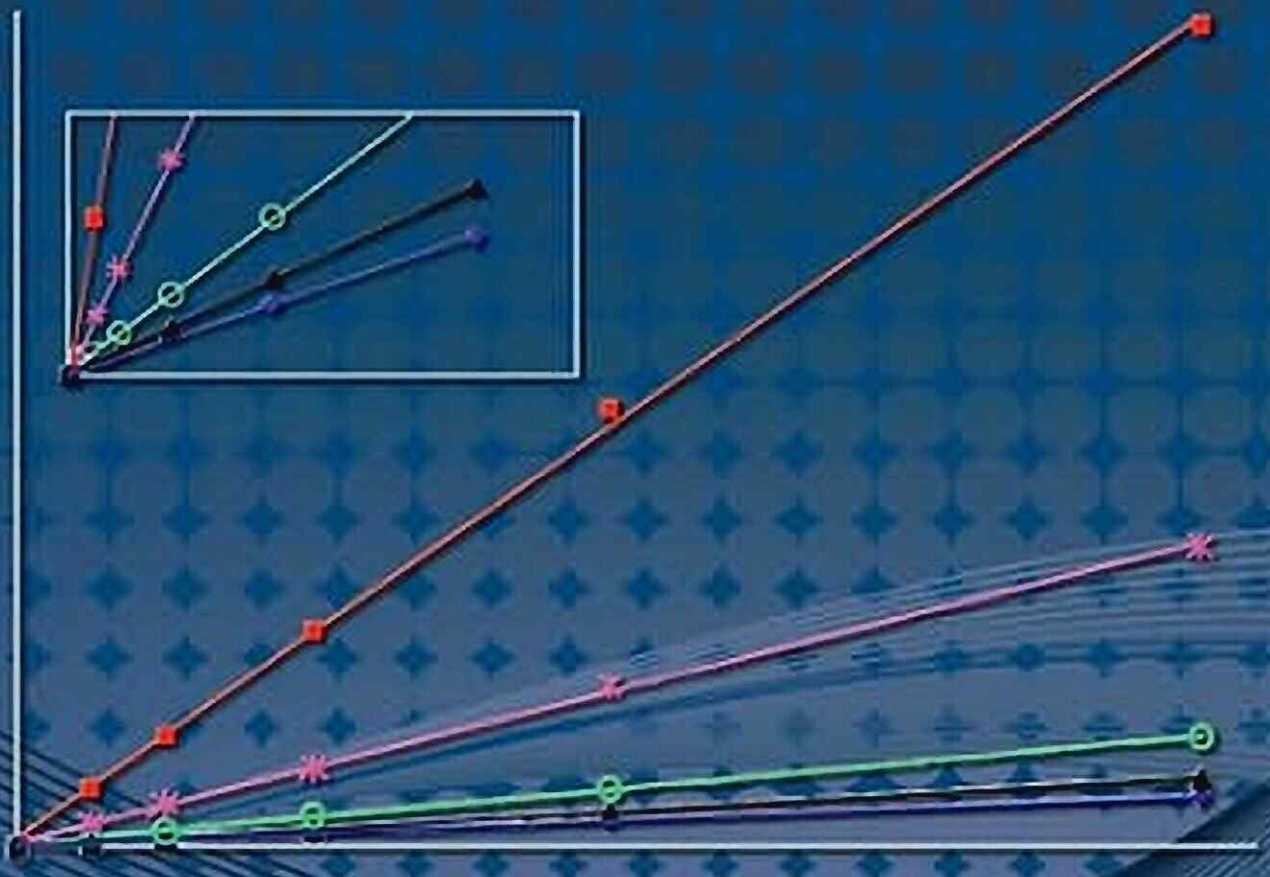
ENCYCLOPEDIA OF CHROMATOGRAPHY

Third Edition



EDITED BY

JACK CAZES

CRC Press
Taylor & Francis Group

ENCYCLOPEDIA OF
CHROMATOGRAPHY

Third Edition

VOLUME I, II, and III

Encyclopedias from Taylor & Francis Group

Agriculture Titles

Dekker Agropedia Collection (Eight Volume Set)
ISBN: 978-0-8247-2194-7 Cat. No.: DK803X

Encyclopedia of Agricultural, Food, and Biological Engineering
Edited by Dennis R. Heldman
ISBN: 978-0-8247-0938-9 Cat. No.: DK9381

