI study. *Neurology, 57,* 245–254.
Figure 35–5. Unusual brain growth trajectory from early life to 16 years of age in autism. Data plotted from the only MRI study of age-related changes in brain size in autism from toddler years through to adolescent years. Each data point is the MRI-based brain volume from different autistic (open circles) or typically developing (closed circles) boys. Adapted from Courchesne, E., Karns, C., et al. (2001). Unusual brain growth patterns in early life in patients with autistic disorder: An MRI study. *Neurology, 57,* 245–254.

and Courchesne (2007) concluded that while abnormal early brain enlargement appears to be common to both girls and boys with autism, autistic girls may have more severe and possibly slightly different patterns of anatomic abnormality.

By quantifying MRI at all ages from 2 to 16 years, Courchesne et al. (2001) identified three different phases of pathological brain growth (see Figure 35-5). The first phase of pathology was accelerated brain overgrowth: Between the first year of life and 2–3 years of age, the autistic brain becomes abnormally enlarged. After that early period, a second phase of pathology was abnormally slow development or arrested growth: Between roughly 3–5 years and 8–9 years of age accelerated brain growth stops in most autistic children, and further growth is either abnormally slow or arrested. Finally, a third phase of pathology, less clear-cut and distinct than the first two, appeared to be premature decline, possibly due to degeneration. As discussed by Courchesne and Pierce (2005), this unusual and pathological pattern of age-related changes, which has also been found in a new lifespan study of 586 autistic and typical subjects (Courchesne, Campbell, et al., 2010), distinguishes

autism from a large number of other developmental disorders that display enlarged brain size. While overgrowth of the brain as well as frontal and temporal cortices, cerebral white matter, and the amygdala in large samples of young children with autism has now been reported by several independent laboratories (see below), studies show the degree of abnormality varies across autistic children from a subset of individuals that differ little from normal average to the majority with significant enlargement including some with as much as a 50% increase in size (see Figure 35-5).

This first developmental MRI study of 2- to 16-year-olds as well as a recent study of 1 to 50 year olds (Courchesne, Campbell, et al., 2010) make clear one major and fundamental point about autism: The underlying neural pathological processes and structural abnormalities in autism change with age: That is, they are not the same at all ages, and so neural, functional, behavioral, and genetic study of the older autistic brain reflects *outcome,* not the original upstream events and defects that started the disorder. Consider that a host of evidence on the adolescent and adult autistic brain (review: Courchesne, Campbell, et al., 2010) shows reduced size and/or volume loss in cerebral, amygdala, callosum and cerebellar structures (see below), neuron loss in the amygdala, cerebellum and fusiform cortex (Bailey, Luthert, et al., 1998; Schumann & Amaral, 2006; van Kooten, Palmen, et al., 2008), decreased dendritic arbors and minicolumn size (Casanova, Buxhoeveden, et al., 2002; Mukaetova-Ladinska, Arnold, et al., 2004; Buxhoeveden, Semendeferi, et al., 2006; Casanova, van Kooten, et al., 2006; Morgan et al., submitted), the presence of proapoptotic molecules (Araghi-Niknam & Fatemi, 2003), and possible Purkinje cell degeneration with neuroinflammation (Vargas et al., 2005), none of which can account for early brain enlargement. Furthermore, these three separate phases of pathology indicate that autism almost certainly must involve multiple different underlying neural defects and processes and therefore genetic and nongenetic factors associated with each one (Courchesne & Pierce, 2005; Courchesne, Pierce, et al., 2007).

Three new longitudinal studies provide evidence consistent with this theory of three different phases of pathological brain growth in autism. One found significant cerebral enlargement and abnormal cerebral growth trajectories across the ages of 2–5 years in autism (Schumann, Bloss, et al., 2010), while another found evidence of a slightly accelerated rate of loss of cerebral gray matter in several regions including the frontal cortex in older autistic children and preadolescents (Hardan, Libove, et al., 2009). The third found evidence of brain overgrowth in the first years of life but an accelerated rate of loss of brain volume from preadolescence to 50 years of age (Courchesne, Campbell, et al., 2010). Interestingly, in the first quantitative study of age-related changes in the postmortem brain in autism, Morgan et al. (Morgan, Buxhoeveden, et al., submitted) found evidence of enlargement of neuropil space in cerebral gray matter in very young autistic cases but reduction in adolescent and adult cases, which parallels the developmental pattern of early cerebral enlargement and later decline seen via MRI. While there have been only two longitudinal

MRI studies of cerebral growth, there have been a large number of MRI studies of adolescent and adult autism subjects. At these older ages, effects have been variable, with some studies reporting slightly larger cerebral gray matter volumes (Lotspeich, Kwon, et al., 2004; Palmen, Hulshoff Pol, et al., 2005; Hazlett, Poe, et al., 2006), but most reporting either slightly reduced volumes (Courchesne, Karns, et al., 2001) or no difference from normal (Herbert, Ziegler, et al., 2003; Rojas, Peterson, et al., 2006). Nonetheless, the pattern across these several studies is consistent with an overall decline in the difference between autism and normal with age. Further, one study of the distribution of cortical thickness shows widespread but patchy thinning or atrophy in autistic adults in regions involved in social cognition and emotion processing, including frontal, temporal, and parietal areas (Hadjikhani, Joseph, et al., 2006); cortical thinning was also correlated with autism symptom severity.

Because the Courchesne, Karns, et al. (2001) and Courchesne, Campbell, et al. (2010) MRI studies are the only ones to quantitatively and statistically analyze age-related anatomical changes in brain size from early toddler years to adolescence and adulthood, the best objective method for testing their results and conclusions at the present time is via a formal, statistical meta-analysis of all brain size data that has been reported in other more age-limited studies of autism (Redcay & Courchesne, 2005; Stanfield, McIntosh, et al., 2008).

Statistical Meta-Analyses of the Autism MRI and Postmortem Literature: Evidence of Overgrowth, Arrest, and Decline

To test this theory and the generality of age-related changes in MRI-based brain size observed from ages 2 to 16 years in autism, Redcay and Courchesne (2005) analyzed all brain size data available from the autism literature and showed the entire developmental course of brain size in autism. Data from 12 MRI studies on autism were included covering ages 2–46 years, head circumference data from three studies on autism in the first years of life, brain weight data from 55 postmortem autistic cases covering ages 3–65 years, and brain weight data from more than 8,000 postmortem cases from 10 studies covering ages from birth to 70 years. The strength of their meta-analysis was in its large autism subject sample size (n = 531) allowing for the power to detect age-related changes in brain size in autism and to concurrently examine the consistency of findings across measurement type (head circumference, MRI brain volume, postmortem brain weight) and research study.

Their analyses showed that early postnatal brain overgrowth is a phenomenon in autism that is detectable across multiple study samples and measurement methods (Figure 35-6). These findings suggest that "conflicting" reports of brain size may be largely an effect of age. Despite the method of acquisition, when brain size findings were organized according to age, a clear pattern of early brain overgrowth followed by normal brain size in adulthood emerged. Thus, this study confirmed that abnormal brain enlargement in autism is
Figure 35–6. In autism the difference in brain size from normal diminishes with age. (A) Plot of a meta-analysis of 20 studies depicting brain size changes with age in ASD. Adapted with permission from Redcay, E. & Courchesne, E. (2005). When is the brain enlarged in autism? A meta-analysis of all brain size reports. *Biol Psychiatry, 58*(1), 1–9. (B) Autism and control mean brain weight by age. Means of postmortem brain weight values from individual autistic males and mean normative data were calculated for three age groups (3–5, 7–12, 13–70). Comparison of the two lines illustrates that while the normal brain continues to grow into adolescence, the autistic brain has already reached its near maximal weight by 3–5 years of age.

time-delimited to the first 2 to 3 years of life and is followed by arrested or abnormally slow growth, as shown in Figure 35-5. It is especially important to see that the two main but very different methods of measuring brain size—volume from MRI and weight from postmortem analyses—portray the very same picture of early overgrowth in the first years of life followed by arrested growth (compare panels A and B in Figure 35-6). Moreover, by the end of this first phase of growth pathology, the 3- to 5-year-old autistic brain has already reached a size not very different from a normal adult or adolescent (see panel B of Figure 35-6). So, in autism, full brain size is achieved 8 to 10 years prematurely, but unlike many other disorders involving macroencephaly, this excess size does not persist in most cases into the preadolescent, adolescent, and adult years. This demonstrates an important aspect of the unusual brain growth profile in autism. In addition, these analyses indicate that at the age of typical clinical diagnosis of the disorder (i.e., 3–4 years), the critical early period of pathological growth and arrest has likely already passed, leaving clinicians and researchers with

an outcome, rather than process, of pathology for study and treatment intervention.

Stanfield and colleagues (Stanfield, McIntosh, et al., 2008) conducted another major meta-analyses of the entire autism MRI literature. Their results are consistent with those of Redcay and Courchesne (Redcay & Courchesne, 2005) and extend them in many important ways including the addition of 4 new MRI brain volume studies (for a total of N = 16 MRI studies) and the inclusion of calculations of effect sizes and age-effects for many other major regions of interest. Many key findings result from their work: First, they showed age-related changes in brain overgrowth with maximum abnormality at the youngest ages and then steadily decreasing differences thereafter with negligible differences by adulthood, a pattern that confirms the original cross-sectional findings of Courchesne, et al. (2001) and the Redcay and Courchesne (2005) brain development meta-analyses. In short, the abnormal brain size findings change with age in autism. Second, in the first formal meta-analyses of other brain regions in autism, Stanfield et al. also

demonstrated that for many other structures, effects also change with age in autism. Like overall brain volume, amygdala volume is enlarged in 3- to 4-year-old autistic children, as first discovered by Dawson and colleagues (Sparks et al., 2002), but this difference declines with age so that by adulthood, the amygdala is *reduced* in size (see further discussion below). Third, in some regions that are significantly *smaller than normal at the youngest ages in autism*, such as the cerebellar vermis lobules VI–VII, there is an age-related change whereby they become *near normal in size by adulthood* (Stanfield, McIntosh, et al., 2008) (see further discussion below).

In sum, a major discovery in autism comes out of these cross-sectional, longitudinal, and meta-analysis studies of age-related changes in brain structure in autism: The landscape of neuroanatomic abnormality in autism changes significantly with age from birth through early childhood to adulthood. Effects should be *expected* to vary somewhat from study to study so that negative findings need to be considered in the larger frame of reference of the literature rather than as "contradictory" evidence, small sample sizes may not be as desirable as very large ones, and age is a major factor that must always be taken into account.

Specific Regions Showing Early Overgrowth

The Frontal and Temporal Lobes

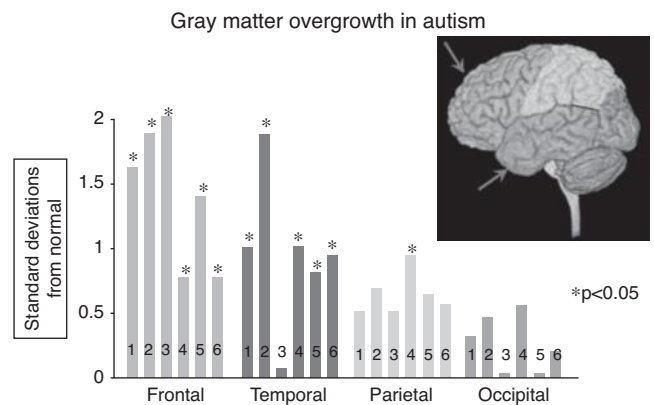
Signature abnormalities of autism in the first years of life are deficits in higher-order social, language, communication, and emotion functions, each one heavily dependent on frontal and temporal lobes. Conversely, relatively spared in autism are visual-spatial abilities mediated by posterior cortical areas, especially occipital cortex. To test the hypothesis that frontal and temporal lobes are indeed developmentally abnormal at the time of clinical onset, Carper et al. (Carper, Moses, et al., 2002) conducted the first autism MRI study to separately measure frontal, temporal, parietal, and occipital lobes. They found overgrowth of frontal and temporal, but not parietal and occipital, gray matter in autistic 2- to 4-year-olds as compared to typically developing children (Figure 35-7). Since then a number of MRI studies have also separately measured each of these lobes in autistic subjects. In the youngest age group studied to date, 2-year-olds with autism had enlargement of frontal, temporal, and cingulate cortices (Schumann, Bloss, et al., 2010). As seen in Figure 35-7, across multiple studies (Carper, Moses, et al., 2002; Kates, Burnette, et al., 2004; Hazlett, Poe, et al., 2005; Palmen, Hulshoff Pol, et al., 2005; Bloss & Courchesne, 2007; Schumann, Bloss, et al., 2010) frontal and temporal gray matter volumes are most abnormally enlarged while occipital is the least. Within frontal cortex, dorsolateral and mesial prefrontal gray matter volumes (Carper & Courchesne, 2005) and cingulate gray matter volume (Schumann, Bloss, et al., 2010) are most enlarged in very young autistic children, while orbital gray matter is little affected. Thus, frontal areas that mediate social, language, communication, and higher-order cognitive functions are most developmentally abnormal in autism.


Figure 35–7. Summary of observed gray matter abnormalities (standard deviations from normal) from studies of children and adolescents with autism. Included data from: (1) Carper et al., 2002; (2) Bloss & Courchesne, 2007; (3) Kates et al., 2004; (4) Palmen et al., 2005; (5) Hazlett et al., 2005; (6) Schumann, Bloss et al., 2010. Note the general gradient of abnormality, with frontal and temporal regions most profoundly enlarged. Adapted from Courchesne, E., Pierce, K., et al. (2007). Mapping early brain development in autism. *Neuron, 56*(2), 399–413. (See Color Plate Section for a color version of this figure.)

These effects vary somewhat with gender. First, as compared to 2- to 5-year-old boys with autism, 2- to 5-year-old girls with autism show somewhat more severe enlargement in frontal and temporal cortices (Bloss & Courchesne, 2007; Schumann, Bloss, et al., 2010). Second, in 2- to 5-year-old girls with autism, the temporal cortex is much more abnormal than frontal cortex, while in young boys, abnormality may be slightly greater in frontal (Bloss & Courchesne, 2007; Schumann, Bloss, et al., 2010). In the first longitudinal MRI study of cerebral cortex during early development, 2- to 5-year-old boys and girls with autism had abnormal growth rates in multiple cortical regions (overall cerebral gray, frontal gray, temporal gray, cingulate gray, and parietal gray) except occipital gray, but the girls with autism had a more pronounced abnormal growth profile in more cerebral regions than did boys with autism.

White matter also shows striking regional differences, with both volumetric (Carper, Moses, et al., 2002) and DTI (Ben Bashat, Kronfeld-Duenias, et al., 2007) measures being most deviant in frontal regions and least in occipital lobe in 2- to 5-year-old children with autism. Roughly parallel to these regional differences, Herbert et al. (2003) report that the greatest deviation in their 7- to 11-year-old subjects with autism was in short-distance white matter immediately underlying frontal cortices and the least deviation in long-distance pathways and in occipital white matter.

Missing are studies of cortical folding patterns, surface area, and thickness in specific frontal and temporal regions at very young ages in autism. Such studies would provide invaluable clues to the neural and connectivity defects that underlie the early abnormal overgrowth. One study of sulcal patterns in 10-year-olds with autism (Levitt, Blanton, et al., 2003)

found a tendency for some frontal and temporal sulci to be more posterior-superiorly positioned than normal—which could be consistent with frontal and temporal overgrowth. Another study (Nordahl, Dierker, et al., 2007) found significant cortical shape differences between autistic and control 7- to 12-year-olds, primarily in the inferior lateral frontal cortex. Because segmentation and surface reconstruction in the infant and toddler pose special challenges to most commonly used MRI analysis programs, studies of cortical thickness and surface area are susceptible to mismeasurement. Unfortunately, many such programs were originally developed to process adult gray, white, and CSF voxel signals that differ in important ways from the young developing brain, and they can make substantial errors when applied to young populations. Further, surface rendering algorithms that operate best in the mature brain whose sulci have much more CSF than the young developing brain, can make even more substantial errors in correctly finding the entire surface of deep sulci in young brains. Nonetheless, advances in this area will be crucial to discovery of the underlying neural and connectivity defects present in the abnormally enlarged frontal and temporal cortex in autistic babies and toddlers.

Arrested or abnormally slowed growth in frontal and temporal lobes occurs sometime during early to middle childhood, but there is too little information to be certain of the timing of this and how it might vary across autistic individuals and with clinical variables. To date, only two cross-sectional MRI studies provide information (Carper, Moses, et al., 2002; Carper & Courchesne, 2005). Carper, Moses, et al. (2002) show that between 2 and 4 years of age and later childhood, frontal and temporal lobes undergo robust increases in gray and white matter in typical children but little or no growth in children with autism. By late childhood, the autistic frontal and temporal lobe is marginally different in size compared to typical children.

If verified, this would mean that studies of the clinical and biological correlates of frontal and temporal anatomical abnormality should target infants and toddlers when the abnormality is most quantitatively evident. Since overgrowth effect sizes are small to medium for many of the measures reported for frontal and temporal lobes, it will be necessary to image large samples of both typically developing and autistic infants and toddlers in order to detect replicable anatomico-clinical and anatomico-biological correlations. The recent work by Piven and colleagues is currently the best example of a successful design aimed at testing specific brain overgrowth–genetic relationships. In a large sample of very young autistic children, they (Wassink, Losh, et al., 2007) found cerebral and frontal gray matter overgrowth related to a functional promoter polymorphism of a gene that modulates serotonin reuptake, SLC6A4. During early stages of development, serotonin plays an important role in neurite outgrowth and possibly synaptic stabilization, and so change in its availability for release at synapses could impact neurite growth and connectivity.

A major gap in knowledge in autism is the absence of data that explain the frontal and temporal overgrowth in the first years of life. While every paper reviewing the literature has made interesting speculations, virtually no evidence has been found to support any current conjecture. In brief, no cellular or molecular study of the young autistic postmortem brain has been published, with the exception of rare individual cases (e.g., Buxhoeveden, Semendeferi, et al., 2006; Kennedy, Semendeferi, et al., 2007). When one or two young autism cases have been included, statistical analyses have not examined age-effects. For instance, some have speculated that overgrowth is due to an excess number of minicolumns. However, the number of minicolumns in frontal or temporal regions has never been quantified. Further, while adult autism cases have been repeatedly shown to have abnormally narrow minicolumn widths, two recent studies do not find this abnormality in very young autism cases (Buxhoeveden, Semendeferi, et al., 2006; Morgan, Buxhoevede, et al., submitted), but instead find evidence of neuropil increases at young ages. A popular explanation for autism and overgrowth is abnormal, perhaps excess, synaptogenesis or failure of synaptic pruning and connections. However, synapse numbers and morphology have never been examined in the young autistic brain. Excess local connectivity and disproportionately reduced long-distance functional connectivity have been speculated in numerous papers (Belmonte, Cook, et al., 2004; Courchesne & Pierce, 2005; Just, Cherkassky, et al., 2007; Geschwind & Levitt, 2007), but this has never been verified by postmortem analyses, and no one has addressed how disconnection could produce excess growth in early life in autism.

There is a simple reason for this lack of key knowledge: Almost all of the more than 40 postmortem publications have examined the autistic brain at older ages, and so their observations may well reflect the *long-term outcome pathological process* rather than the original pathology that causes overgrowth and autism in the first place. Studying early defects is possible. For instance, Morgan et al. (submitted, personal communication), in frontal cortex minicolumns, has examined neural and glial spatial organization and microglial activation in autistic cases ages 3 to 50 and analyzed for age-related effects. In one of these studies, for instance, at the youngest ages, there was an increase in neuropil space, but with age there is a failure of further growth and eventually minicolumns become reduced. In another, at the youngest ages microglial density and size was already abnormally greater in autism than controls.

With the exception of Piven and colleagues (Wassink, Losh, et al., 2007; Davis, Hazlett, et al., 2008), there have been no studies aimed at identifying genes associated with early brain, including frontal and temporal lobe, white and gray matter overgrowth. Across genomewide association studies, CNV studies, specific gene association, and gene expression studies of autism, more than 400 genes have been implicated at one time or another in the disorder. A large number of these have to do with synaptic structure and function, neurite growth, apoptosis, and many other developmental and brain organization functions and would thus serve as a good beginning point for targeted brain-gene analyses, provided the brain data came from very young autism subjects and not only from adolescents or adults with autism whose brain measurements would not be a good index of early growth pathology.

The importance of establishing the genetic, molecular, and cellular bases of early frontal and temporal lobe maldevelopment in autism is very high because functional imaging studies (e.g., fMRI, EEG, and ERP) and core clinical symptoms all point to deficits in these regions, the amygdala (see below), and cerebellum (see below) as fundamental to autism.

The Amygdala

The amygdala has long been a site of intense interest in the search for neuropathology in the brains of people, given its well-established role in the production and recognition of emotions and modulatory role in social behavior (Adolphs, 2001). However, the heterogeneity and unknown etiologies of autism, variability of methods employed between laboratories, and different age groups studied have limited the consistency of results across structural MRI studies of amygdala volume (Schumann & Amaral, 2009). It was only when the age of the subject was considered to be a critical factor did an interesting pattern of amygdala development in children with autism emerge (Schumann, Hamstra, et al., 2004). Four studies of toddlers and young children with autism have found the amygdala to be enlarged by ~15% relative to age-matched controls (Sparks, Friedman, et al., 2002; Schumann, Hamstra, et al., 2004; Mosconi, Cody-Hazlett, et al., 2009; Schumann, Barnes, et al., 2009). However, studies of older adolescents, adults, or a wide age range of subjects, have found either no difference in (Schumann, Hamstra, et al., 2004; Palmen, Durston, et al., 2006) or even smaller (Aylward, Minshew, et al., 1999; Pierce, 2001; Nacewicz, Dalton, et al., 2006) amygdala volumes in individuals with autism. In addition, the amygdala continues to grow in size throughout adolescence in typically developing male children (Giedd, 1997), but this growth pattern does not seem to take place in male children with autism (Schumann, Hamstra, et al., 2004). Therefore, the amygdala appears to be initially larger than normal in children with autism, but does not undergo the same age-related increase in volume that takes place in typical children (Figure 35-8). This hypothesis parallels the general theory of early brain overgrowth, as discussed above (Courchesne, Karns, et al., 2001; Courchesne, Pierce, et al., 2007), although the aberrant growth trajectory of the amygdala may extend to a later age of development relative to cortical regions (Schumann, Hamstra, et al., 2004).

Sparks and colleagues were the first to suggest that the amygdala may be enlarged in young children with autism at 36–56 months of age (Sparks, Friedman, et al., 2002). In this same cohort of children, Munson et al. (Munson, Dawson, et al., 2006) found that the amygdala enlargement in the children with autism was associated with more severe social and communication impairments on the ADI and Vineland Adaptive Scales and poorer outcome at 6 years of age. In a recent longitudinal study of children at 2 and 4 years of age, bilateral amygdala enlargement was also observed in children with autism compared to a control group that consisted of typical and developmentally delayed children (Mosconi, Cody-Hazlett, et al., 2009).

Figure 35–8. Summary of findings on amygdala volume in autism from 11 MRI studies showing age-related changes in differences from normal size. Upward arrows indicate studies that found greater amygdala volumes in autism compared to normal average; short horizontal lines indicates studies finding no amygdala volume differences between autism and normal; and downward arrows indicate studies findings smaller amygdala volumes in autism compared to normal average.

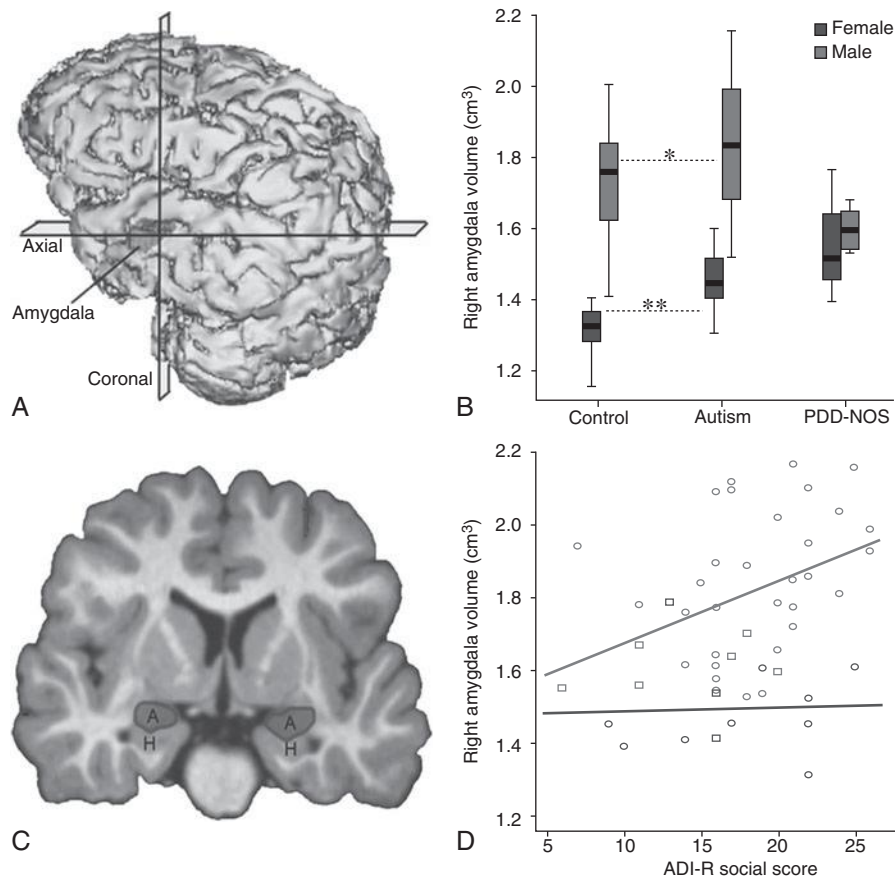
Schumann and colleagues (Schumann, Barnes, et al., 2009) recently carried out a prospective study to measure amygdala volume in toddlers at risk for autism at the age of first clinical detection compared to age-matched typically developing children; the children underwent an MRI around 3 years of age and returned later at 5 years of age for clinical diagnosis and testing. They found further evidence that the amygdala is enlarged in young children with autism and that the overgrowth must begin before 3 years of age, at about the time symptoms become clinically evident (Figure 35-9). As found in the Sparks (Sparks, Friedman, et al., 2002) and Mosconi (Mosconi, Cody-Hazlett, et al., 2009) studies, the amygdala was disproportionately enlarged relative to total cerebral volume at 3 years of age. This study differed from previous studies on amygdala volume in that one of the primary goals was to characterize the neuropathological and behavioral profiles of males and females with autism independently. Strikingly, amygdala enlargement in females with autism was found to be more severe, compared to age- and gender-matched typically developing counterparts, than in males with autism (Figure 35-9). This significant difference was present despite a group size of only 9 females with autism in their cohort. In male, but not female, toddlers who later received a diagnosis of autism, the degree of amygdala enlargement at 3 years of age was associated with the severity of the child's social


Figure 35–9. Amygdala enlargement in toddlers and young children with autism. (A) Three-dimensional reconstruction of MRI scan; (B) Right amygdala volume (in cm³) for children at about 3 years of age by diagnostic group (*$p < .05$; **$P < .01$ significantly different from sex-matched control); (C) Amygdala (A) and Hippocampus (H) in the coronal plane; (D) Linear regression scatter plot showing a positive correlation for right ($r = 0.52$, $p = .001$) amygdala volume (in cm³) and Autism Diagnostic Interview-Revised (ADI-R) social score in males with autism spectrum disorder. Adapted from Schumann, C. M., Barnes, C. C., et al. (2009). Amygdala enlargement in toddlers with autism related to severity of social and communication impairments. *Biol Psychiatry, 66*, 942–949. (See Color Plate Section for a color version of this figure.)

and communication impairments at final clinical evaluation at ~5 years of age (Figure 35-9). This finding is similar to reports of other brain regions, in which enlargement at 3–5 years of age is associated with the severity of symptoms at 5–8 years of age (Munson, Dawson, et al., 2006). Previous studies (Bloss & Courchesne, 2007), including our own longitudinal studies of this cohort (Schumann, Bloss, et al., 2010), have also found more robust differences in cortical volumes in females than males. Although speculative at present, the Schumann et al. (Schumann, Barnes, et al., 2009) study suggests that autistic males may be a more heterogeneous group in amygdala volume, which varies with the degree of clinical impairment, compared to autistic females, who may have a more homogeneous neuropathological profile of an enlarged amygdala regardless of the degree of their behavioral impairment.

Collectively, studies suggest that the amygdala is enlarged in young children with autism (Sparks, Friedman, et al., 2002; Schumann, Hamstra, et al., 2004; Mosconi, Cody-Hazlett, et al., 2009; Schumann, Barnes, et al., 2009). However, Schumann, Amaral, and colleagues (Schumann, Hamstra, et al., 2004) found that the period of amygdala enlargement in

children with autism appears to be limited to early development, due to the continued growth of the amygdala in typically developing males which increases in size by 40% from 5 to 18 years of age (Giedd, Snell, et al., 1996; Giedd, 1997). Therefore, by adolescence, amygdala size in the typically developing child has caught up with, and likely surpassed, amygdala size in the child with autism (Schumann, Hamstra, et al., 2004). Studies of older populations have found that amygdala volume is actually smaller in adolescents and adults with autism relative to age-matched typical controls (Aylward, Minshew, et al., 1999; Pierce, 2001; Nacewicz, Dalton, et al., 2006). In one study by Nacewicz and colleagues (Nacewicz, Dalton, et al., 2006), a smaller amygdala volume was associated with gaze avoidance and more severe behavioral impairments as measured with the ADI-R. This relation is the opposite pattern of that observed in younger children in both the Munson et al. (Munson, Dawson, et al., 2006) and Schumann et al. (Schumann, Barnes, et al., 2009) studies. It remains unknown if autism subjects that demonstrate early overgrowth and more severe behavioral impairments also demonstrate reduced amygdala size later in adulthood,

as preliminarily suggested by these findings; this awaits confirmation from a longitudinal study on brain growth throughout development in people with autism.

How might pathology in the amygdala relate to specific behavioral abnormalities? Pierce and colleagues (Pierce, Haist, et al., 2004; Pierce & Redcay, 2008) found that the amygdala in young autistic children as well as autistic adults can be responsive in the presence of stimuli that represent high reward value, such as mother's face or the face of children. Conversely, reduced activation to adult stranger faces may reflect reduced attention and interest. Diminished attention to faces early in development may be part of a developmentally early cascade of impairments that lead to later emotional and social deficits (Osterling & Dawson, 1994; Pierce & Redcay, 2008). An emerging hypothesis is that the amygdala may play a role in mediating or directing attention to the eye region of the face to detect emotion or danger (Adolphs, 2001). Indeed, autistic subjects show abnormal visual scan paths during eye-tracking studies when viewing faces, typically displaying less time attending to core social features such as the eyes (Klin, Jones, et al., 2002; Pelphrey, Sasson, et al., 2002). Dalton and colleagues (Dalton, Nacewicz, et al., 2005) utilized functional imaging and eye-tracking technology simultaneously while showing subjects familiar and unfamiliar faces; the amount of time persons with autism spent looking at the eye region of the face was strongly positively correlated with amygdala activation. Thus, more attention-getting, interesting, and perhaps socially rewarding stimuli may engender greater amygdala activation in autism, with uninteresting adult stranger faces triggering less activation than normal. Recently, Kleinhans and colleagues (Kleinhans, Johnson, et al., 2009) found evidence of reduced activation in the amygdala to neutral faces in autistic as compared to control subjects, but also less habituation to the faces; interestingly, more socially impaired autistic subjects showed less habituation.

No study to date has evaluated younger postmortem cases with autism to determine what cellular properties account for the early overgrowth in volume, but there is some evidence that a decreased number of neurons may be contributing to the reduction in volume later in adulthood. Schumann and Amaral (2006) carried out a stereological study to count the number of neurons in postmortem amygdala tissue from 9 male autism and 10 male control cases. In their cases ranging from 10 to 44 years of age, they found a reduction in the number of neurons in the autism cases relative to controls in the amygdala as a whole and in its lateral nucleus. Younger autism cases need to be evaluated with postmortem stereological techniques to determine at what stage of development the decrease of neurons occurs in relation to the overall abnormal growth trajectory.

How might pathology in the amygdala generate specific behavioral abnormalities? We and others have found that the volume of the amygdala in individuals with autism is associated with the severity of their social and nonverbal impairments as measured on the ADI and Vineland Adaptive Scales. Given that each score is comprised of several domains, the correlation analyses carried out are exploratory, and it would be inappropriate to make inferences on the effect of amygdala pathology on any specific behavior. There is also considerable overlap of the behaviors observed for the social and nonverbal communication scores on both algorithms. For example, both scores include observing social smiling, gaze direction, facial expressions, imaginative and imitative social play, and seeking to share enjoyment with others. Many of these behaviors are associated with amygdala function, and therefore it is not surprising that amygdala pathology might be associated with the severity of these impairments in people with autism. From human and nonhuman primate studies, a pathological amygdala can be associated with increased anxiety, unusual fear, gaze avoidance, social avoidance, and inappropriate modulation of social behavior (see Osterling & Dawson, 1994; for review Adolphs, 2010; Amaral, Bauman, & Schumann, 2003).

Age-Related Changes in Other Brain Regions in Autism

The Cerebellar Hemispheres and Vermis

The first hypothesis that cerebellar abnormality might play a part in autism was based on the recognition of its complex and important involvement in numerous functions known to be deficit in autism (Courchesne, Yeung-Courchesne, et al., 1988). As with anatomical studies of the cerebrum in autism, studies of the cerebellum and its subregions and output pathways highlight a major topic in MRI studies of autism: the potential for different patterns of growth across development in different regions within a larger structure. As mentioned above and highlighted by Courchesne et al. (Courchesne, Karns, et al., 2001), overall brain and cerebral volumes in individuals with autism peak early in development, potentially suggestive of aberrant excessive early growth with later slowing of growth during middle childhood and adolescence. Yet, within the cerebrum, some regions display this early overgrowth, while others do not (see Figure 35-7). Similarly, studies of the cerebellum also may be extremely sensitive to age-related factors, with potentially differing patterns of growth within the cerebellar hemispheres and the cerebellar vermis.

Overall cerebellar enlargement has been reported in autistic toddlers and young children (Courchesne, Karns, et al., 2001; Webb, Sparks, et al., 2009), but this enlargement may be related to cerebellar white matter, as 2- to 3-year-olds with ASD show volumes much larger than controls. Suggestive of atypical later growth, in one study (Courchesne, Karns, et al., 2001), increases in cerebellar white matter from 2–3 years to 12–16 years was only 7% in the ASD group as compared to 50% in typically developing children. Cross-sectional samples in older children are also supportive of this pattern of slowed later development resulting in volumes becoming more in-line with those seen in controls. Herbert et al. (Herbert, Ziegler, et al., 2004) found increased absolute

volume but in proportion to overall increased head size in 7- to 11-year-olds (also see Kates, Burnette, et al., 2004 for 5- to 13-year-olds); in contrast, in slightly older samples, McAlonan et al. (McAlonan, Cheung, et al., 2005) found reduced white matter bilaterally in the cerebellum in children aged 8–14 years (also see Boddaert, Chabane, et al., 2004 for children 7–15 years) (see Figure 35-10).

In contrast to the development of the cerebellar hemispheres, analyses of the vermis suggest that some of its subregions are disproportionately smaller in young children with autism and remain so throughout the lifespan (e.g., Figure 35-10). One of the first quantitative MRI studies of autism targeted the superior posterior vermis (i.e., neocerebellar vermis lobules VI–VII) for quantitative analyses and found hypoplasia of this cerebellar subregion in a subset of autistic patients (Courchesne, Yeung-Courchesne, et al., 1988). Because MRI methodology and analytic approaches at the time were underdeveloped, several studies that attempted to replicate the discovery failed due to methodological and statistical errors. In more recent years, however, newer studies with higher quality methodologies, stronger analytic approaches, and larger sample sizes have reported that the vermis is indeed reduced in

Figure 35–10. Changes in cerebellar volume and vermis lobules VI-VII size from infancy to adulthood in ASD. Percent differences from normal average in each study for autistic subjects are plotted for cerebellar volume (bold numbers) and vermis lobules VI–VII cross-sectional area (grey numbers) against age. Regression lines are shown for cerebellar volume (dotted line) and vermis lobules VI–VII area (dash line). The solid line represents normal average. Data originated from: (1) Hashimoto et al., 1995; (2) Courchesne et al., 2001; (3) Akshoomoff et al., 2004; (4) Webb et al., 2009; (5) Carper et al., 2000; (6) Kleiman et al., 1992; (7) Kaufmann et al., 2003; (8) Kates et al., 2004; (9) Mitchell et al., 2009; (10) Herbert et al., 2003; (11) Elia et al., 2000; (12) Cleavinger et al., 2008; (13) Ciesielski et al., 1997; (14) Hardan et al., 2001; (15) Piven et al., 1992; (16) Hallahan et al., 2009. Asterisk is from the first report of hypoplasia of vermis lobules VI–VII In autism (Courchesne, Yeung-Courchesne, et al., 1988).

size in autism (Kates, Mostofsky, et al., 1998; Carper & Courchesne, 2000; Courchesne, Karns, et al., 2001; Sparks, Friedman, et al., 2002; Kaufmann, Cooper, et al., 2003; Webb, Sparks, et al., 2009; Scott, Schumann, et al., 2009) for meta-analysis and review see (Stanfield, McIntosh, et al., 2008). Specifically addressing early autism, Webb et al. (Webb, Sparks, et al., 2009) found that total vermal areas were disproportionately smaller in children aged 3–4 years with ASD; when children with ASD were compared to children with developmental delays (age- and mental age–matched), the groups demonstrated similar smaller total vermal areas compared to chronological age–matched controls. Examining the development of the vermal areas, (Hashimoto, Tayama, et al., 1995), with a sample of 102 individuals with ASD from 6 months to 20 years, found that total vermal area was smaller in autism than controls but increased with age in a manner similar to controls.

One region within the vermis, however, has not shown the same consistency. Specifically, the anterior vermis (i.e., paleocerebellar vermis lobules I–V) in children with ASD has been found to be normal in 3- to 16-year-olds (Courchesne, Karns, et al., 2001), increased in 1.9- to 5.2-year-olds (Akshoomoff et al., 2004), and decreased in 3- to 4-year-olds (Webb, Sparks, et al., 2009). Hashimoto et al. (Hashimoto, Tayama, et al., 1995) also found that the anterior vermis was generally smaller during infancy and early childhood in ASD, but the regression slope was significantly steeper in early life in the ASD group than in the control group, suggesting that the size of this region "catches up" to typically developing individuals.

More consistently, the superior posterior midsagittal vermis (lobules VI–VII) has been found to be about 12% smaller in autistic as compared to typical subjects (Figure 35-10; Courchesne, Yeung-Courchesne, et al., 1988; Courchesne, Saitoh, et al., 1994; Hashimoto, Tayama, et al., 1995; Kates, Mostofsky, et al., 1998; Carper & Courchesne, 2000; Courchesne, Karns, et al., 2001; Kaufmann, Cooper, et al., 2003; Akshoomoff, Lord, et al., 2004; Webb, Sparks, et al., 2009). This pattern of decreased superior posterior vermis area may be a general anatomical finding associated with ASD, consistent with the results of older meta-analyses, which noted that between 84% and 92% of individuals with ASD exhibited vermal hypoplasia (Courchesne, 1997), and with a more recent meta-analysis of all MRI studies of this vermis subregion in autism (Stanfield, McIntosh, et al., 2008). Hashimoto (Hashimoto, Tayama, et al., 1995) found that the regression slope was significantly steeper especially during infancy and toddler years in the ASD group than the control group, again suggesting that the size of this subregion "caught up" to typically developing individuals (also see Stanfield, McIntosh, et al., 2008). In contrast, Courchesne et al. (Courchesne, Karns, et al., 2001) did not find age-related changes in autism in this vermis subregion across ages 2–16 years. Hashimoto, Tayama, et al. (1995) was the first quantitative MRI study to examine a substantial number of ASD infant and toddler patients as well as young children, preadolescents, and adolescents, potentially suggesting that the inclusion of data from the early period of autism onset may change our

understanding of the slope of neuroanatomic growth in this disorder. It will be important in future work to include sample sizes that will allow more sophisticated modeling of the growth associated with this vermis subregion.

Lastly, the inferior posterior vermis (vermis lobules VIII–X, which includes both paleocerebellum and vestibulocerebellum) has been found to be both decreased (Hashimoto, Tayama, et al., 1995; Levitt, Blanton, et al., 1999) and normal (Webb, Sparks, et al., 2009). Hashimoto et al. (Hashimoto, Tayama, et al., 1995) found this region to remain smaller across development, thus suggestive of little catch-up growth.

Why might there be differences in age-related growth in different vermis subregions? The enormity and diversity of afferent and efferent tracts, which connect neocerebellar, paleocerebellar, and vestibulocerebellar regions of both cerebellar hemispheres and vermis to brainstem, limbic, and neocortex regions likely results in multiple critical periods of circuitry formation (also see Hashimoto, Tayama, et al., 1995). This is supported by results from diffusion tensor imaging of the cerebellum in autism that indicates impairment in white matter microstructure in the cerebellar peduncles and intracerebellar fibers (Catani, Jones, et al., 2008; Brito, Vasconcelos, et al., 2009) resulting in alterations in intracerebellar circuitry. Abnormal functional connectivity between the cerebellum and frontal cortex in autism was also suggested by Carper and Courchesne (2000) based on evidence of an inverse relationship between frontal lobe size and cerebellar vermis measures.

Cerebellar abnormalities in autism have important implications for understanding many behavioral deficits in this disorder because the cerebellum plays a role in a wide range of functions including timing and coordination of movement, learning of complex motor skills, evaluation of the match between intention and action, providing feedback information to adjust the operations of the cortex and brain stem, motor learning, predictive learning, exploration of the environment and objects, behavioral inhibition, attention, and visual orienting. More specifically, the cerebellar vermis has been associated with modulation of limbic functions including emotion and sensory reactivity and salience detection, while the cerebellar hemispheres have been linked to numerous higher-order cerebral functions including language, working memory, planning, and behavioral sequencing (e.g., Courchesne & Allen, 1997; Steinlin, 2008; Stoodley & Schmahmann, 2009a, 2009b). It has been argued that the cerebellum is one of the single busiest neural intersections in the brain, receiving signals from and sending signals back to nearly every major neural system (Courchesne & Allen, 1997). In neurologically typical individuals, larger cerebellum size is correlated with better neurophysiological functioning, including memory, fine motor dexterity, and IQ (Andreasen, Cizadlo, et al., 1993; Paradiso, Andreasen, et al., 1997). In a recent functional connectivity study using fMRI methodology ("rs-fcMRI") in normal adults, Greicius et al. (Greicius, Supekar, et al., 2009) demonstrated that the neocerebellum participates in several higher-order functional networks via corticocerebellar loops involved in executive control, salience detection, and episodic memory/self-reflection. They argue that the largest portions of the neocerebellum take part in the executive control network implicated in higher cognitive functions such as working memory. Especially germane to autism is a new fMRI study that shows cerebellar involvement in the early stages of development of language perception in typically developing 1- to 3-year-olds (Redcay, Haist, et al., 2008).

While the theoretical implications of abnormalities of the cerebellar hemispheres and vermis are clear, the functional relation of abnormal anatomy to behavior in ASD has been less precise, although likely due to both age-related effects and the functional specialization of different regions of the cerebellum. Specifically focusing on motor behaviors that are known to involve the cerebellum, during sequential finger tapping, 8- to 12-year-old children with ASD showed decreased cerebellar activation (ipsilateral anterior cerebellum and contralateral cerebellum lobes IV–V), increased supplemental motor activation, and decreased functional connectivity within the motor network (Mostofsky, Powell, et al., 2009). In contrast, adults with ASD during a repetitive single finger-tapping task showed decreased premotor (Muller, Pierce, et al., 2001) and increased ipsilateral cerebellar activation (Allen, Muller, et al., 2004). In relation to eye movements, regions VI–VII (occulomotor vermis) were found to be related to saccade and smooth pursuit function in adults with autism (Takarae, Minshew, et al., 2004). Deficits in rapidly orienting visual spatial attention are associated with smaller vermal lobes VI–VII in ASD adults (Townsend, Courchesne, et al., 1999) and are predictive of later orienting deficits in ASD children (Harris, Courchesne, et al., 1999). Cerebellar volume has been related to performance IQ in 8- to 26-year-olds with ASD (Cleavinger, Bigler, et al., 2008). Pierce and Courchesne (2001) found that reduced vermal lobe VI–VII area in 3- to 7-year-old children was associated with less active exploration and more repetitive movements. Webb et al. (2009) did not find any relation between more general indices of symptom severity, IQ, or adaptive functioning and vermal area or cerebellum volume in 3- to 4-year-olds with autism (also see Harris, Courchesne, et al., 1999). In children aged 6–14 years, white matter abnormalities (as measured by fractional anisotropy using DTI) were found to be associated with repetitive behaviors assessed via the ADI (Cheung, Chua, et al., 2009); in adults, fractional anisotropy in the superior cerebellar peduncles was associated with social behaviors via the ADI (Catani, Jones, et al., 2008). Kates et al. (Kates, Burnette, et al., 2004) also found that cerebellar white matter, specifically the discrepancy in volume between twins, was associated with discrepancies in the twins' ADOS scores. Adults with ASD and psychosis compared to adults with ASD (without psychosis) also showed a reduction in grey and white matter volume in the cerebellum (Toal, Bloemen, et al., 2009).

What is the underlying neuropathology of cerebellar structural and functional abnormalities in autism? Postmortem studies have consistently reported reduction in the number of a vital type of cerebellar neuron, the Purkinje neuron, in the hemispheres and vermis in the majority of autism cases

(Bailey, Luthert, et al., 1998; Kemper & Bauman, 1998; for review Allen et al., 2005). Reduction in Purkinje numbers in autism is strikingly evident because these cells normally form a very distinctive monolayer (layer 2) within the 3-layer cerebellar cortex. In addition to being reduced in number, Purkinje neurons that do remain have, in some cases, abnormal morphological features. Degenerating Purkinje neurons have also been reported (Vargas et al., 2005), and new evidence shows that the reduction in number is not due to reduction in Purkinje genesis or abnormal migration during development, but instead is due to later loss of previously present Purkinje cells (Whitney et al., 2009). The amount of Purkinje cell loss varies widely across postmortem autism cases from extreme to little or none (Whitney, Kemper, et al., 2008). With the exception of very small focal sites of cerebellar cortical malformation in one postmortem autistic case (Lee, Martin-Ruiz, et al., 2002), gross cerebellar malformation does not appear to occur in autistic postmortem cases, unlike many other neurodevelopmental disorders of the cerebellum (Bolduc and Limperopolus, 2009).