Encyclopedia of Animal Science
Edited by Wilson G. Pond and Alan Bell
ISBN: 978-0-8247-5496-9 Cat. No.: DK2206

Encyclopedia of Pest Management
Edited by David Pimentel
ISBN: 978-0-8247-0632-6 Cat. No.: DK6323

Encyclopedia of Pest Management, Volume II
Edited by David Pimentel
ISBN: 978-1-4200-5361-6 Cat. No.: 53612

Encyclopedia of Plant and Crop Science
Edited by Robert M. Goodman
ISBN: 978-0-8247-0944-0 Cat. No.: DK1190

Encyclopedia of Soil Science, Second Edition (Two Volume Set)
Edited by Rattan Lal
ISBN: 978-0-8493-3830-4 Cat. No.: DK830X

Encyclopedia of Water Science, Second Edition (Two Volume Set)
Edited by Stanley W. Trimble
ISBN: 978-0-8493-9627-4 Cat. No.: DK9627

Chemistry Titles

Encyclopedia of Chromatography, Third Edition (Three Volume Set)
Edited by Jack Cazes
ISBN: 978-1-4200-8459-7 Cat. No.: 84593

Encyclopedia of Supramolecular Chemistry (Two Volume Set)
Edited by Jerry L. Atwood and Jonathan W. Steed
ISBN: 978-0-8247-5056-5 Cat. No.: DK056X

Encyclopedia of Surface and Colloid Science, Second Edition (Eight Volume Set)
Edited by P. Somasundaran
ISBN: 978-0-8493-9615-1 Cat. No.: DK9615

Engineering Titles

Encyclopedia of Chemical Processing (Five Volume Set)
Edited by Sunggyu Lee
ISBN: 978-0-8247-5563-8 Cat. No.: DK2243

Encyclopedia of Corrosion Technology, Second Edition
Edited by Philip A. Schweitzer, P.E.
ISBN: 978-0-8247-4878-4 Cat. No.: DK1295

Encyclopedia of Energy Engineering and Technology (Three Volume Set)
Edited by Barney L. Capehart
ISBN: 978-0-8493-3653-9 Cat. No.: DK653X

Dekker Encyclopedia of Nanoscience and Nanotechnology, Second Edition (Six Volume Set)
Edited by Cristian I. Contescu and Karol Putyera
ISBN: 978-0-8493-9639-7 Cat. No.: DK9639

Encyclopedia of Optical Engineering (Three Volume Set)
Edited by Ronald G. Driggers
ISBN: 978-0-8247-0940-2 Cat. No.: DK9403

Business Titles

Encyclopedia of Library and Information Science, Third Edition (Seven Volume Set)
Edited by Marcia J. Bates and Mary Niles Maack
ISBN: 978-0-8493-9712-7 Cat. No.: DK9712

Encyclopedia of Public Administration and Public Policy, Second Edition (Three Volume Set)
Edited by Evan M. Berman
ISBN: 978-0-4200-5275-6 Cat. No.: AU5275

Encyclopedia of Wireless and Mobile Communications (Three Volume Set)
Edited by Borko Furht
ISBN: 978-0-4200-4326-6 Cat. No.: AU4326

These titles are available both in print and online. To order, visit:

ENCYCLOPEDIA OF
CHROMATOGRAPHY

Third Edition

VOLUME I, II, and III

EDITED BY

JACK CAZES

CRC Press
Taylor & Francis Group
Boca Raton London New York

CRC Press is an imprint of the
Taylor & Francis Group, an **informa** business

Encyclopedia of Chromatography
Third Edition

Volume I
Pages 1–828
Absorbance through Extra

Encyclopedia of Chromatography
Third Edition

Volume II
Pages 829–1636
Fast through Open

Encyclopedia of Chromatography
Third Edition

Volume III
Pages 1637–2457
Optical through Zone

CRC Press
Taylor & Francis Group
6000 Broken Sound Parkway NW, Suite 300
Boca Raton, FL 33487-2742

CRC Press is an imprint of Taylor & Francis Group, an Informa business

No claim to original U.S. Government works

Printed in the United States of America on acid-free paper
10 9 8 7 6 5 4 3 2 1

International Standard Book Number: 978-1-4200-8459-7 (Hardback)

Library of Congress Cataloging-in-Publication Data

Encyclopedia of chromatography / editor, Jack Cazes. -- 3rd ed.
p. cm.
Includes bibliographical references and index.
ISBN 978-1-4200-8459-7 (hardcover : alk. paper)
1. Chromatographic analysis--Encyclopedias. I. Cazes, Jack, 1934- II. Title.

QD79.C4E63 2010
543'.803--dc22 2009031443

This work is dedicated to my lovely grandchildren,
Matthew, Monica, Brett, and Evan,
the shining lights of my life,
and to my wife, Eleanor,
who has stood by my side
and made this ambitious project possible

Contributors

Concepción Abad / *Department of Biochemistry and Molecular Biology, University of Valencia, Valencia, Spain*
Maged S. Abdel-Kader / *Department of Pharmacognosy, King Saud University, Riyadh, Saudi Arabia*
Mohamed Abdel-Rehim / *Research and Development, AstraZeneca, Södertälje, and Department of Chemistry, Karlstad University, Karlstad, Sweden*
Hassan Y. Aboul-Enein / *Pharmaceutical and Medicinal Chemistry Department, Pharmaceutical and Drug Industries Research Division, National Research Center, Dokki, Cairo, Egypt*
Manuel Acosta / *Department of Plant Biology (Plant Physiology), University of Murcia, Murcia, Spain*
Ibrahim A. Al-Duraibi / *Pharmaceutical Analysis Laboratory, King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia*
Serge Alex / *Center for Chemical Process Studies of Quebec (CEPROCQ), Montreal, Quebec, Canada*
Imran Ali / *Department of Chemistry, Jamia Millia Islamia (A Central University), New Delhi, India*
Abdul-Rahman A. Al-Majed / *Department of Pharmaceutical Chemistry, King Saud University, Riyadh, Saudi Arabia*
Maria de Fatima Alpendurada / *Faculty of Pharmacy, University of Porto, Porto, Portugal*
Juan G. Alvarez / *Department of Obstetrics and Gynecology, Beth Israel Deaconess Medical Center, Boston, Massachusetts, U.S.A.*
P.B. Andrade / *Requimte, Department of Pharmacognosy, Faculty of Pharmacy, University of Porto, Porto, Portugal*
Victor P. Andreev / *Institute for Analytical Instrumentation, Russian Academy of Sciences, St. Petersburg, Russia*
M.J. Arín / *Analytical Chemistry, Department of Applied Chemistry and Physics, University of León, León, Spain*
Marino B. Arnao / *Department of Plant Biology (Plant Physiology), University of Murcia, Murcia, Spain*
Christine M. Aurigemma / *Pfizer Global Research and Development, Pfizer Inc., La Jolla, California, U.S.A.*
Yoshinobu Baba / *Department of Medicinal Chemistry, University of Tokushima, Tokushima, Japan*
M.A. Bagool / *Wockhardt Research Centre, Aurangabad, India*
Eunmi Ban / *Research Institute of Pharmaceutical Sciences, Seoul National University, Seoul, South Korea*
James J. Bao / *Advanced Medicine Inc., San Francisco, California, U.S.A.*
M.A. Barbirato / *Chromatography Laboratory, University of São Paulo, São Carlos, Brazil*
Csaba Barta / *Novartis Agricultural Discovery Institute, Inc., San Diego, California, U.S.A.*
M. Barut / *BIA Separations d.o.o., Ljubljana, Slovenia*