Because Purkinje neurons are the *only* output from the cerebellar cortex (which when unfolded is about three quarters the size of the cerebral cortex), massive loss of Purkinje neurons effectively disconnects this huge and important multifunction processing structure from the rest of the brain. Purkinje neurons exert inhibitory control over deep cerebellar nuclei, and so their loss could cause unregulated and excessive excitatory signaling from the deep nuclei to brain stem, limbic, and cerebral structures. Interestingly, there has been one report observing what appear to be hypertrophied neurons in the deep nuclei in younger autism cases but then abnormally small deep neurons in older autism cases (Kemper & Bauman, 1998). This has raised the hypothesis that initially loss of Purkinje neuron inhibitory signals allows deep nuclei to be abnormally excitable stimulating abnormal growth but continued unregulated and aberrant activity eventually triggers synapse and process elimination in these same cells (Courchesne, Townsend, et al., 1994; Carper & Courchesne, 2000; Allen, McColl, et al., 2005). The combination of loss of this important processing system plus the injection of disruptive excitatory signals likely contributes to the abnormal functioning of limbic and cerebral systems (Allen, Buxton, et al., 1997; Courchesne & Allen, 1997).

The difficulty in establishing precise cerebellar-behavior and cerebellar-autism symptom correlations is due to the absence of studies mapping the distribution of Purkinje neuron loss in autistic cerebellar cortex. Like the cerebrum, the cerebellum has a complex functional representational map. Therefore, in the absence of quantitative and statistical information about precisely which functional locales have Purkinje loss, cerebellar-behavior and cerebellar-symptom correlations in autism will remain a challenge to establish.

The etiology of cerebellar abnormality in autism, including the age when Purkinje neuron loss begins, is largely unknown, although important clues have emerged recently. Of note, work has implicated engrailed 1 and 2 (EN1 and EN2) as potential candidates for cerebellar pathology in humans as well

as in mice (e.g., Millonig, Graziadei, et al., 2004); human EN2 maps to a region of chromosome 7 that has been linked to ASD (e.g., Gharani, Benayed, et al., 2004); and the EN2 mouse mutants display cerebellar anatomical abnormalities that are similar to those seen in autism, such as reduced number of Purkinje cells (Millen, Wurst, et al., 1994; Kuemerle, Gulden, et al., 2007) and mild behavioral problems such as reduced exploratory behaviors (Cheh, Millonig, et al., 2006) similar to the findings of Pierce and Courchesne (2001). In addition, like the autistic cerebellar cortex, the cortex in the EN2 mouse model retains its basic 3-layer form despite the Purkinje neuron loss. The loss in the EN2 mouse occurs after Purkinje neurogenesis and early stages of cerebellar corticogenesis. In fact, in the EN2 mouse, Purkinje loss occurs after the first week of postnatal life. Such observations in various developmental cerebellar mouse models raise the question of whether Purkinje neuron loss in autism also occurs during the first years of life. While the Whitney et al. (2009) study indicates that reduction in Purkinje numbers in autism is due to secondary loss (and not to reduced developmental neurogenesis), the youngest case in that study was 19 years. However, except for a single case report of a 4-year-old autistic boy with no loss of Purkinje cells (Bailey, Luthert, et al., 1998), there is a lack of information about whether Purkinje loss is occurs in the very young autistic brain. Thus, the age when Purkinje loss begins in autism is unknown and, so, there is a need for quantitative stereological studies of Purkinje neuron numbers in the youngest autistic cases. Since MRI abnormalities in autism vary with cerebellar subregion and age, stereological studies would need to quantify Purkinje numbers separately in each of the vermis and hemisphere subregions and statistically test for age effects.

A second genetic link may be MET (transmembrane receptor tyrosine kinase of the hepotocyte growth factor/scatter factor), which is suppressed in the developing nervous system and implicated in neuronal development in the cerebellum (Ieraci, Forni, et al., 2002) and has been implicated in genetic analyses of 7q in autism families (IMGSAC, 1998; Sousa, Clark, et al., 2009). Another possibility is that Purkinje neuron loss in the cerebellum may result from neuroinflammatory reactions (i.e., neuroglial activation) associated with activation of the CNS immune system in the cerebellum (Vargas, Nascimbene, et al., 2005). In mouse models, prenatal viral infections result in dysregulation of myelin associated genes in the cerebellum (Mytl1, MAG, MAL, MBP, MobP, MOG), which leads to alterations in fractional anisotropy in the white matter of the cerebellum (Fatemi, Reutiman, et al., 2008; Fatemi, Folsom, et al., 2009).

Regions Less Studied During the Early Years of Development: Hippocampus, Thalamus, Brain Stem, Basal Ganglia

The investigation of other subcortical regions beyond the amygdala that may be affected in autism is limited. There is evidence of abnormalities in the hippocampus (though somewhat inconsistent), including increased volume in young

autistic children 3–5 years of age (Sparks et al., 2002) and older children and adolescents (Schumann, et al., 2004), decreased cross-sectional area of the dentate gyrus (Saitoh et al., 2001) in autism subjects from 2 to 42 years of age, and more recently in atypical shape (Nicolson, DeVito, et al., 2006; Dager, Wang, et al., 2007). There is little evidence for abnormalities in the thalamus (Tsatsanis, Rourke, et al., 2003; Hardan, Girgis, et al., 2006; Hardan, Girgis, et al., 2008; Hardan, Minshew, et al., 2008) and inconsistent findings of either no difference or decreased brain stem gray matter volume in adults with autism (Hsu, Yeung-Courchesne, et al., 1991; Jou, Minshew, et al., 2009). There are currently no studies of thalamic or brain stem volume in very young children with autism.

The most interesting findings of these regions come from studies of the basal ganglia (Sears, Vest, et al., 1999; Hardan, Kilpatrick, et al., 2003; Hollander, Anagnostou, et al., 2005; Rojas, Peterson, et al., 2006; Langen, Durston, et al., 2007; Hazlett, Poe, et al., 2009) which have consistently found an increased caudate nucleus volume in adolescents and young adults with autism. These studies also suggest that an enlargement of the caudate nucleus may be correlated with the presence of repetitive and ritualistic behaviors (Sears, Vest, et al., 1999; Hollander, Anagnostou, et al., 2005; Rojas, Peterson, et al., 2006), although this has yet to be explored in young children with autism.

The Corpus Callosum

In the only MRI study of the corpus callosum in very young autistic children, *no* difference from normal was seen (Boger-Megiddo, Shaw, et al., 2006). The 3- to 4-year-old autistic children in this callosal study were from the same sample for whom abnormal enlargement of the cerebrum had been previously reported (Sparks, Friedman, et al., 2002). Not surprisingly, then, the ratio of the callosum to cerebrum in those autistic children was less than typical children, raising the question of whether cerebral enlargement was at the expense of a normal callosal connectivity or due to defects not directly related to callosal development. Clearly, additional studies of corpus callosum development during the first years of life in autism are needed. Because abnormal left-right asymmetry in fMRI and EEG activation patterns in very young as well as older autism subjects is commonly reported especially in studies of language processing (e.g., Redcay & Courchesne, 2008), it is possible that this abnormality of hemispheric specialization emerges from abnormal organization, size, or functioning of callosal axons.

In contrast, since the first MRI report of callosal reduction in autism (Egaas, Courchesne, et al., 1995), the great majority of subsequent studies of the callosum in older autistic children, adolescents, and adults have also found reductions in overall callosum size or in the size of specific callosal subregions (Piven, Bailey, et al., 1997; Manes, Piven, et al., 1999; Hardan, Minshew, et al., 2000; Chung, Dalton, et al., 2004; Vidal, Nicolson, et al., 2006; Alexander, Lee, et al., 2007). A few have found no abnormality (e.g., Rice, Bigler, et al., 2005). Nonetheless, the callosum may be one of the more consistent sites of anatomic abnormality in the autism literature.

Hardan et al. (Hardan, Pabalan, et al., 2009) provide a comprehensive overview and meta-analysis of the corpus callosum in autism. Their analyses examined ten studies representing 253 autistic and 250 control subjects with mean ages across studies ranging from 10 to 27 years (except for the Boger-Megiddo, Shaw, et al., 2006). Results showed overall reduction in callosal size in autism across those ages. Callosal subregions that convey frontal and temporal axons, according to lesion-based (Moses, Egaas, et al., 2000) and DTI-based (Hofer & Frahm, 2006) studies, had the most reduction; callosal subregions that primarily convey occipital and parietal axons had the least. This pattern of greater anterior and lesser posterior callosal pathology parallels the distribution of early cortical gray matter overgrowth pathology in autism, with frontal and temporal cortices being most abnormal in this disorder.

Ideally, future autism studies would analyze data on the size of callosal subregions, DTI values in those same subregions and gray matter in specific cortical subregions all in the same autistic subjects during the first years of life when callosal growth, axon pruning and change is at a peak in normal children.

Functional Implications of Early Brain Overgrowth

Because of the extensive connectivity of the brain, disruption of the rate of growth in frontal, temporal, and amygdala structures has wide implications for connectivity in other regions. Abnormalities in brain growth in autism may be best characterized by an aberrant gradient of growth, with early atypical (broad based) acceleration of growth represented generally by increased brain, frontal lobe, temporal lobe, and amygdala volumes, and then a plateau or slowing of continual growth represented generally by volumes in abnormal regions normalizing in later childhood or adolescence. Thus, the slope of growth may be of critical importance in this disorder.

If development is represented by a pattern of change from variability to consolidation, this might be reflected in a more diverse neural response (anatomically and temporally) that becomes localized and efficient (or even automated). Development and learning result from a more consistent neural response with a greater signal relative to noise. Infants and toddlers at risk for autism may fail to show this pattern both anatomically and behaviorally. For example, the early phase of brain overgrowth occurs at a time when language should be both consolidating and expanding, represented by increased expertise for the child's own language, loss of the ability to distinguish nonnative language sounds, and concurrent with expression moving from babbling to functional single word production. Language may be critically disrupted by the early phase of overgrowth such that stable, functional circuits do not arise from the noise. That is, regions that should be engaged in ongoing pruning and stabilization of functional circuits may be overwhelmed with the growth of novel circuitry resulting in greater noise relative to signal.

This period of overgrowth seems to "end" in early childhood for children with autism, although specific timing

is unknown and may differ by region, and is followed by relatively slowed growth over childhood and adolescents. This may also result in less opportunity for plasticity and responsive cortical tuning. That is, later in development, stable circuits are available, but these may be less functional circuits, represent earlier learning patterns, provide less flexibility in learning, and result in greater rigidity in the system. Potentially, differences in symptom trajectory, such as during childhood when many children make positive intellectual growth or adolescence where symptoms seem to worsen, may reflect the influence of this slowed growth period on short-term and long-term outcome.

A Sea Change In Biological Research On Autism

The above evidence shows three major discoveries in the past decade from autism MRI research: (1) early brain overgrowth occurs in autism in the first postnatal years and is most pronounced in frontal and temporal lobes and the amygdala, (2) the age of maximum MRI anatomic abnormality in autism is at this early age, and (3) MRI anatomic effects change with age requiring findings on autism to be organized and interpreted according to age. Given that overgrowth clearly begins before 2 years of age, future longitudinal studies would benefit from inclusion of infants and toddlers at-risk for autism.

This suggests that studies of autism at the youngest ages have the best chance of revealing the original biological bases of autism. Clearly, early biomarkers of risk for autism, diagnosis, prognosis, and treatment outcome will most likely come from studies of the youngest ages and not from studies of older subjects. Discovery of effective interventions addressing original neural and functional defects are also most likely to emerge from studies of autism during these early years of initial brain growth pathology.

The discovery of arrest of growth and possible premature decline is vital for all types of biological studies, especially those involving older autistic children and adults, to consider. This new phenomenon signals significant changes in underlying genetic and nongenetic factors and molecular mechanisms as well as changes in the pattern of neural circuits and their functioning. It could be an indication of changes in survival of neurons, connections, and synapses. This second stage of pathology in autism may reflect reactive changes in response to the original upstream defects that produce autism. As such, studies of older children and adults with autism are forewarned that abnormalities detected at that age could reflect this second stage of pathology. Therefore, theories of the possible causes and brain and behavioral bases of autism derived from older subjects should be considered with considerable caution.

The striking early brain growth changes in autism signal the need for a sea change in autism biological research. Autism is a disorder of early brain maldevelopment, and the best opportunity to identify the biology that causes it is at the youngest ages when the abnormality is first occurring and at

its maximum expression. Even studies of the genetics of autism may benefit from this change in approach. That is, even though autism is understood to be a highly heritable disorder, the genes and genetic pathways involved have been elusive and a deeper guiding principle of the genetics underlying autism has yet to emerge. Instead, it sometimes appears that each new and larger genetic study of autism has challenged previous reports and introduced new candidate genes, genetic functions, and/or loci. Perhaps a different and more powerful approach to the genetic study of autism would employ early biological as well as behavioral phenotypic profiles.

Challenges And Future Directions

Future challenges include the following:

- establishing the underlying cellular, molecular, and genetic bases of early brain overgrowth and functional abnormalities in autism;
- defining the timing of aberrant growth and its specificity to autism outcomes; and
- characterizing the relationship between regional maldevelopment and formation of abnormal functional connectivity.

Autism as a Developmental Neurobiological Disorder: New Insights from Functional Neuroimaging

⊞
Points of Interest

- A paradigm shift in autism research, involving conceptualizing the syndrome as a developmental *neurobiological disorder* rather than a behavioral disorder, is critical to reconcile a gulf between behaviorally oriented researchers, clinicians, geneticists, and developmental neurobiologists and to address the most pressing questions about the etiology, brain bases, and effective treatments for autism spectrum disorders (ASD).

- A developmental neurobiological approach emphasizes a search for the underlying brain mechanisms when examining the manifestations of a disorder, which includes *both* the pattern of deficits as well as intact, or even enhanced, abilities and "associated signs and symptoms."

- An emerging body of genetic, functional and structural neuroimaging, and behavioral work suggests that defects in early neuronal organizational events during brain development disrupt the *connectivity of neural systems*.

- There appears to be a trade-off such that there is enhanced local neural connectivity, leading to preserved and potentially enhanced elementary information processing abilities, and disrupted connectivity among more distributed and integrative regions of the brain at the systems level, which leads to a deficit in complex information processing across multiple domains of functioning.

- Our investigations into the psychological mechanisms of visual processing in autism reveal relative preservation (and perhaps even enhancement, on some accounts) in more elemental, simple, or featural processing, whereas information processing that requires the integration of the simple elements is disproportionately affected. The imaging data yield a similar profile: relative preservation of earlier parts of the visual system and more pronounced atypical activation in higher-order regions.

These alterations have a profound impact on how the brain in autism processes information and, in turn, how individuals with autism "see" the world differently.

With the first evidence of neurologic dysfunction in autism spectrum disorders (ASDs) in the 1950s and 1960s, there have been "neurobehavioral" theories were proposed to explain autism. These early theories typically focused on a behavioral feature of the syndrome and then inferred its relation to a localized region of the brain. These behavioral symptoms, or neurobehavioral deficits, were posited to be causally related to all other manifestations for the entire syndrome. These kind of localized region and single primary deficit theories for the cause of autism dominated the field for nearly 70 years, despite the recent structural and functional imaging evidence implicating widespread involvement of the cerebral cortex and associated white matter, and disruptions to functional neural systems. Importantly, this historical approach was not informed by an understanding of developmental neurobiologic events, particularly neuronal organizational events, in the developing brain, nor of knowledge about how disease processes affect the developing brain. As a result, there exists a conceptual and pragmatic gulf in autism research between 1) behaviorally oriented researchers and clinicians, who attempt to identify a causative feature of the syndrome that is anchored to impaired behavior, and 2) geneticists and developmental neurobiologists, who study genetic risk factors linked to disruption in neuronal organizational events.

In this chapter, we argue that a paradigm shift is critical to the study of autism in order to reconcile this gulf and address the most pressing questions about how genetic and developmental neurobiological findings can be integrated with findings about the characterization of the behavioral syndrome, which has become increasingly well defined in the last few decades. We propose that this paradigm shift involves conceptualizing autism as a *developmental neurobiological disorder* rather than a behavioral disorder when considering its

cause(s). The benefit of this approach is that it is informed by an understanding of basic principles of neurological disorders, including the notions that such disorders do not result in single primary deficits, that they typically have a genetic basis, and that, when they are nontraumatic or arise de novo, as in the case of ASDs, they are multiorgan system disorders. This approach also emphasizes a search for the underlying brain mechanisms when examining the manifestations, which includes *both* the pattern of deficits as well as intact, or even enhanced, abilities and "associated signs and symptoms." An emerging body of genetic, functional and structural neuroimaging, and behavioral work suggests that a potential underlying brain mechanism in autism is a disruption in the *connectivity of neural systems*. More specifically, due to defects in early neuronal organizational events, there may be a systematic trade-off between enhanced local neural connectivity within posterior and perhaps frontal regions of the brain, leading to preserved and potentially enhanced elementary information processing abilities, and disrupted neural connectivity among more distributed regions of the brain at the systems level, which may lead to a deficit in complex information processing across multiple domains of functioning. We review the evidence suggesting that a disruption in neural connectivity is fundamental in autism. Also, we highlight our own findings, particularly in the domain of visual processing, to illustrate the strength of our interdisciplinary approach that seeks to integrate and correlate genetic, neurobiological, and behavioral findings to understand the etiology, brain bases, and effective treatments for the complex disorder of ASD.

The chapter is organized as follows. First, we provide a brief review of the current "neurobehavioral" theories of autism. Second, we challenge these theories by reviewing current evidence, particularly from longitudinal studies of infants at high risk for developing autism, which challenges the notion of a single causative behavioral or cognitive feature of the syndrome or even a cluster of core causative behavioral or cognitive features. Third, we propose that research on ASDs would benefit enormously from taking the perspective that autism is a developmental neurobiological disorder, rather than a behavioral or single systems disorder. In this section, we describe the principles of neurologic disorders, the neuropsychological profile of autism, potential neural mechanisms of ASDs, including disruptions to neuronal events that fundamentally organize cortical systems during brain development, and the genetic factors that predispose individuals who go on to develop autism and are linked to disruptions in these early neuronal events. The key concept of this section is to demonstrate how this neurological approach to the study of autism leads directly to the search for underlying *brain mechanisms*, as opposed to behavioral phenotypes, that result in both the pattern of deficits and the intact abilities that are observed in ASD as well as the associated signs and symptoms of "comorbid disorders." Third, we review the evidence that a disruption in the connectivity of neural systems resulting from a disturbance early in neuronal organization is a likely candidate for such an underlying brain mechanism. Finally, we describe

our program of research in the domain of visual processing that illustrates the strength of this interdisciplinary approach to uncover novel relations between the behavioral and brain bases of autism and that supports our claim that disruptions to neural connectivity are a fundamental contributing factor to the etiology of autism.

"Neurobehavioral" Theories of Autism and Challenges to Such Theories

The predominant single deficit models at present are the social primacy theories (e.g., Schultz, 2005; Klin et al., 2002; Dawson, 2008), and their alternative, the dimensional approaches (Happe & Ronald, 2008). The social primacy theories postulate that a social impairment comes first in time and is of sufficient severity to be viewed as causative of subsequent deficits, which are thus viewed as secondary to the social impairment. According to this model, autism is primarily, if not solely, a social-communication disorder both in terms of early etiological events and in terms of later presentation.

The dimensional hypotheses were proposed after investigators failed to find satisfactory evidence of a single or even a triad of primary deficits to account for the clinical syndrome, and hypothesized a cluster of independent core symptoms/signs that co-occur in autism but that are independently inherited (e.g., central coherence, theory of mind, executive function, repetitive behavior; Happe et al., 2006). These investigators tested their hypotheses by assessing typical populations for evidence of autism traits to ascertain their occurrence independently or in association with each other (Happe & Ronald, 2008; but see also Constantino et al., 2004).

Notice that both of these classes of "neurobehavioral" theories primarily focus on a functional analysis of *problematic behavior*. In other words, the central goal of these theories is to examine behavior to understand the cause of the disorder. A significant drawback of this approach is that focusing on describing an underlying mechanism is based on the behavioral impairments that present most severely, which may actually overestimate their significance in the etiology of the disorder. Furthermore, this approach does not emphasize an understanding of the abilities that are selectively preserved and even enhanced in the disorder. Our early work hinted that there are significant challenges to this approach and that the search for underlying brain mechanism(s) in autism must include an investigation of the profile of impaired *and* intact abilities.

Neuropsychological Studies Challenging Single Deficit and Dimensional Theories of Autism

Our initial approach to the investigation of autism was to pursue a comprehensive definition of the profile of functioning across all major neuropsychological domains, not just those that present with impairments in ASDs (Minshew et al., 1992; Minshew et al., 1997). We studied 33 individually matched pairs

of adolescents and adults with and without high-functioning autism (HFA), and assessed a broad range of abilities within each domain from the most basic to higher-order skills. Our original hypothesis was that the brain dysfunction causing autism diffusely and symmetrically involved altered development of connections with association cortex. We therefore proposed that higher-order abilities across multiple domains would be selectively affected. For this reason, elementary and higher-order abilities in all domains were assessed. At the time, there were some proposals of primary deficits in basic skills like elementary sensory perception, various aspects of attention, and basic associative memory abilities (see Minshew et al., 1997, for review of early theories). Assessments of nonverbal language and social abilities were not included in this study, since tests of these abilities in verbal individuals were not widely available at that time.

We found deficits across a number of domains, which enabled us to describe a broader pattern of deficits than had been previously reported in autism. The results revealed deficits in: skilled motor movements, higher cortical sensory perception, memory for material that required use of an organizing strategy or identification of an organizing strategy, higher-order language meaning, and concept formation. Notice that we identified deficits in several affected domains that were not previously considered to be integral parts of the autism syndrome, including aspects of the sensory-perceptual, motor, and memory domains. Hence, the evidence suggested that autism affected the brain far more generally than the single deficit and dimensional theories indicated. We also reported evidence of intact and sometimes enhanced abilities across multiple domains, including attention, elementary motor abilities, elementary sensory abilities, basic associative memory abilities, formal language skills (vocabulary, spelling, fluency, decoding), and the rule-learning aspects of abstraction. Again, unlike any previously reported findings, we observed enhanced skills and impaired abilities within the same domains (e.g., language). We have since completed an additional study with a younger sample of 56 children with autism and 56 controls that replicated this pattern of results with appropriate developmental modifications in the abstract reasoning domain (Williams, Goldstein, & Minshew, 2006).

Finally, we also evaluated single deficit theories about the role of cerebellar dysfunction in autism. We performed a study of postural control in 79 individuals with autism and 61 typical controls between 5 and 52 years. We observed delayed maturation of postural control and failure to achieve adult levels (Minshew, Sung, Jones, & Furman, 2004). The impairments were related to inadequate multimodal sensory integration across vestibular, visual, and position senses by the brain. There was no evidence of a cerebellar or motor contribution to postural instability in autism. These findings reinforced the notion that autism impacts neural connectivity and information integration very broadly and provided further evidence for the need to reconceptualize autism to accommodate these findings.

We were able to draw several conclusions from this constellation of findings. First, in all domains that we tested, the deficits were not in the acquisition of information as reflected in intact performance on multiple measures of attention, elementary sensory perception, and associative memory. In fact, we found that more elementary skills in each of these domains were intact or enhanced. Instead, the deficits selectively involved the most demanding aspects of information processing within each domain. Because the subjects were matched on gender, age, and IQ scores, this pattern of results indicated that the individuals with autism were unable to perform the more challenging tasks that might have been predicted based on their age and IQ scores and on their enhanced performance on the simpler tasks. We argued that this pattern of impairments and preserved abilities could be summed up as follows. First, the abilities that placed the highest demands on information processing or integration within the affected domains were most likely to be impaired, and the domains with the most prominent symptoms (concept formation, thematic and idiomatic language) were those that had the highest information processing demands. Hence, we proposed that the common denominator of the impaired abilities was the higher-order or "complex" information processing demands. Second, the abilities that were most likely to be preserved required elementary information processing demands (see Minshew, Webb, Williams, & Dawson, 2006, for detailed explanation). In sum, our early work challenged the "neurobehavioral" theories of autism primarily on the basis that they could not account for the comprehensive pattern of both deficits and intact aspects of the disorder both within and across multiple domains.

Beyond the Neuropsychological Profile of Autism

Our characterization of autism, based on all the neuropsychological testing, was that its manifestations reflected a disorder of information processing that disproportionately impacted complex information processing while preserving, or even enhancing, elementary information processing skills. This led to a novel hypothesis that we should observe an inverse relation between the impairments and the intact abilities at a neurobiological level as well (Kuschner, Bodner, & Minshew, 2009; Damarla et al., 2011).

We then began to investigate difficulties in information processing as a general construct. We pursued two lines of research. Because concept formation appeared common to impairments in conceptual understanding, cognitive memory, story theme creation and detection, and face recognition (in the sense of the requirement to integrate information for configural processing), we explored concept formation extensively. This line of research led to forays into the development and maturation of object categorization, the development of face identity and emotion recognition, and later the study of the emergence of these abilities in infants at high risk for autism (e.g., Best et al., 2010; Gastgeb et al., 2009; Gastgeb et al., 2006; Gastgeb et al., 2011; Humphreys et al., 2007; Iverson & Goldin-Meadow, 2005; Iverson & Wozniak, 2007; Newell et al., in press; Rump et al., 2009; Scherf, Behrmann, Minshew, & Luna,

2008). The second line of research focused on the area of visual information processing and used microgenetic techniques and fMRI studies to carefully investigate information processing in children, adolescents, and adults with autism (e.g., Behrmann et al., 2006; Hasson et al., 2009; Humphreys et al., 2008; Scherf, Luna, Kimchi, Minshew, & Behrmann, 2008; Scherf, Luna, Minshew, & Behrmann, 2010). Throughout this research program, we have considered how the profile of results implicates neurobiological mechanisms of brain development that could lead to atypical cortical specialization and a proclivity to use local rather than distributed representations for information processing. This approach was novel in the way we extended the definition of the syndrome to the neurologic realm and framed the issue in terms of information processing and integration, which was readily translatable to mechanisms within the brain and neural systems.

However, our findings were somewhat limited in the sense that they were conducted in children, adolescents, and adults, in whom a significant amount of brain and behavioral development had occurred. Given that ASDs are a developmental disorder first manifest in the first two years of life, it was critical to obtain earlier developmental data to truly and fully evaluate the explanatory power of the early "neurobehavioral" theories of autism.

High Risk Infant Studies Challenge Single Deficit and Dimensional Theories of Autism

Very recently, longitudinal studies of infants at high risk for developing autism (because they have an older sibling who has already been diagnosed with autism) have provided this critical early developmental data. These studies have been able to document the earliest identifiable signs of autism as emerging between 9 and 12 months of age (Rogers, 2009). Interestingly, the earliest identifiable manifestations of autism are not in the form of a primary social impairment, as the social motivation theories had long predicted, but instead in the form of unusual responses to sensory stimuli, unusual but subtle odd motor movements, and unusual visual regard for objects (Rogers, 2009). These findings were also inconsistent with the predictions of the dimensional theories. For example, Rogers (2009) explained:

> not only the core symptoms like joint attention deficits, repetitive behaviors, and language delays appear at 12 months and grow more severe over time, but even what were previously considered secondary symptoms—irritability, sensory responsivity, activity level, and poor gross motor development, are on board, and in some cases appear well before the social problems! These findings do not support the view that autism is [etiopathophysiologically] primarily a social-communicative disorder and instead suggest that autism disrupts multiple aspects of development rather simultaneously. (p. 133)

These longitudinal studies indicate that social and language impairments, long considered the *causative* features of autism,

emerge later between 12 and 24 months. Furthermore, in some children, the diagnosis of autism could not be made until 2 to 3 years of age, when the classic symptoms and signs were obviously observable, and "it was particularly notable that disturbances in temperament, self-regulation, and hyperactivity emerged along side of these core symptoms," (Rogers, 2009).

These findings provide direct and clear evidence that there is no single primary deficit, brain region, or neural system causing autism, but also that a causative set of "core" symptoms is equally unlikely. Rather, Roger finds that autism broadly affects many abilities at the same time and systematically from its earliest presentation and continuing throughout life. This is exactly the view that we proposed previously based on our work with children, adolescents, and adults with autism (Minshew et al., 1992; Minshew et al., 1997; Williams, Goldstein, & Minshew, 2007). Additionally, the concept of associated and comorbid symptoms as representing the co-occurrence of other conditions is also clearly not supported by these data. This integrated perspective was particularly evident in the early observation of presentation of mental retardation and various regulatory disturbances in these infants and toddlers later diagnosed with autism. Rather, the evidence suggests that these conditions are part and parcel of the same disorder, resulting from atypical developmental brain processes (i.e., neuronal organizational events) that cause all the signs and symptoms of ASDs. Rogers concluded, "autism is not a disorder that profoundly affects social development from the earliest months of life. Rather, it is a disorder involving symptoms across multiple domains with a gradual onset" (p. 135).

Rogers made two more comments directly relevant to the present discussion. She noted that the high rate of autism and related manifestations in the infant siblings was striking, which supporting the importance of genetic contributions to its etiopathophysiology. To this she added that the absence of discernable behavioral manifestations at or before 6 months was likely a reflection of the limitation of behavioral measures in infants and the need for biologic measures in these early months.

Autism as a Neurological Disorder Rather Than a Behavioral Disorder

Given that there is significant evidence to discredit the notion that a single behavioral deficit, or even a core set of deficits, cause autism, we argue that a paradigm shift is critical to the study of autism. We propose that this paradigm shift involves conceptualizing autism as a *neurological and developmental neurobiological disorder* rather than as a behavioral disorder. There are several benefits of this approach, including that it is guided by an understanding of basic principles of neurological disorders, brain development, and how disease processes affect brain development. In this section, we briefly review principles of neurological disorders, the neuropsychological profile of autism, potential neural mechanisms leading to

ASDs, and the genetic contributions that may affect these neural mechanisms.

Principles of Neurological Disorders

Neurological disorders tend to conform to a common set of well known principles. First, such disorders produce a pattern or constellation of deficits and intact abilities that reflects the underlying disease mechanism. In other words, neurological disorders do not result in single primary deficits. The search for a single primary causal deficit of a neurologic disorder at the behavioral or cognitive level is not compatible with mechanisms of neurologic disease or dysfunction. Second, neurologic disorders that develop de novo (i.e., absent trauma or other injury) typically have a genetic basis. Hence, idiopathic autism is likely to have its origins in complex genetics (superimposed on the background of individual familial inheritance), as do innumerable other childhood neurological disorders that appear to have a sudden onset (e.g. see neuronal ceroid lipofuscinosis, which has three forms expressed at very different developmental time points from the first month to adolescence). Thus the work investigating genetic vulnerabilities for autism is critical for understanding the etiology of the disorder. Third, most nontraumatic neurologic disorders are *multiorgan system disorders* because they result from genetic errors that are present in all tissues in the body though not necessarily functionally expressed (Campbell et al., 2009).

To this set of core principles, we also add the concept that symptoms of a pediatric neurological disorder are expressed at a developmentally appropriate time window (i.e., when the affected skills are developing). Our characterization of the syndrome of autism is consistent with an emerging body of work that suggests that autism is largely a disorder of what neurologists call "higher cortical functions." Based on this characterization, it is to be expected that disruption in these higher-order functions becomes much more apparent in the second year of life when complex information processing abilities and their underlying neural systems are emerging.

We argue that research investigating the etiology of autism must focus on identifying aspects of the disorder that are consistent with tenets of neurological disorders. Furthermore, based on the existing work, we suggest that the focus of such an approach should be on discerning known neurological and neurobiological mechanisms for disruption to the development of higher cortical brain functions.

Developmental Neurobiologic Mechanisms and the Clinical Syndrome of Autism

ASDs are becoming increasingly recognized as developmental neurobiological disorders (Geschwind & Levitt, 2007; Minshew, Williams, & McFadden, 2008; Volpe, 2008). The notion that a disturbance in a developmental neurobiological mechanism could cause autism is consistent with early reports of truncated dendritic tree development in hippocampal neurons (Bauman & Kemper, 1994), increased brain weight in children and decreased brain weight in adults (Bauman & Kemper, 1998), and premature acceleration in head growth at 9 months followed by a plateau in growth (Dawson et al., 2007). In particular, it is likely that a developmental neurobiological mechanism that guides or regulating *neuronal organizational* event is strongly implicated in the etiology of autism.

Neuronal organizational events are described in clinical neurology texts as "the sequence of organizational events that result in the intricate circuitry characteristic of the human brain" (Volpe 2008, p. 51). In fact, autism is now described as a clinical example of a neuronal organizational disorder (Volpe, 2008). Neuronal organizational events occur between 5 months gestation and many years if not decades after birth. The neuronal laminar pattern is established by 3 years of age, and the bulk of the cortical axonal density is present by 12 years of age. "The major developmental features of neuronal organization events include the following: 1) the establishment and differentiation of subplate neurons; 2) attainment of proper alignment, orientation and layering of cortical neurons, 3) the elaboration of dendritic and axonal ramifications, 4) establishment of synaptic contacts, 5) cell death and selective elimination of processes and 6) proliferation and differentiation of glia" (Volpe, 2008, p. 82). When reviewing histologic displays of cortical neurons and images of the whole brain and cortex undergoing maturational events from 22 weeks gestation through several years postnatal age, it becomes apparent that organizational events have a widespread impact throughout the cerebral cortex, and are more symmetric than not. The cerebral cortex goes from a nearly smooth surface to a highly folded surface in the last trimester; organizational changes in the cortex and brain continue long after birth. These events are responsible for the amazing capacity of cortical neurons to send and receive innumerable connections within and between hemispheres and to ultimately form the systems level organization responsible for the many specialized functions of the human forebrain.

The aspects of brain development that have been most clearly implicated in autism are neuronal organizational events, though some cases have also implicated neuronal migration events (Strauss et al., 2006; Volpe, 2008). In addition, ASD has been identified in 20–30% of young children with cerebral palsy who were extremely premature (born at or before 28 weeks gestational age) at birth (Moster et al., 2008), a time in brain development when neurons destined for the cerebral cortex are in the periventricular region. The periventricular region is also the premature infant's the watershed zone, or vulnerable region during compromised vascular perfusion of the brain in extreme premature infants. This pathophysiology raises the possibility that a stroke induced disturbance in neuronal number and/or in early neuronal migrational events during which neurons travel from the periventricular region to cortex might be the basis of the autism syndrome in association with cerebral palsy (Kuban et al., 2009; Minshew, 2010 in press, 2011; Volpe, 2008).

Though research studies have demonstrated widespread disturbances in cortical functioning in ASD, the disturbances are also somewhat selective. The cellular basis for this selectivity is

not yet known other than that the disturbance involves cerebral cortical neurons that are involved in forming *distributed systems*. The developmental neurobiological events that produce the development of this circuitry are highly genetically regulated. It is reasonable to expect that the process of identifying genetic causes of ASD (and carrier status) will unfold the same way as did the causes in other child neurological disorders. That is, ASDs will be found to result from numerous related errors in the genetic code for a selected aspect of neuronal organization, just as many other childhood neurological disorders that develop de novo have been found to be the result of groups of abnormal genes. An error in the genetic code for a fundamental aspect of neuronal organization could potentially produce a broad profile of similar deficits (e.g. autism versus William's syndrome; Minshew, 2010; see also Volpe, 2008, pp. 82–102).

Genetic Foundations of ASDs

Developmental neurobiological events are extraordinarily complex, require precise guidance, and are known to be under strict genetic control (see Chapter 30 by J. Rubenstein, in this volume). Currently, approximately 20 or so mostly rare genes (and an occasional common gene or gene sequence) have been discovered that contribute to the cause up to 15–20% of cases of autism and ASD (Abrahams & Geschwind, 2008; Bolton, 2009; see also Commentary by Geschwind in this volume). Though "heterogeneous," these genes have in common a role in the development of connectivity among neurons and share common molecular signaling pathways (Geschwind & Levitt, 2007; Minshew, 2010a; Minshew, Williams, & McFadden, 2008).

The identification of these genes followed two decades of neuroimaging research establishing premature acceleration in brain growth as measured by total brain volume, including cerebral gray and white matter, followed by growth deceleration (reviewed in Levy et al., 2009; Mosconi, Zwaigenbaum, & Piven, 2006; and Chapter 35 in this volume). These are classic signs of disturbances in developmental neurobiological events. Furthermore, this research has also indicated disruptions in connectivity of cortical systems as a major etiopathophysiologic mechanism in autism and ASD (summarized in Minshew & Williams, 2007; and Chapter 54 in this volume). The convergence of genetic and neuroanatomical evidence for neuronal connectivity disturbances provides strong support for the notion of a developmental neurobiologically based model of autism and the ASDs. Imaging genetics, a comparison of genotype variability with imaging and behavioral phenotype variability, holds promise for additional insight into genetic contributions to the heterogeneity of the behavioral expression of the syndrome (see, for example, Raznahan et al., 2009; Wassink et al., 2007). In the discussion above, autism and ASD were referred to separately to indicate that the gene mutations were often found to be associated with both autism and ASD, often in the same families, supporting common underlying neurobiological and genetic mechanisms rather than separate etiologies for autism, Asperger's disorder, and Pervasive Developmental Disorders Not-Otherwise-Specified.

The identification of genes in autism has led to a number of major advances. The first is the development of a molecular pathophysiology for syndromic autism (e.g., tuberous sclerosis and TSC1 TSC2 genes, 22q deletion and SHANK3 gene, Rett syndrome and MECP2 gene, Fragile X syndrome and FMR1 gene, Timothy syndrome and CACNA1C gene), and some instances of nonsyndromic autism, (e.g., NRXN1, MET, and NLGN3; Abrahams & Geschwind, 2008). The development of animal models of these genes (primarily gene-neuroanatomical relationships with limited cognitive-behavioral correlates of autism) is enabling the development and study of neurobiological interventions (for example: Dolen et al., 2007; Ehninger & Silva, 2011; Silva & Ehninger, 2009), which confirm a connection between gene-to-brain development and autism-ASD phenotypes. This line of research has led directly to clinical trials with Rapamycin, an mTor inhibitor, for prevention of seizures, mental retardation, and ASD in infants and toddlers with genetically diagnosed tuberous sclerosis (Ess, 2009; Nie et al., 2010), providing clear proof of concept of the merits of uncovering molecular mechanisms for brain dysfunction in ASD. Animal models also provide opportunities for investigating potential molecular and cellular mechanisms of cortical dysfunction, such as the hypothesized role of an excitatory-inhibitory imbalance as a mechanism of cortical dysfunction and seizures in autism (Gogolla et al., 2009).

Another line of research supporting a developmental neurobiological model and connection between gene abnormality, cortical development, and manifestations of ASD has been the *MET* receptor research. This work was initiated as a result of reports of an increased association of the *MET* receptor CC allele with autism (Campbell, Sutcliffe, Ebert, et al., 2006; Campbell, Sutcliffe, Persico, & Levitt, 2008). Subsequently, researchers discovered increased *MET* mRNA expression levels in ASD brains (Campbell, D'Oronzio, Garbett et al., 2007), correspondence between *MET* mRNA levels in temporal lobe in ASD and language status (Campbell, Warren, Sutcliffe, et al., 2009), and correspondence between the presence of the *MET* gene and presence of gastrointestinal difficulties in ASD individuals (Campbell, Buie, Winter, et al., 2009) all provided additional support for a critical role of the MET receptor gene in autism. The *MET* receptor gene codes for cortical and cerebellar development, gastrointestinal repair, and immune competence (Campbell et al., 2006; Campbell et al., 2007), thus providing an example of a single genetic explanation for multiple organ involvement in ASD. Together, this body of imaging and genetic findings in ASD over the past decade has established a firm foundation for autism as a developmental neurobiological disorder and has identified a number of genetic abnormalities and mutations likely to be causative, which, though "heterogeneous," share signaling pathways at a molecular level involved in the development of neuronal connectivity (Levitt & Campbell, 2009).

The rapid growth in gene technology makes it highly likely that the list of ASD causative and associated genes will expand quickly and, with it, the delineation of a highly complex and heterogeneous molecular pathophysiology for autism. It is also likely that the growing number of gene variants and

mutations discovered in ASD will nonetheless be found to contri-bute to a select number of common neuronal signaling pathways involved in developmental neurobiological events that result in the connectivity disturbances and growth dysregulation that is now well documented in autism (Minshew, 2010a). It is also likely that increasing knowledge about the variation in implicated genes will account for the variability in brain growth trajectories that has been observed in autism and ASD (Lainhart et al., 2006), as well as the variability in symptom severity. Greater genetic and developmental neurobiological diversity can be expected in very low functioning individuals with ASD, since there is less specification or restriction of events that can result in the absence of functional cortical connectivity compared to genes that are very selective in their impact on cortical connectivity.

With all of this in mind, the next question is how to connect the genetic and developmental neurobiological findings with the behavioral syndrome, which has been defined in growing detail over the past seven decades. Thus far, the answer has been found in altered development of cortical systems connectivity in autism.

Disruptions in Cortical Connectivity as the Brain Basis for Autism

Given 1) our previous findings of a simple-complex dissociation in the neuropsychological profile of autism with deficits in higher-order abilities across multiple domains and 2) the work implicating a disruption in neural organization events related to particular genes; we launched a program of research to investigate the role of disruptions in *cortical connectivity* as the brain basis of autism.

Language Domain

One of the simple-complex dissociations that we and many others have observed in autism in the language domain is that many individuals are superb spellers but have trouble understanding sentence meaning. Understanding this dissociation became the basis for our first functional neuroimaging study that resulted in a theory proposing cortical functional underconnectivity in autism (Just, Cherkassky, Keller, & Minshew, 2004). We used fMRI to measure brain activation in adults with high-functioning autism and typically developing, verbal, IQ-matched controls as they read sentences. The autism group exhibited increased activation in Wernicke's area, but reduced activation in Broca's area compared to controls. These findings map onto the behavioral profile of increased word knowledge and reduced sentence knowledge in the participants with autism. Furthermore, the functional connectivity (i.e., the degree of synchronization or correlation of the time series of the activation) between these cortical areas was consistently lower for the autism than the control participants. These findings suggested that the neural basis of disordered language in

autism entails a lower degree of information integration and synchronization across the large-scale cortical network for language processing. This was the first of many subsequent studies showing a reduced collaboration among a network of cortical regions that support higher order function. It was a critical first step in support of our theory that connectivity within and between cortical systems is fundamentally underdeveloped and may be a central pathophysiologic mechanism for autism (see Chapter 54 in this volume).

Alterations in Connectivity More Broadly in the Brain

Subsequent studies also demonstrated reduced connectivity between posterior cortical regions and frontal cortex, and more bilateral activation within posterior visual and visuospatial cortex than occurs in typically developing individuals (Kana, Keller, Cherkassky, et al., 2009; Koshino, Kana, Keller, et al., 2008; Sahyoun, Belliveau, Soulieres, et al., 2010). We have proposed that these findings reflect underdevelopment of systems-level connectivity between cortical regions and frontal cortex, as well as enhanced local connectivity within visual cortex (see next sections on visual processing in autism). Other investigators have documented underdevelopment of cortical connectivity with amygdala and related circuits to account for the fundamental disturbances in affective contact in autism, and alterations in frontal-amygdala and striatal connections to account for difficulty in comprehending and regulating emotions (Gaigg & Bowler, 2007, 2008; Kleinhans et al., 2008). Analogous disturbances have been demonstrated in motor systems connectivity (Mostofsky et al., 2009).

Underconnectivity of cortical systems is now a widely accepted characterization of the structural and functional brain abnormality in autism. The initial index of functional underconnectivity was reduced synchronization between fMRI-measured activation in coactivating cortical areas during a sentence comprehension task (Just et al., 2004), which was subsequently demonstrated across a wide range of tasks to broadly involve cerebral association cortex (Just et al., 2007; Schipul et al., 2011). Over the course of many studies, *frontal-posterior* underconnectivity emerged as a common finding (Kana et al., 2009). The second characteristic of the altered task-related cortical connectivity in autism was enhanced activation of occipitoparietal areas. This activation pattern was hypothesized to result from *increased local connectivity* in posterior regions and to account for the unusual strengths also typical of autism. The dissociation between impaired higher order skills and intact basic skills was commonly characterized in the past in terms of a distinction between verbal and visuospatial abilities, rather than in terms of reduced frontal and enhanced posterior neural connectivity.

A recent fMRI study of the neural networks underlying visuospatial and linguistic reasoning has provided direct evidence that verbal individuals with average IQ scores and HFA have increased activation and connectivity of occipitoparietal and ventral temporal circuits, greater reliance on visuospatial

skills for solving both visual and verbal problems, and reduced activation and connectivity of frontotemporal language areas (Sahyoun, Beliveasu, Soulieres, et al., 2010). The study concluded that the HFA group's engagement of posterior regions along with its weak connections to frontal language areas resulted in reliance on visual mediation even for higher order cognitive tasks. This study recapitulates the findings of the connectivity studies and adds some of the clearest evidence yet to support the neural basis of the visuospatial processing strengths in autism.

One outstanding and perhaps puzzling issue concerns the underconnectivity (defined here as reduced correlation in activation profile between two areas of cortex) between cortical regions and the concurrent evidence for increased white matter connectivity between disparate cortical regions in ASD. For example, in one of our recent studies with high functioning autistic adults, we observed an increase in white matter connectivity in long intrahemispheric fibers such as the inferior longitudinal fasciculus and the inferior fronto-occipital fasciculus, but not in the homotopic callosal fibers (Thomas et al., 2010). One might have predicted that an overproliferation or overabundance of white matters fibers would be associated with an increase in cross-areal correlation and yet the studies, such as Kana et al. (2009), suggest otherwise. A possible resolution to this apparent discrepancy between the reduced correlations and the increased white matter tracts is that the signal propagated across the increased tracts may not have sufficient fidelity with the consequence that the correlation across regions will be substantially impeded.

Understanding the Neurobiological Substrates of Autism Through Studies of Visual Information Processing

Many of our studies conducted over the last few years have focused on the cortical visual system of individuals with ASD and have provided converging evidence for the claim that sensory-perceptual function evinces the same simple-complex dissociation, as described in other more abstract domains such as language. Because the same dissociation between simpler versus more complex information processing is evident in the visual system in ASD, we think the same underlying neurobiological process is likely implicated. Thus, whereas more elementary visuoperceptual skills are preserved, or possibly even enhanced (Ashwin et al., 2009; Mottron et al., 2006; Mottron et al., 2009; Soulières et al., 2009) relative to typical controls, more complex information processing requiring the synthesis of disparate bits of information is disproportionately impacted. We begin this section by reporting data from visuoperceptual processing in adults and in children with autism and then turn to describe a series of recent imaging investigations conducted with the same populations. The associated imaging investigations, which we describe, also offer supportive evidence for a biological system in which local or short-range connectivity is better preserved but longer-range connectivity especially with multi-modal association cortex and in particular with frontal cortex, necessary for integration at the neural and information processing level, is compromised.

Visual Processing: Behavioral Studies

One of the most essential visuoperceptual skills for humans is face processing. Interestingly, impairments in face processing are a widely accepted aspect of the behavioral profile of autism. The impairment involves difficulty remembering faces (Boucher & Lewis, 1992), processing facial expressions (Ashwin, Baron-Cohen, Wheelwright, O'Riordan, & Bullmore, 2007), and knowing which components of faces convey especially important communicative information (Joseph & Tanaka, 2003). One of the key behavioral processes considered critical for intact face perception is the ability to perceptually organize, or integrate, disparate components of the input rapidly and efficiently. Moreover, the failure to do so impacts both facial identity and emotional expression recognition. Both face perception and perceptual organization have been shown to be compromised in autism, and the studies we describe below document the atypicalities in both domains and suggest an association between the difficulties in these processes in individuals with autism. We start off by examining the *local processing bias*, or enhancement, in individuals with autism and then discuss the difficulties in face perception.

In contrast with the documented difficulties in higher-order perceptual abilities, such as those engaged for face processing (Gastgeb et al., 2011; Klin et al., 2002; Joseph & Tanaka, 2003; Humphreys et al., 2008; Lahaie et al., 2006; Pellicano et al., 2007; Scherf, Behrmann, et al., 2008), individuals with autism have been shown to exhibit hyper- or enhanced sensitivity to the more simple local elements of the input (Mottron et al., 2009; Soulières et al., 2009). For example, compared to age-matched, typically developing individuals, those with autism exhibit superior abilities to detect local targets in visual search tasks (Plaisted et al., 1999), ignore the influence of increasing numbers of distracters during visual search (O'Riordan et al., 2001), and identify fine stimulus features in spatial tasks like the Wechsler block design and Embedded Figures Task (Shah & Frith, 1993; Jolliffe & Baron-Cohen, 1997), to name but a few such observations. At the same time, individuals with autism appear to be limited in their ability to derive organized wholes from perceptual parts, which has been linked to their limited use of gestalt grouping heuristics (Brosnan et al., 2004), the failure to process inter-element relationships (Behrmann et al., 2006), and/or the failure to consider the entire visual context (Happé, 1996). Several studies have argued that this focus on local features is specifically detrimental to face recognition processes (Hobson et al., 1988; Boucher & Lewis, 1992; Davies et al., 1994; Klin et al., 2002; Joseph & Tanaka, 2003; Lahaie et al., 2006), and we consider this further below.

Although there is general consensus that the perceptual abilities of individuals with ASD are atypical (for review see Behrmann et al., 2006; Dakin & Frith, 2005), there still remains some controversy both about the nature of the atypicality as

well as the source of this atypicality. Some researchers have suggested that children with autism exhibit limited abilities to integrate local elements into a coherent global shape (Plaisted et al., 1999; Rinehart et al., 2000; Wang et al., 2007), whereas others have reported typical processing of both the global and local information in hierarchical visual stimuli (Ozonoff et al., 1994; Mottron et al., 2003; Iarocci et al., 2006; Plaisted et al., 2006).

To explore both the difficulty in global organization and perhaps the undue focus on local elements, in a recent study (Scherf, Luna et al., 2008b), we conducted two related investigations in children, adolescents, and adults with high-functioning autism (HFA) and age- and IQ-matched typically developing (TD) controls, using a well-known task of global/local processing with compound letter stimuli as well as a more novel, fine-grained microgenetic priming paradigm with hierarchical shapes including both few and many local elements.

In the first investigation, we employed the well-known hierarchical compound stimuli (Navon, 1977), which included global letters composed of smaller local letters that were either consistent or inconsistent with the global letter in identity (see Figure 36-1A). This design allows for performance measures, such as the speed of identification and asymmetric interference during inconsistent trials (for example, a global 'H' made of small 's's), to be used to infer the advantage of one level over the other (Navon, 1977, 1983). Participants were required to respond

Figure 36–1. A) The compound letter stimuli used in the global/local task to evaluate developmental differences in sensitivity to global (big letter) and local (small letters) information. B) The hierarchical shape stimuli used in the microgenetic priming task (few- and many-element).

by key press (is an H or S present) to indicate letter identity. Identification of the global or local letter was required in different blocks of trials. As expected and as predicted from well-established findings, the typically developing (TD) adults were faster to identify letters at the global level (for example, a global 'H' made of small 's's) than at the local letter (for example, the small 's's in the global 'H'), reflecting the so-called forest before the trees finding and indicating a bias to perceptually organize the disparate local elements to perceive the global letter. Importantly, this bias to perceptually organize the local elements increased linearly with age in the TD group. This pattern of results was not true for the HFA group, who was faster to identify letters at the local level, clearly revealing the bias to perceive the local (trees) rather than global (forest) arrangement of the letters. These findings are consistent with the idea that the emergence of the local processing bias in autism becomes prominent in adolescence and never transitions into a global bias in adulthood as in the TD individuals.

To confirm these findings, we conducted a second study in the same participants and, in this investigation, we assessed the temporal evolution of the organized visual percept, instead of simply measuring reaction time to identify a global or local letter as we had done in the first investigation reported above. To do so, we adopted a paradigm developed by Kimchi (1998, Expt 1) to test perceptual organization processes in typical adults. In this paradigm, participants view (but ignore) an ambiguous prime (for example, a diamond made of four circles in the "few" element condition or a diamond made of many circles in the "many" element condition) followed immediately by a pair of test figures (probes). Participants are required to judge whether the two probe images are the same or different and to indicate their response by key press. As evident from Figure 36-1B, both the prime and probe stimuli include patterns (i.e., global diamonds composed of smaller circles) with few large elements or with many small elements. Each test stimulus includes two probes from one of two conditions, defined by their similarity to the prime stimulus (see Figure 36-1B). In the *element-similarity* (ES) condition, probes are similar to the prime in their local elements (circles), but differ in their global configuration (global square instead of global diamond). In the *configuration-similarity* (CS) condition, probes are similar to the prime in their global configuration (diamond), but differ in their local elements (local squares instead of local circles).

The (ignored) prime is presented at several durations, providing multiple temporal windows over which the representation evolves prior to the onset of the probe, and behavioral responses are compared across the prime durations. The expectation is that, at short prime durations, only the most dominant characteristic of the percept of the priming stimulus is represented (e.g., for the few element stimuli, only the local information may be represented this early). When the test figures share these entry-level or early characteristics with the prime stimulus, responses will be facilitated. At longer prime durations, it is possible that both local and global characteristics are represented, in which case the prime would enhance
both of these dimensions in responses to the test figures. Because we know that grouping into a whole is easier when there are many local elements, we expect there to be an advantage for the configuration-similarity probes for the many versus few elements and this advantage may even manifest at early prime durations, reflecting the rapid organization into a gestalt in the typical visual process.

Unsurprisingly, we replicated the original Kimchi (1998) data, and showed that it takes longer (at longer prime durations) for the TD adults to evince an advantage for the "few" *configuration-similarity* (CS) condition both because the local elements are few and prominent in their own right, but also because they are somewhat spatially distant and have to be integrated to form a global whole and this is perceptually demanding. Of particular importance to us here, and again like the Kimchi data, these TD adults encode global shape information in the entry-level units (at very brief prime durations) of the representation for the "many" element displays, indicating the rapid and efficient integration of local information and access to global shape information. The question then is how individuals with ASD fare under these experimental conditions.

We found that HFA adults are faster to make similarity judgments about test figures that share local elements (ES trials) rather than global shape information (CS trials) with the prime, regardless of the prime duration or the number and size of the elements (Behrmann et al., 2006; also reported in Scherf, Luna et al., 2008). These results indicate that, in the HFA adults, both the entry-level units and the final percept of hierarchical visual stimuli are dominated by information about the local elements, regardless of whether the elements are few and large or small and many. This result is consistent with the data from the first investigation using compound stimuli in which the local bias dominated performance in the HFA individuals, even in the adults with HFA. The same investigation with CS and ES test trials conducted with HFA adolescents and children revealed a similar finding to that of the HFA adults: they are faster to say "same" to the *element-similarity* (ES) probes across nearly all exposure durations. Thus, not only do they **not** glean the advantage for the configuration at early prime durations, but, interestingly, they show a much greater advantage for the element similarity probes than do their matched controls, perhaps reflecting the hypersensitivity to the local elements (even though they are many and small).

In the few-element displays, children, adolescents, and adults in both groups were biased to encode the local elements, regardless of the prime duration, indicating that the ability to individuate elements presented in hierarchical displays with few, large items matures quite early in both TD and HFA populations. These results suggest that, beginning in childhood, local information dominates the formation of a percept in autism from the entry-level units to the longer-term visual representation, regardless of the stimulus characteristics of the local elements. Furthermore, the ability to group local elements perceptually in order to perceive a global shape does not appear to mature during the developmental transition from adolescence

to adulthood in HFA as it does in TD individuals, as was apparent in the results from the many-element condition.

In sum, the findings from both the few- and many-element displays indicate that local information dominates the formation of a percept in children, adolescents, and adults with autism regardless of whether the local items are few and large or small and many. The local information is encoded in the entry-level units of the percept (results from short prime durations) and organizes the final percept (results from long prime durations). We only found evidence for superior processing of local information in the many-elements task, which is present by childhood. TD children, adolescents, and adults encode more global shape information from the many-element displays (as evidenced by their weaker ES advantage), while those with autism exhibit enhanced perception of the local elements. The atypical development of these perceptual organizational processes in ASD may contribute directly to disruptions in the processing of visually presented objects, which may, in turn, fundamentally influence the development of major aspects of the social and emotional deficits characteristic of autism (see New et al., 2010, for recent discussion of social deficit and complexity of this deficit). We go on now to explore the relationship between the obvious local bias and higher order pattern recognition in ASD.

These atypical perceptual organizational processes, we have argued, may contribute to the difficulties in more complex visual processing, such as face perception, in ASD. In particular, ASD individuals may be more focused on local elements of faces and less able to integrate the elements into a whole. This process of integration is thought to become even more critical when faces are similar and the featural differences themselves do not suffice for differentiation. The focus on local aspects of faces is well captured in this comment by Temple Grandin:

> I often get into embarrassing situations because I do not remember faces unless I have seen the people many times or they have a very distinct facial feature such as a big beard, thick glasses or a strange hairstyle. (*Thinking in Pictures and Other Reports from My Life with Autism* by Temple Grandin)

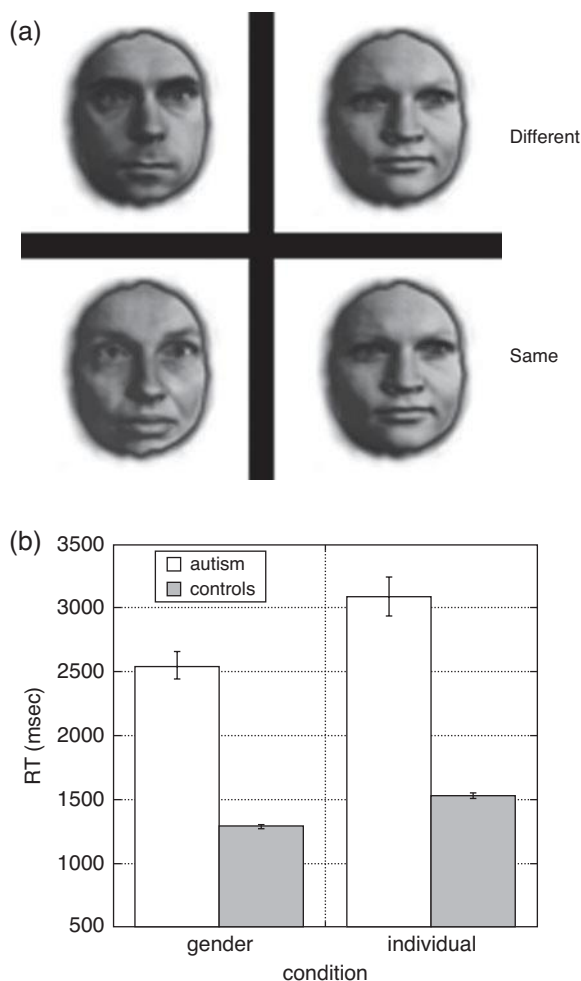
To evaluate whether the same HFA individuals who showed an undue local bias in the compound letter task and micro-genetic task described above also show a difficulty in face recognition, especially as faces become more similar to one another, the same adults with HFA who participated in the studies above, made same/different judgments to two faces presented alongside each other, for unlimited duration, in the center of a computer screen. On "different" trials, the faces could be either two faces from different genders or, in the more perceptually taxing case, two different faces of the same gender (see Figure 36-2a). It is in this latter condition that the reliance not only on featural information but also on the second-order relational information among the features becomes even more necessary. As shown in Figure 36-2b, not only were the ASD adults slow at making the similarity judgments, but they were disproportionately slower for judging the more


Figure 36–2. a. Examples of stimuli for face discrimination experiment, including one trial where faces differ on the basis of gender and one trial where faces differ on the basis of individual identity. b. Mean of median RT (and 1 SE) for correct different trials as a function of conditions of discrimination for autistic and control groups.

similar faces (albeit a "different" judgment). Taken together, these behavioral findings not only reveal the slow responses in face perception in the HFA adults, but also the disproportionate difficulty in the more demanding face task that requires perceptual binding of the elemental features.

We have shown atypical perceptual processing in tasks requiring holistic grouping or binding of elements and we have shown disproportionate slowing in face discrimination in the same individuals. To establish whether there is any association between performances on these two tasks, we took the median RT for each HFA individual on the "individually different/same gender" and correlated them with the local advantage from the compound hierarchical letter task. This analysis yielded a significant r^2 value of .61 (p = 0.03). Although correlation is not causation, the relationship between RT in face processing and the local bias is clear in the autistic adult individuals and is highly suggestive of some common atypicality.

In sum, the behavioral data we have reported here document not only the advantage for processing local elements

in individuals with HFA across the age span but also the association between the local bias and the difficulty making fine-grained discrimination between faces. The view we have taken here is that the slowing in face processing in autism, a higher-order visual task that requires the integration of many local elements, might arise from a more fundamental visual (and possibly even sensory-independent) bias toward the local elements and perhaps simultaneous or resultant difficulty in integrating local components of a stimulus into a whole. We have also argued that this fundamental perceptual form of processing is likely not restricted to faces but may impact visual processing of other, nonface objects, too, when the demands for discrimination and recognition are high, as is true in the case of faces (Behrmann et al., 2006; Scherf, Behrmann, et al., 2008).

These findings are not easily accounted for by views that argue for a primary social, rather than perceptual, deficit in autism. The perceptual deficit that we and others have documented may exist independently of a social deficit. Alternatively, perceptual and social deficits may work in tandem: the lack of experience and the inadequate attention to faces may limit the acquisition of the normal configural perceptual skill and/or the perceptual deficit may constrain the ability to acquire typical face representations (see also Grelotti et al., 2005). Either way, there appears to be some fundamental dissociation between the ability to process local elements and the ability to integrate these elements efficiently for higher order pattern perception.

Visual Processing: Imaging Investigations

In our pursuit to understand the relation between the neurobiological and behavioral manifestations of autism, we have also undertaken several functional neuroimaging studies of visuoperceptual processing in adults and adolescents with autism.

Activation of Earlier Versus Later Visual Cortex.

One prediction that arises from the behavioral studies is that individuals with ASD should show reduced or minimal activation of those regions of visual cortex that support higher-order visual perception, while earlier parts of the visual system should remain intact. Our own experiments have focused on the former point, although there are good data to suggest that there is preservation (even if not totally normal activation) of the earlier parts of the visual system (Hadjikhani et al., 2004). We also note that some recent investigations have suggested enhancement of activation in earlier parts of the cortical system (Mottron et al., 2006), and a recent study reports an increase in grey matter in auditory and visual primary and associative perceptual areas. These last results demonstrating potential structural brain correlates of atypical auditory and visual perception in autism provides possible support for the enhanced perceptual functioning model (Mottron, Dawson, Soulières, Hubert, & Burack, 2006; Mottron, Dawson, & Soulières, 2009).

Consistent with the claim that higher-order regions of visual cortex (such as the fusiform gyrus or "fusiform face area"; FFA) are engaged in face processing, and that individuals with autism do not respond preferentially to faces, many studies (Corbett et al., 2009; Critchley et al., 2000; Schultz et al., 2000; Pierce et al., 2001; Hall et al., 2003; Hubl et al., 2003; Humphreys et al., 2008; Ogai et al., 2003; Piggot et al., 2004; Wang et al., 2004; Dalton et al., 2005; Grelotti et al., 2005; Deeley et al., 2007) have found reduced BOLD activation in the fusiform face area (FFA, Kanwisher et al., 1997). However, other studies have failed to replicate this finding (Hadjikhani et al., 2004; Hadjikhani et al., 2007; Pierce et al., 2004; Bird et al., 2006), and so there remains some controversy surrounding the brain-behavior correspondences in FFA and ASD.

To explore the integrity of higher-order visual cortex and to map out cortical activation for faces in a broader network that extends beyond the FFA to include the occipital face area (OFA) and superior temporal sulcus (STS), but also for other images such as places and objects, ASD and TD adult participants viewed naturalistic, real-time movies of unfamiliar faces, buildings, navigation through open fields, and objects in a blocked fMRI paradigm (Figure 36-3a; Humphreys et al., 2008). Rich, moving stimuli from multiple categories, such as

these (see Figure 36-3a), have been shown to induce stronger activation in ventral cortex than do static, black and white images, and so we used them to increase our chances of uncovering robust cortical response profiles in the HFA group. We also note that this task has been used successfully to map category-selective activation in the ventral visual cortex in other populations (Hasson et al., 2004; Avidan et al., 2005; Scherf et al., 2007). There are no specific task demands in this investigation, and so performance differences between the autism and comparison groups cannot account for any different levels of functional activation.

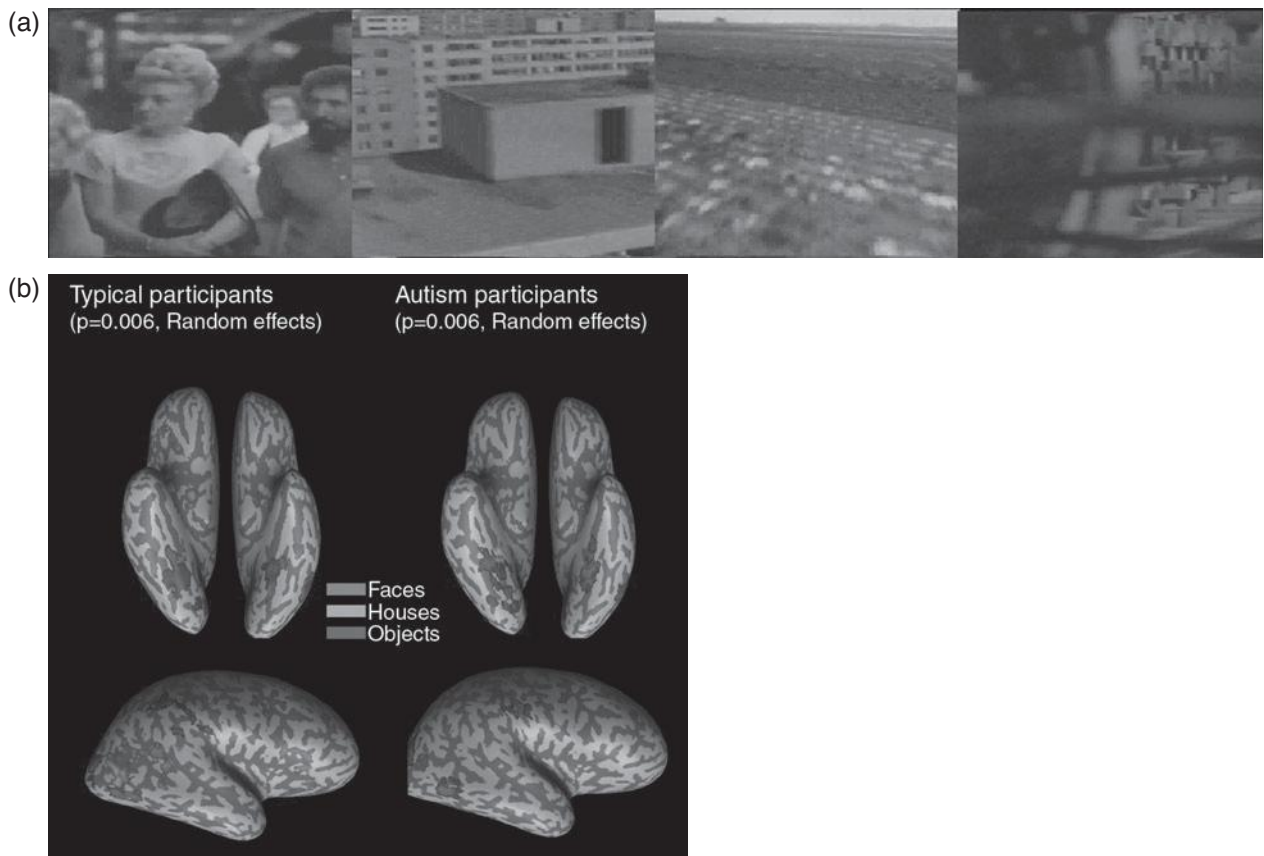
Figure 36-3b shows the average activation maps for the autism and typical adults in this experiment projected into a single inflated brain with both lateral and ventral projections. Note that we group together the building and scene related activation, as both typically activate the parahippocampal place area (PPA) in the collateral sulcus (Scherf et al., 2007). The findings from the typical group largely replicate the standard findings with extensive activation for faces (red) and objects (blue). The building/scene-related activation (green) in PPA appears somewhat reduced, especially in the left hemisphere but this has been noticed in other studies as well (Avidan et al., 2005). The most marked feature is the clear


Figure 36–3. Functional MRI study using moving pictures of faces, buildings, scenes, and objects: (a) examples of the stimuli; (b) group averaged cortical maps from the typical and autism groups showing activation in response to faces, buildings, landscapes, and objects. The first map shows the average activation map for typical individuals and the second for individuals with autism. (See Color Plate Section for a color version of this figure.)

reduction in face-related activity in the ASD group and the only face-related activity at this threshold for the autism group is in the right OFA. In contrast, object-related activity in object-related lateral occipital cortex (LO) appears more extensive for the ASD than comparison group, this time in both hemispheres. Ventral visual cortex appears to be organized differently in high-functioning adults with autism, at least for face-selective regions, although subtle differences may also exist for other categories such as objects. These findings are compatible with the other studies that have demonstrated atypical activation in FFA and other face-related regions in ASD and are also compatible with those studies showing enhancement in object related activation (Baily et al., 2005).

Recently, we also evaluated whether functional organization in the ventral visual pathway is fundamentally disrupted in individuals with HFA during adolescence, the important period of visuoperceptual development when HFA individuals fail to develop mature perceptual organizational abilities (Scherf, Luna, Minshew, & Behrmann, 2010). We used the same fMRI paradigm described above to map face-, object-, and place-related activation in 10 high-functioning (FSIQ > 80) adolescents with autism (ages 11–14) and 10 age- and IQ-matched controls. Although the HFA adolescents exhibited typical organization in object- and place-related cortex, as a group they failed to show consistent face-selective activation in classical face regions (FFA, OFA, STS). These results suggest that the functional topography of face-related cortex is selectively disrupted in autism and that this alteration is present in early adolescence, an important stage of cortical specialization for TD adolescents. Furthermore, for those adolescents with autism who do exhibit face-selective activation, face-selective cortex tends to be located in traditionally object-related regions, which supports the hypothesis that perceptual processing of faces in autism may be more akin to the perceptual processing of common objects in typically developing individuals. Such alterations could result from direct pathology to regions within the face-processing network, like the fusiform gyrus (van Kooten et al., 2008), and/or to the structural and functional connections between such regions. Also, alterations in the visual experiences that individuals with autism have with faces as a result of social aversion and/or excessive focus on features may configure these regions in the face-processing network atypically (Grelotti et al., 2005).

Cortical Response Profile Under Naturalistic Conditions

The fMRI studies conducted with ASD individuals, to date, focus predominantly on documenting the cortical response profile of an area or subset of areas of cortex. To examine the claim that multiple higher-order areas, engaged more in integration of information, are more atypical than lower order areas, we have also explored whole brain activation in a group of ASD adults. In perhaps the most naturalistic imaging study we have run to date, we compared the functional connectivity between disparate regions of cortex from data obtained while adults with autism and typical controls lay in a MRI scanner

watching a common, popular movie. We mapped the whole-brain activation profile by comparing the evoked fMRI response time courses across different subjects (inter-subject correlation, inter-SC; Hasson et al., 2004). Computing the inter-SC within the typical individuals (typical-typical), on a voxel-by-voxel basis, quantifies the reliability of the response time-courses in each brain area across members of the typical group. Recently, using this technique, Hasson et al. (2009) demonstrated that, across typical observers, approximately 30–65% of the cerebrum evinces similar shared reliable response time-courses under free-viewing of complex naturalistic stimuli, and this provides a benchmark against which to assess the inter-SC in ASD. Computing the inter-SC between the typical and the autism groups (typical-autism) provides a measure of similarity in the functional response in each brain areas across the two groups. Low inter-SC between the typical-autism group in conjunction with high inter-SC within the typical group would indicate that the response time course in a given brain area is markedly different in individuals with autism from that of the typical individuals. Moreover, computing the inter-SC within the autism group (autism-autism) alone can identify reliable response time courses, which are unique to the ASD group and are not observed in the typical subjects.

All participants watched a 10-minute excerpt from the popular movie, *The Good, the Bad, and the Ugly,* directed by Sergio Leone, and answered questions posed afterward to probe their comprehension of the plot and sequence of events. After normalizing all brains to the Talairach coordinate system, we calculated the inter-SC across the entire movie sequence within the typical group on a voxel-by-voxel basis (see Hasson et al., 2004; Hasson et al., 2009, for more details). This was done separately for every voxel. Figure 36-4A shows the activation profile sampled from the vicinity of the calcarine sulcus, which includes the primary visual cortex and nearby early visual areas (termed in the paper as area V1+) for each individual in each group, plotted across the entire movie sequence (600s). We also show the correlation among the typical individuals (0.32), reflecting strong similarity in the individual time courses, and among the ASD individuals (0.14), reflecting rather different time courses in each individual. This area was chosen as a clear illustrative example of the findings, but similar results were obtained in the other regions of cortex (see Figure 36-4D). In sum, the response time-courses in area V1+ were highly reliable across all typical subjects whereas the time-courses from the same area in the individuals with autism, although highly fluctuating, were poorly correlated across individuals.

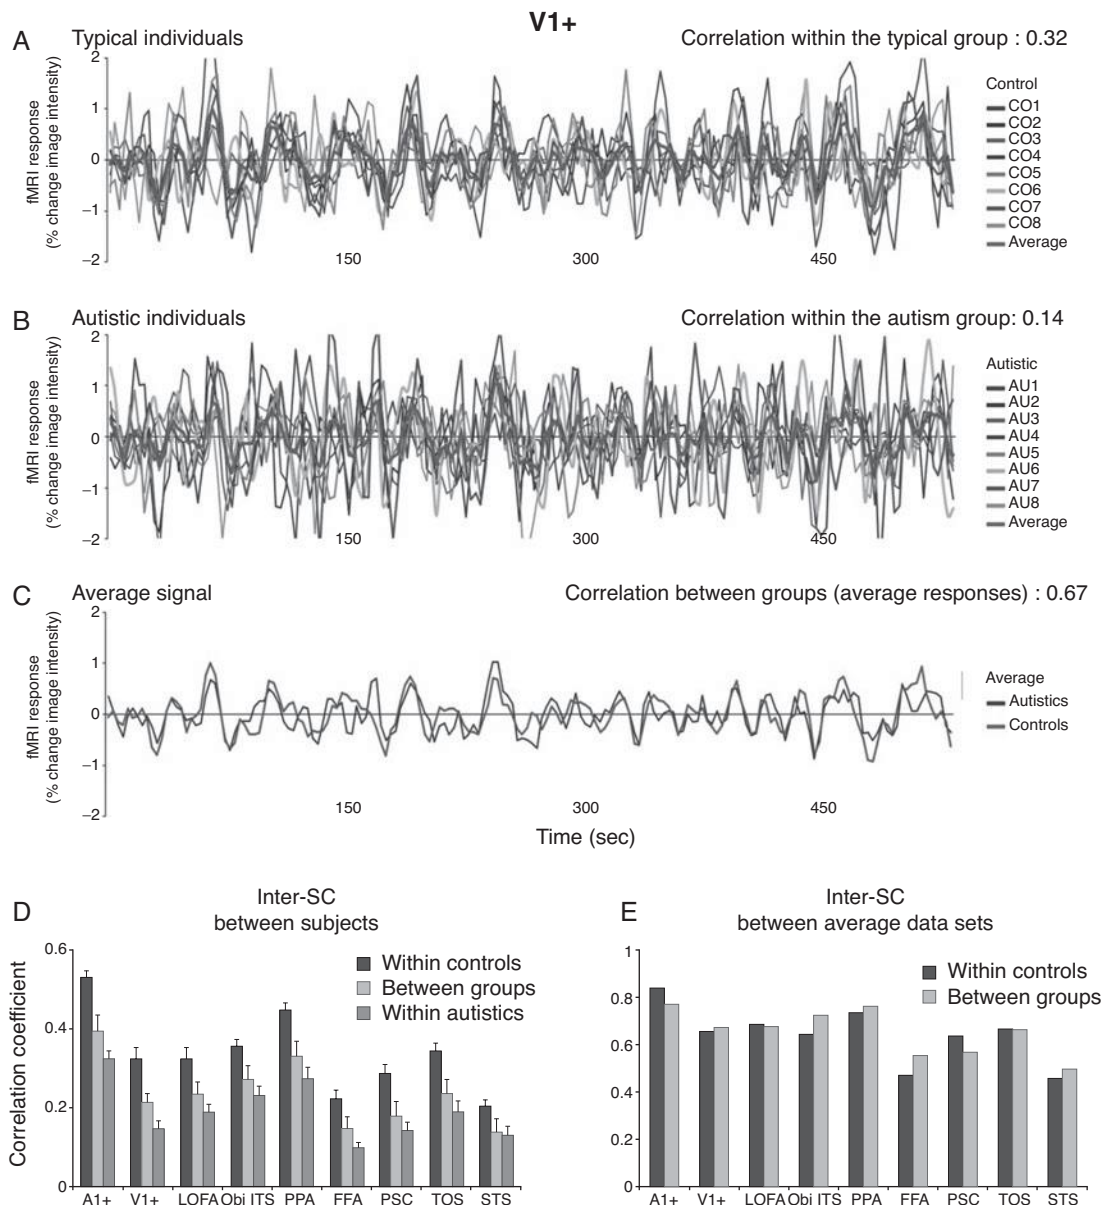
The reduction in the correlation of the response time courses in individuals with autism held across large regions of posterior cortex. Figure 36-4D presents the average inter-SC values for the within- and between-group comparisons across the preselected ROIs. The high correlation values within the group of control subjects (typical-typical: red) replicate previous findings (Hasson et al., 2004). In all ROIs (including early and higher-order regions), the autism-autism analysis (dark green) and the autism-control analysis (light green) showed a substantially reduced correlation of about 40–50%,


Figure 36–4. Signal fluctuations within ROIs. Visual cortex (V11) response time courses for (A) each typical subject and (B) each participant with autism. (C) The average signal for the typical group (red line) and autism (blue line) group. (D) The mean inter-SC values for the within-typical group (typical–typical, red bars), within-autism group (autism–autism, light green bars), and between the two groups (autism–typical, green bars) for selected ROIs. ROI abbreviations: A11, primary and secondary auditory cortices; V11, primary and secondary visual cortices; LOFA, lateral occipital cortex responsive to pictures of faces; Obj-ITS, object-related area in the inferior temporal sulcus; PPA, parahippocampal place area; FFA, fusiform face area; PCS, posterior central sulcus responsive to pictures of objects; TOS, transverse occipital sulcus responsive to pictures of places; STS-Face, area in superior temporal sulcus responsive to pictures of faces. (E) The inter-SC between the average autism–typical time courses (green bars) and the typical–typical time courses (red bars) in each ROI (same abbreviations as in D). Note the extent of variability in signal fluctuation in the autism individuals relative to the typical subjects. Moreover, note that by averaging the time courses within a group the responses become highly correlated across groups. (See Color Plate Section for a color version of this figure.)

relative to the typical subjects' inter-SC values. An important observation, however, is that the overall inter-SC values are higher in primary sensory cortices than in higher-order association cortex, consistent with the hypothesis that more primary regions of cortex, whose responsibility it is to mediate more simple forms of processing, might be better preserved in ASD than those regions whose role it is to integrate the higher-order statistics of the more complex input.

Visual Processing: Conclusions

Taken together, our investigations into the psychological and neural mechanisms of visual processing in high-functioning individuals with ASD reveal a similar pattern: there is relative preservation (and perhaps even enhancement, on some accounts) in more elemental, simple, or featural processing, whereas information processing that requires the integration

of the simple elements is disproportionately affected. The imaging data yield a similar profile: relative preservation of earlier parts of the visual system and more pronounced atypical activation in higher-order regions. These alterations, while appearing subtle, nonetheless have a profound impact on how the brain in autism processes information, and, in turn, how individuals with autism "see" the world differently (Behrmann, Thomas, & Humphreys, 2006).

These findings exemplify some of the major advances that have occurred in delineating the neurobiological basis of neuropsychological functioning in autism in the past decade in large part due to the impact of numerous, carefully executed functional MRI studies in conjunction with equally meticulous cognitive studies. These findings have created a convergent and consistent picture of distinctive alterations in cortical functional connectivity in ASD characterized by intact and or increased local connectivity in posterior or occipital parietal regions (and probably other primary cortical regions too) and decreased systems connectivity that particularly impacts connectivity with frontal cortex. This distinctive alteration in circuitry has been shown to alter how the brain processes a broad range of social and nonsocial information, how the person with ASD perceives the world, and how the person with ASD thinks and feels.

General Conclusions

Across all domains impacted by autism, the common thread is the preservation of elementary skills and greatest impairments in those abilities that require on-line integration of information. In previous decades, this dissociation was characterized as a contrast between intact visuospatial abilities and impaired verbal abilities, which was considered nearly pathognomonic of autism. With technologic advances, this pattern is now understood in terms of selective disturbances in cortical connectivity. Recent genetic advances have identified a multitude of abnormal and mutated genes for ASD that all share a role in the development of neuronal connections and share common molecular signaling pathways. A little is known about the molecular pathophysiology of ASD but far from enough to explain the specific connection of these genes to the impact ASD has on cortical circuitry. These findings have produced a convergent developmental neurobiological model of autism as a disorder of neuronal organization and in some cases neuronal migration as well as the first neurobiologically based treatment for prevention of syndromic autism.

Challenges and Future Directions

- In the next 5 years, our hope is that investigators will work to advance the knowledge in their respective areas

to diminish the gaps and increase the specificity of detail essential to designing treatments for autism.
- The focus on future work should strive to explain autism as a developmental neurobiological disorder with disturbances in cortical circuitry to create an integrated, multidimensional definition of the cause of autism from gene to behavioral variability.
- Interdisciplinary research that seeks to integrate and correlate genetic, neurobiological, neurological, and behavioral findings will be crucial for making progress in understanding the etiology, brain basis, and effective treatments for the complex disorder of ASD.

Electrophysiological Research on Autism

⠿
Points of Interest

- EEG activity is exquisitely sensitive to neural timing, on a resolution that is not matched by other methodologies, providing the ability to scrutinize physiological changes at a unique level of analysis.
- EEG/ERP paradigms can be designed for use both across the age continuum and across variable cognitive functioning.
- ERP components enable one to disentangle and differentiate sensory processing from integration and higher order cognitive abilities, which may be important in understanding autism.
- A failure or delay in activating neural structures that are normally specialized for a given process could result in a failure to integrate social information.

Electroencephalography (EEG) is the measurement of electrical activity produced by the brain. More specifically, scalp recorded EEG is a noninvasive method of measuring postsynaptic activity that is rhythmic and continuous, transient and episodic. While scalp EEG is not a direct measurement of brain activation, the recordings reflect the propagation of electrical activity to the scalp arising from the synchronous activation of a population of neurons that have a similar spatial organization. These generators or sources of scalp recorded activity are located parallel to each other and oriented radially to the scalp.

EEG can be examined in many different ways, providing valuable information about the functioning of the brain including: (1) EEG oscillatory activity, which is the frequency and amplitude of synchronized neural activity and characterizes the "state" of the brain; (2) evoked potentials (EPs) or event-related potentials (ERPs), which reflect measurements that are time-locked to the presentation of an external stimulus; and (3) coherence, in which functional connectivity in

brain networks can be inferred from statistical relations between neurophysiological signals measured over spatially separated neuronal regions.

The benefits of this methodology are easy to identify. EEG is noninvasive, only requiring the participant to wear an electrode hat for the length of the experiment. In contrast to other neuroimaging methodologies, EEG generally does not necessitate adherence to strict behavioral requirements. Participant movement and compliance can be evaluated in real time and can be tolerated to a greater extent than in other imaging methods. EEG also has exquisite temporal resolution, with recordings reflecting electrical activity changes on the scale of milliseconds. Limitations have also been recognized including: poorer spatial resolution than other imaging modalities, increased sensitivity to generators that are closer to the surface, and insensitivity to sources that are located tangential to the skull, located in sulci, or located in deep structures (e.g., hippocampus).

Why Utilize Electrophysiology Measures for the Study of Autism?

EEG has been used to study both typical and atypical brain processes since its first recording in humans by Hans Berger in the 1920s; the first (published) reports focusing on autism emerged in the 1960s. The usefulness of EEG measurements in autism arises from both theoretical and methodological considerations. Theoretically, EEG allows the evaluation of hypotheses with respect to the timing of brain functioning, alterations in resting and active brain states, and the potential under- and overfunctional connectivity of the brain in individuals with autism. Methodologically, EEG paradigms can be created that reduce demands for behavioral compliance or manual/vocal responses. The implementation of passive paradigms, such as passive viewing of faces or listening to phonemes, allows the same paradigm to be used both across the age continuum and across variable cognitive

functioning. This approach provides useful information about the whole of the autism spectrum. As well, some EEG technologies allow for the application of the scalp electrodes quickly and for recordings to be conducted over short time periods, accommodating limited attention or behavioral compliance.

Electrophysiology is a broad topic; we have chosen to focus on EEG and ERPs in response to visual stimuli during perceptual and attention processes, social processes, and background neural processes.

Event Related Potentials to Perceptual and Attention Processes

Theory and Methods

ERPs in response to visual stimulation can be recorded within a short time of stimulus onset. Basic level processing to black and white checkerboards can be characterized within milliseconds of stimulus onset over occipital electrodes and likely reflects the activity of the extrastriate visual cortex. More complex stimuli, which evoke more complicated "higher-level" perceptual and cognitive processes, likely reflect the activity and contributions of many different neural systems that overlap in time and spatial distribution. The resulting waveform is composed of multiple potentials, each with a characteristic latency range and spatial distribution.

A careful analysis of ERPs enables one to disentangle and differentiate sensory processing from integration and higher-order cognitive abilities, which may be important in understanding autism. If a sensory system is limited in its ability to perceive the environment, this would be represented in abnormal sensory ERPs such as brain stem evoked potentials or early visual evoked potentials. If autism, however, is better represented by a failure of integration or a limitation in overall capacity for information processing, this would be represented in abnormal endogenous, later cognitive components of the signal, or decreased coherence.

Visual Processing

While not specifically captured in the diagnostic criteria for autism, the existence of altered perceptual processing has been proposed as an important phenotype of the disorder. The early visual component C1 peaks approximately 60–100 ms after stimulus onset and is thought to be generated by the primary visual cortex (V1, area 17) (e.g., Clark et al., 1995; di Russo et al., 2001). During perception of Gabor patches, sinusoidal luminance patterns, children with pervasive developmental disorder (PDD) demonstrated shorter latency to the peak of C1 compared to matched typical controls. Higher Childhood Autism Rating Scale scores were correlated with faster latency (Milne, Scope, Pascalis, Buckley, & Makeig, 2009). Given the simplicity of the stimuli, the

authors concluded that the faster neural response was consistent with the behavioral findings of faster visual detection in individuals with PDD and suggested that this behavior may be due to varying mechanisms of perception rather than attention.

In another simple visual paradigm using gratings, Boeschoten, Kenemnas, van Engeland, and Kemner (2007) found increased N80 responses to high spatial frequencies in children with PDD compared to controls but a failure to show differential sources of activity for high and low spatial frequencies (also see Milne et al., 2006). The P1, thought to be generated by the extrastriate cortex V2 (e.g., Mangun, Buonocore, Girelli, & Jha, 1998; Di Russo, Martinez, Sereno, Pitzalis, & Hillyard, 2002), was smaller in children with PDD than in controls, and the inferior medial sources were weaker with increased supplementary source activity in the superior lateral area. The authors concluded that this represented a failure of anatomical separation for the N80, decreased specialized processing of frequencies, and decreased extrastriate activity.

Visual boundary detection mechanisms, but not surface segregation, have been found to be abnormal in adults with ASD compared to typical controls. ERP results in adults with ASD suggested reduced perception of boundary detection starting 121 ms after stimulus presentation consistent with impaired (behavioral) identification of boundaries (Vandenbroucke, Scholte, van Engeland, Lamme, & Kemner, 2008). This was hypothesized to reflect a deficit in horizontal connections within visual areas; intact surface segregation was interpreted as associated with normal recurrent or feedback processes from higher-level areas.

While the number of early visual processing reports is relatively small, there are some general conclusions that can be made. First, activity within the primary visual cortex seems to be intact or potentially enhanced. Second, ERPs located originating from the extrastriate cortex demonstrate a pattern suggestive of perceptual impairment. Area V2 receives direct projections from V1 and shares many similar properties but is also modulated by more complex properties including figure/ground separation. Bertone et al. (2005) have suggested that individuals with autism have reduced efficiency of neurointegrative mechanisms within the perceptual systems, which would invariably impact the relatively more integrative processes of the extrastriate cortex. Both Milne et al. (2009) and Vandenbroucke et al. (2008) are consistent with this interpretation.

Attention

Central Attention: Target Processing

ERPs can be collected during selective attention paradigms in which a rare, novel, infrequent, or unattended stimulus is compared to a standard, frequent, or attended stimulus. This type of experiment results in a N1, P2, N2, and P3 complex (or LPC). The P3 is thought to reflect neural generators in the

temporal, parietal, and frontal areas, and amplitude of the P3 is thought to be related to the amount of attention and processing capacity. Smaller P3 amplitudes are thought to reflect decreased processing capacity or allocation of resources, abnormal executive functions (e.g., Halgren, Marinkovic, & Chauvel, 1998), working memory (e.g., Donchin & Coles, 1988), or completion of perceptional processes and associated release of neural inhibition that follows task resolution (e.g., Kutas, McCarthy, & Donchin, 1977; Verleger, 1988). Of note, individuals with a wide range of conditions demonstrate abnormal P3 responses, including but not limited to schizophrenia, depression, ADD, dyslexia, alcoholism, multiple sclerosis, and normal aging (Picton, 1992; Polich & Criado, 2006).

During auditory/visual divided attention tasks, for example, when the participant is required to attend to a stimulus in a primary modality (e.g., tone) and ignore the presence of irrelevant (unattended) probe a in a second modality (e.g., square), reduced P3 amplitude to the attended stimuli is thought to reflect attention trade-offs. Several studies suggest that individuals with autism fail to reduce activation to the attended stimulus (Ciesielski et al., 1990; Hoeksma, Kemner, Verbaten, & van Engeland, 2004). For example, Hoeksma et al. (2004) found that when the task load was increased, children and adolescents with PDD showed increased early responses to unattended (visual) probes and failed to show normal reduction of processing to attended (auditory) probes. The authors suggested this represented abnormal allocation of attention but not necessarily a decreased processing capacity. This pattern of results was clearly found in the children but was less characteristic of the adolescents. It is unclear if this represents delayed development of the attention system or potentially subtle differences in subgroups of individuals with ASD.

Central Attention: Novelty Detection

Some findings suggest that late visual evoked parietal P3b to novel stimuli is abnormal in individuals with ASD (Novick et al., 1979; Verbaten, Roelofs, van Engeland, Kenemans, & Slangen, 1991), but that these responses to visual stimuli may be less impaired than responses to auditory stimuli (Courchesne et al., 1989; Courchesne, Lincoln, et al., 1985). Lincoln, Courchesne, Harms, and Allen (1993) propose that the decreased P3b amplitudes noted in ASD may reflect difficulty in changing expectancies in response to contextually relevant information. Furthermore, the authors suggest that a basic disturbance in the habituation process results in difficulties in discriminating novel information. An alternative hypothesis is that a failure to extract relevant information in order to create a "standard" category results in impairments in differentiating novel stimuli *to the same degree* as controls (Gastgeb, Strauss, & Minshew, 2006).