I. Bataille / *Galilee Institute, University of North Paris, Villetaneuse, France*
Maria Bathori / *Department of Pharmacognosy, University of Szeged, Szeged, Hungary*
S. Battu / *Analytical Chemistry and Bromatology Laboratory, University of Limoges, Limoges, France*
Ronald Beckett / *Water Studies Centre, Monash University, Melbourne, Victoria, Australia*
Eva Benicka / *Institute of Analytical Chemistry, Slovak University of Technology, Bratislava, Slovakia*
A. Berecka / *Department of Medicinal Chemistry, Medical University of Lublin, Lublin, Poland*
Philippe J. Berny / *Toxicology Unit, National Veterinary School of Lyon, Marcy L'Etoile, France*
Alain Berthod / *Laboratory of Analytical Sciences, University of Lyon I, Villeurbanne, France*
Clayton B'Hymer / *National Institute for Occupational Safety and Health, Centers for Disease Control and Prevention, U.S. Department of Health and Human Services, Cincinnati, Ohio, U.S.A.*
Peng-Yu Bi / *College of Science, Beijing University of Chemical Technology, Beijing, China*
Jacques Bodennec / *Department of Biological Chemistry, Weizmann Institute of Science, Rehovot, Israel*
Pierina Sueli Bonato / *Faculty of Pharmaceutical Sciences of Ribeirão Preto, University of São Paulo, Ribeirão Preto, Brazil*
Frederic Bonfils / *French Agricultural Research Center for International Development (CIRAD-CP), Montpellier, France*
Evropi Botsoglou / *Laboratory of Hygiene of Foods of Animal Origin, Department of Veterinary Medicine, University of Thessaly, Karditsa, Greece*
Nikolas A. Botsoglou / *Laboratories of Nutrition, Faculty of Veterinary Medicine, Aristotle University of Thessaloniki, Thessaloniki, Greece*
Natasa Brajenovic / *Institute for Medical Research and Occupational Health, Zagreb, Croatia*
E. Brandsteterova / *Department of Analytical Chemistry, Slovak Technical University, Bratislava, Slovakia*
Michael Breslav / *Johnson & Johnson Pharmaceutical Research and Development, LLC, Spring House, Pennsylvania, U.S.A.*
Silvia H.G. Brondi / *Embrapa Livestock Southeast, São Carlos, Brazil*
Yefim Brun / *Waters Corporation, Milford, Massachusetts, U.S.A.*
Christopher E. Bunker / *Propulsion Directorate, Air Force Research Laboratory, Wright-Patterson Air Force Base, Ohio, U.S.A.*
Jean-Pierre Busnel / *Physical Chemistry of Material Polymers, University of Main, Le Mans, France*
S. Bilal Butt / *Central Analytical Facility Division, Pakistan Institute of Nuclear Science and Technology, Islamabad, Pakistan*
Yong Cai / *Department of Chemistry, Florida International University, Miami, Florida, U.S.A.*
Agustín Campos / *Institute of Materials Science, University of Valencia, Valencia, Spain*
Antonio Cano / *Department of Plant Biology (Plant Physiology), University of Murcia, Murcia, Spain*
Ping Cao / *Biology Department, Tularik, Inc., South San Francisco, California, U.S.A.*
Wenjie Cao / *Huntsman Polymers Corp., Odessa, Texas, U.S.A.*
Philippe Cardot / *Analytical Chemistry and Bromatology Laboratory, University of Limoges, Limoges, France*
Susana Casal / *Requimte, Bromatology Service, Faculty of Pharmacy, University of Porto, Porto, Portugal*

M. Caude / *Analytical Chemistry Department, City of Paris Industrial Physics and Chemistry Higher Educational Institution (ESPCI), Paris, France*
Teresa Cecchi / *Department of Chemical Science, University of Camerino (UNICAM), Camerino, Italy*
Zhikuan Chai / *Research Center for Eco-Environmental Sciences, Chinese Academy of Sciences, Beijing, China*
Jeffrey J. Chalmers / *Department of Chemical and Biomolecular Engineering, Ohio State University, Columbus, Ohio, U.S.A.*
Huan-Tsung Chang / *Department of Chemistry, National Taiwan University, Taipei, Taiwan*
Bezhan Chankvetadze / *Department of Physical and Analytical Chemistry and Molecular Recognition and Separation Science Laboratory, School of Exact and Natural Sciences, Tbilisi State University, Tbilisi, Georgia*
C. Char / *French Agricultural Research Center for International Development (CIRAD-CP), Montpellier, France*
Kenneth L. Cheever / *National Institute for Occupational Safety and Health, Centers for Disease Control and Prevention, U.S. Department of Health and Human Services, Cincinnati, Ohio, U.S.A.*
Bailin Chen / *Department of Chemistry, University of Kentucky, Lexington, Kentucky, U.S.A.*
Sarah S. Chen / *Analytical Science, GlaxoSmithKline, King of Prussia, Pennsylvania, U.S.A.*
Oscar Chiantore / *Department of Inorganic, Physical, and Material Chemistry, University of Torino, Torino, Italy*
Tai-Chia Chiu / *Department of Chemistry, National Taiwan University, Taipei, Taiwan*
Josef Chmelík / *Institute of Analytical Chemistry, Academy of Sciences of the Czech Republic, Prague, Czech Republic*
Du Young Choi / *Center for Advanced Bioseparation Technology and Department of Chemical Engineering, Inha University, Incheon, South Korea*
Irena Choma / *Department of Chemical Physics, Marie Curie-Sklodowska University, Lublin, Poland*
Christodoulos Christodoulis / *Department of Chemical and Physical Examinations, Forensic Science Division, Hellenic Police Headquarter, Athens, Greece*
Witold Ciesielski / *Department of Instrumental Analysis, University of Łódź, Łódź, Poland*
Gabriela Cimpan / *Sirius Analytical Instruments Ltd., East Sussex, U.K.*
Alessandra Cincinelli / *Department of Chemistry, University of Florence (UNIFI), Florence, Italy*
Christa L. Colyer / *Department of Chemistry, Wake Forest University, Winston-Salem, North Carolina, U.S.A.*
Danilo Corradini / *Institute of Chromatography, Rome, Italy*
Tibor Cserháti / *Institute of Chemistry, Chemical Research Center, Hungarian Academy of Sciences, Budapest, Hungary*
James Curry / *Senior Scientist, Research and Development, R.P. Scherer North America, St. Petersburg, Florida, U.S.A.*
S.-L. Da / *Department of Chemistry, Wuhan University, Wuhan, China*
José Almiro da Paixão / *Department of Nutrition, Center of Health Sciences, Federal University of Pernambuco, Recife, Brazil*
Victor David / *Department of Analytical Chemistry, University of Bucharest, Bucharest, Romania*
Cristiane Masetto de Gaitani / *Faculty of Pharmaceutical Sciences of Ribeirão Preto, University of São Paulo, Ribeirão Preto, Brazil*
M. de Moraes / *Chromatography Laboratory, University of São Paulo, São Carlos, Brazil*