Shifting Attention from Central to Peripheral Stimuli

Behaviorally, individuals with autism demonstrate a number of impairments in orienting. Children with ASD,

when attending to targets in the periphery, demonstrate reduced LPC amplitude and smaller P3b amplitudes accompanied by high variability in performance (Verbaten, Roelofs, van Engeland, Kenemans, & Slangen, 1991). Similarly, Townsend et al. (2001) found reduced accuracy to targets in the visual periphery, delayed or missing early LPC during attention to peripheral visual fields, and smaller amplitudes over the parietal cortex during conditions when context updating was of paramount importance. The authors interpreted this as a disruption of spatial attention networks and consistent with abnormalities in the cerebellar-frontal/parietal spatial attention systems. When the central stimulus overlapped with the peripheral target, Kawakubo et al. (2007) found increased amplitude activity during the presaccade period in adults with ASD as compared to neurotypical adults, which was interpreted as a difficulty in disengagement during visuospatial attention.

Summary

The studies reviewed here suggest that individuals with ASD may have subtle impairments in the integrative stages of visual processing and attention allocation. Abnormalities in these early stages of information processing have the potential to disrupt integrative cognitive processes that require complex information. For example, if visual stimuli are being encoded without correct figure-ground information or the correct balance of high/low spatial frequency information, then systems that must utilize this to identify and respond accordingly would organize around incorrect or degraded information. This might result in reduced attention to and differentiation of social stimuli.

Electrophysiology and Social Processes

Theory and Methods

Much of what we think of as social represents a dynamic interaction between two or more people. One of the constraints of ERP methodology is that social processes must be decomposed into time locked segments. These simple component parts can be presented as static images and contrasted to nonsocial categories or perceptual matches. However, EEG recordings in general do not have this temporal constraint, and more recent work has focused on changes in the state of brain activity during dynamic protocols.

Face Processing

A sizable amount of literature exists regarding the exploration of the neural circuitry of face processing via ERPs and other neuroimaging methods of individuals with typical development. One ERP component, called the N170, has been identified as a face sensitive component because it is greater in

amplitude and shorter in latency to face stimuli relative to other types of stimuli (e.g., Bentin et al., 1996). Recorded over the posterior temporal region and peaking between 130 and 170 ms in response to faces, the N170 is larger in amplitude to eyes than inverted faces and upright faces. Likewise, these stimuli result in a larger N170 amplitude than the presentation of noses or mouths (e.g., Bentin et al., 1996).

In individuals with ASD, reports suggest abnormalities in the precursor N170 in 3- to 4-year-old children with ASD, and the N170 in adolescents and adults with ASD, as well as in parents of children with ASD (Dawson et al., 2005; McPartland, Dawson, Webb, Panagiotides, & Carver, 2004; Webb, Dawson, Bernier, & Panagiotides, 2006). Three- to 4-year-old children with autism showed a faster response to objects than faces (Webb et al., 2006). In contrast, children with typical development demonstrated a faster precursor N170 to faces than objects in the right hemisphere, while children with developmental delay (chronologic and mental age controls) failed to demonstrate any differential responses.

Adults with autism spectrum disorder (ASD) also show disruptions in face processing measured via ERPs. McPartland et al. (2004) found that 9 adolescents and adults with ASD had slower N170 responses to faces than objects (also O'Connor et al., 2007). O'Connor et al. (2005) found that the group with Asperger's (ASP) had slower P1 and N170 responses to facial expressions of emotions compared to controls Additionally, the ASP group had reduced amplitude at the N170 compared to the typical group. O'Connor et al. (2005, 2007) interpreted these results as reflecting impaired holistic and configural processing of faces, potentially due to decreased attention to internal features or a failure of expertise processing. In contrast, in a recent report that explicitly directed the subject's attention toward the eye region of the face, Webb et al. (2009) found that 32 high-functioning adults with ASD demonstrated P1 and N170 responses to faces that were greater in amplitude and faster in latency than to houses. This pattern is similar to that found in neurotypical adults. Adults with ASD, however, failed to show any inversion differences. Namely, they failed to differentiate upright and inverted faces at the ERP component level. This failure to differentiate upright and inverted faces in the temporal domain was related to self-reported social skills. Specifically, a faster response to upright vs. inverted faces, was correlated to less social anxiety and distress, greater social competence, and fewer autism social symptoms. Similar to Jemel et al. (2006), we concluded that if face processing was a pervasive and encompassing deficit in ASD, we would expect the results to be similar across reports.

It has been hypothesized that altered face processing ability might be an endophenotypic trait associated with autism. Parents of children with ASD failed to show a differential latency of the N170 to faces versus nonface stimuli and failed to show a right-lateralized N170 distribution (Dawson et al., 2005). During a task involving the processing of a facial emotion, again, parents of children with ASD failed to demonstrate differential latency of the N170 to neutral and happy faces versus fear faces and N170 (amplitude) hemispheric differences. Within the parent group, atypical hemispheric activation was associated with poorer performance on the Reading the Mind in the Eyes task (Dawson et al., 2008). These ERP findings parallel ERP responses to emotional faces in young children with autism (Dawson et al., 2004).

Face Memory

Several studies with infants and children have evaluated face and object memory processes using ERPs (e.g., Carver et al., 2003; de Haan & Nelson, 1997, 1999; Webb, Long & Nelson, 2005). In these studies a highly familiar stimulus, such as a picture of the child's mother or favorite object, is compared to a picture of an unfamiliar face or an unfamiliar object, respectively. In this paradigm, both image categories, familiar and unfamiliar, are presented in the same manner within the experimental setting, but differ in the child's a priori experience with them. By 45 to 54 months, typical children show a faster latency and increased amplitude response to unfamiliar faces than to familiar faces. In contrast, responses to familiar and unfamiliar objects are similar (Carver et al., 2003).

In 3- to 4-year-old children with ASD, the Nc does not differ in response to the mother's face versus an unfamiliar face, but does differ between a favorite toy as compared to an unfamiliar toy (Dawson et al., 2002). Chronologically age-matched typical children, demonstrated a greater Nc amplitude response to both the unfamiliar face compared to the familiar face and the unfamiliar object compared to the familiar object. By 6 years of age, both children with ASD and chronologically and mentally age matched children show differential temporal processing of familiar and unfamiliar faces at the Nc as well as the pr-N170. As seen in Figure 37-1, children with ASD continue to show delays in latency when processing face stimuli compared to control children—both children with developmental delay and neurotypical development (Webb, Dawson, Bernier, & Panagiotides, 2008).
Figure 37–1. Latency (in milliseconds) of pr-N170 response to faces and objects (left) and familiar and novel face (right) in 6-year-old children with ASD or controls. Both groups demonstrate a faster response to faces than objects, and a faster response to familiar than novel face. However, the ASD group's responses remain significantly slower to all categories compared to those by the control group.

Emotion

Many researchers have suggested that the ability to use or understand information from faces is a core deficit in autism (e.g., Baron-Cohen, 1994; Dawson et al., 2002; Frith, 1989). Given that emotion is often displayed in the face, differentiating a deficit in face processing from impairments in understanding and recognizing facial expressions is difficult. However, studies have shown intact recognition of facial expressions despite significant deficits in facial recognition in patients with prosopagnosia (Shuttleworth et al., 1982). On the other hand, patients who underwent an amygdalectomy demonstrate the reverse pattern, i.e., exhibiting a deficit in expression recognition but retaining facial recognition processes (Adolphs et al., 1994). These findings suggest that the two abilities can be separated at the neural and theoretical level (Bruce & Young, 1986).

Differential ERPs to distinct facial expressions of emotion have also been shown in infants (Nelson & de Haan, 1996) and young children (Batty & Taylor, 2003), suggesting that some discrimination of facial expressions may occur at early processing stages. In preschoolers aged 3 to 4 years, with ASD or typical development, only the typical group displayed a faster and larger early (300 ms) ERP response and a larger slow wave amplitude ERP response to the fear face than the neutral face. In contrast, children with ASD did not differentiate the fear face at either stage of processing. These findings suggest that ASD is associated with abnormal processing of facial expressions of emotion and that these abnormalities originate during early stages of processing. Given that the processing of facial expression requires facial processing, it is likely that any abnormalities in the initial stages of face processing would disrupt further processing of the emotion displayed on the face.

Conflicting evidence exists for impairment in processing emotional expressions in children with ASD. In older children, differential processing of emotions via ERPs has not shown pervasive impairments in ASD. Wong et al. (2008) found normal patterns of ERP and behavioral responses to emotional expressions. However, using source localization, the children with autism displayed slower and weaker responses to emotional expressions in regions responsible for face perception and emotion processing (Wong, Fung, Chua, & McAlonan, 2008). Supporting this finding, another ERP study failed to find a difference in emotional face processing between high-functioning, 9-year-old children with ASD compared with mental-aged-matched typically developing children (Burner, Webb, & Dawson, 2008). In summary, these results suggest that further examination of factors such as age and verbal abilities in individuals with ASD is warranted in the area of facial emotion processing.

Eye Gaze

Eye contact and eye gaze serve as important functions in social interaction and communication. Individuals with autism often display atypical eye contact (Baranek, 1999;

Charman et al., 1997; Osterling, Dawson, & Munson, 2002), atypical gaze fixation patterns (Klin, Jones, Schultz, Volkmar, & Cohen, 2002), and eye gaze processing impairments (Mundy et al., 1986; Dawson et al., 1998) that may contribute to their social cognitive deficits. These behavioral observations of eye gaze behavior have led to the examination of the neural basis of eye gaze processing in individuals with autism, which has produced inconsistent results. A few studies have found a larger response (measured by the N2, a face specific occipitotemporal component) to direct gaze than to averted gaze in children with ASD (Grice et al., 2005; Kylliainen, Braeutigam, Hietanen, Swithenby, & Bailey, 2006) while others have failed to find a difference in the N2 between direct and averted gaze in individuals with ASD (Senju, Hasegawa, & Tojo, 2005). In addition, response to eye gaze in the N2 was bilaterally distributed in children with ASD, whereas the response was lateralized on the right side in typically developing children (Senju et al., 2005).

Developmental and contextual factors may account for these different results since the Senju et al. (2005) study included older children and required attention to be paid to the direction of the gaze. Another possible interpretation of these contrasting findings comes from a recent behavioral examination of eye gaze detection. The study found that similarly to typically developing children, children with autism detect direct gaze faster and more efficiently than averted gaze. However, children with ASD tended to use featural information to detect direct gaze whereas typically developing children relied on configural information (Senju, Kikuchi, Hasegawa, Tojo, & Osanai, 2008). The authors interpreted these findings in the context of previous neuropsychological research showing that direct gaze elicits a larger ERP response than averted gaze in children with autism, but not typically developing children (Grice et al., 2005; Kyllianinen et al., 2006). This is possibly because the children with autism are using a featural strategy that may rely on low-level psychophysiological features in eye gaze detection.

Imitation

In the 30-year history of imitation research in autism, imitative deficits in individuals with ASD have consistently been observed, and several researchers have suggested that imitation deficits are one of the core impairments of autism (e.g., Rogers & Pennington, 1991; Williams, Whiten, Suddendorf & Perrett, 2001). Despite the variability in imitation testing methodologies, sample characteristics, and control groups employed, 19 of 21 well-designed studies have found imitative deficits in autism. This imitation impairment is most marked by deficits in imitation of nonmeaningful gestures and reversal errors (Williams et al., 2004).

The EEG mu rhythm, first observed by Gastaut and Bert in 1954, is believed to reflect activity of an execution/observation matching system—the mirror neuron system (Pineda, 2005; Muthukumaraswamy & Johnson, 2004). The EEG mu rhythm band falls between 8 and 13 Hz (generally the alpha frequency

band) but is recorded from central electrodes. Underlying neurons fire synchronously when an individual is at rest, but during the execution and observation of an action, the underlying neurons activate, and this results in the attenuation of the mu rhythm amplitude. This attenuation pattern of the mu wave has been consistently observed in adults and children (e.g., recent papers include Babiloni et al., 2003; Cochin et al., 2001; Lepage & Theoret, 2006; Martineau & Cochin, 2003; Muthukumaraswamy, Johnson, & McNair, 2004).

Recent work analyzing the EEG mu rhythm in individuals with ASD suggests differential activation of mu related to action execution and observation (Bernier et al., 2007; Oberman et al., 2005; Oberman, Ramachandran, & Pineda, 2008). Oberman and colleagues reported on 10 males with ASD ranging from 6 to 47 years of age and 10 age- and gender-matched controls. Participants executed a simple hand movement or watched videos of a moving hand, two bouncing balls, or television static (Oberman et al., 2005). In the typical group, as expected, the authors found characteristic mu attenuation during the execution and observation of the hand movements but not during the two control conditions. However, the ASD group failed to show attenuation of the mu rhythm during the observation condition. In a second study of adults with ASD utilizing the EEG mu rhythm, Bernier and colleagues replicated Oberman's findings, using a paradigm in which participants executed a grasp of a wooden block and observed the experimenter grasping the block (Bernier et al., 2007). In this study of adults with ASD compared to age and cognitive ability matched adults with typical development, the typical adults showed attenuation of the mu rhythm during both the conditions of execution and observation. The adults with ASD showed mu attenuation only during the execution of the simple hand action. Additionally, the adults with ASD showed significant impairments in imitative ability behaviorally. However, imitation ability was also significantly correlated with degree of mu wave attenuation. As imitative ability increased so did the degree of mu rhythm attenuation when observing movement. This correlation was strongest for mu attenuation and the ability to imitate facial expressions (Figure 37-2).

Summary

Impairments in multiple aspects of face processing and imitation have been documented in individuals with ASD using both behavioral and EEG methods. Recent results examining the N170 suggest that early stages of face processing may be relatively more impaired in young children with autism, with variable impairments in adults. This pattern would suggest that performance of the face processing system may be influenced by associated processing related to the type of task (e.g., attention) and ultimately more amenable to developmental mechanisms or intervention. Similarly, our recent finding that mu attenuation during observation of action is correlated with behavioral performance suggests that there may be important neural variability within the autism phenotype. Given the heterogeneity

within the social symptom domain in individuals with ASD, addressing this source of variability will be important.

Background Neural Processes

Theory and Methods

Most EEG research in ASD focuses on scalp recordings in awake human subjects. Cortical neural populations that exhibit a high degree of oscillatory synchrony over relatively large areas (on the order of at least 100–1000 mm^2) can generate electrical potentials that are measurable with electrodes placed on the scalp (Lopes da Silva & Pfurtsceller, 1999; Nunez & Srinivasan, 2006). This neuronal activity is spatially low-pass filtered by the poorly conducting skull, limiting the spatial resolution of scalp recorded EEG. Estimates of spatial resolution are dependant on the density of the electrode array employed, ranging from 20 cc^3 or more in low density (19 electrode arrays) to 6–8 cm cc^3 in higher density (128 channel) arrays (Ferree et al., 2001).

Epilepsy

A striking feature of ASD is the increased but variable risk of epilepsies among affected individuals. Seizure occurrence is common, with prevalence estimates ranging from 5% to 39% (Tuchman et al., 2002). These EEG instabilities are proposed to result from atypical cellular, molecular, and local excitatory-inhibitory neuronal circuits (Rubenstein & Merzenich, 2003) that result in imbalanced cortical function due either to increased excitatory glutamatergic signaling, or reduced inhibitory GABAergic activity. Proposed disruptions in
Figure 37–2. Mu suppression (difference in mu power between observe and baseline) and face summary score for the behavioral imitation measure. Greater mu suppression is correlated with higher (better) face imitation scores.

interneuron development (Levitt, 2005) that contribute to seizure activity may reduce neural synchrony, as coupling among interneurons underlies the generation of oscillatory and synchronous activity in the cerebral cortex (Buzsáki & Chrobak, 1995). At a larger scale, cortical minicolumns appear narrower and more numerous in ASD, with constituent neurons more dispersed, and a suspected coincident deficit of GABAergic inhibition (Casanova et al., 2002), which may serve to diminish local connectivity. Brain stem abnormalities may also play a role in atypical electrical activity. Welsh et al. (2005) suggested ASD may be associated with disruptions in synchronization among neural networks in the inferior olive, in which rhythmical oscillation in membrane potentials, mediated by altered connexin36 receptors, could contribute to reduced neural synchrony in ASD.

Spontaneous EEG Rhythms in ASD

Spontaneous EEG generally refers to recordings made without time locking to an external stimulus, often in an awake but resting subject (similar to "default mode") (e.g., Raichle, 2001). Spontaneous activity is typically interpreted across predefined frequency bands that represent the speed of neural oscillations: delta (< 4 Hz), theta (4–8 Hz), alpha (8–12 Hz), beta 1 (12–20 Hz), beta 2 (20–30 Hz), and gamma (30–80 Hz). These wide frequency bands are functionally defined in adults. Understanding the development of these rhythms poses a significant challenge for pediatric research, as functional reactivity in any particular frequency range can differ according to age. Spontaneous EEG is generally reported in terms of absolute or relative power. Relative power measures, which express amplitudes in a particular frequency band as a percentage of the wider power spectrum, serve to normalize the EEG and facilitate comparisons between subjects without bias from individual amplitude differences. However, relative power creates interdependencies across frequency bands. Optimally, both relative and absolute measurements should be analyzed.

Delta, Theta, and Alpha Range EEG in ASD

Accumulating evidence suggests elevated power in the theta range is frequently associated with ASD. Murias et al. (2007) found significantly increased relativez power in ASD adults compared to controls at theta range (3–6 Hz) frequencies. This appears consistent with Daoust et al.'s (2004) observations of elevated absolute frontal theta power among ASD subjects during sleep and waking states. Similarly, Coben et al. (2008) found relative, but not absolute, theta was greater and reduced relative delta amplitudes in the ASD group. Murias et al. (2007) found decreased relative power in the alpha (9–10 Hz) range, consistent with pediatric findings of Cantor et al. (1986) and Dawson et al. (1995), both of which noted decreased absolute alpha power in frontal regions among children with ASD.

Higher Frequency Rhythms

The higher frequency EEG bands beta 1, beta 2 and gamma span 12–80 Hz and are thought to be generated in neuronal networks that include excitatory pyramidal cells and inhibitory gamma-aminobutyric acid (GABA)-ergic interneurons (Whittington et al., 2000). Murias et al. (2007) discerned that a lower beta range (13–17 Hz) relative power increase existed at posterior scalp locations in adults with ASD. Orekhova et al. (2007) demonstrated a pathological increase of gamma (24.4–44.0 Hz) in two separate populations of boys with ASD. Consistent with the theory of imbalanced excitatory/inhibitory mechanisms in ASD (Rubenstein & Merzenich, 2003), the abnormally high levels of spontaneous gamma activity in autism suggests high levels of excitability, reflecting noisy cortical networks.

Lateralization

In participants with ASD, Dawson et al. (1982) found atypical patterns of cerebral lateralization, involving right-hemisphere dominance for both verbal and spatial functions, suggesting selective impairment of the left cerebral hemisphere. Stroganova et al. (2007) found abnormal lateralization in children with ASD, especially in the right temporal cortex. Resting anterior EEG asymmetry in high-functioning children with ASD who displayed right frontal asymmetry displayed more symptoms of social impairments and better visual analytic skills than did children who displayed left frontal asymmetry (Sutton et al., 2005).

Connectivity

Theoretical conceptions of ASD have postulated abnormalities in connections among distributed neural systems (Belmonte et al., 2004; Rippon et al., 2007; Courchesne & Pierce, 2005; Just et al., 2004). Anatomical support for disordered cortical connectivity includes the observation of increased white matter in ASD, with frontal lobe white matter showing the greatest increase (Herbert et al., 2004). Decreased volumes of the corpus callosum have been observed in adults (Hardan et al., 2000) and children (Boger-Megiddo et al., 2006; Manes et al., 1999; Vidal et al., 2006) with ASD. This suggests that the symptoms of ASD may be related to impaired interactions within brain networks, rather than impaired function of specialized cortical regions. Other factors beside white matter contribute to connectivity, for example, reduced cortical inhibition in ASD would tend to decrease the degree of synchrony of widely distributed regions (Courchesne & Pierce, 2005).

The levels of synchronization between neural populations can be estimated from EEG recordings via coherence measurements. The coherence statistic is a squared correlation coefficient that provides a measure of the linearity of the relation between two EEG electrodes at one particular frequency. High coherence between two EEG signals indicates the contribution of synchronized neuronal oscillations to each

electrode, suggesting functional integration between neural populations, while low coherence suggests functional segregation. EEG coherence is primarily a measure of phase correlation and with a sufficient density of recording electrodes is believed to reflect functional cortical connectivity on a centimeter scale (Nunez & Srinivasan, 2006; Srinivasan et al., 1998) either directly via corticocortical fiber systems or indirectly through networks that include other cortical or subcortical structures. The dynamics of EEG coherence may be more sensitive to changes in the developing brains than power measures. Srinivasan et al. (1999) differentiated genuine spatial correlations from volume conduction and reference electrode effects, and found cortical areas contributing to the alpha rhythm to be far more weakly correlated with each other in preadolescent children than in adults.

In adults with ASD with the eyes closed in a resting state, Murias et al. (2007) reported globally reduced EEG coherence in the 8–10 Hz frequency range (Figure 37-3). Coherence was markedly diminished within frontal electrode sites, and between frontal and temporal, parietal, and occipital sites. In contrast to the globally reduced alpha rhythm, this study found local ASD increases in theta range (3–6 Hz) coherence in temporal regions that were independent of frontal lobe power findings. The nature of these findings suggests that the frontal lobe has weak functional connections with the rest of the cortex in the alpha frequency range and appears consistent with metabolic studies showing reduced correlated blood flow between frontal and other regions (Horwitz et al., 1988; Villalobos et al., 2005). Coben et al. (2008) reported decreased coherences in children with ASD in delta, theta, and alpha ranges.

Challenges

Methodology

Similar to other scientific domains, differences in analytical methods employed by different investigators make comparisons across EEG and ERP studies difficult. For EEG, of particular importance is the definition of frequency bands. Reports of EEG spectra averaged over broad frequency bands provide only coarse frequency resolution and allow for the possibility that frequency-specific effects within bands cancel out or go otherwise undetected.

Any choice of reference electrode placement distributes the signal at the reference site throughout the array of electrodes. For example, the use of either one ear potential or the average of two ear potentials as a reference confounds coherence estimates by redistributing the potentials at the reference site (Srinivasan et al., 1998; Nunez & Srinivasan, 2006). Historically, many ERP studies have shifted from low-density arrays using ear, nose, or vertex references to high-density average reference arrays. Specifically, recordings made from sparse electrode arrays with a linked-ears reference strategy limit interpretation of prior literature in developmental psychopathology. Depending on the nature of the (unknown) signals at "recording" and "reference" sites, changes in power or phase at the reference location can easily be reflected as changes in coherence or amplitude between two other recording electrodes. With a sufficiently large number of recording electrodes the average reference approximates reference independence.
Figure 37–3. Eyes closed, resting EEG averages from 18 high functioning adults with autism, and 18 age- and IQ-matched controls. The power spectrum of frontal electrode Fz, shown at left, shows that groups do not differ in peak frequency of the alpha rhythm (10 Hz), but peak alpha amplitude is significant reduced in the ASD group. The coherence spectra between two frontal electrodes is shown at right, showing reduced coherence in the ASD group.

Volume conduction (the passive flow of current across the scalp, skull, and cerebrospinal fluid) also strongly influences scalp potential EEG coherence (Srinivasan et al., 1998; Nunez & Srinivasan, 2006), and has been shown in electrical models of the head to introduce artificial coherence between electrodes separated by less than 10–12 centimeters. Thus, EEG potential coherence measurements are only meaningful with regard to widely spaced electrode pairs. Coherence between closely spaced EEG electrodes is elevated even when the underlying brain sources are entirely uncorrelated, such that increases in the strength of one cortical source region will increase coherence between two electrodes located within 10 cm of the source region, confounding source strength with coherence. Spatial enhancement methodologies such as the Laplacian derivation (Nunez & Srinivasan, 2006) and finite element deblurring (Gevins & Illes, 1991) avoid spatial filtering by volume conduction, but may be insensitive to low spatial frequency source dynamics, especially those generated in broadly distributed cortical or subcortical regions.

Functioning of Subjects

Individuals with ASD have substantial adaptive functioning difficulties, including variable cognitive performance and sensory abnormalities. Behaviors related to verbal understanding, tactile hypersensitivity, hyperactivity, and inattention will impact compliance, which in turn can impede recording of quality data and lead to subject selection bias that can reduce the representativeness of the findings. Appropriate methodological and behavioral strategies in the EEG lab can mitigate these issues (Foote, 2004). Training in methods for desensitizing individuals with ASD to the EEG lab and methods for monitoring attention and compliance is essential. However, practical problems such as motion artifact and short recording times contribute substantially to difficulties in interpreting across studies.

Benefits and Risks of EEG/ERP

To a large degree, the risks and benefits of utilizing EEG/ERP methodologies to elucidate autism profiles are similar to other methodological domains. As stated previously, EEG (and MEG) activity is exquisitely sensitive to neural timing, on a resolution that is not matched by other methodologies, providing the ability to scrutinize physiological changes at a unique level of analysis. Benefits also include the ability to develop and utilize passive paradigms that are not reliant on the insight of participants, not under explicit control (i.e., most participants can not purposely alter brain activity), and may be less subjective to experimenter bias during data collection. Given the variability in the autism phenotype and the necessary focus on *development*, data can be collected under (relatively) similar paradigms across functioning levels and across the lifespan. Similarly, EEG can be utilized in other species, increasing our ability to model and evaluate similar neural processes under more tightly constrained circumstances.

With any methodology, risks are also present in the development, analysis, and interpretation of research findings. Primarily, behavioral compliance and resulting noise/error within EEG recordings is a significant issue. Second, known (and unknown) differences in anatomical architecture will impact and contribute to signal propagation and the scalp recording of EEG activity. These differences may reflect within and between group variability, as well as natural variability in the developmental trajectory of neural architecture. The spatial resolution of EEG may be improved with source localization methods, specifically when used in combination with MRI images. Third, similar to behavioral paradigms, researchers often assume that two individuals or two groups are "participating" in the same manner; that is, similar external behaviors reflect a similar internal strategy. Even under directed states, such as counting or resting with eyes closed, participants may have different strategies for completing the same task. Lastly, facility with EEG analysis can be varied and often the detection of noise, eye blinks or eye movements, and other noise signals is subjective or poorly defined across reports.

Conclusion

In the study of autism, EEG/ERP findings have demonstrated slowed neural speed, lack of stimulus or condition differentiation, both reduced and increased activation, and altered topographical distribution. Each of these results has independently contributed to our understanding of autism and has been used to redefine our understanding of the processes that contribute to autism behaviors. For example, a failure or delay in activating neural structures that are normally specialized for a given process such as the fusiform gyrus for faces, could result in a failure to interconnect information such as linking a facial movement to vocalization. Temporal asynchrony in processing has consequences for both the formation of neural circuits and the behaviors that directly result from the utilization of that circuitry (Dawson, Webb, & McPartland, 2005; Brock, Brown, Boucher, & Rippon, 2002). As well, alterations in coherence across the frequency spectrum may signal distinct patterns of over- and underconnectivity supporting neuroanatomical models of autism (Horwitz et al., 1988; Just et al., 2004) that may be directly assessed as risk factors, predictors, and measures of response to treatment.

Our current understanding of autism has benefited greatly from the integration of information across multiple levels of analysis. The EEG methodology provides information that allows us to get closer to neural functioning, to divide the behaviors of autism into meaningful endophenotypes that can be investigated across the spectrum of the disorder, and to characterize stages of cognitive and affective processing. This methodology is also well suited for developmental studies as it can be utilized with individuals from infancy through late adulthood. EEG has promise as an endophenotype or biological marker of variability, which will allow for more refined

measurements and may yield greater precision in investigating the systems that contribute to risk and outcome in individuals affected by autism.

Challenges and Future Directions

- The risks of utilizing EEG/ERP methodologies to elucidate autism profiles are similar to other methodological domains and include within- and between-group variability, verbal understanding, tactile hypersensitivity, hyperactivity, and inattention.

Commentary ⠿ Pat Levitt

Toward a Neurobiology of Autism

Careful examination of the major sections of *Autism Spectrum Disorders* epitomizes well the current understanding of the autisms (plural noun used here to emphasize the heterogeneous nature of the spectrum; see Geschwind & Levitt, 2007)—long on clinical description and characterization of the breadth of associated phenotypic features in fine detail and in cataloging the plethora of strategies used in diagnosis and treatment; short on neurobiological characterization and mechanisms that actually generate the spectrum disorders. The latter is challenged by the very nature of the disorder—targeting perhaps the most complex of human cognitive skill sets that are built developmentally through a hierarchical process in which elementary circuitry that mediates basic skills (homeostatic control, attention, motivation, and reward) are integrated with more complex networks that ultimately mediate the abilities and desire of an individual to interact with the outside world through social engagement and communication (Hammock & Levitt, 2006). For the neurobiologists among us, I highly recommend further examination of the other major sections of the book, because the chapters are illustrative of the high degree of clinical complexity beyond the three core domains used to diagnose a child on the spectrum. Co-occurring medical, psychiatric, sensory, and motor conditions are the norm, not the exception for children, adolescents, and adults on the spectrum (Geschwind, 2009). Thus, attempts to model the clinically defined autism spectrum disorders in biological systems more tractable than humans may not be the best use of time. Rather, a dimensional approach to examine specific neurobiological processes that one believes are disrupted developmentally (see Modi & Young, Chapter 34), with each being examined in great detail and with precision in experimental systems may be a more fruitful strategy as the field continues to move forward.

⠿
Challenges First

Of all the dimensions of the autisms covered in this book, understanding neurobiological mechanisms that cause the disorder remains the most deficient in a working knowledge base for the scientific field. However, the growth curve for accumulating data is rapidly accelerating, and that bodes well. It is important to emphasize that *development* in its simplest form can be defined by "change over time." Inherent to this equation, therefore, is a moving target of a genetic blueprint that lays out fundamental brain architecture prenatally, which is then acted on by experience to sculpt a homeostatically balanced set of circuits that perform sensory, motor, cognitive, and regulatory functions (Thompson & Levitt, 2010). Rubenstein, in Chapter 30, provides a brief summary of our state of knowledge in this area, and in fact, we know quite a lot about the progression of neurodevelopment, particularly in nonprimate species. He raises an interesting point that there are dramatic changes in scale in the developing primate brain, and perhaps this feature has created a stress on assembling a far more complex set of circuits. If this is the case, then we need to understand a great deal more about the intimate details of normal primate brain development, which to date has focused mostly on prenatal histogenic events (Rakic, 2006). Moreover, we recognize that risk for the autisms are highly heritable, as noted in great detail in the section on genetics and genomics in this book. Thus, there is a clear role for genetic mechanisms (though not to the exclusion of currently ill-defined environmental factors), and there are replicated findings of common polymorphisms, de novo copy number variations, and rare mutations that implicate genes involved in developmental processes (Abrahams & Geschwind, 2008; Geschwind, 2008; Levitt & Campbell, 2009). But most of the genome is expressed in the developing brain at some point in time, which means that most genes can be implicated when a variation is defined. Moreover, we have a very limited knowledge base from which to draw basic information regarding when and where risk genes even are expressed in the brain (and other organ systems) during development. It is likely to be insufficient to extrapolate from rodent datasets with regard to this issue, because of the fundamental differences in the time period over which neurogenesis, cell migration, synaptogenesis, and myelination occur in the primate

(Levitt, 2003), and the evolutionary advances in establishing primate-specific circuitry.

Current Thinking

So where are we with understanding the neurobiological basis of autism spectrum disorders? Our starting point is that the autisms collectively can be viewed as an alteration in the trajectory of neurodevelopment, and thus the current gene X environment puzzle is somehow impacting the *change over time* computation There is clear evidence for this, as recent accumulation of multiple structural imaging studies (highlighted by Courchesne et al., Chapter 35) is consistent with early changes in the events that contribute to brain growth. It is important to emphasize as with many other childhood or adult onset neurodevelopmental disorders, the impact on structural integrity is subtle (5–10% difference range), but it may be that the *absolute* values of increases in frontal, parietal and temporal gray and white matter, and reduced corpus callosum are less important than the *kinetics* of how the growth occurred. Thus, the *slope* of *change over time* becomes essential to monitor, as Giedd and colleagues have done for neurotypical populations in relation to IQ (Shaw et al., 2006). A very recent longitudinal structural imaging study emphasizes the issue regarding developmental trajectory (Schumann et al., 2010), an approach that is far more tractable in model systems, but rarely performed. It also is evident from neuropathological studies reviewed by Schumann et al. (Chapter 31, this volume), as challenging as these are to do because of small sample sizes and the spread of subject age (child to adult), that there are likely a multitude of very modest changes that occur (e.g., reduced cell number in the amygdala, altered cell packing density in neocortex) through primary and secondary adaptive processes. The latter is a hallmark of typical brain development, so the challenge will be to understand whether the plasticity and adaptation exhibited by children with autism spectrum disorders is qualitatively different from typically developing individuals. Compared to adult-onset neurodevelopmental disorders (e.g., schizophrenia) or neurodegenerative disorders, the fine details of neuropathological changes in the autisms are missing—even taking into account our knowledge of syndromic disorders such as Fragile X syndrome or tuberous sclerosis with a high prevalence of autism codiagnosis. Reported changes overall are sufficiently variable and very modest in scope across autistic disorders. For example, cortical excitation: inhibition imbalance has been suggested as a common neurobiological feature (P. Levitt, Eagleson, & Powell, 2004; Rubenstein & Merzenich, 2003), but this is based almost entirely on clinical data reporting high prevalence of seizure disorder in the autisms (estimates range from 10–60%) and syndromic disorders with known genetic etiology. We remain in the dark regarding the site(s) of action—altered interneuron number, GABA receptor subunit changes, glutamate receptor trafficking or expression changes, local circuit connectivity—all could be at risk in the autisms. The specific

details are important to learn, of course, because strategies for intervention will vary depending on the therapeutic targets.

Is atypical brain wiring at the heart of the clinical phenomena? Neuropathological and structure imaging is consistent with this, with the very best neurobiological evidence to date coming from the use of modern imaging and psychophysiological tools in humans. Chugani, Webb et al., Minshew et al., and Dager et al., (in this volume, Chapters 32, 33, 36, and 37, respectively) suggest that indeed this is a core neurodevelopmental deficiency. Each chapter emphasizes different components of neural and neurochemical pathways that clearly are not functioning in individuals with autism spectrum disorders as they do in neurotypical individuals. The concept of the autisms likened to neurological disconnection syndromes (Geschwind & Levitt, 2007; Minshew, Goldstein, & Siegel, 1997) has face validity in the variety of combined neuropsychological, neuroimaging, and ERP studies that suggest long-range connections that are relevant for integrating information across sensory and cognitive domains are dysfunctional, whereas local connectivity in some neocortical regions, including frontal, temporal, and polysensory association regions may be enhanced (discussed by Minshew et al., Chapter 36). The imaging and ERP studies (Webb et al., Chapter 33) are consistent—there are local regions of greater responsiveness, coherence across domains that may be decreased or increased, and a disturbed topography. The latter is particularly important, because the current evidence suggests that the fundamental neurobiological substrate for dysfunction may be both quantitative (under- or overconnectivity of otherwise normally organized circuits) and qualitative (miswiring in cortico-cortical and cortico-subcortical circuits). Consistent as these findings may be, the situation grows more complex as an ever-increasing array of information is gathered. The Magnetic Resonance Spectroscopy findings to date (Dager et al., Chapter 33) suggest that there may be fundamental metabolic changes that are widespread in individuals on the spectrum. This could establish differential challenges for the maturation of specific circuits that are more sensitive than others to metabolic challenges. Thus, not all neural processes will be at great risk. Because dysfunction of information processing is a fundamental feature of the autisms, and the brain uses neurotransmitters to distribute and process information, it comes as no surprise that even cursory measures of specific neurochemicals are demonstrating changes (Chugani, Chapter 32). As with analyses of metabolic disruption, assigning specificity and functional relevance is problematic thus far, because neurotransmitter systems are so highly adaptive under normal and pathophysiological conditions. As attractive as the hypotheses may be, a specific neurobiological understanding of neurotransmitter dysfunction in the clinical syndrome remains distant. Finally, we are gaining steam in certain areas with regard to a developmentally relevant, molecular understanding of signaling pathways that may, more often than not, be direct targets in the autisms. This is discussed in other sections of *Autism Spectrum Disorders*, and is mentioned by Rubenstein in Chapter 30. It has relevance here because certain cell signaling pathways ultimately control the building of early brain architecture and guiding later growth through gene X

environment mechanisms. Thus, syndromic disorders such as tuberous sclerosis, neurofibromatosis, Angelman syndrome, rare mutations in the genes encoding pTEN and Akt, and a convergence of genetic findings indicate that the PI3 Kinase/ERK pathways are common neurobiological targets in the autisms (Levitt & Campbell, 2009). More complex network analyses are beginning to bear fruit in identifying key elements of these pathways and others that we know are intimately involved in the control of cellular growth (Bill & Geschwind, 2009). From any view, the disruption of growth control, broadly defined neurobiologically (e.g., early regionalization of the neocortex, synapse formation, dendritic and spine growth, axon branching, myelination, and cell migration are all biological growth phenomena) is a primary defect in the autisms.

The Future of Neurobiological Discoveries

A recent Policy/Forum commentary by Akil et al. (2010) served as a call to arms for genomics and the neural sciences to integrate in a far more refined way, because the solutions to understanding brain disorders lie in defining the circuits that are at greatest risk for disruption, which we understand can likely occur through a variety of mechanisms. For developmental neurobiologists, this bodes well with regard to an increasing appreciation for careful studies in developing clinical populations and a more discerning and restricted set of strategies for developing a better biological understanding in animal models of dimensions that are targeting in the autisms. Here are a few suggestions for looking forward:

- define disrupted circuitry longitudinally (e.g., Schumann et al., 2010).
- clinical probes of function through ever-improving methods can provide greater insight when done in combination with approaches that define genetic risk (that make sense biologically) in the same study populations.
- moratorium on developing animal models of the autisms—replaced by an expanding effort to define far better the core mechanisms that underlie the *development* of specific behaviors and skills that are targeted in the autisms. For example, social behavior, of which we know little regarding ontogeny, can be examined across models in ethologically relevant contexts that will provide a new appreciation of developmental trajectory and how it can be disrupted (see Modi & Young, Chapter 34)–and ultimately improved through best intervention practices.
- The initial neuropathological studies in the field, with limited resolution and power, can be replaced by larger analyses with sufficient statistical power and appropriate specificity and sensitivity of the assays. To date, the replicable changes that have been discovered are small in size—thus assay quality control is essential to discern these subtle, yet functionally relevant alterations.
- this section of the book *Autism Spectrum Disorders* has a "cortical-centric" focus. The clinical picture is far

more complex. As ill-defined as the neuropathology and structure/function disruptions are in the cerebral cortex, there is far less known regarding nonneocortical circuits. Renewed efforts here will pay dividends for neurobiologists who may have sensitive assays to probe functions that are at the beginning of the functional hierarchy of social behavior and communication.

Whole Genome Linkage and Association Analyses

Points of Interest

- Autism is a behaviorally defined lifelong neurodevelopmental disorder, with strong evidence for a complex genetic predisposition.
- Many linkage and candidate gene association studies have been carried out over the last decade to identify genetic variants increasing risk of autism spectrum disorders, and have yielded ambiguous results.
- Recent advances in genomic technology now provide greater ability to assay genetic variation, enabling genomewide association and copy number variation studies.
- The results from these genomewide studies, together with other recent genetic findings, implicate both common and rare variants in genes involved in the postsynaptic density, synaptogenesis, and neuronal cell-adhesion in susceptibility to autism.
- These genetic variants often show incomplete penetrance and imperfect segregation and may also influence risk of mental retardation and other neurodevelopmental and psychiatric disorders, suggesting that considerable genetic and clinical heterogeneity is likely to underlie autism spectrum disorders.
- These results underscore the complex genetic architecture of autism, suggesting that interdisciplinary, convergent approaches, large sample sizes, and in-depth phenotyping may be required to further elucidate the risk variants and biological pathways involved.

Autism spectrum disorders (ASDs) are a group of behaviorally defined lifelong neurodevelopmental disorders. Several twin and family studies have indicated a high heritability for autism, with evidence for a strong genetic basis first reported from twin studies published 20–30 years ago (Folstein & Rutter, 1977; Steffenburg et al., 1989). The risk of autism in siblings of autistic individuals is reported as approximately 15–20%,

which is considerably higher than the general population prevalence (Baird et al., 2006; Fombonne, 2005). Similarly, there is an increased risk for the Broader Autism Phenotype in relatives of individuals with autism (Bailey et al., 1998). However, despite this evidence for a genetic susceptibility to autism, only in approximately 10% of cases are the ASDs associated with a recognized cause ("syndromic" autism); in the remaining 90% of cases the cause is unknown ("idiopathic" autism). Increasingly intensive research has been carried out since the initial reports of a genetic basis with the aim of identifying the genetic variants predisposing to idiopathic autism. It is hoped that discovery of the etiological mechanisms will lead to an increased understanding of the disorder, offer improved diagnosis and the possibility of better intervention and treatment. It is now over a decade since the first whole genome screen for linkage in ASD was reported (International Molecular Genetic Study of Autism Consortium [IMGSAC], 1998). This chapter gives an overview of the linkage, association, and copy number variation studies that have been published during this period, and reflects on what has been learned about the probable genetic architecture of autism and how this theory impacts on the likely success of different strategies for variant discovery. It also considers the ways in which experimental technology and practice have evolved to meet these challenges.

Linkage and Association Analyses are Strategies for Identification of Genetic Risk Variants

In recent years typically the first strategy to identify susceptibility genes for common complex disease has been to conduct a whole-genome linkage scan using several hundred polymorphic genetic markers in families with more than one affected individual. Linkage aims to identify regions of the

genome containing genetic marker alleles that are shared between affected relative pairs more often than expected by chance, or less often in the case of relative pairs discordant for the disease. This is based on the expectation that these regions have a higher probability of harboring genetic variants increasing susceptibility to the disorder, as the genetic markers map close to (are linked to) the disease locus. The likelihood of the observed sharing data is compared to the likelihood of the observed data due to chance alone, and the result expressed most commonly as the logarithm of the odds (LOD) score. This results in a genomewide LOD score profile, with a LOD score ≥ 2.2 accepted as suggestive evidence of linkage and a LOD score ≥ 3.6 giving genomewide significant evidence for linkage (Lander & Kruglyak, 1995). This method may enable mapping of the disease risk variant to a relatively small chromosomal interval, although considerable additional work is required after the genome screen to refine the linked region and to identify and confirm the risk alleles in affected individuals. Linkage is a powerful approach to detect rare, highly penetrant disease alleles, and has been used with great success in mapping monogenic disorders segregating in large families. Although this approach can be used successfully in the presence of allelic heterogeneity where there are many different disease causing alleles at the same locus, linkage rapidly loses power in the presence of locus heterogeneity when the same phenotype is caused by risk alleles at multiple different loci.

> **Monogenic:** caused by a single gene.

Recently, due to rapid technological advances in high-throughput genotyping, association studies have become the method of choice to identify risk alleles for common complex diseases. In a case-control association study, the frequency of alleles or genotypes of polymorphic genetic markers—usually single nucleotide polymorphisms (SNPs)—are compared between affected individuals and unaffected controls to detect those that differ significantly between the two groups. This method assumes that a significant proportion of "unrelated" affected individuals carry one of a few, or the same, common ancestral mutations. Hence, marker alleles that differ in frequency between the affected and unaffected groups are presumed to be directly causative, or located close to the disease risk variant. Family-based association studies test for linkage in the presence of association by evaluating the number of alleles that are transmitted versus nontransmitted from parents to affected offspring. Association studies have more power than linkage to detect common variants of small effect that confer only a very modest disease risk. However, association is less powerful in the presence of extensive allelic heterogeneity where multiple variants at the same locus contribute to disease risk.

> **Single Nucleotide Polymorphism (SNP):** a DNA sequence variation involving a single base pair.

Hence, linkage and association approaches have both potential advantages and disadvantages for identifying genetic variants underlying disease risk, with the relative strength and likely success of each approach depending on the unknown underlying genetic architecture.

Whole Genome Linkage Analyses

The first whole genome screen for linkage in autism was reported over a decade ago (IMGSAC, 1998). Since this initial publication, many genomewide linkage and follow-up studies have been carried out, and regions of nearly every chromosome have been linked with susceptibility to ASD (Auranen et al., 2002; Barrett et al., 1999; Buxbaum et al., 2001; Lamb et al., 2005; McCauley et al., 2005; Philippe et al., 1999; Risch et al., 1999; Schellenberg et al., 2006; Shao et al., 2002b; Yonan et al., 2003; and reviewed by Abrahams & Geschwind, 2008; and Gupta & State, 2007). These studies have generally used 350–400 microsatellite markers and tens to hundreds of largely Caucasian families. In studies of autism, the most widely used approach has been the affected sib pair approach, which looks at the sharing of markers between two or more affected siblings, although some studies have included more distantly related relative pairs such as cousins or avuncular pairs. Although several studies have been published reaching criteria for genomewide suggestive or significant evidence for linkage (for example, see Auranen et al., 2002; Liu et al., 2001; IMGSAC, 2001; Yonan et al., 2003; Barrett et al., 1999; and Auranen et al., 2002; Liu et al., 2001; IMGSAC, 2001; respectively), a unifying theme from these data is the lack of consistency in the linked regions between studies, and even within extended studies from the same group (IMGSAC, 2001; Lamb et al., 2005; Yonan et al., 2003; Liu et al., 2001). Several reasons have been posited for this lack of reproducibility, including the limited size of sample cohorts, sample heterogeneity resulting from differing diagnostic and inclusion criteria for subjects and cohort ascertainment between research groups, use of different genetic markers and statistical analyses, and the presence of false positives.

In an effort to identify rare founder mutations segregating in families, a small number of reports have focused on large, extended multiple-generation pedigrees from genetically isolated populations, for instance, from an isolated region of central Finland, in an approach resembling that of traditional linkage studies for monogenic disorders (Auranen et al., 2002; Auranen et al., 2003; Allen-Brady et al., 2008; see also Chapters by Rehnstöm & Peltonen, and Morrow & Walsh in this volume). A recent linkage analysis of a 6-generation pedigree from Utah with seven affected males using the Affymetrix 10k SNP array identified two regions on chromosome 3q and a region on chromosome 20q meeting criteria for genomewide significance, while regions on 7p and 9p met suggestive criteria for significance (Allen-Brady et al., 2008). Analysis of haplotype sharing within these five chromosomal regions showed that five of the

seven affected cases shared multiple chromosome regions with other affected subjects. However, no single haplotype was shared between all seven affected individuals, suggesting genetic heterogeneity even within this single large pedigree.

> **Haplotype:** a set of DNA sequence variations that are close together on the same chromosome and tend to be inherited as a unit.

Larger Sample Sizes May Increase Power to Detect Linkage Signals

In an effort to garner statistical power, two partial meta-analyses of the published linkage data have been carried out. The first study analyzed data from four studies and identified genomewide suggestive evidence for linkage to chromosomes 7q and 13q (Badner & Gershon, 2002). The second study applied a heterogeneity-based genome search meta-analysis approach to six of the published genome scans (including some of those in the previous meta-analysis) and identified significant evidence for linkage to chromosome 7q22-32, and suggestive evidence for linkage to the neighboring region 7q32-qter (Trikalinos et al., 2006).

> **Meta-analysis:** a combined statistical analysis of several separate but related studies to test the pooled data for statistical significance.

However, the most definitive combined linkage analysis carried out to date is the study recently published by the Autism Genome Project (AGP) Consortium (Szatmari et al., 2007). This collaboration involved greater than 20 research institutions across the United States, Canada, and Europe, with a joint sample size of approximately 1500 families containing at least two individuals with ASD, thus creating a sample three times larger than any autism linkage study carried out previously. For the first phase of this project, 1181 families were genotyped using two sets of genomewide markers on two different genotyping platforms; the Affymetrix GeneChip® Human Mapping 10K SNP Array (Szatmari et al., 2007) and a panel of approximately 450 microsatellite markers. Using the Affymetrix 10k SNP Array, this study identified suggestive linkage to chromosome 11p12-p13 (Szatmari et al., 2007), a region not identified previously as significant by other genomewide scans. However, as none of the linkage results could be interpreted as statistically significant, this study demonstrates that despite the large increase in size of the sample cohort the significance of the linkage findings did not increase in parallel. In the AGP study, use of the same genetic markers and methods for statistical analysis argues against these reasons for the lack of consistency in the previously published linkage findings from the constituent groups making up the AGP. However, there are theoretical reasons why increasing the sample size in the presence of locus heterogeneity may actually decrease the LOD score at a true susceptibility locus (Vieland et al., 2001; Bartlett & Vieland, 2007). Nonetheless,

the absence of more significant results from this large study and the fact that the genomewide linkage profile did not appear significantly different from those previously published by the smaller constituent groups suggests that extensive genetic heterogeneity underlies ASD, and only a small effect size may be attributable to any given variant contributing to ASD at the population level.

Autism Subphenotypes Offer Hope of Increased Sample Homogeneity

The lack of reproducibility of the linkage results and the suggestion of underlying genetic heterogeneity have led to sample cohort subdivision in an effort to identify more genetically informative phenotypes and illuminate biological pathways. Autism-related subphenotypes, or endophenotypes, have been used on the premise that they are more directly related to the underlying susceptibility variants than the psychiatric diagnosis and are therefore more tractable to genetic dissection than the disease state itself (Flint & Munafo, 2007). Anatomical, physiological, or developmental endophenotypes, such as head circumference, whole-blood serotonin levels, or language impairment, have been investigated in autism. Linkage analysis in a subset of families with more severe obsessive-compulsive behaviors resulted in stronger evidence for linkage to chromosome 1 than in the whole sample (Buxbaum et al., 2004). Studies incorporating diagnostic measures of language, for example, subsets of families containing probands meeting criteria for "delayed onset of phrase speech" have also demonstrated increased evidence for linkage to chromosomes 2q (Buxbaum et al., 2001; Shao, Raiford, et al., 2002) and 11p (Liu et al., 2008), and a study incorporating information on proband and parental language phenotypes showed increased linkage to chromosomes 7q and 13q (Bradford et al., 2001). Other classifications, for example using measures of IQ (Liu et al., 2008) and "strictness" of diagnostic criteria (Szatmari et al., 2007; IMGSAC, 2001; Yonan et al., 2003) have also been investigated. It has been suggested that the subclassification of affected sibling pairs according to their sex may index genetic heterogeneity, as one of the characteristics of autism is a gender bias of 4 times as many affected males as females and a higher reported recurrence risk for siblings of female versus male probands (Ritvo et al., 1989). Consistent with this, several studies have indicated increased evidence for linkage to specific genomic regions in male-only or female-containing affected sibling pairs (Lamb et al., 2005; Stone et al., 2004; Szatmari et al., 2007; Cantor et al., 2005; Ma et al., 2007), including a male-specific locus identified on chromosome 17q11q21 in families from the Autism Genetics Resource Exchange (Stone et al., 2004), which was subsequently replicated in an independent family sample (Cantor et al., 2005).

> **Endophenotype:** a heritable simpler intermediate trait of a complex psychiatric disorder than the disease syndrome itself.

So, has categorizing samples using subphenotypes really increased cohort homogeneity, or is increased statistical significance in the linkage signals solely due to stochastic variation? Several studies that have examined subgroups have resulted in very small numbers of cases in each group, raising doubts about the robustness of the findings. Therefore, it is probable that, as with other linkage findings, the results reflect both true and false positives. The success of the use of subgroups or endophenotypes will depend on whether the distinct aspects of ASD are under independent genetic control or due to shared risk factors. A principal components factor analysis of data from the Social Responsiveness Scale in children with and without pervasive developmental disorders suggested the existence of a single, continuously distributed underlying factor contributing to multiple distinct aspects of the phenotype (Constantino et al., 2004). Conversely, a recent population-based study of 3000 twin pairs aged 7–9 from the Twins Early Development Study (TEDS) found high heritability for each of the three areas of the "triad of impairments" of autism; the social, communication, and repetitive and/or restrictive domains, both for children across the distribution and at the extremes of the distribution. However, there was only modest to low correlation between the three core areas of the triad, and individuals with extreme scores in one domain did not necessarily have extreme scores in the other domains (Ronald et al., 2006). This suggests that the majority of genes contributing to ASD have symptom specific action, and indicates that the use of cohorts of individuals showing extreme scores in one area of the triad of impairments may be more effective than looking for genes for autism as a whole (Happe et al., 2006). This view is supported by the observation that "unaffected" relatives of individuals with autism show only isolated traits of the Broader Autism Phenotype. Moreover, the relative ease of phenotyping subphenotypes may make them more amenable for collecting the large samples required for statistically reliable analysis of complex genetic traits using large population-based or epidemiological approaches. It seems likely that use of anatomical or physiological subphenotypes such as head circumference or presence/absence of seizures might provide a less subjective biomarker than measures, for example, of repetitive behavior or language ability. Indeed, examination of subgroups of individuals with autism and macrocephaly has led to identification of mutations in the *PTEN* gene (Butler et al., 2005; Buxbaum et al., 2007; Herman et al., 2007; Varga et al., 2009) (see Box 38-1).

Quantitative Linkage Analyses May Increase Power to Identify Autism Loci

Linkage studies to date have generally used a discrete binary trait approach for phenotype classification and subsequent analysis in cohorts of individuals with autism. However, the analysis of quantitative traits should offer improved power for linkage through added dimensionality of the phenotype leading to measurement of more subtle differences over a continuum, and the ability to include relatives previously classified

---

Box 38–1

Mutations in *PTEN* are identified in individuals with autism and macrocephaly

Mutations in the *PTEN* (phosphatase and tensin homologue) tumour suppressor gene have been identified in individuals with autism and macrocephaly (Buxbaum et al., 2007; Butler et al., 2005; Herman et al., 2007; Varga et al., 2009). Previous research has shown that individuals with hamartoma disorders such as Cowden Syndrome, Bannayan-Riley-Ruvalcaba syndrome and Proteus syndrome, which are characterised by germline *PTEN* mutations, may have autistic behaviours as well as overgrowth and macrocephaly. Progressive macrocephaly is one of the most consistent findings in autism (reviewed in (Lainhart, 2006)). This overgrowth is usually not present at birth but develops during the first year of life, and is found in approximately 20% of individuals. Four studies of subsets of individuals with autism and macrocephaly (defined as head circumference ≥2 standard deviations above the mean) were carried out by mutation analysis and sequencing of the coding and putative regulatory regions of the *PTEN* gene. These studies identified germline mutations of the *PTEN* gene in 1.1-16.7% of individuals with autism, which were not found in control individuals (Buxbaum et al., 2007; Butler et al., 2005; Herman et al., 2007). These data suggest that there is an important role for *PTEN* in brain development. This is supported by the observation that conditional knockout mice which lack *Pten* in the cerebral cortex and hippocampus exhibit macrocephaly, neuronal hypertrophy and abnormal dendritic spine morphology (Kwon et al., 2006), and further research showing that *PTEN* is involved in mechanisms controlling synaptic function and myelination abnormalities (Fraser et al., 2008). Taken together, these data suggest that individuals with autism and pronounced macrocephaly should be screened for *PTEN* gene mutations.

---

as "unaffected." In contrast to the development of diagnostic instruments, the refinement of measures and application of quantitative traits to ASD are still in their infancy, despite the use of both univariate and multivariate (simultaneous analysis of several traits) quantitative trait approaches in other neurodevelopmental disorders, for example dyslexia (Fisher et al., 2002; Marlow et al., 2003) and specific language impairment (Specific Language Impairment Consortium (SLIC), 2004; Monaco, 2007).

In autism, quantitative approaches have most often been limited to "affected" individuals, for example, the Autism Genetic Resource Exchange (AGRE) Consortium found that use of "age at first word" as a quantitative trait in their genome scan analysis generated the strongest evidence for linkage on chromosomes 3q and 17q, with a subset of families linked to chromosome 7q (Alarcon et al., 2005). Analysis of five quantitative traits related to autism from the Broader Phenotype Autism Symptom Scale (BPASS) using multivariate models showed that social motivation and range of interest/flexibility had the highest heritabilities, as well as the highest genetic

correlation (Sung et al., 2005). A further study using a measure of autistic-like behavior from the Social Responsiveness Scale evaluated in both affected and "unaffected" individuals identified a locus on chromosome 11 that reached the level of suggestive linkage (Duvall et al., 2007). The IMGSAC has recently developed and refined Family History Interview (FHI; Bolton et al., 1994; Folstein et al., 1999) based instruments using informant (FHI-I) and subject (FHI-S) interviews and an observational measure of autism related broader behavioral phenotypes (Bailey et al., 1998). However, a quantitative genome screen for the broader phenotype carried out using these measures yielded no significant evidence for linkage at a genomewide level (Falcaro, Lamb, & Pickles, unpublished data). The largest quantitative genomewide linkage analysis using total scores of the reciprocal social interaction and restricted, repetitive, and stereotyped patterns of behavior domains from the Autism Diagnostic Interview-Revised also failed to identify significant evidence for linkage in 976 multiplex families from the Autism Genome Project Consortium (Liu et al., 2008) (see also Chapter by Cantor in this volume).

How Much Faith Should We Place in Published Linkage Results?

Does the inability of numerous research groups to identify consistent and statistically robust linkage signals over the last decade suggest a lack of utility of this approach to identify risk variants for ASD? Are most of the published linkage findings really just noise? The relative value of this approach will be determined by the successful identification of disease risk alleles underlying the linked loci, and the subsequent elucidation of biological pathways. While the absence of more convincing linkage results from the large AGP study (Szatmari et al., 2007) suggests that only a small effect size may be attributable to any given variant contributing to ASD at the population level, there have been some successes using a linkage approach; methyl-CpG-binding protein 2 (*MECP2*) was identified as the gene mutated in Rett syndrome, an autism spectrum disorder (Amir et al., 1999), and more recently, variants in Contactin-Associated Protein-Like 2 (*CNTNAP2*) have been implicated in autism by linkage and subsequent association analysis (Alarcon et al., 2008; see below). Similarly, linkage and association mapping led to the identification of a risk haplotype in the *KIAA0319* gene associated with dyslexia (Fisher et al., 1999; Francks et al., 2004), which has subsequently been replicated in several independent studies (Cope et al., 2005; Harold et al., 2006; Paracchini et al., 2008). This risk haplotype was shown to reduce expression of the gene leading to impaired neuronal migration in the developing cerebral neocortex (Paracchini et al., 2006), and the putative causal regulatory variant has subsequently been identified (Dennis et al., 2009).

The likely success of a linkage approach will depend on the unknown genetic architecture underlying susceptibility to autism (covered in further detail below). In the meantime, it is the responsibility of authors and scientific journals to try to ensure publication of robust scientific data, both positive and negative, using well-designed studies.

Genetic Association Studies

The general inability of several research groups to refine linked intervals using extended sample sizes or subphenotypes over the last decade has led to follow-up genetic association studies targeting these linked regions using a positional candidate gene approach. The hypothesis that common complex diseases are likely to be caused by a combination of both common and rare variants has also led to an increase in the number of candidate gene association studies, as association offers more power than linkage to detect common variants of small effect that confer only a very modest disease risk.

Furthermore, as technologies for higher throughput SNP genotyping have evolved from the ability to genotype a single variant, to tens, hundreds, thousands, and currently over a million variants in a single experiment, so too have the regions targeted expanded from isolated genetic variants, to whole genes, genomic loci, and now even the whole genome can be investigated in a single experiment.

Candidate Gene Association Studies

To date, the majority of published association studies have been limited to the investigation of a relatively small number of candidate genes using a similarly small number of genetic variants. These genetic variants have typically been single nucleotide polymorphisms (SNPs), the most common form of variation in the human genome, but also microsatellites or insertion/deletions. Collectively, many candidate genes have been investigated using this approach. These studies have generally examined a combination of known genetic variants and novel variants identified through screening the coding and putative regulatory regions of candidate genes in a small subset of the sample cohort. These genes have been selected as they map to a region of linkage, or because they are plausible biological candidates for involvement in autism etiology based on putative gene function, or patterns of expression (see Abrahams & Geschwind, 2008, for review). A tacit assumption of the former approach is that both linkage and association are powered to detect the same genetic risk variants. Moreover, the candidate gene approach is reliant on an ability to select good functional candidates, based on imperfect knowledge of biological function.

A common limitation arising from these association studies, as with the linkage analyses, is a lack of replication between studies. Again, many reasons have been posited for this lack of reproducibility, including genetic and phenotypic heterogeneity between samples due to ascertainment differences and suboptimal sampling, heterogeneity in subject exposure to environmental influences, data overinterpretation, and disparity in sample sizes between research groups

leading to false-positive or false-negative results because of differing power to detect real effects (Zondervan & Cardon, 2004). A further challenge in genetic association studies is the need to appropriately match cases and controls in order to avoid spurious results arising from population stratification. In retrospect, it is increasingly clear that the sample sizes used in early candidate gene studies were an order of magnitude too small to detect the moderate risks associated with common variants underlying complex disease. Furthermore, the first published study likely represents an overestimate of the true effect size due to a phenomena known as the "winner's curse," suggesting that replication of both association and linkage studies will require larger sample sizes than the initial detection study (Trikalinos et al., 2004; Zollner & Pritchard, 2007).

> **Population stratification:** systematic differences in allele frequencies between subgroups of a population (in this context, cases and controls) that arise due to different ancestral and demographic histories between the two groups.

Nevertheless, as understanding of the pitfalls and limitations of association studies has improved, there has been a trend toward more methodologically robust experiments, using larger and better powered samples, more rigorous statistical thresholds and analytical methods, and with an increasing requirement for independent replication before publication and functional evidence to support the results. One such example of this is an investigation of the *MET* (proto-oncogene hepatocyte growth factor receptor) gene.

A Common Promoter Variant in the *MET* Gene is Associated with Autism

The *MET* gene is a proto-oncogene, but *MET* signaling also participates in cerebral cortex and cerebellar growth and maturation, immune system regulation, and peripheral organ development and repair (such as gastrointestinal), consistent with medical complications reported in some children with autism. *MET* maps to a region linked to autism on chromosome 7q31.2 (Lamb et al., 2005; Trikalinos et al., 2006; Badner & Gershon, 2002), and thus represents a good positional and functional candidate for involvement in autism susceptibility. In an initial study, association of the common allele of an SNP in the promoter region of the *MET* gene was identified in 204 families with autism ($P = 0.0005$; Campbell et al., 2006). This association was confirmed in a replication sample of 539 families with autism ($P = 0.001$) and in the combined sample ($P = 5 \times 10^{-6}$), with multiplex families exhibiting the strongest association. The authors subsequently carried out functional assays which showed that the associated allele resulted in a 2-fold decrease in *MET* promoter activity and altered binding of specific transcription factor complexes. In a follow-up study, the authors showed altered expression of *MET,* and three other genes that regulate *MET* signaling activity, in *post-mortem* cerebral cortex from ASD cases compared to matched controls (Campbell et al., 2007). However, despite the robust initial finding and replication in an independent cohort, a second group failed to replicate association of the common promoter variant in their independent sample of 325 multiplex families and 10 trio families, instead demonstrating association to a different SNP in intron 1 ($P < 0.004$; Sousa et al., 2008). These conflicting results between the two studies epitomize the challenges facing autism genetics researchers, and may indicate false negative or false positive results, the presence of allelic heterogeneity and the influence of different regulatory variants on *MET* expression, or differing ancestral histories between the two study samples.

Association Studies of Implicated Genomic Regions

Several groups have adopted a high-density SNP genotyping association approach to follow up regions identified by genomewide linkage studies. Three such examples are investigation of the linked regions on chromosomes 2q and 7q in the IMGSAC sample (Maestrini et al., 2009), and investigation of the chromosome 17 male-specific linked locus (Stone et al., 2004; Yonan et al., 2003; Cantor et al., 2005) and 7q35 language delay QTL (Alarcon et al., 2002; Alarcon et al., 2005) in the AGRE sample. In the first study, 3000 SNPs were genotyped in each ~40Mb genomic region targeting ~170 and 270 known genes and additional highly conserved noncoding sequences on chromosomes 2 and 7 respectively. Association analysis revealed association to several genes, including inner-mitochondrial membrane protease-like (*IMMP2L)* and dedicator of cytokinesis 4 (*DOCK4*), a guanine nucleotide exchange factor gene involved in dendritic morphogenesis, on chromosome 7. Evidence for a role of *DOCK4* in autism susceptibility was supported by replication of the results in an independent European sample and the finding of a submicroscopic deletion (copy number variant; see section on structural variation below) segregating to both affected siblings in one family. In the second study, a dense panel of 2053 SNPs with an average intermarker distance of 6.1kb was genotyped across the 13.7Mb chromosome 17 linkage interval, which contains ~180 known genes. These SNPs were analyzed in 219 independent families containing only affected male siblings using a parent-child trio based study design, but no single SNP or haplotype association survived correction for multiple comparisons or was sufficient to account for the initial linkage signal (Stone et al., 2007).

A Regional Association Approach Identifies Contactin-Associated Protein-Like 2 as a Susceptibility Gene for Autism Spectrum Disorders

A two-stage approach was used to test 2758 SNPs across the 15Mb 7q34-q36 region encompassing the language-related autism QTL (average intermarker distance of 5.6Kb) and containing approximately 200 known genes (Alarcon et al., 2008). In the first stage, 172 parent-child trios were tested for

association to the quantitative trait "age at first word." These analyses identified association to four genes including Contactin-Associated Protein-Like 2 (*CNTNAP2*), primarily driven by the male-only affected sibling pair containing families, and this association to *CNTNAP2* was subsequently confirmed in 304 independent parent-child trios. A relatively large microdeletion within *CNTNAP2* was also identified in this study in a proband and his father, but not in his affected sibling or in 1000 control chromosomes. Regional gene expression analyses in eight human fetal brains demonstrated that *CNTNAP2* is enriched in regions of the brain that may be important for language development. These findings led the authors to suggest that common variation within *CNTNAP2* contributes to ASD and related conditions, and increases risk of language delay (Alarcon et al., 2008). *CNTNAP2* is one of the largest known genes in the genome and encodes a member of the neurexin family of neuronal cell adhesion molecules that are known to mediate cell-cell interactions in the nervous system, and may play a role in axon differentiation. As such, it is a good functional candidate for autism susceptibility. Two concurrent studies published in the same journal also reported a possible role for *CNTNAP2* in susceptibility to ASD (Arking et al., 2008; Bakkaloglu et al., 2008). The first study reported association of a common noncoding variant at the 5' end of the *CNTNAP2* gene in 72 families with a strict qualitative definition of autism (overlapping with the AGRE families reported above), which was supported in an independent sample of 1295 parent-child trios, albeit with a broader definition of autism than in the initial sample. This study also identified a parent-of-origin and gender effect for association of this common variant (Arking et al., 2008). The second study investigated the possible involvement of rare *CNTNAP2* variants in individuals with ASD, again from the AGRE Consortium (Bakkaloglu et al., 2008). In this study, a de novo chromosomal inversion that disrupted *CNTNAP2* in a child with cognitive and social delay led the authors to sequence the 24 coding exons of the gene in a large cohort of 635 ASD cases and 942 unselected controls, and those changes that were identified only in the case or the control group were genotyped in an additional control sample of 1073 unrelated Caucasian subjects. This identified 13 rare (defined as allele frequency less than 1 in 4000 in the combined control sample) and unique variants in the case group, eight of which were predicted to be deleterious to protein function by bioinformatic approaches and/or altered conserved residues across all species examined, and 11 rare or unique variants in the control group, of which six were predicted to be deleterious or conserved. However, despite this increase in mutation burden in the cases, this did not reach statistical significance. The possible involvement of rare *CNTNAP2* mutations in susceptibility to ASD is supported by the prior identification of a rare homozygous mutation in *CNTNAP2* in an extended Old Order Amish family with cortical dysplasia-focal epilepsy, in which affected individuals had seizures, relative macrocephaly, language regression, and 67% of affected individuals had pervasive developmental delay or autism (Strauss et al., 2006).

Furthermore, a complex cytogenetic abnormality disrupting *CNTNAP2* was also identified in an affected father and his two affected children with Gilles de la Tourette syndrome and obsessive compulsive disorder (Verkerk et al., 2003), and deletions of varying size have been observed in individuals with epilepsy and schizophrenia (Friedman et al., 2008). However, a balanced translocation disrupting *CNTNAP2* has also been described in phenotypically normal individuals (Belloso et al., 2007), again highlighting the complexity of inferring causality of genetic variants in ASD.

Genomewide Association Studies

The pursuit of genomewide association studies (GWAS) has been facilitated largely by two major advances in molecular genetics: the rapid improvement in genotyping platforms, and

---

Box 38–2

Gene expression profiling in individuals with autism implicates biological pathways

Several recent studies have profiled gene expression in peripheral blood or lymphoblastoid cell lines derived from individuals with autism (Gregg et al., 2008; Hu et al., 2006; Nishimura et al., 2007), and it has been shown that differentially expressed genes are able to distinguish individuals with autism from controls, and to distinguish individuals with autism based on their genetic etiology due to a fragile X mutation or a 15q11-q13 duplication (Nishimura et al., 2007). Although these data require independent confirmation and there appears to be little overlap between the results emerging from separate studies, developing bioinformatic resources of gene and protein interactions and pathways enable researchers to make inferences about the underlying molecular and physiological mechanisms. These results suggest that several genes within the 15q11-q13 interval and genes from Gene Ontology pathways including ubiquitin conjugation, SH3 domain containing proteins, GTPase regulator activity, and alpha–protocadherin genes are over-represented within the differentially expressed genes in autism (Abrahams & Geschwind, 2008). These findings are supported by the results of a recent genomewide CNV study and the identification of neuronal cell-adhesion molecules as genes involved in ASD susceptibility. Nonetheless, these bioinformatic resources are currently far from complete, and time will determine whether the complex genetics of autism converges on a single genetic pathway, or multiple distinct pathways. The different developmental trajectories of ASD also emphasise the need for temporally and spatially restricted gene expression studies. The integration of gene expression data with high density SNP genotype data enables an expression QTL (eQTL) approach, whereby SNPs are investigated for association using gene transcript levels as the quantitative trait (Stranger et al., 2007; Dixon et al., 2007). This may provide a more direct correlate of risk than the neurobehavioural phenotype.

the advent of the International HapMap Consortium (2003). The innovation in genotyping platforms has been driven by the emergence of commercially available high density microarrays (chips) that can simultaneously characterize DNA sequence variation at hundreds of thousands of genetic variants at ever declining costs. Phases I and II of The HapMap Project have identified and genotyped over 3.1 million SNPs spread throughout the genome in 269 samples from four different ethnic populations (International HapMap Consortium, 2005; Frazer et al., 2007). This information has been made publically available through the HapMap website (www.hapmap.org). These advances have made it possible to attempt to survey all the variation in the human genome, including noncoding sequence, in a single experiment. However, even with current array density, it is still not feasible to directly genotype all known variants in the human genome, as this would be prohibitively expensive. This has led to the use of an "indirect" approach, which takes advantage of linkage disequilibrium (LD), whereby the genotypes of variants in strong LD are correlated, therefore creating redundancy between SNPs. Two general strategies for indirect GWAS have been taken: the first using a random set of SNPs spread across the genome; the second taking advantage of the LD data from the HapMap Project to select subsets of highly informative "tagging" SNPs based on the LD between them, which can then be used as a proxy to effectively capture the entire set of ungenotyped common SNPs throughout the genome. This latter tagging approach has been shown to provide greater coverage of ungenotyped common (minor allele frequency > 5%) variants throughout the genome (Barrett & Cardon, 2006; Pe'er et al., 2006). However, the development of imputation approaches to infer genotypes at ungenotyped loci (Burdick et al., 2006; Marchini et al., 2007) has reduced the drive to develop arrays of ever-increasing density.

> **International HapMap Project:** aims to determine the common patterns of DNA sequence variation and common haplotypes in the human genome, as a resource for genetic association studies. This project initially investigated samples of African, Asian, and European ancestry, and is now being expanded to seven additional populations.

> **Linkage Disequilibrium (LD):** the nonrandom association of alleles at two or more genetic loci.

These genomewide approaches are unbiased with regard to the likely biological candidacy of the genomic region tested, and rely less on the ability of the researcher to identify "good" biological candidates a priori. The parallel development of gene-based discovery projects such as the Seattle SNPs Variation Discovery Resource (http://pga.gs.washington.edu/) and Innate Immunity Programs (http://innateimmunity.net), which aim to identify all variation in candidate genes and pathways that underlie inflammatory responses and innate immunity respectively, enables a combination of gene-based and indirect genomewide association approaches.

Over the last 2 to 3 years, there has been a dramatic increase in the number of GWAS of common complex diseases published, facilitated by the development of large collaborative networks with access to thousands of samples (Wellcome Trust Case Control Consortium, 2007; Manolio et al., 2007). These studies have resulted in the identification of common genetic variants associated with disorders such as asthma (Moffatt et al., 2007; Himes et al., 2009), Type 2 diabetes (Sladek et al., 2007; Takeuchi et al., 2009; Wellcome Trust Case Control Consortium, 2007; Zeggini et al., 2007), coronary artery disease (Erdmann et al., 2009; Helgadottir et al., 2007; Samani et al., 2007; Wellcome Trust Case Control Consortium, 2007), breast cancer (Easton et al., 2007; Stacey et al., 2007; Stacey et al., 2008), and traits such as height (Weedon et al., 2008; Sanna et al., 2008; Lettre et al., 2008) and obesity (Frayling et al., 2007; Loos et al., 2008). Many of these associations have been convincingly replicated in independent sample cohorts. These studies are providing valuable insights into the genetic architecture of complex disease, and are uncovering potential new mechanistic connections between diseases, for example, the association of *PTPN22* and *IL2RA* with both type 1 diabetes and rheumatoid arthritis, and *JAZF1* with aggressive prostate cancer and type II diabetes. These studies have been reviewed by Iles (2008) and McCarthy et al. (2008) and cataloged online at the National Human Genome Research Institute (http://www.genome.gov/26525384).

Genomewide SNP Association Studies of Autism Spectrum Disorders

Two SNP GWAS of autism spectrum disorders have been very recently published, and further GWAS are currently underway by large collaborative groups such as the AGP. Wang et al., (2009) investigated a cohort of 780 families with 1299 affected children from AGRE, and a second cohort of 1204 affected individuals and 6491 control subjects, all of European ancestry. A meta-analysis of the two combined discovery cohorts identified six SNPs in a 100kb intergenic region between the cadherin 10 (*CDH10*) and cadherin 9 (*CDH9*) genes on chromosome 5p14.1 with strong association signals, the most significant result being a *P* value of 3.4×10^{-8}. These signals were replicated in two independent cohorts, and generated combined discovery and replication *P* values of 7.4×10^{-8} to 2.1×10^{-10}. These intergenic SNPs may have a regulatory effect on the expression of *CDH10* and *CDH9*. These genes encode neuronal cell-adhesion molecules, which are involved in cell adhesion and generation of synaptic complexity in the developing brain. Two pathway-based association approaches applied to the genotype data again suggested that cadherin genes are significantly associated with ASD, thus implicating these genes in the pathogenesis of ASD. Weiss et al. (2009) carried out a genomewide linkage and association study of 1553 affected offspring from 1031 multiplex families using more than 500,000 SNPs on Affymetrix arrays, with subsequent examination of the most significantly associated

regions in additional families. Initial analysis of the discovery sample did not reveal any SNPs showing association with genomewide significance. However, a SNP on chromosome 5p15 between the semaphorin 5A (*SEMA5*) and taste receptor type 2 (*TAS2R1*) genes was significantly associated with autism in the combined discovery and replication cohorts ($P = 2 \times 10^{-7}$). *SEMA5A* has been implicated in axon guidance during neuronal development, and expression of *SEMA5A* was subsequently shown to be reduced in brain tissue from individuals with autism compared to controls, hence implicating this gene in susceptibility to autism.

What Can We Learn from the Candidate Gene and Genomewide Association Studies of Complex Disease Published So Far?

A recent evaluation of GWAS and published linkage studies for Type II diabetes suggests that there is little concordance in the genomic location of the significantly associated variants and linked loci, again indicating that these approaches are powered to detect different variants (E. Zeggini, personal communication). Hence, with some exceptions such as *CNTNAP2* (Alarcon et al., 2008) and *KIAA0319* (Paracchini et al., 2006), linkage followed by association may have limited success to detect susceptibility variants for common complex disease. The extent to which variants identified by GWAS support those implicated by candidate gene association studies has yet to be formally investigated, but many GWAS suggest previously unsuspected biological pathways. Furthermore, in many cases the most strongly associated SNPs map to genes of unknown function or to intergenic regions far from the nearest coding sequence, again suggesting a limited ability to select good functional candidates for complex disease a priori. Given that known coding regions make up less than half of the evolutionarily conserved sequence in the human genome (Birney et al., 2007), this finding should not be surprising. Moreover, finding an association with an intragenic SNP does not mean that this SNP or gene is necessarily involved in disease pathogenesis, as it may be indirectly associated with the true functional variant outside the transcription unit.

As genotyping technologies have evolved, study designs and statistical methodologies have also become more robust—both by necessity and by design—with studies including larger samples with better power, more rigorous quality control and statistical thresholds, and analytical methods built on a combination of population and statistical genetics and epidemiology (Altshuler & Daly, 2007). The GWAS carried out to date have generally used a case-control design, as these samples are cheaper and easier to collect than those using a family-based approach due to the thousands of samples required. In addition, family-based association methods generally have reduced power, and several statistical methods to detect and adjust for population stratification between cases and controls have been developed, with minimal loss of power (Price et al., 2006; Devlin & Roeder, 1999).

A major challenge in GWAS is interpretation of the results and identification of variants that survive a stringent correction for multiple tests, due to the large number of genotype-phenotype associations investigated. Given that there are estimated to be in excess of ten million SNPs genomewide and few true associations for which GWAS are adequately powered, the prior probability of detecting a true association is low, and spurious associations will substantially outnumber true ones. Stringent *P*-value cut-offs, for example, $P < 5 \times 10^{-7}$, have therefore been applied (Wellcome Trust Case Control Consortium, 2007) in order to avoid an abundance of false positive associations. However, the confidence that can be attributed to any given significance level is a function of sample size, and Bayesian approaches, which incorporate prior information on the likely number of true associations, are increasingly being used. Typically, the most compelling signals identified have shown very modest effects in the disease samples investigated, with heterozygote odds ratios generally less than 1.5. However, due to imperfect LD, a modest GWAS finding might ultimately lead to identification of variants with larger effect sizes. Furthermore, the biological insight into disease pathogenesis provided by identification of associated loci is not necessarily correlated with the effect size of the variants identified.

> **Bayesian:** statistical approaches, based on Bayes' theorem, that assess the probability of a hypothesis being correct by incorporating prior probabilities, which are then revised after obtaining experimental data.

The extent of reproducibility of GWAS for some disorders, especially psychiatric disorders, is still unknown, and limited statistical power is demonstrated by the tendency of different GWAS of the same phenotype to find partially overlapping association results. It has been suggested that the effect size of common variants underlying psychiatric disorders may be smaller than those detected for other complex diseases due to an adverse influence on reproductive fitness and subsequent elimination of variants conferring a high degree of risk from the population (Craddock et al., 2008). This suggestion is supported by the existing genomewide association data from studies of autism and other psychiatric disorders, and it is possible that ongoing and future GWAS of psychiatric disorders may yield a raft of nonreproducible associations, akin to those resulting from candidate gene association studies. However, some loci may be missed even by well-powered GWAS due to insufficient coverage of the causal variants by SNPs on the genotyping array. Therefore, the absence of an association signal does not necessarily mean that a gene or region can be excluded.

Recently, guidelines for the design, conduct, analysis, and publication of GWAS and replication studies have been suggested (Chanock et al., 2007), including those of a working group convened on replication in association studies (Chanock et al., 2007). This group suggested that claims of replication should be reserved for effects of a similar

magnitude, with the same allele or haplotype (or those in perfect LD), analyzed for the same phenotype and population and using the same genetic model, and that equal preference for publication should be given to well-conducted negative studies.

> **Genetic model:** model of how a genetic locus affects susceptibility to a disease or trait.

To date, most GWAS have reported single SNP analyses, and association of haplotypes or 2-locus or higher-order interaction between SNPs has not been explored. However, for N biallelic markers there are 2^N possible haplotypes, so the greater information offered by haplotypes or tests for epistasis is offset by the cost of multiple testing. Incorporation of longitudinal data on environmental exposures would enable assessment of modifying environmental variables. The large majority of GWAS also have been carried out in Caucasian samples, and there is a need to extend these studies to other populations. HapMap Phase 3 is carrying out genomewide SNP genotyping and targeted sequencing in 1,301 DNA samples from 11 human populations (including the 270 samples from the four populations originally genotyped in Phases I and II of the project), which should aid this endeavor. The large collaborative networks and expanding sample sizes provide investigators with the ability to study a range of phenotypes simultaneously using the rich sets of data available, and including information on peripheral traits such as height. New public data archives, such as the Database of Genotypes and Phenotypes (dbGaP; Mailman et al., 2007), have been introduced to facilitate analysis of existing datasets employing new hypotheses and methods by investigators carrying out approved research according to study principles. This presents the additional challenge, in common with candidate gene and regional association studies, of a retrospective and prospective need to correct for an unknown number of statistical tests when a successive series of analyses are published independently. Again, it is the responsibility of authors and journals to present a balanced and thoughtful interpretation of research data, both positive and negative.

> **Epistasis:** a circumstance where the expression of one gene is affected by the expression of one or more other genes at a different locus.

Association Studies are Underpowered to Detect Rare Variation

A recent review of 54 genomewide association studies for 22 different diseases published to February 2008 suggests that the frequency distribution and effect size of alleles associated with common disease are more reflective of study power than of the true underlying disease allele frequency distribution; even when the causative genetic variants are mostly rare, the significantly associated alleles are expected to be common, as they are the easiest to detect (Iles, 2008). This may imply that

the many, likely more common, intergenic associated variants identified is a reflection of statistical power, rather than true underlying disease biology. Although population theory models indicate that the allelic spectrum of variants contributing to common complex disease is likely to be small (the "common disease-common variant" hypothesis; Reich & Lander, 2001), several studies have suggested that multiple rare variants with an intermediate penetrance at a number of loci may have a considerable influence on disease susceptibility (Pritchard & Cox, 2002). These low-frequency variants may explain a significant proportion of the missing genetic risk identified by genomewide association studies. The involvement of rare variants in susceptibility to ASD has long been known from the presence of cytogenetic anomalies, and rare copy number variants and coding mutations have been recently identified (see structural variation below). The importance of rare variants is supported by empirical data identifying many rare variants in two candidate genes for neuropsychiatric phenotypes in an ethnically diverse reference sample (Glatt et al., 2001), in genes contributing to variation of triglyceride levels in a population-based cohort (Romeo et al., 2007) and in three renal salt handling genes contributing to blood pressure variation (Ji et al., 2008). Thus, common complex diseases are more likely to be caused by a combination of both common and rare variants.

These rare variants are not sufficiently high risk to be detected by linkage, and association approaches are unable to detect them due to poor coverage of rare variation by commercially available genotyping arrays, and the fact that even very large sample sizes do not provide the statistical power necessary to establish an association due to rare variant frequency (Zeggini et al., 2005). Hence, the definition and detection of common versus rare variation is largely determined by the study power, and a more extensive set of loci influencing common complex disease may be found by GWAS of greater power, or by meta-analysis of existing GWAS data, as has been demonstrated for several disorders including type 2 diabetes (Zeggini et al., 2007; Zeggini et al., 2008; Scott et al., 2007; Saxena et al., 2007).

Recent years have seen a proliferation of novel large-scale sequencing approaches, with dramatically increased throughput and reduced costs (Margulies et al., 2005; Service, 2006), enabling the detection of rare sequence variants. However, genome sequencing strategies are still considerably more expensive than those to detect common variation. The difficulty of establishing statistical significance for overrepresentation of a rare variant in cases versus controls has led to the use of mutation burden analysis, in which the collective rare variant frequency is compared in cases versus controls, as discussed for *CNTNAP2* above (Bakkaloglu et al., 2008). However, proving the relevance of rare variants may still take some time, and other methods are required to demonstrate causality, for example, evidence of a functional effect, demonstrating biological relevance in a model system, or finding additional rare variants in other genes in the same biological pathway or in the same gene in related phenotypes.

Structural Variation May Underlie Susceptibility to Common Complex Disease

Although estimates of the number of genes in the human genome have decreased as our knowledge of genome structure has evolved (International Human Genome Sequencing Consortium, 2004), our knowledge of the extraordinary variability and apparent structural complexity among human genomes is rapidly increasing. The recent technological advances in array-based genotyping and comparative genomic hybridization (array-CGH) now allow investigation of the genome for chromosomal imbalances at a resolution that is considerably higher than that offered by conventional karyotyping. Recent research has highlighted that structural variation is ubiquitous and common throughout the human genome (Eichler et al., 2007; Wong et al., 2007; Korbel et al., 2007; Conrad et al., 2009; Redon et al., 2006). These variants include deletions, insertions, inversions, and duplications, and encompass copy number variants (CNVs) as well as more complex variation, ranging from kilobases to megabases in size (see Feuk et al., 2006, for review). This structural variation comprises millions of nucleotides of sequence heterogeneity and is an important contributor to phenotypic diversity, evolution, and disease susceptibility. To date, over 8000 distinct regions of the reference human genome assembly have been annotated to harbor nearly 30,000 CNVs in healthy control individuals (see the Database of Genomic Variants (dGV) at http://projects.tcag.ca/variation/, version hg18, August 05, 2009). These CNVs may affect gene expression directly by disrupting genes and altering dosage or indirectly through a position effect or unmasking of recessive mutations or functional variants on the remaining allele in the case of a deletion.

Copy number variant: a submicroscopic structural variation that results in gain or loss of genomic material.

Copy Number Variants are Associated with Autism Spectrum Disorders

Much research published over the last 2 decades has shown that there is a high rate of microscopic chromosomal anomalies in individuals with autism spectrum disorders, which may contribute to autism in approximately 7% of cases (for an online catalog see http://projects.tcag.ca/autism/). The majority of these abnormalities arise de novo in simplex rather than multiplex families, with the majority found in syndromic forms of ASD. However, several recent studies have suggested that the proportion of cases of ASD attributable to rare submicroscopic structural variation may be even higher than the 7% identified by standard cytogenetic approaches. Thus, rapid advances in array technology coupled with an increase in knowledge of genetic structural variation have led to the search for copy number variants increasing risk of autism.

Syndromic autism: autism secondary to another known disorder.

The first genomewide array–CGH investigation of chromosomal rearrangements in autism was carried out in 29 karyotypically normal individuals presenting with syndromic forms of ASD using arrays at 1Mb resolution. In this study, unique rearrangements of 1.4–16Mb in size were observed in 27.5% of cases (Jacquemont et al., 2006). Since this publication, several genomewide studies of CNVs in autism using increasingly high resolution arrays have been carried out. An investigation of individuals with idiopathic autism from 118 singleton, 47 multiplex, and 99 control families, including families from the Autism Genetic Resource Exchange (AGRE), found that the cumulative frequency of de novo CNVs was higher in individuals with ASD than in unaffected individuals ($P = 0.0005$), and more common among female and sporadic cases than in multiplex families, with most of the CNVs detected being deletions (Sebat et al., 2007). This led the authors to suggest a causal role of de novo mutation in autism. This paper demonstrated for the first time that chromosomal anomalies are present in idiopathic individuals with ASD, rather than solely in those with mental retardation or syndromic forms of autism, a finding subsequently replicated by several other groups. The Autism Genome Project analyzed their Affymetrix 10k SNP data for linkage (see above) and CNVs in 1181 multiplex families (Szatmari et al., 2007). This revealed several recurrent or overlapping CNVs in multiple unrelated affected individuals and CNVs coincident with published autism rearrangements, suggesting that these CNVs may be involved in susceptibility to ASDs. A hemizygous deletion of coding exons of neurexin 1 (*NRXN1*), a neuronal cell-adhesion gene on chromosome 2p16.3, was also identified in two affected siblings. An array-CGH study using a 19K whole genome tiling path bacterial artificial chromosome (BAC) array with ~200kb resolution was carried out on 397 unrelated individuals with ASD from AGRE and 372 controls (Christian et al., 2008). This study identified 51 autism-specific CNVs in 46 ASD subjects (11.6%), of which 9 were de novo and 42 were inherited. Recurrent CNVs were identified at 3 loci: maternal duplications of 15q11-q13, duplications of 22q11, and de novo microdeletions of 16p11.2 (see below). The CNVs were present at a relatively higher frequency in the female subjects (M:F ratio of 0.84 in individuals with CNVs compared to 1.4 in the study population). A study using the Affymetrix 500k SNP array identified CNVs in 44% of 427 ASD families that were not present in 500 controls, or in a further 1152 controls subsequently examined (Marshall et al., 2008). Although most of these CNVs were inherited, de novo CNVs were again observed at a higher frequency in families having one child compared to those with two or more affected children (7.1% vs. 2% respectively), and recurrent or overlapping autism-specific CNVs were observed at 13 loci in unrelated cases. The most recent study of genomewide copy number variation examined a cohort of 859 ASD cases and 1409 healthy children of European ancestry using the

Illumina HumanHap550 SNP array (Glessner et al., 2009). A replication cohort of 1336 ASD cases from AGRE were subsequently investigated. In addition to the identification of CNVs in previously reported autism susceptibility genes such as *NRXN1* and contactin 4 (*CNTN4)*, several new CNVs in neuronal cell-adhesion molecules including Neuroligin 1 (*NLGN1*) and astrotactin 2 (*ASTN2)* were enriched in ASD cases compared to controls ($P = 9.5 \times 10^{-3}$), again implicating these genes in susceptibility to ASD. CNVs in genes involved in ubiquitin pathways were also identified in cases, but not in controls.

In an innovative homozygosity linkage mapping and CNV approach, the Homozygosity Mapping Collaborative for Autism recently investigated 88 consanguineous families in which the parents were first cousins, to detect autosomal recessive alleles underlying susceptibility to ASD (Morrow et al., 2008). This approach has previously proved to be highly successful in mapping disease genes for autosomal recessive disorders, including autosomal recessive mental retardation (Noor et al., 2008; Alders et al., 2009). Using the Affymetrix 500k SNP array, Morrow et al. mapped several loci containing large, rare, inherited homozygous deletions within linked regions. These deletions were present in 5/88 (6.4%) of consanguineous pedigrees, ranging in size from 18kb to >800kb, and mapped to chromosomes 2q24, 3p12, 3q24, 4q28, and 6p12. Notably, this limited overlap of the linked regions between pedigrees suggests considerable genetic heterogeneity. Furthermore, the majority of these deletions did not contain known genes, suggesting that effects may be mediated through defective regulation of expression of nearby genes; these included solute carrier family 9 (*SLC9A9/NHE9)* protocadherin 10 (*PCDH10*), contactin 3 (*CNTN3),* and sodium channel, voltage-gated, type VII, alpha (*SCN7A)*. Potential mutations of *SLC9A9* were also identified in cases with unrelated parents, with the finding of a nonsense mutation in two male siblings with autism that was not identified in greater than 3800 control chromosomes. Rare, nonconservative coding changes identified by resequencing were also more common in individuals with autism and epilepsy than in controls (5.95% versus 0.63%, Fisher's exact test $P = 0.005$), further implicating this gene in autism susceptibility.

Recurrent Copy Number Variants of *SHANK3* and Chromosome 16p11.2 are Identified in Autism

Two of the most notable recent genetic findings in ASD are the identification of a recurrent 16p11.2 copy number variable region spanning ~500kb and a copy number variant of chromosome 22q13 including the SH3 and multiple ankyrin repeat domains 3 (*SHANK3*) gene*;* a synaptic scaffolding protein involved in structural organization of the postsynaptic density (Sebat et al., 2007; Kumar et al., 2008; Weiss et al., 2008; Christian et al., 2008).