Melgardt M. de Villiers / *School of Pharmacy, University of Wisconsin, Madison, Wisconsin, U.S.A.*
Yulin Deng / *Neuropsychiatry Research Unit, University of Saskatchewan, Saskatoon, Saskatchewan, Canada*
Yves Denizot / *Immunology Laboratory, University of Limoges, Limoges, France*
A.A. Deo / *Wockhardt Research Centre, Aurangabad, India*
M.T. Diez / *Analytical Chemistry, Department of Applied Chemistry and Physics, University of León, León, Spain*
N. Dimov / *Chemical Pharmaceutical Research Institute (NIHFI), Bulgarian Pharmaceutical Group Ltd., Sofia, Bulgaria*
Hui-Ru Dong / *College of Science, Beijing University of Chemical Technology, Beijing, China*
Vasile I. Dorneanu / *Analytical Chemistry Department, Grigore T. Popa University of Medicine and Pharmacy, Iasi, Romania*
Qizhen Du / *Institute of Food and Biological Engineering, Zhejiang Gongshang University, Hangzhou, China*
N.M. Edwards / *Grain Research Laboratory, Canadian Grain Commission, Winnipeg, Manitoba, Canada*
Jahangir Emrani / *Department of Civil and Environmental Engineering, North Carolina A & T State University, Greensboro, North Carolina, U.S.A.*
William P. Farrell / *Pfizer Global Research and Development, Pfizer Inc., La Jolla, California, U.S.A.*
Petr S. Fedotov / *Vernadsky Institute of Geochemistry and Analytical Chemistry, Russian Academy of Sciences, Moscow, Russia*
Y.-Q. Feng / *Department of Chemistry, Wuhan University, Wuhan, China*
I.M.P.L.V.O. Ferreira / *Service of Bromatologia, Pharmacy College, University of Porto, Porto, Portugal*
Sam J. Ferrito / *Analytical Services Department, Cooper Power Systems, Franksville, Wisconsin, U.S.A.*
John C. Ford / *Department of Chemistry, Indiana University of Pennsylvania, Indiana, Pennsylvania, U.S.A.*
Esther Forgács / *Institute of Chemistry, Chemical Research Center, Hungarian Academy of Sciences, Budapest, Hungary*
George M. Frame II / *Wadsworth Laboratory, New York State Department of Health, Albany, New York, U.S.A.*
Kenneth G. Furton / *Department of Chemistry, International Forensic Research Institute (IFRI), Miami, Florida, U.S.A.*
M.C. García-Alvarez-Coque / *Department of Analytical Chemistry, University of Valencia, Valencia, Spain*
J.C. Garcia-Glez / *Physical Chemistry Department, University of León, León, Spain*
Rosa Garcia-Lopera / *Institute of Materials Science, University of Valencia, Valencia, Spain*
Dimitrios Gavril / *Physical Chemistry Laboratory, Department of Chemistry, University of Patras, Patras, Greece*
Barbara Gawdzik / *Faculty of Chemistry, MCS University, Lublin, Poland*
Kalliopi A. Georga / *Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece*
Árpád Gerstner / *Novartis Agricultural Discovery Institute, Inc., San Diego, California, U.S.A.*
H.G. Gika / *Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece*