The recurrent microdeletion at 16p11.2 was first observed in 2/180 probands from the Autism Genetic Resource Exchange (AGRE), and was not present in 372 control subjects using a 19k whole genome tiling array (Kumar et al.,

2008). Screening an additional 532 probands and 465 controls for this CNV identified two more cases but no controls with the microdeletion, indicating a combined frequency of 0.6% in autism (4/712 autism versus 0/837 controls). The reciprocal duplication of this region was observed in one individual with autism and in two controls. Bioinformatic analysis of the CNV region localized 12 of the 25 known genes to a single interaction network that included genes involved in cell-to-cell signaling and interaction, whereas pathways for 3 of the 25 genes included postsynaptic density genes (Kumar et al., 2008). A second higher-resolution study used the Affymetrix SNP array 5.0, which contains probes for ~500,000 SNPs and a similar number of nonpolymorphic probes for detection of copy number variation (Weiss et al., 2008). This study identified five individuals from 4/751 multiplex families, again from AGRE, with the same de novo deletion. This finding was followed up and observed in 5/512 children referred for developmental delay, mental retardation, or suspected ASD, as well as in 3/299 individuals with autism from the Icelandic population. Using three different control groups, the deletion was also observed in 3/2814 control samples, which included individuals with bipolar disorder but unscreened for ASD, and in 2/18,834 unscreened Icelandic control subjects, but not in 434 clinical samples from children where ASD, developmental delay, or mental retardation was not indicated. The 16p11.2 duplication occurred in 7 affected individuals from the AGRE families, in 4 of the 512 follow-up children and in 7 of the control individuals. Apart from the known maternal duplication of chromosome 15q11-q13, no other recurrent de novo events > 20kb were identified that were not present in control subjects. In total, deletion and duplication events at 16p11.2 were observed in nearly 1% of multiplex families with autism, in 1% of individuals with autism from a general population sample, and in more than 1.5% of clinical samples from individuals with a developmental or language delay, but at less than 0.1% in the general population. The Affymetrix 500k SNP array study by Marshall et al., (2008) also identified this 16p11.2 CNV at a frequency of ~1% in individuals with autism. Thus, the 16p11.2 deletion and reciprocal duplication appears to contribute to up to 1% of cases with autism, and suggests that one or more genes in the region may be dosage sensitive.

The CNVs and sequence variants observed in *SHANK3* also showed a combined frequency of ~1% in ASD cases and were observed in individuals with autism and Asperger's syndrome (Durand et al., 2007; Marshall et al., 2008; Moessner et al., 2007). Similarly, the deletion of 16p11.2 was also observed at a markedly increased rate in subjects with a psychiatric or language disorder, including schizophrenia, bipolar disorder, attention-deficit hyperactivity disorder (ADHD), dyslexia, and panic disorder, anxiety, depression, or addiction (Weiss et al., 2008). This 16p11.2 CNV is flanked by segmental duplications with >99% sequence identity, a characteristic common of genomic disorders. Although the 16p11.2 deletion appears to have more severe phenotypic consequences than the duplication, the finding of asymptomatic carriers and variable penetrance for both the 16p11.2 and *SHANK3* CNVs suggests that interpretation of their significance is complex.

Notably, some large, well-powered studies have failed to identify the 16p11.2 CNV at elevated frequency in cases compared to controls (Glessner et al., 2009). Nonetheless, the frequency of CNVs of *SHANK3* and 16p11.2 suggests that these variants should be given careful consideration in a clinical diagnostic setting.

Considerations for CNV findings in Autism Spectrum Disorders

The frequency of CNVs reported in the studies above probably represents an underestimate, as balanced rearrangements cannot be identified, and syndromic cases of autism were excluded from the majority of these studies. Although rare copy number variants can be detected by genomewide SNP arrays in contrast to rare SNPs, which are not well represented (see above), the resolution of detection is limited by current technology, and the semiquantitative methods for CNV detection may be more error prone than those for SNP genotyping. Furthermore, while common CNV associations can be identified as described above for SNPs, the same principles for demonstration of statistically significant association with disease apply for rare CNVs as for rare SNPs, leading several groups to adopt a cumulative CNV frequency or mutation burden approach. Moreover, it is not yet known whether CNVs are effectively a monogenic cause of ASD, or contribute only as risk factors in the presence of other susceptibility variants. Notably, several of these studies again report findings from overlapping patient cohorts, therefore further studies in independent samples are required. Hence, differentiating pathogenic from nonpathogenic CNVs will be challenging, and empirical evidence to demonstrate how a CNV affects gene function or expression will be required in order to identify CNVs that are causally related to disease.

Genetic Risk Variants Do Not Obey Diagnostic Boundaries

Autism spectrum disorders are a group of behaviorally defined heterogeneous disorders with diverse symptoms. A growing body of genetic research supports the concept of an ASD continuum, or "the autisms," with an increasingly blurred distinction of the relationship between ASDs, mental retardation (MR), and other psychiatric and neurodevelopmental disorders. This is supported by the observation of many individuals with isolated difficulties in one aspect of the triad of autistic impairments of a severity comparable to autism (Ronald et al., 2006). The current edition of the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV) identifies nearly 300 subcategories of psychiatric disorder (Abbott, 2008), and the boundaries between these subcategories evolve with time. Indeed, a recent study of adults with a history of developmental language disorder supports evidence for diagnostic substitution in autism, as 8 of 38 individuals met criteria for autism using contemporary diagnostic instruments, and 4 met criteria for milder forms of ASD (Bishop et al., 2008).

The suggestion that the same genetic variants arising on a different genetic background may give rise to a different phenotype is illustrated by the *SHANK3* and 16p11.2 microdeletions described above. A rare 15q13.3 microdeletion between the distal breakpoints of the Prader-Willi/Angelman locus identified in approximately 0.3% of individuals with mental retardation (Sharp et al., 2008) was also observed in two studies of copy number variation in schizophrenia in 0.17% cases versus 0.02% population controls, and in nine cases and no controls (Stefansson et al., 2008; Stone et al., 2008). This microdeletion also segregates with autism in a family with three affected male siblings (Pagnamenta et al., 2009). Very rare nonsense and missense mutations have also been identified in individuals with nonsyndromic autism in the neuroligin genes *NLGN4* and *NLGN3* (Jamain et al., 2003), and in a pedigree with MR and ASD (Laumonnier et al., 2004), and a familial deletion of *NLGN4* was also observed in a family with autism, Tourette syndrome, ADHD, depression, and anxiety (Lawson-Yuen et al., 2008). Hence, the same copy number variants and rare variants may lead to an array of abnormal neurobehavioral phenotypes, and clinical presentation may be modulated by additional interacting factors such as common genetic variation. This suggests that combining data from multiple studies may enable researchers to leverage this genetic heterogeneity to identify phenotypic signatures related to the underlying genetics. The possible utility of this approach is hinted at by the identification of mutations and CNVs of chromosome 22q13 including *SHANK3*, where an individual with the deletion presented with autism and severe language delay, whereas her brother with the duplication had Asperger's syndrome and precocious language development (Durand et al., 2007). This necessitates a "bottom-up" approach to genetic homogeneity, rather than the "top-down" phenotypic approach suggested using autism subphenotypes above, and indicates that individuals within the grey areas of phenotypic overlap between disorders and mixed clinical samples may be required to identify genetic boundaries and commonalities. This latter approach is being explored by the Psychiatric Genomewide Association Study Consortium, which aims to carry out cross-disorder meta-analysis of genomewide association data of 59,000 individuals from studies of autism, bipolar disorder, ADHD, major depressive disorder, and schizophrenia to identify convincing genotype-phenotype associations common to two or more disorders, and associated comorbidities (The Psychiatric GWAS Consortium Steering Committee, 2009).

Should We Have Paid More Attention to Penetrant Monogenic Causes of Autism Spectrum Disorders?

There is a significant body of published research showing that autism is observed at a higher than expected frequency in disorders due to single genetic abnormalities, for example, in Fragile X syndrome or tuberous sclerosis (reviewed in Zafeiriou et al., 2007). Moreover, methyl-CpG-binding

protein 2 (*MECP2*) was identified as the gene mutated in Rett syndrome, an autism spectrum disorder (Amir et al., 1999). The growing list of genetic abnormalities that appear to be sufficient to result in an ASD phenotype further supports the concept of a continuum of autisms, and fractionation of the ASD phenotype. This is similar to mental retardation, where the collective phenotype is attributable to many relatively rare penetrant mutations, each accounting for a small percentage of cases (Chelly et al., 2006). In the case of MR, array-CGH has a successful history of identification of de novo submicroscopic chromosome aberrations, and particularly in those individuals with dysmorphic features. This suggests that Mendelian disorders could contribute significantly to our understanding of genetic susceptibility to phenotypically related common complex disorders. Does this mean that most published genetic studies of ASD have minimized our chances of identifying risk variants by excluding those individuals, for example, with dysmorphology? The answer to this question depends on the unknown underlying genetic architecture, in which increased power from sample homogeneity is balanced against biological insight into disease pathogenesis offered by identification of more rare variants.

What Can Linkage, Association, and Copy Number Variation Studies Tell Us About the Genetic Architecture of Autism Spectrum Disorders?

As discussed previously, the unknown genetic architecture of ASDs impacts on the likely success of different approaches to identify risk variants. The question of how many variants contribute to ASD susceptibility within an individual, within a population, and between populations, and the relative frequency of these variants, is still largely unknown. The high heritability of the distinct core domains of ASD and the occurrence of related autistic traits and rapidly decreasing recurrence rates of autism in relatives with decreasing genetic relatedness supports the influence of several common genetic variants. However, the influence of a small number of genes should have been identified by linkage or association studies, even allowing for the presence of multiple disease alleles at each locus (allelic heterogeneity) in the case of linkage. In contrast, the difference in monozygotic to dizygotic twin concordance rates in autism (Bailey et al., 1995; Folstein & Rutter, 1977; Steffenburg et al., 1989) is consistent with the contribution of multiple rare variants (Risch, 1990). It has been suggested that the reduced fecundity associated with severe psychiatric disorders negatively selects against risk alleles, and this may explain why common variants that increase risk in disorders such as autism, schizophrenia, and mental retardation have not been consistently identified (Stefansson et al., 2008). This suggests that rare variants may account for a larger fraction of disease risk than previously assumed, and is supported by the identification of possible etiological CNVs at relatively low frequency.

The finding of increased de novo CNV rates in simplex compared to multiplex families (Sebat et al., 2007; Marshall et al., 2008) suggests that different genetic mechanisms may contribute to ASD risk in these families, namely spontaneous mutation and inherited variation, although the presence of identical de novo CNVs in multiple affected siblings suggests that paternal or maternal germline mosaicism may contribute to autism pathogenesis. This also raises the intriguing possibility of somatic mosaicism and the suggestion that CNVs may be differentially expressed in different tissue types. The relatively high incidence of de novo CNVs in autism (Sebat et al., 2007; Marshall et al., 2008) and schizophrenia (Stefansson et al., 2008; Stone et al., 2008; Xu et al., 2008), but relatively low population frequency again suggests the action of negative selection. A recent formal analysis of recurrence risk in multiplex families with autism suggested that the data is consistent with a significant contribution from two major risk categories: a majority of low-risk families in which autism is caused by de novo mutations with high penetrance in males and relatively poor penetrance in females, where there is little genetic risk for autism in other family members; and a minority of high-risk families in which there is dominant inheritance in males transmitted from these unaffected carrier females (Zhao et al., 2007).

It seems likely that the majority of nonsyndromic autism is caused by a combination of common and rare variants, with common variants exerting a subtle effect on the ASD phenotype and rare mutations exerting a more major effect. It is not yet known whether rare de novo events represent effectively monogenic forms of ASD, cause specific ASD endophenotypes, or interact as modifiers of common variant effects, as suggested by the variable phenotypic presentation. Similarly, it is not known whether the complex genetics of autism converges on a single genetic pathway, or multiple distinct pathways. Increased knowledge of two-locus or higher order interactions between variants will lead to better understanding of the mechanisms underlying autism pathogenesis. Studies of large multigenerational families are needed in order to assess the segregation and penetrance of putative risk variants and how distinct variants interact. The effects of gender and modifying variables such as environmental exposures or the influence of epigenetics, together with stochastic effects, also need to be incorporated into genetic models.

Epigenetic: heritable genetic variation that is not due to changes in DNA sequence.

Increasing Sample Sizes and the Challenge of Data Interpretation

In recent years, genetic research in autism has moved from the challenge of overinterpretation of too little data to the challenge of mining the wealth of data generated by increasingly high-throughput genomic technologies and expanding

sample cohorts. This data must be collated, stored, and analyzed, posing a computational and statistical hurdle.

While the absence of more significant linkage results from the Autism Genome Project study (Szatmari et al., 2007) suggests that future increases in sample size may not lead to more significant linkage findings, genomewide association and CNV studies of common complex disease generally have illustrated that the more samples the better for detection of common variants of moderate effect and rare risk alleles. These studies are facilitated by large consortia and publically available resources such as the Autism Genetic Resource Exchange (AGRE). The drive by funding bodies and scientists toward a more holistic, interdisciplinary approach, the implementation of infrastructures to support data sharing between investigators, and the impetus to make biomaterials and genotype data available to the scientific community has both a positive and negative impact on scientific research. While publically available resources lead to a wealth of informative analyses using different approaches, this also leads to multiple reporting and nonindependence of results, so that repeated publication of the same or partially overlapping data becomes accepted "fact" in the autism literature. This is exacerbated by individuals with autism and their families who are motivated to participate in multiple studies, leading to resampling of the same individuals. The pressing need for sample sizes considerably larger than those currently available is supported by online resources such as the Interactive Autism Network (IAN: http://www.ianproject.org/). Population-based samples such as these and epidemiological cohorts allow exploration of the boundaries and overlap between genetic and clinical presentation, but lead to a conflict between broad-brush phenotyping and large samples via Web-based resources, versus the need for detailed diagnoses and phenotyping.

Conclusions

The last decade of research into the genetics of autism spectrum disorders has been notable for the general lack of reproducibility of results from whole genome linkage and candidate gene association studies. However, recent advances in genomic technology now provide greater ability to assay genetic variation, enabling genomewide association and copy number variation studies. It remains to be seen whether the findings of published and ongoing genomewide association studies will prove to be more consistent than those from previous candidate gene association studies. Nonetheless, several copy number variants and rare mutations that appear to increase risk of autism have been recently discovered by multiple groups. The identification of associated variants, structural variation, and rare sequence mutations in genes such as *CNTNAP2, CDH10, SHANK3, NRXN1,* and the neuroligin genes is beginning to offer insight into the underlying biology, suggesting that genes involved in the postsynaptic density, neuronal cell-adhesion, and glutamatergic synaptogenesis may be involved in susceptibility to ASD. Some of these genes

are also implicated in mental retardation and other neurodevelopmental and psychiatric disorders. These findings have led to a clear shift in thinking about the genetic basis of autism, indicating extensive genetic heterogeneity with the likely contribution of both common and rare variation in multiple genes with diverse functions. As technologies emerge for genetic research into complex neurodevelopmental disorders, theories of causality also evolve, and the technologies and theories regarded as state of the art and complex today will probably be regarded as routine and simplistic tomorrow. In spite of this, significant progress in understanding the genetic variation underlying ASD has been made in the last 2 to 3 years. This suggests that despite major challenges, there is cause for optimism for continued discovery of autism risk variants and illumination of the etiological biological mechanisms.

Challenges and Future Directions

- The identification of multiple rare mutations and CNVs that are involved in ASD susceptibility suggests that large consortia and convergent interdisciplinary approaches will be required to further elucidate the risk variants and biological pathways involved. This need for large sample sizes conflicts with the need for improved phenotypic resolution.
- The real translational benefit from this genetic research is likely to come from an improved understanding of disease mechanisms and risk in the population.
- Considerable in vitro and in vivo functional evidence will be required to demonstrate causality of putative risk variants, and to understand how they influence clinical presentation.
- The likely etiological overlap with other neurodevelopmental and psychiatric disorders suggests that epidemiological and longitudinal studies will be required to identify additional genetic, epigenetic, environmental, and stochastic risk factors and to understand how these different risk factors interact functionally. This complicates potential therapeutic translation and hinders progress to effective generic or personalized clinical intervention.
- The rapid development of next generation sequencing technologies means that in the near future the genomes of individuals with autism will likely be investigated at nucleotide resolution, bringing with it the challenge of managing and interpreting this wealth of biological data.

Autism Endophenotypes and Quantitative Trait Loci

Points of Interest

- Twin, linkage, and association studies indicate that ASD is genetically complex, and may be the result of different subsets of multiple risk genes interacting to produce this phenotype.
- Analytic strategies to reduce the complexity of ASD are needed to reveal its genetic etiology.
- Identification of ASD-related quantitative endophenotypes that are heritable and have sufficient variation is an important first step.
- Ascertaining study samples with ASD, measuring related endophenotypes in family members, genotyping, and conducting linkage analyses to detect quantitative trait loci (QTL) is an effective approach to reduce complexity.
- For ASD, QTL studies have been conducted and loci have been replicated. In one case quantitative association studies reveal the predisposing gene.

1.0 ASD: Genetic But Not Mendelian

During the 6 decades since ASD was defined there has been a growing recognition of the importance of genes in its etiology. This was first revealed by twin studies; the ASD concordance rate in monozygotic (MZ) twins who share all of their genes has been estimated at 90%, while that rate in dizygotic (DZ) twins, who share on average 50 percent of their genes, is much lower, at 10% (Bailey et al., 1995). Despite this substantive support for genetics, efforts to identify ASD genes exhibit inconsistent linkage results and weak association effects (Lamb, Parr, Bailey, & Monaco, 2002). These are likely to reflect its genetic complexity (Veenstra-Vanderweele, Christian, & Cook, 2004). In contrast, single-gene Mendelian disorders that exhibit clear family segregation ratios of

50 percent for dominant traits and 25 percent for recessive traits, yield linkage signals that are usually unambiguously significant at one locus, allowing the responsible genes and their predisposing alleles to be localized and then identified by positional cloning techniques. As an example, the single gene for cystic fibrosis, an autosomal recessive Mendelian disorder, was one of the first to be discovered using linkage studies followed by positional cloning. Even though follow-up studies in patients from around the world indicate that there are over 1000 causal mutations in this gene (Farrell et al., 2008), linkage analysis was successful in localizing it as well as those for other Mendelian disorders.

1.1 Linkage Analysis for Mendelian Disorders

Linkage studies are designed to find the chromosome regions harboring the genes that contribute to phenotypic differences among individuals. The statistical algorithms to test for linkage have evolved over time to accommodate changes in the nature and complexity of the phenotypes and the numbers of markers available for mapping. However, all linkage studies require the ascertainment of pedigrees with members that show variation in the phenotype and have genotypes at informative markers. The statistical algorithms and computer programs for linkage analysis identify where the cosegregation of trait values and marker alleles within pedigrees is greater than what one would expect by chance alone. Linkage results at each locus reflect the statistical information that has been combined across all pedigrees in the analysis (Cantor, 2006; Ott, 1999).

Initially the traits in linkage studies were binary, such as the presence or absence of disease, and the models of inheritance used in the analyses were Mendelian dominant or recessive. Using model based or classical linkage analysis, the statistical evidence for linkage is evaluated by LOD scores. The LOD score is the log of the odds of linkage compared to the null hypothesis of no linkage at a marker. The LOD is

calculated by comparing the statistical likelihood of the observed cosegregation of trait values and marker alleles in the study pedigrees to the statistical likelihood of the cosegregation in the same pedigrees at the same marker that is expected by chance alone when there is no linkage. Traditionally, a LOD greater than 3 (odds of 1000 to 1) has been taken as evidence supporting linkage to the region containing the genetic marker. Significant linkage implies that the disease gene is in the chromosome region containing the marker. Following a successful linkage analysis, positional cloning, association analyses, or sequencing studies designed to detect predisposing genes and causal alleles are conducted in the linked regions.

1.2 ASD is Genetically Complex

In addition to inconsistent linkage and association results, the genetic complexity of ASD is revealed by the large discrepancy between the MZ and DZ twin concordance rates. That is, when there is a multigene model with no allelic or gene interactions, the DZ twin concordance rate is expected to be about one half that seen in MZ twins. The large difference estimated for ASD (90% vs. 10%) is explained by a model of inheritance that includes numerous interacting genes and alleles (Ijichi et al., 2008; Risch et al., 1999), with each making a small contribution to the ASD phenotype. The complex genetics of ASD is also likely to include significant genetic heterogeneity (Happe, Ronald, & Plomin, 2006; Ronald et al., 2006). Thus, a realistic model of inheritance might include 20 or more predisposing ASD genes, with each having numerous risk alleles. One individual with ASD might have a particular subset of those genes and alleles, while another with ASD could have a different but overlapping or completely different subset. In addition, the environment is likely to play an important role, and its effects may be unequal among the affected individuals.

In summary, there are a very large number of genetic models that could each be invoked to explain the genetic risk for ASD, with none being correct. Linkage analyses of ASD cannot employ simple models of inheritance such as the dominant and recessive ones used for Mendelian disorders, as the true model is very complex and remains unknown. Given this genetic complexity, designing an appropriate gene identification study remains a challenge. However investigators continue to feel a pressing need to use the current molecular and analytic tools to tackle gene identification for ASD and other common complex disorders that are clearly genetic, but not Mendelian. The trajectory of this endeavor has been accelerated by the molecular and bioinformatics tools developed and refined in conjunction with the Human Genome (Roberts, Davenport, Pennisi, & Marshall, 2001) and HapMap (Manolio, Brooks, & Collins, 2008) projects.

1.2.1 Model Free Linkage for Complex Traits

Linkage methods that do not require a genetic model have been developed to address the genetic complexity. They are referred to as model free methods, and some approaches used in QTL mapping are based on them. While no model of inheritance is put forth, the principle on which the methods are based is that if a chromosome region contains a disease gene, siblings or other relative pairs who both have the disease will share marker genotypes in the region containing a disease gene more often than one would expect by chance alone. Thus, chromosomal loci exhibiting excess marker allele sharing identical by descent (IBD) (or the same allele inherited from common ancestors) by affected sibling pairs are linked to the disorder. Marker allele sharing IBD is illustrated in Figure 39-1.

In this pedigree with a mother, a father, and their two children, the parents have genotypes A1A2 and A3A4 respectively. The mother passes A1 and the father passes A3 to their daughter. If the son gets A2 from the mother and A4 from the father, these two siblings share 0 alleles IBD, which is expected to occur 25% of the time. If the son gets A1 and A4, the siblings share one allele IBD. Sharing one allele could also occur if the son gets A2 and A3, so sharing one allele IBD is expected to occur 50% of the time. If, like the daughter, the son also gets A1 and A3 from their parents, the siblings share 2 alleles IBD, which is expected to happen 25% of the time. The null hypothesis of no linkage or no excess allele sharing has a probability distribution of 25%, 50%, and 25% for sharing 0, 1, or 2 alleles IBD. If, for example, in a panel of sibling pairs ascertained for ASD, an observed distribution of 15%, 40%, and 45% for a marker provides evidence of ASD linkage to the chromosome region containing the marker indicating the presence of an ASD gene at that locus.

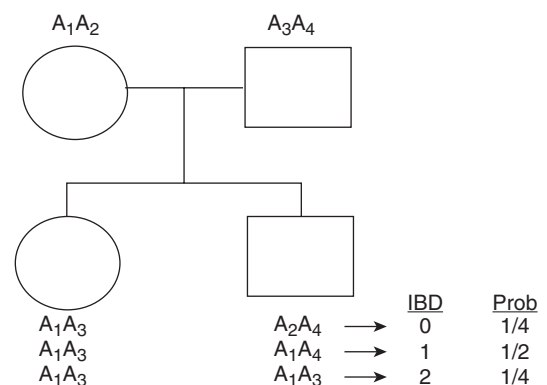
Model free linkage analysis tests for deviations of the observed IBD distributions from the expected IBD sharing distribution under the null hypothesis of 25%, 50%, and 25%. Various statistics have been used to assess the significance of the deviations, and some methods provide a LOD score (Cantor, 2006; Ott, 1999). A threshold for significance should be set to declare linkage. Setting this threshold is not straightforward, but researchers often use a LOD score of 3 (or a p-value equivalent to it), which is the same as the one used for parametric linkage analysis. Replication in an independent sample is a hallmark of success in mapping complex traits.


Figure 39–1. Illustration of allele-sharing identical by descent.

ASD, like many other genetically complex disorders, shows evidence of linkage to numerous chromosome loci, but only a few replications have been observed (Cantor et al., 2005). Thus, even model free linkage methods may not be adequate for a phenotype with this degree of genetic complexity. This suggests that ASD is appropriate for well-designed QTL studies.

1.3 Genomewide Association Studies

Currently, studies are employing an alternative to linkage analysis as the first step in gene detection. That is, preliminary linkage analyses are not conducted to localize genes, but the whole genome is tested for association with ASD or other complex disorders using 500,000 to one million single nucleotide polymorphisms (SNPs) to identify the predisposing genes and alleles (Simon-Sanchez & Singleton, 2008). The rationale is that linkage studies have some drawbacks, and the tools to identify risk genes through association analysis are now available (Frazer et al., 2007). One drawback is that linkage studies require the collection of families, which can be difficult to find and expensive to ascertain. Also, linkage analysis is not sensitive enough to detect the alleles that confer small risks.

Genomewide association studies (GWAS) conducted on large samples of cases and well-matched controls can identify alleles with small effects. They capitalize on the likely linkage disequilibrium between genetic risk variants and the nearby SNPs that have traveled with them on the same chromosome throughout the history of the population. It is thought that there are 10 million SNPs in humans, and that a large fraction of the genetic variants that contribute to the risk of disease will be captured by the commercial panels of 500,000 to 1,000,000 SNPs available for these studies. The mechanism by which fewer genotyped SNPs capture the variation of others is referred to as "tagging." GWAS has met with success in a number of complex disorders, but in many of those cases the associated variants explain very little of the genetic risk for the trait (Willer et al., 2009). ASD GWAS studies are currently being conducted. In preliminary findings, significant associations with common variants have not been observed, and the focus has been mainly on rare copy number variants. Although genetic models are not needed for GWAS studies, strategies to reduce genetic complexity will be important. As with linkage, methods are available to test quantitative endophenotypes for association with SNP panels.

2.0 ASD: Reducing Genetic Complexity

Identifying the genetic contributions to complex disorders such as ASD has not been straightforward. Study designs and analytic methods that have been suggested (Almasy & Blangero, 2001), indicate that a more successful path to gene identification would include the identification and analysis of traits with simpler genetic models. There are two straightforward strategies to reducing complexity. The first is to stratify the members of the study sample by a factor thought to contribute to genetic heterogeneity. For example, one could know or assume that those with ASD who are nonverbal have a different set of predisposing genes than those who are affected and verbal. Depending on the analysis conducted, the members of the ASD study sample are stratified by a feature of ASD and separate gene finding analyses are conducted in the two samples.

A second strategy is to analyze a quantitative trait or endophenotype that is associated with ASD and known or assumed to capture a single or reduced number of genetic dimensions of the disorder. It is anticipated that the endophenotype is likely to result from fewer genes and alleles acting with less complexity. This approach can be successful if there are common genetic variants serving as the basis of the endophenotype (Wijsman, 2007). Using this strategy, genes predisposing to features of ASD are mapped through QTL analyses, an approach that is addressed here. To clarify, the goal is to identify heritable traits that have substantial variance and are known to be associated with or can contribute to a diagnosis of ASD. A common example illustrates this point. The genes that contribute to triglyceride levels, a continuous and heritable trait, are also likely to contribute to the risk for coronary artery disease (CAD), as high triglycerides are seen in those with CAD. Therefore triglyceride levels provide a good CAD endophenotype for QTL mapping. Identifying appropriate quantitative traits associated with ASD poses a greater challenge, because our understanding of its biology is not as well developed as that for CAD.

2.1 Quantitative Endophenotypes

The goal is to distill the genetically complex phenotype into more specific heritable features. That is, for many complex disorders including ASD, the diagnosis of being affected results from positive responses on a checklist of observed features or behaviors. For example, a genetically complex autoimmune disease like systemic lupus erythematosus is diagnosed if any of four out of eleven criteria are met (Hochberg, 1997); metabolic syndrome, which is also complex, is associated with diabetes and coronary artery disease and diagnosed when several criteria involving disturbances in metabolism and lipids are met (Qiao et al., 2009). Most relevant to ASD, neurobiological disorders are diagnosed when an individual exhibits a pattern of behaviors consistent with criteria listed in the *Diagnostic and Statistical Manual* (American Psychiatric Association, 1994)**.** Focusing on single traits from these checklists may reveal entities that derive from the major effects of fewer genes with a simpler genetic model. Also, since the analysis of quantitative traits is more statistically powerful than the analysis of discrete traits, identifying quantitative features of the ASD phenotype can provide a robust approach to gene identification.

2.1.1 A Quantitative Trait Model

The genetic contribution to a quantitative trait or endophenotype can be illustrated by a simple arbitrary model with 3 genes. While the genetics of any "real" quantitative trait

will be more complex, the principles illustrated by this model can be applied. In this hypothetical model, there are 3 genes each with 2 alleles contributing to Trait1 in an additive fashion. The alleles are "A" and "a" for gene1, "B" and "b" for gene2, and "C" and "c" for gene 3, and each capital letter allele contributes 3 to the trait value, while each lower case letter allele contributes 1. Thus, a person with genotype AA, Bb, and cc would have a trait value of 12. The maximum and minimum trait values are 18 and 6, respectively. Complexities might include gene-gene or gene-environment interactions that would alter the trait values. If the alleles with capital letters exhibit dominance at each locus, someone with genotype AA, Bb, and cc would have a trait value of 14. Interactions among loci would produce a wider number of possible trait values. Ascertainment of an informative study sample is critical, and gene finding efforts are enhanced if the sample is drawn from families exhibiting the entire range of the trait. These related individuals are expected to be correlated in their trait values because they share common genes. Identifying the genes by QTL analyses capitalizes on the expected relationships of trait values and marker allele sharing by the relative pairs in the pedigrees.

2.1.2 Three Criteria for Good QTL Endophenotypes

QTL mapping, like linkage analysis, is directed toward finding the chromosomal loci that harbor genes contributing to a trait, however here the trait is a quantitative endophenotype. Specific criteria must be met for an endophenotype to be appropriate for QTL mapping. The first is that the endophenotype exhibit substantial variation in the study sample under analysis. Achieving this can sometimes be difficult. A powerful study design consists of genotyped individuals in pedigrees ascertained for those with the complex disorder, where both the affected and unaffected are measured. The contrast of these individuals provides good power to detect the correlation of trait value differences and allele sharing that is used to map the genes. Thus, pedigrees with a large number of affected individuals are more powerful.

Sometimes the trait can only be measured in those who are affected. An example is the age of onset of the disorder. A common design consists of multiplex nuclear families with at lease two affected members measured for the endophenotype. This design will provide less power than one including unaffected individuals from the families, but it may be necessary for the proposed endophenotype. For other disorders, the endophenotype can only be assessed effectively in unaffected individuals. This will reduce the statistical power to identify the predisposing genes, as it leads to an enrichment of alleles that have very small effects on the trait value, since the bigger effects are likely to occur in the affected who have the disturbed trait values. Trait variation can be continuous, such as IQ, or ordinal, such as the degree of dysfunction (mild, moderate, or severe). A statistical power calculation taking the nature of the study sample, level of significance, and distribution of the trait can be conducted. It will allow the investigator to estimate the detectable effect size of the predisposing alleles.

Since there is no simple approach that can be used in every situation, it is important to evaluate the distribution of the quantitative trait in the choice of analytic method and interpretation of results.

The second criterion for effective QTL mapping is that the endophenotype should be associated with the binary definition of the disorder. That is, one should be able to subdivide the values of the trait so that it correlates with binary definition of the disorder. Figure 39-2 illustrates this point. Here, in Figure 39-2a, the horizontal axis reflects the observed values of the trait, and the vertical axis reflects the percent or probability of each of those values. Hypothetically, the vertical line that is drawn divides those who are affected from those who are not. This indicates there is a perfect relationship between the endophenotype and the binary disorder. In reality, the relationship will not be that strong. This is illustrated in Figure 39-2b, where, as in 39-2a, the white color reflects the trait values of those who are affected and the grey color reflects the trait values of those who are not affected, but a clean vertical line cannot be drawn. Since the quantitative trait is not used to diagnose the disorder directly, there are no strict rules regarding this expected relationship between quantitative values and diagnosis, and the judgment of the investigator as to the acceptability of this correlation is important.

The third critical criterion is that the endophenotype have a significant heritability. The heritability of a quantitative trait is the fraction of the trait variance that can be attributed to genes. Narrow heritability is operating if the genes act in an additive fashion, as illustrated by the example in section *2.1.1*. Broad heritability is the estimate that includes the interactive effects of genes, also discussed in that section. Because these interactions are difficult to identify or predict, investigators usually make the simplifying assumption that all gene effects are additive, and they estimate the narrow heritability. The closer the genetic model is to one that is additive, the easier it is to map the QTL.

2.1.2.1 Estimating Heritability

The heritability of a trait in a given population can be estimated by calculating the observed trait correlations in classes of relative pairs, such as siblings, and adjusting them for their degrees of relationship. The most informative pairs are MZ twins, as they share all of their genes and their correlation without an adjustment is a direct estimate of trait heritability. DZ twins share on average half of their genes and doubling their correlation provides an estimate of heritability. Their contrast, twice the difference in these correlations, provides a better estimate of heritability because it accounts for the sampling error and environmental correlations in these estimates. There are more complex methods to estimate heritability that involve analyses of trait variance (Rice, 2008).

Sometimes only sibling pairs are available for a heritability estimate. While the trait correlation for these pairs can be doubled for a rough estimate of trait heritability, it includes the effects of common family environment. Thus, it provides an upper bound for the heritability of the trait, which can be
Figure 39–2. Relationships of a quantitative endophenotype and a binary diagnosis.

much smaller. Using multiple types of relative pairs provides a more refined estimate, but the "gold standard" is derived from data on MZ and DZ twin pairs. For most study designs, the heritability estimate has a standard error that can be used to test the null hypothesis that it is zero.

The heritability of a quantitative trait provides an upper bound for the heritability contributed by any one locus, referred to as the locus specific heritability. For example, if three genes contribute to the trait, the heritability will be divided among the three loci, although not necessarily evenly, giving some of the loci with bigger effects a better chance of detection by QTL analysis. If many genes contribute to the trait value, the heritability can be high and the locus specific heritabilities can all be low. Thus, a high heritability for a trait that is polygenic does not guarantee that a QTL will be identified. A well-defined study for a highly heritable trait, a sufficient sample size, and luck will all be important.

3.0 ASD: Quantitative Endophenotypes

The identification of quantitative endophenotypes for ASD is at an early stage of development, and QTL studies may be premature for many quantitative traits. However, several authors have addressed the value of identifying endophenotypes for general psychiatric disorders (Gottesman & Gould, 2003; Szatmari et al., 2007; Walters & Owen, 2007), and others provided general guidance for their definition in ASD (Allison et al., 2008; Chiu et al., 2008; Pickles et al., 2000; Viding & Blakemore, 2007; Wijsman, 2007). Their general guidelines for ASD suggest quantifying the features of a particular symptom and including normally functioning adults who also

exhibit aspects of the trait, when this is feasible. The guidelines acknowledge that often the traits can only be assessed in those who are affected, limiting the range of variability. Suggested classes of traits include dimensions of mental skills that can explain features of ASD (Baron-Cohen, Wheelwright, Skinner, Martin, & Clubley, 2001). For example, employing an instrument to assess and measure the degree of central coherence could allow investigators to capture and quantify the skill that permits savant behavior, because it is thought to be explained by weak central coherence (Viding & Blakemore, 2007).

3.1 Behavioral Questionnaire Endophenotypes

Appropriate endophenotypes can come from instruments devised to assess the features of (Hoekstra, Bartels, Verweij, & Boomsma, 2007; Skuse, Mandy, & Scourfield, 2005) and diagnose ASD (Piven, Palmer, Landa et al., 1997). The Quantitative Checklist for Autism in Toddlers (QCHAT), a 25-item checklist with a score of 0–4 on each item provides a number of possible traits for analysis. These items are correlated with ASD, as the mean scores for those with ASD are significantly higher than for those who are unaffected (Allison et al., 2008). Additional analyses of the heritability or familiality of the scores would be important for further work. The broad autism phenotype (BAP) is described by features of language and personality, ranging from mild to severe. It is correlated with, but does not lead to autism, and can be quantified as a potential endophenotype (Losh & Piven, 2007; Piven, Palmer, Jacobi, Childress, & Arndt, 1997). The Broader Phenotype Autism Symptom Scale (BPASS) is a good source of endophenotypes. A trained clinician measures social motivation, social expressiveness, conversational skills, and flexibility in ASD-affected individuals and their family members

along a quantitative continuum (Dawson et al., 2007; Dawson et al., 2002). Developers of this instrument anticipated the possibilities of QTL studies, as they identified BPASS traits that are familial (Sung et al., 2005) and correlated with ASD.

The Social Responsiveness Scale (SRS) (Constantino et al., 2006; Constantino & Todd, 2003) provides a quantitative score measuring the deficit in this defining feature of ASD. The SRS score is highly correlated with ASD and provides a measure of a single dimension of social skills. It has been validated, and found to be heritable in normal individuals, as assessed by twin studies. It can be administered to pedigree members and provides an excellent trait for QTL mapping. A small QTL study was conducted in nuclear families with ASD, which is discussed more extensively in section 5.0.

3.2 Behavioral Traits: Autism Diagnostic Instrument Revised (ADIR)

The ADIR, which has been used extensively to diagnose ASD (Lord, Rutter, & Le Couteur, 1994), provides a wealth of potential endophenotypes for QTL analyses. It assesses deficits in the domains of language and social skills and identifies the presence of stereotyped and repetitive behaviors. Quantification of these deficits and their specific features provides candidate endophenotypes for QTL analyses. These capture the global degree of deficit in language or social skills or focus on the quantitative assessment of a single dimension of language or social skills, such as the degree of delay in speech.

The ADIR is an assessment of approximately 100 ASD features by trained clinicians interrogating caregivers. Many questions address the levels at which the child exhibits particular deficits. The value for each item varies from 0 to 3, with a higher score reflecting a greater deficit. Thus, scores are elevated in those with ASD. A single item provides an ordinal score and combinations of items provide a more continuous range of values. Scores for item combinations can be achieved by direct addition or derived from multivariate statistical methods like factor analysis (Afifi, Clark, & May, 2004), which is applied to find a linear combination of the scores on individual items reflecting language deficits that are most correlated with each other in those with ASD. More sophisticated analytic methods are also available to find multivariate quantitative traits appropriate for QTL analysis (Kutner, Nachtsheim, & Neter, 2004).

3.3 Autism Diagnostic Observation Schedule (ADOS)

The ADOS is a semistructured assessment with diagnostic modules that are customized for both nonverbal and verbal patients and tailored for individuals that range in age from toddlerhood to adulthood. The assessment is open-ended, and an examiner uses a series of situations and interview questions to elicit behavior and verbal responses from the individual tested. An overall assessment is used to discriminate among forms of ASD, such as autism itself, pervasive

developmental delay, or Asperger's syndrome. Since it involves direct observation of a person's behavior by an examiner who is taking careful note of traits and behaviors central to the diagnosis of autism, it is difficult to convert this instrument into a tool with quantitative traits. Thus, the ADOS is much less adaptable to QTL analyses than the ADI-R and the other instruments discussed in this chapter. These differences indicate that one must recognize that it is not only the quality of the traits that must be considered for QTL studies, but the nature of their measurement as well. An interactive tool for diagnosis may not adapt well to providing a consistent and well-defined phenotype.

3.4 Biological Endophenotypes

Although knowledge of the biology of ASD is currently limited, investigations suggest a number of ASD-correlated, heritable, and variable biological endophenotypes appropriate for QTL analyses. For example, an increased number of those with ASD exhibit a large head circumference for their age and sex (Fombonne, Roge, Claverie, Courty, & Fremolle, 1999; Lainhart et al., 2006; Sacco et al., 2007). Significant familial correlations in head circumference have been observed in family members of those with ASD, indicating this is a good ASD endophenotype for QTL analysis (Spence, Black, Miyamoto, & Geschwind, 2005). The sizes of certain structures of the brain have been implicated as causing the large head (Courchesne et al., 2007), and if the sizes are familial they may also be appropriate endophenotypes for QTL analysis. This endophenotype has already been associated with a genetic polymorphism (Conciatori et al., 2004). Increased blood serotonin levels have been reported in those with ASD (Cross et al., 2008; Weiss et al., 2006). The trait is familial, making it a good candidate for QTL analysis in pedigrees ascertained for individuals with ASD.

4.0 QTL Analyses

QTL analyses are conducted to localize genes that contribute to quantitative traits or endophenotypes. They were originally designed to localize genes in model organisms (Mackay, 2004) and in particular inbred strains of mice (Flint, Valdar, Shifman, & Mott, 2005). Inbred mouse strains are derived by breeding siblings for 20 generations until they are homozygous at almost every locus. Mating mice from two different inbred strains that differ significantly in their trait mean provides a straightforward approach to localizing genes contributing to that trait. Using this design, a significant test statistic identifies marker loci where mice differing in their genotypes also differ in their mean trait values. The differences are assessed by t-tests or Analyses of Variance (ANOVA) (Ott & Longnecker, 2000), and the loci with markers exhibiting significantly different trait means reveal the QTL. In inbred mice, gene identification at a QTL is a significant challenge,

because they exhibit reduced genetic variability, making their QTL very broad, and thus encompassing many genes. Very large numbers of mice are needed to narrow the QTL by breeding, and complex study designs have been proposed to address this problem (Rockman & Kruglyak, 2008). After a QTL or gene is identified in mice, the human orthologs can be found using mouse/human comparative maps available at the Jackson Laboratories Web site (http://www.jax.org).

4.1 Methods of QTL Analyses in Humans

This method of QTL analysis for inbred mice has been extended to address gene localization in outbred humans. Multiple analytic approaches are available, and factors that influence the choice are the degree of distributional normality of the trait and the configuration of the study sample. QTL analyses differ when the trait is continuous with a normal distribution and studied in several large pedigrees compared to when it is ordinal with a few categories and studied in a large number of nuclear families. Table 39-1 outlines some of the options in QTL analysis.

4.1.1 Variance Components Analyses

If large pedigrees with most members measured for a normally distributed endophenotype are available, a variance component analysis is the most appropriate and statistically powerful approach. Computer programs that implement this method include SOLAR (Blangero & Almasy, 1996) (Almasy et al., 1999), MENDEL (Lange et al., 2001), and MERLIN (Abecasis, Cherny, Cookson, & Cardon, 2002; Heath, 1997). In each case, the trait variance is partitioned into components attributable to genes, the environment, and when appropriate, their interactions. The partition is achieved by comparing the degrees of the genetic relationships among the pedigree members and the covariances in their trait values, resulting in an estimate of trait heritability. Genetic markers are incorporated into the analysis to estimate marker allele sharing IBD among the relative pairs in the pedigrees and these IBD estimates are analyzed in relation to the covariances among the trait values. The QTL analysis tests whether including the effects of a gene contributing to the trait at that marker locus better explains the data. This is accomplished by a likelihood ratio test, which is similar to what is used by the LOD score linkage analysis. The test statistic compares the likelihood of the data with a trait influencing gene in the chromosome region included compared to the likelihood of the data without this gene. The loci with LOD scores exceeding a predetermined threshold are considered to be QTL, and the analysis allows for an estimate of the locus specific heritability at each QTL.

If the pedigrees under analysis have a large number of affected individuals, and the distribution of their trait values is bimodal, thus violating the normality assumption of this statistical method, transformation of the trait values to fit a normal distribution would satisfy the assumptions of the method. Alternatively, a nonparametric mapping method, such as those in given Table 39-1 may be more appropriate. Algorithms to conduct variance component QTL analyses can use a great deal of computer time, particularly if the analysis is multipoint, which incorporates the information from many markers to estimate the allele sharing IBD, rather than single point, where each marker is analyzed individually. Multipoint analyses consider more information simultaneously, and are thus more powerful statistically.

4.1.2 QTL Mapping for ASD Traits

Since individuals with ASD rarely have offspring, and their parents may respond to the burden of caring for a child with this disorder with stoppage (Slager, Foroud, Haghighi, Spence, & Hodge, 2001), ceasing to have children, it is difficult to identify large pedigrees with substantial numbers of

Table 39–1.
QTL mapping approaches

Study Sample	Genetic Markers	Analytic Method	Software	Comments
Large Pedigrees	Multiallelic Markers or SNPs	Analysis of Variance Components	SOLAR MENDEL MERLIN	The trait variance is partitioned into genetic and environmental components
Nuclear Families	Multiallelic Markers or SNPs	Haseman-Elston Kruskal Wallis test	Sibpal in SAGE Nonparametric in GENEHUNTER	Identity-by-descent allele sharing in siblings is correlated with their trait differences
Parent/Child Trios	SNPs	Family Based Association Test	FBAT	Preferential Transmission of alleles to those with higher trait values
Cases and/or Controls	SNPs	Quantitative Association Measured Genotype	Any General Statistical Package	Analysis of Variance or t-test

ASD-affected individuals for variance components QTL studies. In this case, sibpair analyses are appropriate and families with affected sibling pairs are most often available for QTL studies. Here, the analysis finds QTL contributing to trait variation in those with ASD (Spiker, Lotspeich, Dimiceli, Myers, & Risch, 2002). A more powerful QTL analysis can be derived from panels of ASD parent/affected child trio samples that are being collected for genomewide association studies. Including an unaffected sibling measured for the endophenotype in the study sample provides a powerful contrast to the affected sibling. QTL mapping in these nuclear families can also employ a variance components approach when the trait is normally distributed.

For traits that are not normally distributed, several algorithms are available for sibpair QTL analyses. All are based on IBD sharing in sibpairs. The algorithms compare trait differences and IBD allele sharing, combining the results over the sibling pairs. It is expected that IBD sharing and trait differences will be negatively correlated at a QTL, because for each pair, the greater their allele sharing, the closer their trait values should be. This approach was originally proposed by Haseman and Elston (1972), and it is still in use today. The Statistical Analysis of Genetic Epidemiodogy (SAGE) software conducts these analyses (http://darwin.cwru.edu/sage). Variations on this method include a nonparametric analysis in the GENEHUNTER software (Kruglyak, Daly, Reeve-Daly, & Lander, 1996). Using that algorithm, the trait differences are ranked over the complete sample of sibpairs and the differences are categorized by the observed IBD values in the pairs. The Kruskal Wallis test, a nonparametric ANOVA, is conducted (Ott & Longnecker, 2000). Consistent with other nonparametric statistical methods, using ranks as is done here prevents the undue influence of trait value outliers on the analysis.

4.2 Interpreting QTL Results

QTL are identified by setting a threshold for the test statistic that reflects the strength of the evidence at that locus. The test statistic follows a normal or t-distribution statistic or is reported as a LOD score, depending on the algorithm. Figure 39-3 illustrates the genomewide results of a QTL analysis in graphic form. The genome is represented across the horizontal axis, with the chromosomes listed from one to 22. The vertical axis is a value from the normal distribution. The test is one-sided, so that all the probability is in a single tail. The best result occurs on chromosome 1, with a z-score being a little greater than 3.5. The probability of observing this score or one that is larger when there is no endophenotype gene is approximately .000001, making this a likely QTL. If a z-score threshold is set at 3.0, QTL are also found on chromosomes 4 and 16.

Figure 39-4 illustrates the results of this QTL analysis on chromosome 1 in greater detail. The horizontal axis reflects the distance from the telomere of the chromosome in centimorgans (cM) and the vertical axis reflects the z-score at each point along the chromosome. As with all statistical tests, setting a less stringent p-value will provide more power to detect true signals, but will also permit more false signals to be included. Here we illustrate that QTL are usually wide and encompass many genes. Additional markers interspersed among those that are already in the analysis can often narrow the QTL. While it is more likely that the predisposing alleles are in genes under the peak of the QTL, stochastic variation in genotypes and trait values in the study sample may cause some variation in location of this peak. As with most linkage findings, replication is important. This principle is illustrated by the inclusion of a curve representing the QTL results on this chromosome in an independent sample.
Figure 39–3. QTL along the genome.
Figure 39–4. QTL in original and replication samples.

4.3 Association Studies at QTL

Once QTL have been identified, SNPs in the QTL can be genotyped for association analyses that can lead to gene identification. Table 39-1 gives information on two types of study designs for association analysis of quantitative traits. The first is to ascertain parent/child trios where the child is assessed for the endophenotype. The genotypes of both parents and the child are included to provide information on the alleles that are transmitted to the child and those that are not transmitted. The untransmitted alleles act as "controls" that are matched within each trio for ethnicity and other important factors.

The Family Based Association Test (FBAT) (Horvath, Xu, & Laird, 2001) tests if the transmitted SNP alleles associate with high or low values of the endophenotype more than one would expect by chance alone, while taking into account the alleles that could have been transmitted. If additional members of a sibship are included with the trio, their associations will not be independent, and the level of significance of the association can be a false positive result. Corrections for non-independence of the siblings in a sibship can be achieved by using an empiric p-value or by adjusting the variance of the test, as is programmed in the FBAT software (Horvath et al., 2001). The last line of Table 39-1 refers to the simple design where parents and siblings of affected individuals are not studied. The association test for the quantitative trait is referred to as a measured genotype analysis, which is conducted using an one way ANOVA (Ott & Longnecker, 2000).

Figure 39-5 illustrates the results of association analyses at a QTL. The horizontal axis is the number of base pairs along the chromosome, from 80,000,000 to 220,000,000 and the vertical axis represents the p-values of the test statistics for each SNP. The plot uses the negative of the log of this p-value, where the log of a small p-value becomes a positive number that increases as the result get more significant. In this figure, four SNPs are associated with the endophenotype when the criterion is set at the Bonferroni corrected value of $p < .0001$, for 500 SNPs. These SNPs do not necessarily contribute to variation in the endophenotype directly, but are more likely to be in linkage disequilibrium with SNPs that do. Follow-up
Figure 39–5. Association analysis of SNPs in the QTL.

studies might include replication in an independent sample and sequencing of a sample of those who have the associated variant to potentially identify the causal variants.

5.0 ASD QTL Analyses

Investigators are just beginning to develop sufficient study samples and identify appropriate endophenotypes for effective QTL analyses in ASD. As these evolve, substantial findings may begin to emerge. Currently, there are a number of published manuscripts and abstracts reporting QTL results, and they are summarized in Table 39-2.

Most of the QTL analyses reported in Table 39-2 have been conducted on samples of nuclear families drawn from the Autism Genetics Research Exchange (AGRE, www.agre.org) resource, from which trait and genotype data are freely available to interested investigators (Geschwind et al., 2001). The AGRE study sample currently has about 1400 multiplex families ascertained for two children affected with ASD. The children in this sample have been diagnosed with ASD by trained staff using the ADIR. The data have been developed over the last 10 years, and thus the QTL findings given in Table 39-2 report AGRE samples of differing sizes, depending on when they were conducted and when the quantitative measure were included in the protocol. More complete samples are in the process of being collected.

In addition to providing data on the individual items from the ADIR (Lord et al., 1994), the AGRE data set includes individual responses on the ADOS (Lord et al., 2000), parent and teacher scores on the SRS (Constantino & Todd, 2003), and

measurements of head circumference, all discussed as potential endophenotypes in section 3. Multiallelic genotypes and SNP data are available for QTL analyses. Densely spaced SNPs genotyped on the Affymetrix and Illumina platforms are available for quantitative association analyses (http://www.agre.org).

5.1 QTL Analyses: "Age at First Word"

QTL analyses on data from the AGRE sample began in 2002 with the analysis of the ADIR caregiver report of "age at first word," which is provided for each child who has been verbal at some time in their childhood. Delayed speech is associated with ASD, and this endophenotype is measured in months, providing a correlated trait with sufficient variability. The sibling correlation is .33, which is significantly different from 0, making this endophenotype a good candidate for QTL analyses. The QTL analysis was conducted using the nonparametric option of the GENEHUNTER software, and the strongest evidence for a QTL was found on chromosome band 7q34-36 (Alarcon, Cantor, Liu, Gilliam, & Geschwind, 2002). This sample was expanded, and the same analysis was conducted in the larger sample in 2005. While there was no formal replication, evidence supporting this QTL was attenuated but remained significant (Alarcon, Yonan, Gilliam, Cantor, & Geschwind, 2005).

A QTL analysis of "age at first word" was subsequently conducted in a different collection of multiplex families, also reported in Table 39-2. Schellenberg and colleagues conducted their study on a sample of 222 ASD multiplex United States families from the NIH Collaborative Programs of Excellence in Autism (CPEA) collection (Schellenberg et al., 2006). Using

Table 39–2.
QTL and quantitative association results in ASD family panels

Trait	Reference	Design	Result (Location and p-Value)
ADIR Age at First Word	Alarcon et al., 2002 Alarcon et al., 2005	152 ASD AGRE Families	QTL 7q34-36 (p<.001)
ADIR Age at First Word	Schellenberg et al., 2006	222 CPEA Families	QTL 9q33-34 (p<.0008)
ADIR Age at First Word	Alarcon et al., 2008	172 and 304 AGRE Parent/ Child Trios	CNTNAP2 gene 7q35 Association (p<.002) Replication (p<.005)
Social Responsiveness Scale (SRS)	Duvall et al., 2007	99 AGRE Families	QTL 11p12-13 (p<.0007)
ADIR Nonverbal Communication (NVC)	Chen et al., 2005	228 AGRE Families	QTL 1p13-q12 (p<.0001)
ADIR Nonverbal Communication (NVC)	Yoon et al., 2008	219 AGRE Families	QTL 1p13-q12 Replication (p<.0001)
ADIR Social Interaction Domain (SOC) Behavioral Domain (BEH)	Liu et al., 2008	976 AGP Families	QTL 12q13 (p<.002) QTL 14q22 (p<.001)

the ADIR and the ADOS for diagnosis, the families each had two children meeting the criteria for autism, pervasive developmental disorder, or ASD, which makes the CPEA selection criteria somewhat different from the AGRE selection criteria. The QTL analyses were also conducted using a different analytic algorithm, as the CPEA sample was analyzed using a variance components approach, while the AGRE sample was analyzed using the nonparametric approach. This CPEA study did not replicate the QTL on 7q34-36, but found one at 9q33-34. The lack of replication for this particular trait while disappointing, can be attributed to a reduced sample size, differing clinical ascertainment criteria, and a different analytic method. Using the same diagnostic criteria and analytic methods would be important for a replication study.

5.2 QTL Analyses: The Social Responsiveness Scale

The SRS is an ASD endophenotype that covers a wide range of values and discriminates well among those who are socially adept and those who are not. Twin studies indicate that scores on the SRS are heritable in normal individuals (Constantino & Todd, 2003). A small study was conducted on 99 AGRE families, and a QTL was identified on 11p12-13. The locus was also found to also be linked to the binary trait of ASD in that sample, and the SRS provided greater power (Duvall et al., 2007). The AGRE sample is continuing to expand and include the SRS assessment in the protocol. Future studies in much larger samples may reveal important ASD loci through the analysis of this quantitative endophenotype. Quantitative association studies will be an important component.

5.3 QTL Analyses: "Nonverbal Communication"

The ADIR subscore assessing deficits in nonverbal communication (NVC) provides an appropriate endophenotype for ASD QTL analyses. The NVC score is composed of the individual scores on seven items from the ADIR, where the deficits are categorized in an ordinal fashion from 0 to 3. NVC skills would allow the child to engage with others by doing such things as pointing to share information. Deficits would reflect a lack in the ability to communicate with others that may be considered independent of language skills. This endophenotype is best measured in those who have ASD, and it exhibits the full range of values in that sample. The NVC correlation in ASD affected siblings is .21, indicating it is familial as well as correlated with ASD and variable in the sample under analysis. A nonparametric QTL analysis of 228 AGRE families identified a QTL on 1p13-q12 (Chen, Kono, Geschwind, & Cantor, 2006), which has been replicated in an independent sample of 213 AGRE families, using the same multiallelic genotyping, ascertainment scheme, and analytic approach (Yoon, Alarcon, Geschwind, & Cantor, 2008). The result of p < .0001 in the first sample and p < .0001 in the second provide consistent

evidence of and NVC QTL in this region. This QTL is very broad, and targeted SNP association studies and follow-up sequencing studies are revealing the genes in the region that contribute to this endophenotype.

5.4 QTL Analyses: Autism Genome Project

Large-scale studies of multiple ASD samples are an important focus for the Autism Genome Project (AGP). The AGP conducted a QTL study on its combined sample of ASD multiplex families ascertained at 10 coordinating sites in the United States and Europe over a 30-year period. This sample includes the CPEA and AGRE samples. While genotyping was conducted on all AGP families, the QTL analyses were done on a subset of 976 for whom the quantitative data could be made compatible among the sites (Liu, Paterson, & Szatmari, 2008). In preliminary analyses, the data from the different sites with varying ascertainment and diagnostic criteria were combined to reflect the same phenotypes. Fortunately, the genotype platform and analytic method was the same for all of the families. Two ADIR derived endophenotypes were analyzed in this sample. They are the ADIR total scores on the reciprocal social interaction domain total (SOC), with a heritability estimate of .35 and the restricted, repetitive, and stereotyped patterns of behavior domain (BEH), with a heritability estimate of .52. Since the data were only collected in sibling pairs, these estimates reflect the effects of common family environment, which are likely to be nontrivial. The QTL analyses were conducted using the variance components approach as programmed in the Merlin software (Abecasis et al., 2002). The best QTL signals for these endophenotypes were on chromosomes 12q13.11 (p = .002) for SOC and 14q22.1 (p = .001) for BEH. These results, which exhibit marginal significance in the largest sample analyzed for an ASD QTL, can be explained in a few ways. First the heritability estimates derived from the sibling pairs in this sample include common family environment indicating the true trait heritabilities may be considerably lower than .33 and .52. In addition, there may be many genes contributing to these endophenotypes, each with small locus specific heritabilities that cannot be detected, even with a study sample of this size. It is anticipated that other endophenotype studies in this large sample will result in stronger QTL.

5.4.1 Association of "Age at First Word"

An association study in a sample of the AGRE families was conducted within the 7q34-36 QTL to find the gene influencing "age at first word" in children with ASD. The density of the SNPs was substantial, providing more information than what would be seen in microarray SNP panel. The SNPs were tested for association individually, and haplotypes in a moving window were also tested. While several associations were observed, replication studies in an independent sample of AGRE families implicated only one haplotype that was located in the CNTNAP2 gene (Alarcon et al., 2008). Remarkably, the

same gene showed association with the binary ASD phenotype in the AGRE families (Arking et al., 2008).

These QTL studies followed by association analysis and replication for "age at first word" provides strong support for the QTL approach proposed herein. QTL studies with larger samples and more refined endophenotype are likely to reveal other ASD genes.

5.4.2 A Roadmap for QTL Discovery

From a statistical genetics perspective, the analytic tools for QTL studies are in place. These tools await the application of suitable ASD phenotypes that are variable within the population under analysis, correlated with ASD, and exhibit evidence of a reasonable nonzero heritability. The nature of the study sample and distribution of the trait will limit the feasible analytic approaches.

These same design principles have been successfully applied to the study of coronary artery disease (CAD) through QTL analyses of heritable quantitative traits such as serum cholesterol and triglycerides levels. An important advantage for CAD studies, however, is that long-term epidemiology studies revealed important quantitative risk factors before genomewide studies became feasible.

Thus, it becomes critical to identify the important ASD quantitative traits, although the epidemiology studies are only in their very early stages. Perhaps the best approach currently is to create an environment where experts in the clinical and research features of ASD can participate in collaborative studies with investigators having QTL expertise and epidemiologists focused on revealing important ASD risk factors. It is expected such endeavors are likely to create a synergy among investigators that will lead to success.

Conclusions

The genetic complexity of ASD can be addressed by studying correlated quantitative endophenotypes that have simpler modes of inheritance. Successful ASD endophenotypes will exhibit wide variation and substantial heritability. QTL studies of these endophenotypes involve selecting an appropriate study sample that captures sufficient variation in those who are affected and possibly those who are unaffected. The choice of statistical algorithm for QTL mapping will depend on the individuals who can be studied and the distribution of the endophenotype. Although QTL studies for ASD are at an early stage, its application to ASD led to initial successes. The QTL for deficits in nonverbal communication has been replicated in an independent sample and awaits effective association studies. The CNTNAP2 gene in a language related QTL shows association with the language-related quantitative trait and ASD. Application of this approach to more refined endophenotypes in larger samples can lead to a

substantial increase in our understanding of the genetic etiology of ASD.

Challenges and Future Directions

The identification of the best quantitative endophenotypes for QTL mapping remains a challenge. New study samples of ASD affected children and their unaffected offspring provide opportunities to pursue this approach. Synergy among experts on the ASD phenotypes, ASD epidemiology, and QTL mapping could energize the field. Once QTL are identified, it will be an interesting challenge to integrate GWAS, copy number variation, and sequence data into studies of these endophenotypes.

Autism Subgroups from a Medical Genetics Perspective

Points of Interest

- A first step in the quest for etiologically discrete autism subgroups is the identification of "phenotypic features" that are present in some but not all individuals with autism, are relatively discrete, quantifiable, and pathophysiologically relevant.
- Phenotypes may be physical (e.g., dysmorphology), medical (e.g., seizures), laboratory based (e.g., EEG abnormalities, pupillary light reflex parameters), clinical course elements (e.g., age of onset, regression, trajectory), and genetic indicators (e.g., gender, recurrence risk, family history of autism and related disorders).
- The terms "phenotype," "endophenotype," and "biomarker" are comparable.
- The core autism behavioral symptoms are less likely to separate out etiologically discrete subgroups because by definition they occur in all diagnosed individuals.
- A phenotype is presumed valuable when subgroups defined on that basis differ in clinical course, outcome, response to therapy, and/or genetic indicators.
- Subgroups of families with strong family histories of autism plus another neurologic disorder may allow us to identify shared biochemical pathways and genes.

To unravel the clinical and etiologic heterogeneity within autism or what is best termed the autism spectrum disorders (ASD) is an ambitious but compulsory goal. Because autism is a behavioral disorder with few physical and laboratory features, this has proven much more difficult than for the prototypic single gene disorders (reviewed in Fein et al., 1999; Spence, 2001). Reports of sibs discordant for their autism spectrum disorders led to the disheartening expectation that we would not be able to understand the heterogeneity until we found specific autism genes and we could not find the autism genes until we understand the heterogeneity (DeLong & Dwyer, 1988; Silverman, 2002).

Strategies for Defining Autism Subgroups

Historically, interest in subclassifying autism was focused on assessing validity of the classical autism diagnoses by seeing which clinical symptoms, adaptive behaviors, and cognitive skills occurred together (reviewed in Gillberg, 1992; Fein et al., 1999; Prior et al., 1998). To determine whether there were true diagnostic differences between putative subgroups, analyses considered all symptoms and their variations and used cluster analyses and other taxonomic techniques to see if and what groups of symptoms co-occurred. Many of these studies demonstrated real associations—such as Asperger's subjects were more likely to be male and autism-like subjects compared with autism subjects were more likely to be female—but did not actually identify discrete autism subgroups. And most of the differences identified related more to the level of cognitive and adaptive functioning, rather than distinctive diagnostic behavior patterns. More importantly, the behavioral profiles that were generated were not correlated with biological mechanisms or etiologies.

Recently, there has been a renewed interest in more refined taxometric methods to look at the heritability of autism's core symptoms (Beglinger & Smith, 2001; Constantino, Chapter 29 in this book; Happé & Ronald, 2008; Ingram, Takahashi, & Miles, 2007). The premise underlying all subtyping paradigms is that there is a phenotypic marker that has a taxonomic, i.e., categorical structure, which can identify discrete subgroups with different etiologies, outcomes, or therapeutic responses. In their 2008 review, Happé and Ronald presented evidence that alterations in the separate defining domains of social relatedness, language/communication, and restricted interest/repetitive behavior are separable and that approaches that consider autism as an entity may be ineffective. Ingram et al. (2007) used taxometric methods to look at both behavioral and physical phenotypes to see which varied categorically rather than only by degree. Their analyses support subgrouping subjects

based on variation in social interaction/communication, intelligence, and the essential/complex phenotype; in contrast, subjects varied continuously in repetitive sensory and motor actions, language acquisition, and insistence on sameness. These studies not only highlight the importance of phenotypic clarity but indicate that continuous markers are less useful or at least more complicated to study.

The goal of a medical geneticist is to define subgroups that are etiologically discrete and do not overlap, such that a defined subgroup will not only be homogeneous, but its removal from the pool will leave a more homogeneous remainder. The standard approach to identifying homogeneous subsets of patients with any medical condition is to identify phenotypic features that occur in some but not all of the population. To be useful, the phenotypic features should be consistently present in most if not all autism populations, relatively discrete, quantifiable, and most importantly pathophysiologically relevant. Features that remain constant over time are particularly useful, while those that describe continuous variables are less helpful. Table 40-1 lists

Table 40–1.

Phenotypic variables that may define discrete autism (ASD) subgroups

Phenotypic Variables	Consistently Present in a Proportion of ASD Populations (% of ASD)	Discrete	Continuous or Categorical	Measurable	Constant Over Time	Pathophysiologically Relevant	May Suggest a Genetic Marker
Core Autism Symptoms							
Social functioning	No, 100%	Yes		Yes	No	Yes	Maybe
Communication	No, 100%	Yes	Categorical	Yes	No	Probably	Maybe
Repetitive, stereotypic behaviors and/or preoccupations, obsessions	Yes, but must be scored separately	Yes	Continuous	Yes	No	Probably	Maybe
Functionally Defined Variables							
IQ	Yes	No	Categorical	Yes	Yes/No	Yes	Maybe
Adaptive behaviors (Vineland)	Maybe	No	uk	Yes	No	Probably	No
Outcome measures	Poorly defined	No	uk	Yes, but takes years	No	Probably	No
Response to therapy	Yes	Yes	uk	Yes	Yes	Probably	Maybe
Clinical Course							
Age of onset	Yes	Yes	? Categorical	Yes	Yes	Yes	Yes
Regressive onset	Yes, ~ 30%	Yes	? Categorical	Yes	Yes	Yes	Yes
Adolescent/adult catatonic regression	Yes, ~17%	Yes	? Categorical	Yes	Yes	Yes	Yes
Medical/Neurological							
Seizures	Yes, ~ 25%	No	Categorical	Yes	No	Yes	Yes
EEG abn	Yes, ~ 50%	No	? Categorical	Yes	No	Yes	Yes
Sleep disorder	Yes, ~ 65%	No	Categorical	Yes	No	Yes	Yes
Savant skills	Yes, ~ 5%	?	Categorical	Yes	Yes	Probably	Maybe
Morphology & Growth							
Generalized Dysmorphology	Yes, 15%–20%	Yes	Categorical	Yes	Yes	Yes	Yes
Macrocephaly	Yes, ~ 30%	Yes	Continuous	Yes	Yes	Yes	Yes
Head growth trajectory	Probably	uk	uk	Yes	No	Yes	Yes
Microcephaly	Yes, ~ 5%	Yes	Categorical	Yes	Yes	Yes	Yes
Brain malformations	Yes, ~ 20%	Yes	Categorical	Yes	Yes	Yes	Yes

(*Continued*)

Table 40–1. (*Contd.*)

Phenotypic Variables	Consistently Present in a Proportion of ASD Populations (% of ASD)	Discrete	Continuous or Categorical	Measurable	Constant Over Time	Pathophysiologically Relevant	May Suggest a Genetic Marker
Significant Family History of Related Disorders							
ASD	Yes, 25%	Yes	uk	Yes	Yes	Yes	Yes
Affective Disorders	Probably	Yes	Categorical	Yes	Yes	Yes	Yes
Alcoholism	Yes, 30%	Yes	Categorical	Yes	Yes	Yes	Yes
ADHD	Probably	Yes	Categorical	Yes	Yes	Yes	Yes
Bipolar/Major Affective Disorder	Yes	Yes	Categorical	Yes	No	Yes	Yes

phenotypic variables that have been suggested or used to dissect out autism subgroups. The list is not inclusive, and the assessment of the usefulness of each phenotype is my generalization, since most have not been tested and rarely does a yes or no answer explain the complexity of the answer.

From this table we see that the core autism symptoms are less likely to easily separate out subtypes because by definition they occur in all of the diagnosed individuals, though recent taxometric analyses (Ingram et al., 2007) support the opinion that combined impairments in social interaction and communication into one domain may be a valuable phenotypic variable. A characteristic of the clinical course of autism, regression provides an a priori excellent candidate, though it is often difficult to categorize mild symptoms of regression. Regression is a relatively common phenomenon in many pediatric neurologic disorders and has been linked to genetic diagnoses, including Rett syndrome, mitochondrial disease, and metabolic enzyme deficiency and storage disorders (Clarke, 2005; Weissman et al., 2008). Family histories of autism and alcoholism are attractive candidates because of their clear association with known genetic markers, though phenotypic reliability can be imprecise when obtained through family history alone. Based on this analysis, it is the abnormalities of morphology and growth that emerge as highly likely candidates for subgrouping.

This identification of potentially informative phenotypic variables is only a first step; ultimately each potential variable must be carefully studied to determine its usefulness. This includes investigating the mechanistic basis of the variable to substantiate its biologic relevance. Once that is done, the population can be divided into two or more subgroups based on the study phenotype. Finally, the subgroups are analyzed to look for differences in outcome measures (language, cognitive, adaptive), physical phenotypes (growth, head size, general dysmorphology), clinical course measures (age of onset, type of onset with or without regression, developmental trajectory), medical/neurologic features (seizures, EEG abnormalities), and genetic features (male to female ratio, sib recurrence risk, family history of autism, alcoholism, affective disorders, cognitive and language impairments). Obviously,

this list is incomplete and is constantly expanded as new phenotypic variables are recognized as useful vehicles with which to separate ASD into discrete etiologic subgroups.

Relationship Between Clinical Phenotypes and Endophenotypes

This is probably a good place to discuss the relationship between phenotypes as used by medical geneticists to subgroup populations and endophenotypes. Gottesman and Gould (2003) proposed that phenotypic features that would be most helpful be termed "endophenotypes"—i.e., phenotypes that were more biological and thus more proximally related to the underlying etiologic processes—and that endophenotypes in autism may provide an avenue for homing in on specific neuropsychological mechanisms of biological and genetic significance to autism. Piven, Palmer, Jacobi, Childress, and Arndt (1997) suggested that these endophenotypes might also be traceable in unaffected relatives of individuals with autism. Conceptually, there is no real difference between phenotypes and endophenotypes. From a medical perspective phenotypes may be thought of as clinical, observable symptoms of a disorder and endophenotypes as the results of laboratory tests that measure specific biological actions. Both are used to further describe the disorder in question, in our case autism. A review of the literature illustrates that many autism researchers use these terms interchangeably and consider any circumscribed symptom, such as insistence on sameness or savant skills, as an endophenotype (Spence et al., 2006). The introduction of the term "biomarkers" affords an excellent compromise that envelops the essence of both phenotype and endophenotype.

A few examples of phenotypes and endophenotypes are provided in Table 40-2. As we learn more, there will undoubtedly be many examples of phenotypes being described on a biological level, which can then be used in genetic studies (James et al., 2006). In all cases, the geneticist will try to link clinical phenotypes and endophenotypes with etiologies, outcomes, and responses to therapies.

Table 40–2.

Phenotypes, endophenotypes, and etiologies

Autism Related Phenotypes	Laboratory Tests & Measures as Endophenotypes	Genes/Teratogens/Toxins
Aloof personality (Social-cognition). (This subset of ASD children are aloof, have poorer pragmatic language and poorer friendships)	Eyes Test[1] The Eyes Test is an endophenotype associated with aloof personality.	?
Seizures, sleep, hearing loss, vision loss, facial asymmetry	EEG, sMRI, SPEC Scan, PET scan, Evoked response, ERG, Pupillary light responses etc.	?
Regressive onset	Oxidative stress measures	?
Craniofacial dysmorphology	Facial anthropomorphic measures, Shape analysis of midline brain areas	Developmental genes

Autism Subgroups: Proposed and/or Analyzed

Most of these categories are based on a phenotypic variable that may or may not turn out to identify a distinct and biologically relevant ASD subgroup. Given current uncertainty over which phenotypes will be the most informative, it is appropriate that each phenotypic variable in Table 40-1 be assessed as part of any autism study.

Morphologically Defined Subgroups

In the 1970s and early 1980s a number of studies documented that, taken as a group, autistic children had physical features outside the norm (Mnukhin & Isaev, 1975; Campbell, Geller, Small, Petti, & Ferris, 1978; Walker, 1977; Links, 1980; Links, Stockwell, Abichandani, & Simeon, 1980; Steg & Rapoport, 1975; Gualtieri, Adams, Shen, & Loiselle, 1982). Walker, using the Waldrop weighted scoring scale (Waldrop & Halverson, 1971) for sixteen anomalies, studied 74 autistic and nonautistic children matched for age, sex, socioeconomic group, and geographic domicile, and found that the mean minor anomaly score of 5.76 for the autistic children was significantly higher than the control group score of 3.53. He concluded that this shift to a greater number of anomalies in the autistic subjects proved organicity in autism. Links et al. (1980) recognized that autistic children had more anomalies than their sibs, and that the autistic children with the higher anomaly scores had lower IQs, spent more time in the hospital, had less frequent family histories of psychotic illness, or drug or alcohol abuse. They concluded that the anomalies were the result of some unknown organic factor that played a role in the etiology of autism. Smalley, Asarnow, and Spence (1988) declared that minor physical anomalies (MPAs) result from insults, either genetic or environmental, that occur in the first trimester, and represent an indirect measure of an abnormality in fetal development.

Full understanding of these studies was, however, hindered by the prevailing dogma that autism was homogeneous, and the authors did not speculate that there could be etiologically distinct groups within the autism behavioral diagnosis.

We hypothesized that physical dysmorphology would be a useful phenotypic feature which would allow us to divide autism into subgroups (Miles & Hillman, 2000). The premise was that individuals for whom there is evidence for some insult to early morphogenesis will be etiologically different. They would have developed their autistic behavioral disorder on a different basis than the individuals whose early morphogenesis proceeded normally. The group with evidence of abnormal morphogenesis was described as having complex autism, the remainder essential autism.

Generalized dysmorphology fits our criteria for a potentially useful phenotype. It occurs in a consistent proportion of ASD individuals, is constant over time and most importantly is biologically relevant. Though dysmorphic features used to characterize generalized dysmorphology are usually obvious to the geneticist, they can be subtle and are usually missed by therapists and clinicians not trained to look for them. However, we been able to demonstrate that generalized dysmorphology is measurable, with good reliability (Miles, Takahashi, Hillman, & Martin, 2004, Miles et al., 2008). Most important, physical dysmorphology is a biologically based phenotype that suggests a developmental etiology.

The third step was to determine whether autistic individuals with generalized dysmorphology differ from those in whom there is no evidence of abnormal physical development. For all functional and outcome measures, the individuals with complex autism did less well. They are twice as likely to have IQ scores less than 55 (52% vs. 25%) and less than half as likely to have IQ scores in the normal range (22% vs. 46%). They are twice as likely to develop seizures (39% vs. 17%), and twice as likely to have abnormal brain structure (28% vs. 13%). Our outcome analyses, based on both the acquisition of functional language and IQ scores, show that

though many features correlate with poor outcomes, the diagnosis of complex designation is the most sensitive test, yielding an 86% positive predictive value of poor outcome (Miles et al., 2005). This cross-sectional outcome data is consistent with our study of 19 children with autism who completed 1 year of one-on-one early intensive (22 hrs/wk) behavioral intervention (Stoelb et al., 2004). The most significant predictor of change in performance scores over the year of therapy was dysmorphic physical features (p = .0009). And the presence or absence of dysmorphic features predicted language acquisition for 90% of the nonverbal participants.

Step four is to determine whether the complex and essential subgroups are genetically different. This can be addressed in two ways. First, genetic consequences, including the sex ratio, recurrence risks, and family histories, are compared. Our data (Miles et al., 2005) found that individuals in the essential autism subgroup were twice as likely to be male (6.5:1 vs. 3.2:1), were more than twice as likely to have a family history of autism (20% vs. 9%), and had a sib recurrence risk of 4–6% compared with no recurrences in the 46 families of children with complex autism. The occurrence of lesser autistic traits in sibs of children with essential autism was twice that for complex autism families (12% vs. 6%). The small number of sibs limits the power of the calculations; however, the very similar magnitude of differences for all sibs, latter born sibs, and for classical autism and milder autistic traits illustrates a consistent pattern. The fact we did not observe any recurrence in sibs in these 46 children with complex autism is certainly a statistical aberration. We know that the risk of recurrence is not zero, since children with complex autism may have disorders such as Fragile X syndrome and familial chromosome disorders that confer explicit recurrence risks. Notwithstanding, we feel that parents of children with complex autism, once chromosome disorders, Fragile X syndrome, tuberous sclerosis, and other discrete genetic syndromes have been ruled out, may be counseled that their recurrence risk is lower than the 4–6% observed with essential autism. A number of observations by other laboratories are consistent with this model. Szatmari et al. (1996) noted that relatives of probands with higher IQs were at greater risk than those of probands with lower IQ.

An additional genetic and clinically practical consequence of the separation is that all of the individuals with recognizable syndromes fall in the complex autism diagnosis, or in the case of tuberous sclerosis can almost always be recognized by the dysmorphology examination (Miles et al., 2005). We have not identified any children with chromosome disorders, including the 15q duplications, who have not declared themselves on the dysmorphology examination. It is, however, expected that genome wide chromosomal array technology will discover copy number variants (CNVs) in children with both complex and essential autism, with specific CNVs associated with dysmorphology.

Major ramifications of this distinction come from studying the essential and complex autism subgroups independently. One example is studies attempting to understand the autism 4:1 male to female ratio. Analyzing essential autism has allowed us to make a number of significant observations. First, within the essential autism group, a regressive onset and macrocephaly have both emerged as stronger predictors of poorer outcomes. A history of regression in language at the onset of the autistic symptoms predicts a poor outcome with 46% sensitivity, 73% specificity, and a positive predictive value of 84%. An association between cognitive level and macrocephaly is consistent with a recent report that children with macrocephaly have greater discrepancies between verbal and nonverbal IQ scores (Tager-Flusberg & Joseph, 2003). Tager-Flusberg and Joseph hypothesize that macrocephaly indicates a more severe disturbance of neurocognitive development and organization. Though essential autism remains heterogeneous, with more children having poor than good outcomes, we find that limiting studies to the group of individuals with essential autism has allowed us to begin to identify outcome predictors that we couldn't see before we removed the complex group. Recognizing these outcome predictors is a first step toward designing treatments to improve outcomes. Furthermore, since essential autism is the more heritable subgroup, removing complex autism probands from analyses should improve the power of linkage and sib pair analyses.

The distinction between complex and essential autism represents the first pass at dissecting the etiologic heterogeneity within the autism diagnosis. The distinction fits our criteria for a phenotype we would predict as useful in the delineation of autism subgroups. Though each group remains heterogeneous, the functional and genetic differences indicate that essential and complex autism are inherently different subgroups with different etiologies. The distinction between essential and complex autism also illustrates the overlap between the terms "clinical phenotypes" and "endophenotypes." Complex autism captures the subgroup of children whose physical phenotype indicates a different embryological process. Analysis of specific morphologic abnormalities is expected to point our studies toward specific developmental pathways.

Brain-Size Defined Subgroups

In addition to generalized dysmorphology, specific malformations, especially those related to the brain, are important for delineating ASD subgroups. Macrocephaly, which occurs in 20–30% of ASD children and 37–45% of their nonautistic parents, is the best example (Miles, Hadden, Takahashi, & Hillman, 2000; Fombonne, Bolton, Prior, Jordan, & Rutter, 1999; Lainhart et al., 1997; Lainhart et al., 2006, Sacco et al., 2007, Vaccarino, Grigorenko, Smith, & Stevens, 2009). Its importance was underscored by Bolton's (1999) report, that infantile macrocephaly was a significant predictor (OR = 5.44) for the development of autism. However, the timing and mechanism responsible for increased head size is not well understood. Macrocephaly is generally a reflection of increased brain size in ASD (Stanfield et al., 2007; reviewed in Casanova, 2007), though Aylward, Minshew, Field, Sparks, and Singh (2002) found head circumference was only an accurate index of brain volume in young ASD children, and not in adolescents or adults. Tate, Bigler, McMahon, and Lainhart (2007) found that the relationship between head circumference and

brain volume was not as highly correlated in ASD individuals as in typically developing individuals. Recent analyses of patterns of brain growth are refining our understanding of macrocephaly in autism. At birth, head circumference in infants later diagnosed with ASD has been found to be either similar to typically developing individuals or even reduced (McCaffery & Deutsch, 2005; Courchesne & Pierce, 2005; Pardo & Eberhart, 2007). Our studies indicate that the presence and number of surges in head size occurring throughout childhood in autism is more informative than ultimate head size, which may explain why macrocephaly itself is not an independent predictor of phenotypic or genetic traits or outcome measures (Miles, Hadden, Takahashi, & Hillman, 2000; Keegan, Takahashi, & Miles, 2007). This literature is still complicated by conflicting reports, which are likely due to the inherent heterogeneity within ASD, the scarcity of longitudinal data, and perhaps lack of correlation between head circumference and brain volume in some children.

Macrocephaly, in addition to being a common physical phenotype of idiopathic autism, is a key feature in a number of genetically well characterized syndromes that can cause autism, including Fragile X syndrome, PTEN syndromes, Sotos syndrome, and HOXA1 G alleles. Fragile X syndrome, which is due to expansion of the CGG trinucleotide repeat in the *FMR1* gene, causes many autistic behaviors, including avoidance of eye contact, language delays, repetitive behaviors, sleep disturbances, tantrums, self-injurious behaviors, hyperactivity, impulsiveness, inattention, and sound sensitivities. In one study of 63 males with Fragile X syndrome 30% met criteria for autistic disorder and 30% criteria for PDD-NOS (Harris et al., 2008). Molecular studies indicate the *FMR1* gene may cause the autism phenotype via two mechanisms, RNA toxicity to the neurons and gene silencing, which impacts neuronal connectivity (Schenck et al., 2003; Handa et al., 2005; Hagerman, Rivera, & Hagerman, 2008). Though these mechanisms are not the primary cause of autism, they can offer insight into its pathogenesis. For example, evidence suggests that some molecular defects in autism may interfere with synaptic protein synthesis, as in Fragile X, suggesting that this is one possible pathway leading to autistic phenotypes (Kelleher & Bear, 2008) The PTEN (phosphatase and tensin homolog) gene is a tumor suppressor gene associated with a broad group of disorders referred to as PTEN hamartoma tumor syndromes, which include Cowden syndrome, Bannayan-Riley-Ruvlacaba syndrome, Proteus syndrome, and Lhermitte-Duclos disease. Recently, *PTEN* gene mutations have been associated with autism and macrocephaly (Zori, Marsh, Graham, Marliss, & Eng, 1998; Parisi et al., 2001; Delatycki, Danks, Churchyard, Zhou, & Eng, 2003; Butler et al., 2005; Buxbaum et al., 2007). Correspondingly, *PTEN* is recognized to play an important role in brain development, including neuronal survival and synaptic plasticity. The frequency of *PTEN* mutations as a cause of ASD is unclear; results from studies of children with autism and macrocephaly range from 1% (Buxbaum et al., 2007) to 8.3% (Varga, Pastore, Prior, Herman, & McBride, 2009)

to 17% (Butler et al., 2005). Both de novo and familial *PTEN* mutations have been identified in this population. It may be significant that more of the children studied by Buxbaum et al. (2007) were from multiplex families, whereas in the Butler et al. (2005) study all children were from simplex families. Children with ASD found to have a *PTEN* mutation generally have extreme macrocephaly ranging from +3.7 SD to +9.6 SD (average: +5.4 SD) (Buxbaum et al., 2007). In addition, mutation of *PTEN* is not specific for autism: Varga et al. (2009) found children with macrocephaly and mental retardation but not autism had a similar chance of having a *PTEN* mutation. Sotos syndrome, which is characterized by overgrowth (head circumference and height ≥ 2 SD), typical facial features, cognitive and behavioral problems including difficulty with peer group relationships and a lack of awareness of social cues, though not a significant cause of classic autism—it is caused by a mutation or deletion of NSD1 gene in 80–90% of cases—provides an additional avenue of investigation of the genesis of autistic behaviors. Conciatori et al. (2004) presented evidence that the *HOXA1* G allele correlates with larger head circumferences, explaining approximately 5% of the variance in head circumference in their population. Each of these disorders that overlap clinically and physically with autism has a known etiology. And, as the Fragile X studies of neurotransmission indicate, study of these related disorders is apt to provide insight into mechanisms underlying idiopathic autism. Other genes involved in brain overgrowth have recently been reviewed by McCaffery & Deutsch (2005).

Microcephaly, defined as head circumference at or below 2 standard deviations is also an informative phenotype. It occurs in 5–15% of children with autism and is highly predictive of poor outcome (Fombonne et al., 1999; Miles, Hadden, et al., 2000; Miles et al., 2005). Similar to generalized dysmorphology, microcephaly almost always indicates a neurodevelopmental etiology, especially chromosomal disorders. Though it is likely that some microcephaly/ASD syndromes will be identified, at this time the main use of microcephaly in subgrouping is to identify the complex autism subtype.

Brain-Malformation Defined Subgroups

Numerous lines of evidence suggest abnormalities in brain structure are closely related to the etiology of autism. In addition to brain volume studies (Courchesne et al., 2001; Courchesne, Carper, & Akshoomoff, 2003; Hazlett et al., 2005), there are numerous reports of structural malformations. Levitt et al. (2003) showed that cortical sulcal patterns were significantly different in control children and children with autism, and that these differences were mainly in the frontal and temporal sulci. Using a direct measurement of cortical thickness to examine the gray matter integrity, Hadjikhani et al. (2004) found local decreases of gray matter thickness in the ASD group in the inferior frontal gyrus, inferior parietal lobule, and the superior temporal sulcus (STS). In addition, cortical thinning in these regions correlated with

ASD symptom severity. Barnea-Goraly et al. (2004) found a significant disruption of white matter structures between brain regions implicated in social functioning that might contribute to impaired social cognition in autism, and provide an example of the abnormal brain connectivity theory in autism (Just, Cherkassky, Keller, & Minshew, 2004; Geschwind & Levitt, 2007). Other brain structures such as the brain stem (Hashimoto et al., 1993), thalamus (Tsatsanis, 2003), corpus callosum (Boger-Megiddo et al., 2006; Egaas, Courchesne, & Saitoh, 1995; Piven, Bailey, Ranson, & Arndt, 1997, Vidal et al., 2006), amygdala (Nacewicz et al., 2006), and hippocampus (Dager et al., 2007; Nicolson et al., 2006) have also been reported as abnormal in autism. Results have often ranged from inconclusive to contradictory. For example, Boddaert and colleagues (2004) investigated 21 autistic children and 12 children of normal intelligence and found a bilateral decrease in gray matter concentration in the superior temporal sulcus (STS) and a white matter concentration decrease in the right temporal pole and left cerebellar hemisphere in autistic children compared to control children. But Waiter et al. (2004) investigated 16 autistic children and 16 controls, finding total gray matter to be increased in the autism group, with local volume increases in the right fusiform gyrus, the right temporo-occipital region, and the left frontal pole. Limbic structures, specifically the amygdala and hippocampus have also been implicated with contradicting findings. Increased (Abell et al., 1999; Howard et al., 2000; Sparks et al., 2002; Juranek et al., 2006; Munson et al., 2006; Schumann et al., 2004), decreased (Aylward et al., 1999; Herbert et al., 2003; Pierce & Courchesne, 2001; Nacewicz et al., 2006), and "normal" amygdala volumes (Haznedar et al., 2000) have been reported. As in the amygdala studies, no consistent abnormalities have been reported in hippocampus. Increased (Sparks et al., 2002; Rojas et al., 2004; Schumann et al., 2004; Geuze, Vermetten, & Bremmer, 2005), decreased (Aylward et al., 1999; Herbert et al., 2003; Saitoh, Karns, & Courchesne, 2001; Nicolson et al., 2006), or "normal" (Haznedar et al., 2000; Howard et al., 2000; Piven, Bailey, Ranson, & Arndt,1998; Saitoh, Courchesne, Egaas, Lincoln, & Schreibman, 1995) hippocampal volumes have been reported in autism. These results call to mind the apparent disparities of the dysmorphology studies of the 1970s and early 1980s. It was not until individuals with and without dysmorphology and microcephaly were analyzed separately, that the inherent structural heterogeneity with ASD was appreciated. Based on these lessons from the past, it is suggested that efforts be launched to identify discrete brain morphology subgroups.

Family-History Defined Subgroups

The family pedigree, which consists of documenting the history for at least three generations, is an indispensable part of the clinical genetics evaluation. Data on multiple generations is essential for analysis of modes of transmission including autosomal versus X-linked, recessive versus dominant, and epigenetic patterns. Family ASD studies have revealed significant clustering of neuropsychiatric disorders including depression, manic depression, obsessive-compulsive disorder, social phobia, anxiety disorders, alcoholism and substance abuse, and motor tics, in addition to ASD phenotypes in relatives of autism probands. This genetic overlap between autism and other neuropsychiatric disorders suggests that at least for certain types of autism there are common biochemical and genetic aberrations. Lobascher, Kingerlee, and Gubbay (1970) compared the family histories of 23 autistic children with normal controls and found a greater incidence of alcoholism (35%), psychiatric illness (35%), and mental retardation (26%) in the parents of autistic children. DeLong and Dwyer (1988) reported that 55% of their 51 autism families had a first- or second-degree relative with alcoholism, though the overall incidence rate of alcoholism among all 929 first- and second-degree relatives was only 6.5%. Piven et al. (1991) reported that 12.3% of 81 parents of autistic children were alcoholic compared with 0% of 34 Down syndrome parents; the difference was not statistically significant. In a study of 36 autism families, Smalley, McCracken, and Tanguay (1995) compared the lifetime rates of psychopathology based on direct SADS-LA interviews of parents and adult siblings of autism probands versus controls who had either tuberous sclerosis or an unspecified seizure disorder. They found that 47% (17/36) of the autism families had a first-degree relative with substance abuse, including alcoholism, versus none in the 21 control families. And 22% of first-degree relatives reported substance abuse compared to none in the controls (p = 0.002). They also found increased rates of depression (32.3% vs. 11.1%; p = 0.013) and social phobia (20.2% vs. 2.4%; p = 0.016). Not all family studies have reported increased rates of alcoholism. Bolton, Pickles, Murphy, and Rutter (1998), using direct SADS-L interviews to assess the lifetime prevalence rates of psychopathology found a significant increase in major depression, but not alcoholism in first-degree relatives of an individual with autism.

In 2003 we reported family history analyses of 167 autism families (Miles, Takahashi, Haber, & Hadden, 2003). Families were ascertained through a child with autism and queried using the family history method (Andreasen, Rice, Endicott, Reich, & Coryell, 1986; Orvaschel, Thompson, Belanger, Prusoff, & Kidd, 1982; Yuan, Marazita, & Hill, 1996; Thompson, Orvaschel, Prusoff, & Kidd, 1982; Rice et al., 1995; Davies, Sham, Gilvarry, Jones, & Murray, 1997) to determine the prevalence and pedigree configuration of alcoholism and related neuropsychiatric disorders. Looking at the population as a whole, 13.5% of first-degree relatives and 13.6% of second-degree adults were reported to have alcoholism, including 6.6% of mothers, 20.4% of fathers, 8.4% of grandmothers, and 27.5% of grandfathers. Alcoholism rates in the autism ascertained families were compared to a control population ascertained through a child with Down syndrome and to lifetime alcohol prevalence data reported by three large United States alcoholism epidemiological studies, including a Missouri rural and suburban cohort (Eaton, Kramer, & Drywall, 1989;

Robins et al., 1984; Kessler et al., 1994; Grant, 1997). The Down syndrome families reported significantly less alcoholism in all family members (p < 0.0001). Compared to the 15.2% lifetime prevalence of alcoholism reported for suburban, small town, and rural Missouri (Robins et al., 1984), the overall 13.7% rate of alcoholism reported by the autism families was similar (p = 0.19). Women in our population, however, were significantly more likely to report alcoholism than all women in Missouri (6.6% vs. 4.3%) (p = 0.008).

Since alcoholism, like autism, is a heterogeneous disorder (Johnson et al., 2000; Cloninger, 1987; Brown, Seraganian, & Tremblay, 1994; Litt, Babor, DelBoca, Kadden, & Cooney, 1992; Hesselbrock & Hesselbrock, 2006; Edenberg & Faroud, 2006; Zucker, Ellis, Bingham, & Fitzgerald, 1996), we wanted to distinguish families with strongly genetic alcoholism from those with only sporadic or occasional cases that might be more environmentally induced. Using strict criteria to pick out the families with clusters of alcoholism, we classified 39% (65/167) of the families as having probable genetic alcoholism. A family history was rated as significant or "probably genetic" if the proband had (1) a first-degree relative with alcoholism (manifesting prior to concerns about the health of the proband), (2) a second-degree relative plus at least two additional individuals in the same family branch in a pattern suggesting Mendelian inheritance, or (3) alcoholism in at least four individuals all in the same branch of the family. The high alcoholism families had an elevated percentage of affected relatives in all categories, with 17% of mothers, 52% of fathers, 14% of maternal grandmothers, 41% of maternal grandfathers, 21% of paternal grandmothers, and 45% of paternal grandfathers reported as alcoholic. The remaining 102 families reported scattered individuals with alcoholism in unrelated branches of the family (less than 1% of females and less than 10% males).