Michel Girard / *Bureau of Biologics and Radiopharmaceuticals, Health Canada, Ottawa, Ontario, Canada*
Ivan Gitsov / *College of Environmental Science and Forestry, State University of New York, Syracuse, New York, U.S.A.*
Kazimierz Glowniak / *Department of Pharmacognosy, Medical University of Lublin, Lublin, Poland*
Simion Gocan / *Department of Analytical Chemistry, Babes-Bolyai University, Cluj-Napoca, Romania*
Karen M. Gooding / *Eli Lilly and Company, Indianapolis, Indiana, U.S.A.*
Tomomi Goto / *Aichi Prefectural Institute of Public Health, Nagoya, Japan*
Mohan Gownder / *Huntsman Polymers Corp., Odessa, Texas, U.S.A.*
Henryk Grajek / *Institute of Chemistry, Military University of Technology, Warsaw, Poland*
Susan V. Greene / *Ethyl Petroleum Additives Corp., Richmond, Virginia, U.S.A.*
Nelu Grinberg / *Analytical Research Department, Merck Research Laboratories, Rahway, New Jersey, U.S.A.*
A. Gumieniczek / *Department of Medicinal Chemistry, Medical University of Lublin, Lublin, Poland*
András Guttman / *Diversa Company, San Diego, California, U.S.A.*
David S. Hage / *Department of Chemistry, University of Nebraska-Lincoln, Lincoln, Nebraska, U.S.A.*
J.E. Haky / *Department of Chemistry and Biochemistry, Florida Atlantic University, Boca Raton, Florida, U.S.A.*
Susana Maria Halpine / *STArt! teaching Science Through Art, Playa del Rey, California, U.S.A.*
Jamel S. Hamada / *Southern Regional Research Center, Agricultural Research Service, U.S. Department of Agriculture (USDA-ARS), New Orleans, Louisiana, U.S.A.*
Toshihiko Hanai / *Health Research Foundation, Pasteur Institut, Kyoto, Japan*
Martin Hassellöv / *Department of Chemistry, Analytical and Marine Chemistry, Göteborg University, Göteborg, Sweden*
Mohamed M. Hefnawy / *Department of Pharmaceutical Chemistry, King Saud University, Riyadh, Saudi Arabia*
Michael P. Henry / *Advanced Technology Center, Beckman Coulter, Inc., Fullerton, California, U.S.A.*
Tatsuya Higashi / *Division of Pharmaceutical Sciences, Graduate School of Natural Science and Technology, Kanazawa University, Kanazawa, Japan*
Chuichi Hirayama / *Department of Applied Chemistry and Biochemistry, Kumamoto University, Kumamoto, Japan*
H. Hopkała / *Department of Medicinal Chemistry, Medical University of Lublin, Lublin, Poland*
Y.-L. Hu / *Department of Chemistry, Wuhan University, Wuhan, China*
Chih-Ching Huang / *Department of Chemistry, National Taiwan University, Taipei, Taiwan*
W. Jeffrey Hurst / *Hershey Foods Technical Center, Hershey, Pennsylvania, U.S.A.*
Robert J. Hurtubise / *Department of Chemistry, University of Wyoming, Laramie, Wyoming, U.S.A.*
Christine Hürzeler / *Postnova Analytics, Munich, Germany*
Radovan Hynek / *Department of Biochemistry and Microbiology, Institute of Chemical Technology, Prague, Czech Republic*
Hirotaka Ihara / *Department of Applied Chemistry and Biochemistry, Kumamoto University, Kumamoto, Japan*

Gunawan Indrayanto / *Faculty of Pharmacy, Airlangga University, Surabaya, Indonesia*
Haleem J. Issaq / *National Cancer Institute at Frederick (NCI-Frederick), National Institutes of Health (NIH), Frederick, Maryland, U.S.A.*
Rie Ito / *Department of Analytical Chemistry, Faculty of Pharmaceutical Sciences, Hoshi University, Tokyo, Japan*
Yoichiro Ito / *National Heart, Lung, and Blood Institute (NHLBI), National