Families and children whose pedigrees revealed an apparent genetic distribution of alcoholism (designated high alcoholism families) were compared with those that didn't (low alcoholism families). The family histories differed in two ways. First, the high alcoholism families had a significantly higher proportion of affected (alcoholic) females. In the high alcoholism families, the number of female alcoholics was 18 times the number in the low alcoholism families, whereas males were only 4 times more likely to be alcoholic (15.9% vs. 0.9% females; 38.2% vs. 8.7% males). The ratio of female to male alcoholics was significantly higher in the high alcoholism families compared to the low (0.46 vs. 0.052, p = 0.0001). And compared with unselected Missouri families (126), the females in our high alcohol families were 3.7 times more apt to be alcoholic. Second, high alcoholism families had more relatives with affective disorders, also distributed in a familial pattern (50.8% vs. 24%) (p = 0.0006). This is consistent with previous studies of alcoholism, which report an association between alcoholism and affective disorders in families (Kendler, Heath, Neale, Kessler, & Eaves, 1993; Bierut et al., 1998; Tsuang et al., 1998; Nurnberger et al., 2004). A significant family history of alcoholism did not associate preferentially with any other

family history categories (cognitive, language, dyslexia, ADHD, or seizures).

Evaluation of the autism probands from the high and low alcoholism groups differed in two important autism phenotypes: macrocephaly and type of autism onset. Children from the high alcoholism families were 2.8 times less likely to be macrocephalic (14.7% vs. 40.6%) (p = 0.0006). The very significant inverse relationship between high alcoholism family histories and macrocephaly suggests that whatever the genes are that predispose to both autism and macrocephaly are different and operate independently from gene(s) that predispose to alcoholism and autism. The second difference between the autism probands from high versus low alcohol families was the clinical course of their autistic disorder. Children from high alcoholism families were 1.5 times more apt to present with a regressive onset (52.5% vs. 35.8%) (p = 0.04). This was found predominately in families where the mother was alcoholic (80% vs. 40%) (p = 0.05). There was no correlation with paternal alcoholism. This raised the question of a direct teratogenic effect of alcohol on the developing fetus. However, only one mother with a history of alcoholism reported drinking during the pregnancy. And in all of the children, fetal alcohol syndrome was ruled out by careful physical examinations. We believe that the connection between autism and familial alcoholism is consistent with the idea that there is an alcoholism subtype that is genetically mediated, highly penetrant, and predisposes to the development of autism.

The next step is to look for evidence of some shared biochemical pathways or genes. Theoretically, a maternal factor is of interest since recent studies have reported that autism is associated with the maternal dopamine β-hydroxylase alleles and that there is sib concordance for maternal, but not paternal, alleles linked to dopamine, serotonin, and norepinephrine transmitters (Robinson, Schutz, Macciardi, White, & Holden, 2001). Clarification of our association between regressive autism and maternal alcoholism will depend on replication of the studies in a larger sample of families. Nevertheless, it does recommend that for autism, like other complex disorders parental genotypes should be considered as possible risk factors (Labuda, Krajinovic, Sabbagh, Infante-Rivard, & Sinnett, 2002; DeLong, 2007).

Though the majority of autism candidate genes and regions do not overlap with biochemical pathways or genes implicated in alcoholism, there are common areas. Dysregulation of the major neurotransmitter systems for GABA and serotonin occur in autism and in alcoholism. And recently genes that encode structural cell adhesion molecule subfamilies which specify brain connectivity during development and in adulthood have been linked to both disorders (Geschwind & Levitt, 2007; Garber, 2007; Persico & Bourgeron, 2006; Uhl et al., 2008). Uhl et al. (2008) analyzed convergence data from genomewide association studies identifying 27 candidate genes that link addiction and co-occurring brain disorders ranging from smoking to Alzheimer's disease; three cell adhesion genes (Neurexin 1, Contactin-associated protein-like 2, and Contactin 4) previously linked to autism were identified

in addictive disorder populations. Moreover, addiction and autism share associations with a number of cell adhesion gene subfamilies including nicotine dependence and autism with Neurexin 1 (Nussbaum et al., 2008), and alcoholism with Neurexin 3 (Hishimoto et al., 2007). These data support the concept that the same genetic variants can have overlapping or pleiotropic influences on more than one brain-based disorder.

Clinical Course Phenotypes

As with other medical and developmental disorders, the age of onset and clinical course are generally helpful in separating diseases that have similar symptomatology but different causes. For ASD the most intriguing separation is between children whose autism symptoms are noted from early infancy and those who regress from normal or near normal social and communicative development into autistic disorder, usually accompanied by the development of motor and other stereotypies (Lord, Schulman, & DiLavore, 2004; Stefanatos, 2008; Ozonoff, Williams, & Landa, 2005; Wilson, Djukic, Shinnar, Dharmani, & Rapin, 2003). Simultaneous cognitive declines have been documented (Bryson et al., 2007). Longitudinal studies, typically of the infant siblings of children with ASD, are poised to answer questions about the timing and patterns of early symptom developments (Baird et al., 2008; Rogers et al., 2008). Of equal interest will be results from extended longitudinal studies that permit us to identify which children drop into a prolonged developmental nadir, which undergo multiple periods of cognitive and communicative regression and which groups gradually improve in all areas, often irrespective of the intensity of developmental intervention. Once these developmental groups are better defined, they can be defined in terms of biologically and etiologically linked phenotypes which in turn should lead to the discovery of biological markers.

Core Autism Behavior Based Subgroups

Autism, like most if not all medical disorders, can be described on a variety of levels. Initially described as a psychiatric disorder of childhood, autism was defined by its behavioral variances in social interaction, language, and stereotypic interests and behaviors (Kanner, 1943). A number of behaviorally based autism subgroups were subsequently identified and cataloged by the American Psychiatric Association in the *Diagnostic and Statistical Manual of Mental Disorders* (DSM-IV-TR) manual as Autistic Disorder, Asperger's syndrome, Childhood Disintegrative Disorder, Rett syndrome, and Pervasive Developmental Disorders Not-Otherwise-Specified (PDD-NOS) (American Psychiatric Association, 2000). This remains the standard for definition of the behavioral autism diagnoses. Important research continues to refine diagnostic criteria for each clinical subtype, their boundaries, and treatment responses.

The most widely referenced clinical subgroups, proposed by Wing and Gould (1979), classify children based on the quality of their social interaction; "Socially aloof," "Passive interaction," or "Active-but-odd interaction." Aloof children reject most social contact and have atypical attachment to caregivers, lack pretend play and joint attention, have little eye contact, engage in inappropriate behaviors such as tantrums and are usually nonverbal. Passive children also do not initiate social interaction spontaneously, but accept other's approaches. Their play typically consists of imitative rather than imaginative activities, and their communication tends to be repetitive. Active-but-odd children seek interactions with others but these interactions are one-sided and peculiar. They use language communicatively but may have poor eye contact, speak in a monotone, lack conventional gestures, and have difficulty comprehending idiomatic statements. Based on the Wing Subgroups Questionnaire (Castelloe & Dawson, 1993), the literature supports the validity of the subtypes with most children falling into the aloof group, which correlates with lower IQs, and less change in IQ with early intensive behavioral intervention (Beglinger & Smith, 2001). Though Wing subgroups do correlate with some biological variables (Dawson, Klinger, Panagiotides, Lewy, & Castelloe, 1995), the classification is not always stable over time, with some children in the aloof group maturing into a passive social type. Some authors have questioned whether the Wing subtypes simply reflect IQ; however Volkmar, Cohen, Bregman, Hooks, and Stevenson (1989) found that only 53% of the variance in their study was accounted for by IQ, indicating the validity of this subgrouping paradigm. I am not aware of any association with etiology.

Other groups have focused on language variability to create more homogeneous subgroups. Language competence, like cognitive ability, is under significant genetic control, demonstrated by the robust language correlations reported within sibships, twins, and/or extended family members (Fombonne, Bolton, Prior, Jordan, & Ruter, 1997; Bailey et al., 1998; Piven & Palmer, 1997; Hughes, Plumet, & Leboyer, 1999; MacLean et al., 1999; Pickles et al., 2000; Spiker, Lotspeich, Dimiceli, Myers, & Risch, 2002; Silverman et al., 2002). Silverman et al. (2002) found reduced variance within sibships for speech delays and age at phrase speech. Likewise, in a study of 171 autism sibships Spiker et al. (2002) found a highly significant association within autism sib pairs for language delay and absence of phrase speech. Buxbaum et al. (2001) showed that concordance for delayed speech substantially increased the modestly positive evidence for linkage at loci on chromosomes 2 and 7. Hutcheson et al. (2003) found when presence or absence of language acquisition was used to segregate populations for linkage analysis, higher LOD scores for linkage to the AUT1 region on chromosome 7q region occurred in the more language impaired group. These were the first functional phenotypes to be successfully correlated with genetic linkage. Nevertheless, language development does not appear to be the primary autism genetic determinant, since many nonverbal autistic children have parents and/or siblings with high functioning autism or Asperger's (Eisenmajer et al., 1996; Gillberg, 1999; Gillberg & Wing,

1999; Volkmar, Klin, & Pauls, 1998). Miller and Ozonoff (2000) compared individuals with high-functioning autism with impaired language to individuals with Asperger's, with IQ differences controlled, and found no significant group differences in motor, visual spatial, or executive functions, suggesting language development is primarily IQ dependent.

Repetitive Behaviors

The presence of motor stereotypies together with preoccupations, rigidity, and restricted interests count as one criteria for a diagnosis of an ASD and thus are almost always reported in diagnosed children. However, the type, frequency, and intensity of repetitive behaviors, including stereotypic movements, inflexible routines, repetitive play, and perseverative speech in ASD vary widely. Stereotypies positively correlate with ASD severity and with cognitive deficiency (Bodfish, Symons, Parker, & Lewis, 2000; Bishop, Maybery, Wong, Maley, & Hallmayer, 2006; Goldman et al., 2009). And taken together they are the strongest predictor that an early ASD diagnosis will endure (Richler, Bishop, Kleinker, & Lord, 2007). Recent evidence, however, suggests that repetitive behaviors and interests are complex and probably stem from a number of sources (Beglinger & Smith, 2001; Happé & Ronald, 2008; Ingram et al., 2007). Whereas social and communication symptoms are closely associated and may even stem from the same biologic mechanism, repetitive behaviors, preoccupations, and restricted interests are not inextricably bound to those core symptoms (Happé & Ronald, 2008; Mandy & Skuse, 2008). Moreover, there is evidence that repetitive behaviors are etiologically distinct from restricted interests or obsessions (Goldman et al., 2009; Miles, Takahashi, & Mudrick, 2000b). In our study of 153 children with autistic disorder, those with no prominent motor repetitive behaviors had a lower sex ratio and less family history of ASD, but a greater family history of obsessive-compulsive behavior diagnoses. Recently Wiggins, Robins, Bakeman, and Adamson (2009) reported that tactile, auditory filtering and taste/smell hypersensitivity impairments in children with ASD correlate strongly with measures of stereotypic interests and behaviors. Lam, Bodfish, and Piven (2008), using exploratory factor analysis identified three distinct repetitive factors—repetitive motor behaviors, insistence on sameness, and circumscribed interests—each with distinct associations with subject characteristics such as IQ, age, social/communication impairments, presence of regression, and sib pair correlations. Based on these findings, it appears that repetitive behaviors could become a rich phenotypic trait for defining ASD subgroups. However, much more study is needed to separate this complex collection of symptoms into biologically homogeneous traits.

Cognitively and Functionally Defined Subgroups

A number of approaches for separating autism into subgroups based on function have been proposed. Variance in IQ has garnered the most attention, since between half and three quarters of autistic children have IQ scores below 70 (Lotter, 1966; Rutter & Garmezy, 1983; Steffenburg & Gillberg, 1986; Cohen, Paul, & Volkmar, 1987; Chakrabarti & Fombonne, 2001; Lincoln, Allen, & Kilman, 1995) and because cognitive levels measured in early childhood have been a strong predictor of outcome (Cohen et al., 1987; Lord & Schopler, 1989a, 1989b; Kobayashi, Murata, & Yoshinaga, 1992; Venter, Lord, & Schopler, 1992; Volkmar, 1992; Fein et al., 1999). However, it is clear that IQ is not a primary genetic variable in autism. Le Couteur et al. (1996) found that IQ scores can vary widely in identical twins. Jorde et al. (1990) found that dividing the Utah cohort by IQ revealed no significant differences in recurrence risks and gave no indications of inheritance patterns. Moreover, in the young child with autism, IQ assessment is difficult (reviewed in Bailey, Phillips, & Rutter, 1996), and IQ and DQ scores measured in early childhood may change over time and with therapy. Lord and Schopler (1989a) reported mean differences greater than 23 points comparing test scores prior to age 4 with those at age 8 and older, findings which have been replicated in other populations (Sigman et al., 1999). Even without special treatment, children first assessed in early preschool years are likely to show marked increases in IQ score by school age (Lord & Schopler, 1989b). There is however a correlation between IQ and genetics. In multiplex sibships, nonverbal IQ scores correlate positively (Spiker et al., 2002; Szatmari et al., 1996), indicating that cognitive abilities in autism, as in typically developing populations, were largely genetically determined. In addition, IQ levels have appeared to correlate with a fundamental genetic variable, the male to female ratio; the more severely retarded the population, the lower the male to female ratio (Wing, 1981; Gillberg, 1989; Szatmari, Bartolucci, Bremner, Bond, & Rich, 1989). The greatest male predominance occurs in Asperger's syndrome, as do the highest IQ scores. These examples illustrate the difficulty in determining which variables are primary when defining subgroups. Our studies indicate that it is the essential/complex autism distinction that provides the primary subgroup separation. Individuals with complex autism as a group have lower IQ scores than those with essential autism. When controlled for this distinction IQ scores do not correlate with sex ratios, recurrence risks, family histories of autism, or type of onset (Miles, unpublished data). This, of course, is not surprising since the complex/essential autism is based on the premise that dysmorphology and microcephaly are indicators of disruptions of early embryogenesis and thus more closely related to etiology.

Neurologically and Medically Defined Subgroups

Neurologic and medical symptoms are important variables affecting outcome and quality of life for children with autism. Seizures develop in approximately 25% of children with autism and the rate of electroencephalographic abnormalities is increased even when there is no history of seizures

(Kim, Donnelly, Tournay, Book, & Filipek, 2006; Spence & Schneider, 2009). And though individuals with autism plus seizures are more apt to have moderate to severe mental retardation, motor deficits, and poorer adaptive, behavioral, and social outcomes (Tuchman & Rapin, 2002; Hara, 2007), seizures by themselves are not a sensitive outcome predictor. Seizures and EEG abnormalities, though they fit many of the criteria for a promising subgroup defining phenotypic variable (Table 40-1), have not been successful phenotypic subgroup indicators. This is not surprising since, like autism, seizures are etiologically heterogeneous and are symptomatic of many underlying neurologic mechanisms.

Similar to seizures, sleep disorders and gastrointestinal symptoms are not pathophysiologically discrete entities and thus are too vague to define discrete autism subgroups. That is not to say, however, that future definition of discrete types of seizures, sleep disorders, or GI disorders, with clear linkages to biological mechanisms may not become useful in defining etiologic autism subgroups.

Conclusions: The Nosology of Autism as a Biologically Based Disorder

The transition of autism from a diagnostically inclusive behaviorally defined disorder to an etiological based nosology mirrors the history of mental retardation in the 1960s and cerebral palsy in the 1970s, as well as many less common disorders like X-linked muscular dystrophy (Darras, Korf, & Urion, 2009) and lissencephaly (Barkovich, Koch, & Carrol, 1991; Norman, McGillivray, Kalousek, Hill, & Poskitt, 1995; Dobyns & Das, 2009). In each case, a disorder that had originally been clinically defined was divided into subgroups based on recognition of phenotypic differences plus the introduction of new technologies. Mental retardation's demise as a diagnosis began in the 1950s with the introduction of two "new" techniques; clinical cytogenetics and physical dysmorphology (Jones, 2006). Redefinition of the cerebral palsies began when CT scans became available in the mid-1970s. Subsequently, molecular genetic analysis of subgroups of each of these descriptive diagnoses have resulted in the identification of hundreds of etiology specific diagnoses.

Relative to autism, the history of mental retardation is perhaps most informative, since the successes were based on breaking up hundreds of similar phenotypes into broad categories based on associated symptoms, such as MR plus craniofacial anomalies (Cohen, 2006), MR plus regression versus the static encephalopathies, MR with early overgrowth, or MR plus skin pigment changes, etc. For the geneticist, separating a broad heterogeneous disorder into its separate homogeneous diagnoses, usually depends on finding a "hook." This is a biologically discrete feature or phenotype found in a small proportion of individuals with the general diagnosis. A feature not commonly associated with the general descriptive diagnosis provides specificity to the subgroup. Thus, every sign, symptom, or oddball phenotype that occurs in children with ASDs must be noted and reported, so researchers can assemble putative, etiologically discrete subgroups for fresh and innovative investigations.

Challenges and Future Directions

- Discover the neurologic, biologic, and molecular bases behind the phenotypes that define discrete autism subgroups.
- Develop large autism research populations that are studied jointly by behavioralists, clinical geneticists, neuroanatomists, molecular biologists, and other neuroscientists.
- Pursue longitudinal studies of these same populations to answer the practical translational question "Which phenotypic features or biomarkers are most closely linked to recovery?"

Rare Genetic Variants and Autism Spectrum Disorders

Points of Interest

- The study of rare variation offers important avenues to expand the understanding of autism and related conditions. The investigation of rare genetic syndromes may generalize and shed light on the pathophysiology of autism spectrum disorders (ASDs); the study of unusual families or individuals with ASD may reveal basic biological mechanisms and molecular pathways, resulting in novel conceptual approaches to treating ASD; and new genomic technologies will soon reveal whether individually rare variations may account for a significant proportion of the population risk for social disability.
- Highly productive studies of rare variation have been ongoing for decades with regard to developmental syndromes and ASDs, with key early findings emerging from the study of chromosomal abnormalities.
- Recent advances in technology in the area of copy number variation has offered high-resolution detection of rare variation at a genome-wide scale and has been the basis of a series of key advances in the past several years;
- Next generation sequencing is currently being applied to studies of ASDs and the increasing resolution of genome-wide detection of rare variation will dramatically expand the possibilities for gene discovery in ASDs.
- A key distinction must be drawn between rare variation and "simple" inheritance. Recent CNV analyses and resequencing studies have challenged previous assumptions regarding the manner in which individually rare mutations might contribute to complex common syndromes such as ASDs.
- Recent findings point to a strong likelihood that specific genes associated with ASDs may also be involved with risks not only for mental retardation, specific language impairment, and seizure but potentially a wide array of neuropsychiatric disorders, including schizophrenia.

The latter findings, if replicated, will fundamentally challenge the current psychiatric diagnostic nosology.

The evidence for a genetic contribution to ASDs is incontrovertible. However, the underlying composition or architecture of the genetic variation contributing to social disability as well as the identity of specific changes in DNA sequence or structure accounting for the lion's share of risk remains largely a mystery (O'Roak & State, 2008; State, 2010). This is not to suggest that there has not been dramatic and important progress in elucidating the biological underpinnings of these devastating syndromes (Abrahams & Geschwind, 2008; O'Roak & State, 2008; Toro et al., 2010). Indeed, engendered in part by rapidly advancing genomic technologies, there have been equally remarkable strides in developmental neurobiology and a highly effective collaboration among advocacy groups, researchers, and the federal government. In fact there are few areas in psychiatric genetics where the pace of progress has been as rapid as it has been with regard to ASD over the past several years.

Over this period of time, interest in the potential contribution of rare variation (or alleles), defined as having a frequency of 1% to 5%, and very rare alleles (minor allele frequency <1%) has taken center stage. This transition has been motivated by converging factors: *(1)* the increasing appreciation of the relevance of the phenotypic overlap observed between ASD and rare single-gene developmental disorders such as Fragile X and tuberous sclerosis complex (Abrahams & Geschwind, 2008; Johnson & Myers, 2007; O'Roak & State, 2008); *(2)* the development of technologies that enable the detection of a new class of variation involving submicroscopic changes in chromosomal structure, known as CNVs (Iafrate et al., 2004; Redon et al., 2006; Sebat et al., 2004), an advance that has made affordable high-resolution genome-wide discovery of rare variation; *(3)* the recognition that common variation is likely to account for a smaller fraction of inter-individual variability in common complex disorders

than previously anticipated (Altshuler & Daly, 2007); and *(4)* the rapid pace of advance in the development of next-generation sequencing technology, which will soon allow for genome-wide detection of rare sequence variation to a degree that would have been difficult to conceive of as recently as the end of the past century.

This chapter will elaborate on these developments and focus on the issue of the contribution of rare and very rare genetic variation to ASD. In addition to dividing the discussion broadly based on a dichotomy between common and low-frequency alleles, it is also useful to distinguish three overlapping but distinct areas of investigation in this latter area: *(1)* the study of known rare genetic syndromes that show overlap with ASD; *(2)* the investigation of unusual, or outlier, individuals and families in search of rare variation that may shed light on the pathophysiology of ASD; and *(3)* research into the hypothesis that ASD *writ large* is the result of the accumulation, within the population, of multiple individually rare genetic variations. As other chapters in this volume address issues related to ASD and established genetic syndromes, the ensuing discussion will restrict its focus to the latter two topics.

This discussion will be divided into five sections: the first will provide a basic background into the nature of genetic variation and distinctions between common and rare alleles; the second will describe two competing, but not necessarily mutually exclusive, hypotheses about the genomic underpinnings of ASD, the common-variant: common-disease hypothesis and the rare-variant: common-disease hypothesis; the third will address the so-called "outlier strategy" of gene discovery, in which the focus is on rare and very rare alleles irrespective of their overall contribution to population risk (see Table 41-1); and the fourth will address the emerging evidence regarding the cumulative contribution of rare variation to ASD, including a consideration of opportunities and challenges facing current efforts to tackle this question. Finally, the chapter will close with a consideration of recent rare variant discoveries that have raised the prospect that a given specific genetic mutation may contribute to a broad spectrum of neuropsychiatric and neurodevelopmental outcomes (Eichler & Zimmerman, 2008; McCarthy et al., 2009; Mefford et al., 2008; Stefansson et al., 2008; Weiss et al., 2008) ranging from ASD to mental retardation, seizure, and schizophrenia.

Genetic Variation and Allelic Architecture of Autism Spectrum Disorder

Sequence Variation

The vast majority of the sequence of DNA is identical between any two people. Nonetheless, it is the variation among and between individuals that is most interesting to those studying the relationship of genes to disease risk. Although the biological processes that protect the genetic code from variation are robust, both environmental factors and intrinsic imperfections in the process of DNA replication and maintenance also lead to a slow but steady accumulation of variations over time.

Sequence variation is a change at a specific position within the genetic code of the constituent parts of the DNA molecule, known as bases or nucleotides. These are: A (adenosine), T (thymidine), G (guanine), and C (cytosine). Thus a sequence variation commonly involves either a substitution of one base for another, the loss or gain of a single or small number of bases (referred to as "in-dels" for "insertion-deletion"), or a variation in the number of repeats of a particular sequence motif. In addition, there can be rearrangements of genetic material in the human genome, such as inversions and translocations, which disrupt the expected order of the DNA sequence without leading to a net gain or loss of genetic material. If any of these changes occur in sperm or egg cells, they have the potential to be passed from generation to generation. In addition, if there is a germline mosaicism (i.e., the genetic mutation is present in only the germline of the parent but not in the parental somatic cells), an apparently new, or de novo, mutations may be found in more than one of the offspring. This possibility is one reason that de novo disease-causing mutations may be found in multiple affected individuals in one generation within a family as well as in pedigrees with only a single affected child.

The "life cycle" of germline variation—that is, what happens to an allele once it is introduced into the human genome in a manner that can be passed from generation to generation—is dictated by the interplay of natural selection, time, the mechanics of DNA transmission from generation to generation, and the history of human migration and population growth. Although all of these factors are important, this brief introduction will focus largely on the first—namely, natural selection—as recent evidence has underscored the relevance of this process for understanding the dynamics of human disease genetics.

Recall that the Darwinian notion is that in general, sequence variation that either has no biological consequence or is advantageous to the species will, over time and given reasonable opportunity, rise in frequency within a population and become common. At present, geneticists define this threshold as a minor (meaning the lesser of the two sequence options) frequency of greater than 5%. Alternatively, any variation that finds its way into an individual's germline and is deleterious will be subject, over time, to purifying selection, which will either eliminate the change from the population or drive it to low frequencies. For the sake of this discussion, the notion of good (neutral or advantageous) versus bad (deleterious) variation is very narrowly defined, referring only to the impact on reproductive fitness—that is, the ability of the organism to procreate and thus to pass the DNA from one generation to the next.

Although this dichotomy is a significant oversimplification, the relationship between the impact of a genetic variation on reproductive fitness and its likely frequency within the

Table 41–1.
Genes disrupted by rare variation via several different mechanisms (rare deletions, inversions, point mutations, duplications, translocations, de novo and transmitted CNVs) that are implicated in autism spectrum disorders and discussed in detail in the chapter

population is an important touchstone for understanding contemporary arguments regarding the allelic architecture of childhood developmental disorders. For example, if a phenotype is subject to strong purifying selection, alleles of large effect are likely to be rare. Conversely, common alleles are likely to carry smaller effects compared to very low frequency variations influencing the same phenotype.

Before launching into a discussion of the major competing hypotheses with regard to the allelic contributions to ASD, several related points deserve mention. First, "rare" variation and "deleterious" variation are not synonymous. As suggested above, time, the mechanics of DNA transmission, and the dynamics of human migration and population history influence allele frequencies. For example, any mutation that

has occurred recently is likely to be rare, having not had the time to flourish within a population. Consequently, a highly deleterious mutation is likely to be rare, but a rare variation is not necessarily highly deleterious. Moreover, even if a mutation is deleterious, it may be able to become common by "hitchhiking" through the generations due to its residing very near to an allele that provides survival advantages. Another important caveat is that it can be quite difficult to anticipate what types of phenotypic characteristics will or will not be subject to negative or purifying selection, particularly with regard to common disease. For example, although it is not difficult to predict that a mutation that inalterably leads to fetal demise will be found at low frequency, the manner in which natural selection will act on alleles contributing to adult-onset disorders or childhood syndromes that are not life-threatening may be impossible to anticipate. It is important to recall that such arguments must presuppose the interplay between a phenotypic trait and environmental factors that may have changed over evolutionary time. Third, rare variation is not rare. Although geneticists classify variation based on allele frequency, these categories are not a comment on the overall prevalence of a *class* of variation within an individual or a population. For example, in any given person, a very large percentage of sequence changes will be found to consist of alleles with frequency of less than 5% (Kidd, Pakstis, Speed, & Kidd, 2004; Meigs et al., 2007; Wang et al., 2008).

Common-Variant: Common-Disease

For most of the past decade, gene discovery in ASD has largely focused on common genetic variation. The presumption that common alleles will carry most of the genetic load for a common disorder is known as the "common-variant: common-disease" hypothesis. It is based on the notion that a conspiracy of genetic variations of relatively subtle effect, in combination with environmental factors, is likely to carry the majority of risk for prevalent clinical conditions (including ASD).

This hypothesis emerged in part as a result of the failure of early single-gene models to account for the genetics of common disorders. The earliest successes in gene discovery were the result of mapping rare alleles carrying very large effects for clearly defined (often relatively homogenous) clinical entities, mutations for which there is essentially a one-to-one relationship between possessing the variation and demonstrating a disease phenotype. As genetic tools became increasingly powerful, it was quickly apparent that this model did not hold for neuropsychiatric disorders *writ large* or for most common medical conditions.

Alternative hypotheses shifted the focus from Mendelian mutations carrying very large effects to common variations carrying more subtle risks. It was posited that individual alleles might carry such small risks as to be able to escape purifying selection because only a conspiracy of alleles would result in a phenotype that would impair fitness. Moreover, variation that might have enhanced fitness at one time in history, and thus gained a foothold in terms of allele frequency, could, in a

different environmental context, lead to disease. Several additional related ideas support a role for common variation even for a disorder that *prima face* would appear to reduce reproductive fitness: the first involves so-called "balancing selection" in which genetic changes might enhance fitness in one manner while reducing it in another. Another is that a deleterious variation might be present in sufficiently close proximity to a fitness-enhancing genetic variation that the two alleles would often be passed together from generation to generation, yielding a so-called "hitchhiking allele." Finally, it is worth noting that the overall hypothesis of common variants underlying common disease fits nicely with the Out-of-Africa theory of human history: one can construct a strong theoretical case that in a situation in which there was a very small initial population followed by very rapid growth, it would be likely that at the current stage in human evolution, most common diseases would be accounted for by the same variations that were present in the initial population.

A detailed history of methods to test for the contribution of common variation to common disease is beyond the scope of this chapter. However, it is useful to keep in mind that in general, such studies have involved some variation on a case–control design, performing comparisons of allele frequencies in these groups. Until the last few years, it was only technically feasible to test the relative abundance of alleles by focusing on a small amount of variation at time—for example, investigating one or several common variants located in or near a single or small numbers of candidate genes.

However, with the advent of high-density micro-arrays, it has recently become possible to test many alleles simultaneously. The technology has rapidly advanced from assaying tens to hundreds of thousands and now typically more than a million known alleles in a single rapid and inexpensive experiment. This technology has led to a remarkable proliferation of genome-wide association studies (GWAS), in which variations in and near every gene in the genome are tested simultaneously for association with a phenotype.

This shift, which eliminated the need to specify a gene of interest *a priori,* has had a striking effect, leading to the definitive discovery of many common alleles contributing to common medical conditions, including diabetes (Meigs et al., 2007), inflammatory bowel disease (Weersma et al., 2009), asthma (Moffatt et al., 2007), and intracranial aneurysm (Bilguvar et al., 2008). The rapid maturation of methods for common variant studies has allowed an empirical reappraisal of the common variant common disease hypothesis, leading to the following observations: first, the majority of disorders that have so far yielded to GWAS have shown genotype-relative risks that fall within the range of a 10% to 40% increase in cases versus controls for a given allele, far short of the two- to threefold change that was generally thought to represent a reasonable lower bound for powering common variant studies (Manolio, Brooks, & Collins, 2008). Moreover, this appears to hold true for adult-onset conditions, even when the manner in which the disorder might impair fitness is not clear (e.g., intracranial aneurysm). This observation does not prove, but is consistent

with, the notion that natural selection is a powerful factor in human disease genetics. The fact that only alleles carrying very small risks are found at high frequency in affected populations suggests that alleles carrying larger risks must have been driven down in frequency in the population and have been either eliminated or become rare. A second key observation emerging from the recent rash of GWAS successes is that the total amount of genetic risk that is explained by common alleles has so far also been quite small. Now that studies of some disorders (such as diabetes) have been completed on very large samples (large enough to detect effects in the range of 10%–15%) and multiple risk alleles have been confirmed, it is notable that less than 10% of interindividual variability has been accounted for, compared to the 40%–60% thought to be relevant in most common conditions (Altshuler, Daly, & Lander, 2008; Zeggini et al., 2008). These results suggests several alternatives: *(1)* genetic risks have been vastly overestimated across all of medicine; *(2)* studies of hundreds of thousands of patients will be needed to identify the hundreds of additional alleles that will ultimately be found to carry fleetingly small individual risks; *(3)* new methodologies and approaches will need to be developed to better detect the interactive contributions of multiple genes and environmental factors; and/or *(4)* rare variation accounts for a more substantial population burden of common disease than expected based on the common variant common disease hypothesis.

Rare-Variant: Common-Disease

The early failure of Mendelian genetics to account for a significant proportion of the risk for common conditions did not lead the entire genetics field to abandon the study of rare variation. Indeed, many of the most important advances in human genetics in the contemporary era have come from the search for rare examples of common disorders, including in breast cancer (Miki et al., 1994), Alzheimer's disease (Bertram et al., 2000), and hypertension (Simon et al., 1996).

One of the driving rationales for these studies was that some proportion of the genetic architecture of a common condition would be accounted for by rare, highly penetrant mutations. And, moreover, these variations would be more amenable to mapping using traditional methods *and* more tractable to study in vitro and in vivo given the relative large effect sizes. Most importantly, the studies shared the hypothesis that the insights into molecular mechanisms and disease pathophysiology could be transformative regardless of whether the specific genes discovered accounted for significant population genetic risk. In fact, for many complex disorders, this has turned out to be the case.

A second rational motivating such studies has been the recognition that rare variation could, in addition to accounting for disease in outliers, accumulate in the population to account for an appreciable proportion of common disease (Cohen et al., 2006; Ji et al., 2008). One could imagine that if

variations in multiple different genes or multiple variations in the same gene could lead to similar clinical outcomes, over time, an accumulation of rare variation could accrue, accounting for a significant proportion of a commonly occurring disorder. Moreover, for conditions in which de novo mutation played a significant role, this would obtain—and one would expect to see—a considerable number of apparently sporadic cases (in which only the proband in the family was affected) and a very high rate of monozygotic concordance versus dizygotic (DZ) concordance.

Until very recently, for practical reasons, it has been difficult to test this hypothesis. Evaluating individuals for sequence variation that has previously been discovered, as is typically the case with common variation, is relatively inexpensive and is now both economically and technically feasible to carry out on a genome-wide scale. In brief, once a variation is known, binary assays can be developed that are quite inexpensive, investigating the presence or absence of a given base without having to sequence the corresponding DNA. Conversely, the identification of rare variation often requires some degree of direct DNA sequencing to identify which of the four possible bases is present at each position in the genetic code. This is an order of magnitude more expensive than most binary common variant detection schemes. Consequently, studies at a genome-wide scale have not been yet conducted, and it is only recently, with the advent of "massively parallel" "next generation" sequencing technologies, that such studies are emerging as within reach of the typical genetics laboratories.

Nonetheless, for some time, both the outlier approach as well as the question of the overall contribution of rare variation to common disease risk has been of great interest among a group of investigators (Abelson et al., 2005; Jamain et al., 2003; Marshall et al., 2008; McClellan, Susser, & King, 2007) and has recently become a major area of preoccupation in psychiatry, particularly with regard to autism and schizophrenia, as discussed below.

Rare Variation in Autism Spectrum Disorder

Presently, there is evidence supporting *both* common and rare variation contributing to ASDs. The former is discussed in considerable detail elsewhere in this volume. In fact there are multiple lines of evidence to support the contribution of rare variants to ASDs, both with regard to the relevance of outliers as well as supporting the rare-variant: common-disease hypothesis. For example: *(1)* over the past two decades, microscopic chromosomal abnormalities have been identified at a far greater rate in ASDs than in the typically developing population (Vorstman et al., 2006); *(2)* several recurrent contiguous-gene microscopic chromosomal rearrangements are either known or suspected to increase the risk for ASDs, including maternally-inherited duplications of 15q11-13 and deletions of 22q11; *(3)* rare monogenic syndromes show phenotypic overlap with ASDs, and, not infrequently,

the ASD diagnosis precedes recognition and molecular confirmation of the syndrome (Schaefer & Mendelsohn, 2008); *(4)* recent studies have demonstrated that, as is the case with microscopic cytogenetic abnormalities, large submicroscopic copy number variations are also more commonly identified in individuals with autism than in controls (Sebat et al., 2007) and that such CNVs may either be individually rare or recurrent (Kumar et al., 2008; Weiss et al., 2008); and finally, *(5)* individually rare variations in both chromosome structure and DNA sequence have been either associated with or found to be linked to so-called "idiopathic ASD."

Recent evidence supporting both the utility of outlier approaches as well as evidence supporting the overall contribution of rare variation to the prevalence of ASDs is discussed below.

Rare Variants and Outlier Approaches

Historically, outlier approaches have relied on the characterization of chromosomal abnormalities or the use of traditional multigenerational (parametric) linkage analyses to identify highly penetrant mutations in rare individuals or families. These two approaches are discussed in turn. In addition, over the past several years, the analysis of CNV has become an important means both to expand the search for outliers (discussed here) as well as to assess the overall contribution of rare variation to ASDs (discussed in the subsequent section).

In recent years, it has become commonplace to follow on the characterization of a candidate transcript identified through any of these approaches by re-sequencing the gene or genes of interest in a larger group of individuals. Such an approach is intuitively attractive, but presents some methodological and conceptual challenges that are highlighted below. In addition as suggested above, new sequencing technologies have rapidly emerged as a means to identify most or all rare variation in an individual, a topic which will be addressed in the penultimate section of the chapter.

Molecular Cytogenetics

The earliest studies addressing the question of rare structural variation used the light microscope and converged on an estimated consensus of approximately 3% to 7% burden of balanced translocations, inversions, and aneuploidies in cases of autism that had passed screening for "known" etiologies, a rate that is estimated to be 50- to 100-fold higher than for developmentally typical children (Nielsen & Sillesen, 1975; Nielsen et al., 1982).

More than a decade ago, the first reports describing fine mapping of chromosomal abnormalities in individuals with autism emerged, coincident with the development of molecular cytogenetic techniques (Speicher, Gwyn Ballard, & Ward, 1996). In 1997, Ishikawa-Brush and colleagues (Ishikawa-Brush et al., 1997) reported a chromosome X;8 translocation

in a 27-year-old female with multiple exostoses, autism, MR, and epilepsy that disrupted the gene *gastrin-releasing peptide receptor* (*GRPR*) on the X-chromosome and mapped approximately 30 kilobases from the gene *Syndecan-2* gene (*SDC2* on chromosome 8). The authors were particularly interested in *GRPR* given its position on the X chromosome and disruption by the rearrangement. Moreover, subsequent studies have demonstrated that the receptor is present on GABAergic interneurons of the lateral nucleus of the amygdala (Shumyatsky et al., 2002). So far, additional functional mutations have not been found in either gene clearly associated with developmental delay or autism (Seidita et al., 2008).

Using a similar strategy, Sultana et al. (2002) reported on a chromosomal breakpoint in a pair of twins with ASDs, mapping this to a previously uncharacterized transcript they dubbed *AUTS2*. Interestingly, several subsequent investigations have found CNVs at this locus in individuals with MR and ASDs (Kalscheuer et al., 2007; Sultana et al., 2002) (Bakkaloglu et al., 2007) as well as in normal controls (Redon et al., 2006).

However, the most notable early discovery based on cytogenetic findings was the result of work by Jamain and colleagues in the laboratory of Thomas Buergeron. They were motivated to study transcripts mapping to chromosome Xp22.3 because of the prior finding of deletions of this interval in three females with autism (Thomas et al., 1999). Within this region, they identified the transcript *KIAA1260*, corresponding to *NLGN4X*, a member of the neuroligin family of proteins, later found to be essential for the formation of functional synapses (Lisé & El-Husseini, 2006). They sequenced the gene, as well as the related transcripts *NLGN3* and *NLGN4Y*, in 36 pairs of affected siblings and 122 trios with autism or AS. Within *NLGN4X*, they identified a nonsense mutation that segregated with both autism and AS in a single family, marking the first observation of a clearly deleterious point mutation identified in individuals with apparently idiopathic or nonsyndromic ASDs. In addition, in the transcript *NLGN3*, they identified a missense substitution at a highly conserved residue in a second family. Although subsequent mutation screening studies of relatively small numbers of patients have not identified additional clearly functional mutations in either of these transcripts (confirming their status as outlier findings), the *NLGN4X* finding was confirmed shortly after initial publication by an independent lab investigating a multigenerational family affected with both MR and ASDs using parametric linkage analysis (discussed below) (Laumonnier et al., 2004).

As the technology for mapping chromosomal abnormalities has improved and the identification of genes at chromosomal breakpoint become routine, multiple examples of de novo abnormalities or chromosomal rearrangements have been found disrupting or mapping near brain expressed transcripts in individuals and families with social disability (Borg et al., 2002; Collins et al., 2006; Roohi et al., 2009; Savelyeva et al., 2006; Vincent et al., 2000). The challenges that accompany determining which of these are incidental findings and

which are truly involved in disease risk are considered in subsequent sections of this chapter.

Interestingly, in the wake of the *NGLN4X* findings, several recent studies have provided support for the involvement of synaptic and/or neuronal adhesion molecules in ASDs. For example, in families with ASDs, the Buergeron lab identified rare de novo and transmitted structural and sequence variations in the gene *SHANK3*, a protein present in the postsynaptic density that interacts with a binding partner of *NLGN4* (Meyer et al., 2004). Moreover, in a second study of *SHANK3*, four de novo abnormalities and nine inherited missense variants were identified among 400 families (Moessner et al., 2007). Three of the de novo events were large-scale deletions, encompassing 277 kb, 3.2 Mb, 4.36 Mb, whereas the fourth was a missense variant. The high rate of de novo mutations involving coding segments of *SHANK3* in individuals with ideopathic ASDs identified in independent studies, the finding of developmental delay and autistic features in patients with the 22q13 deletion syndrome (the region in which *SHANK3* resides), and the shared molecular pathway with *NLGN4X* provide strong convergent evidence for the importance of rare mutations in this transcript for ASDs. In addition, two very recent publications found evidence for the association of the gene SHANK2, a closely related scaffolding molecule, with ASD (Pinto et al. Nature. 2010 Jul 15;466(7304):368-72.; Berkel et al Nat Genet. 2010 Jun;42(6):489-91).

Several recent papers have also suggested that variations in *Neurexin 1* (*NRXN1*) a trans-synaptic binding partner for neuroligins (Lisé & El-Husseini, 2006) carries risks for ASDs. The Autism Genome Project Consortium (2007; Szatmari & Consortium, 2007) reported a combined linkage and copy number analysis involving 1168 subjects. This early investigation was one of the first to address the issue of CNVs in autism but was confined to an analysis of only large-scale variations because of the use of a first generation array with 10,000 probes. Nonetheless, one family was identified in which two affected siblings had the same 300-kb deletion, encompassing the coding region of *NRXN1*. This was not present in the parents, again highlighting the phenomena of germline mosaicism. Subsequently, rare missense variants, balanced chromosomal abnormalities disrupting *NRXN1* and an overrepresentation of micro-deletions in cases versus control have all been reported (Feng et al., 2006; Kim et al., 2008; Glessner et al., 2009; Bucan et al., 2009).

Cytogenetic approaches have also highlighted a role for contactin and contactin-associated neuronal adhesion molecules in ASDs (as have common variant studies discussed in detail elsewhere in this volume). Fernandez and colleagues (T. Fernandez et al., 2004; T. V. Fernandez et al., 2008) identified a child with features of a rare deletion syndrome on the short arm of chromosome 3 who also presented with social disability. They identified and mapped a balanced translocation that disrupted the coding segment of the gene *Contactin 4*. Several subsequent studies of CNVs have supported a role for this molecule in ideopathic ASDs (Glessner et al., 2009; Roohi et al., 2009).

In a similar vein, Bakkaloglu et al. (2007) mapped a de novo chromosomal abnormality in the only affected member of a pedigree and found the rearrangement disrupted both the neuronal adhesion molecule *contactin-associated protein 2* (*CNTNAP2;* a.k.a. *Caspr2* in the mouse) and the previously identified transcript *AUTS2* (Sultana et al., 2002). Based on prior evidence implicating contactin molecules in ASDs and a previous study demonstrating that rare recessive mutations in this gene lead to seizures, developmental delay and autism (Strauss et al., 2006), the authors chose to prioritize the evaluation of *CNTNAP2* and comprehensively resequenced this molecule in 635 patients and 942 controls. Among patients, they identified 13 very rare variants, 8 of which mapped to highly conserved sites and/or were predicted to be deleterious by bioinformatics approaches. However, they also identified 11 rare variants, 6 of which were presumed deleterious among the larger group of controls. Among the affected individuals, the majority of very rare variants showed partial penetrance (i.e., as expected for complex disease, some individuals who had the mutation did not appear to be affected), but most of the identified variants did segregate among the affected individuals within a family (i.e., all presumed affected individuals in a nuclear family carried the same putative mutation). One variant at a highly conserved position, 1869T, was inherited by 4 affected children in 3 unrelated families and was not present in 4010 control chromosomes ($p = 0.014$), although the authors were not able to rule out the confound of occult ancestral differences between cases and controls given the data available at that time.

Overall, this large-scale resequencing effort demonstrated a twofold increase in the burden of rare variants in cases versus controls, which did not reach statistical significance. Subsequent deep sequencing studies have highlighted the importance of differentiating rare variation that is deleterious to protein function versus that which is neutral (Ji et al. Nat Genet. 2008 May;40(5):592-9), an effort that is currently underway with regard to CNTNAP2. Nonetheless, as noted below and in other chapters of this volume, work from other groups of investigators has implicated both common and rare variation in *CNTNAP2* with ASDs and language development. In this light, the cytogenetic and resequencing screening data presented in Bakkaloglu et al. (2007) suggest that individually, very rare variants in this transcript may also contribute to the pathophysiology of idiopathic ASDs.

Parametric Linkage Analyses

If the mode of inheritance of a gene is known or suspected, as is often the case for Mendelian conditions, genome-wide parametric linkage analysis is a highly effective approach to gene discovery. Genetic data are analyzed in multiple generations within a family or group of families searching for chromosomal segments that contain (or are linked to) a disease locus and that fit a proposed model (the parameters) of inheritance. The likelihood of observing the data based on the proposed model is compared to likelihood of the same set of

observations being made by chance. This method has been used infrequently in studies of autism, as the mode of inheritance is typically not straightforward. However, when such a strategy has been employed in unusual outlier families or special populations, the results have been striking.

For example, shortly after the publication by Jamain et al. (2003), which reported a truncating *NLGN4X* mutation in ASDs, Laumonnier et al. (2004) described a parametric linkage analysis performed on a single large family with probands affected either with mental retardation, ASDs, or both. They observed segregation in this family consistent with an X-linked mode of inheritance and identified a statistically significant region on the X-chromosome yielding evidence for genome-wide linkage. Within this interval, fine mapping revealed a nonsense substitution in *NLGN4X* that was quite similar, but not identical, to the previous reported mutation (Jamain et al., 2003). This result provided a critical confirmation of the earlier observation.
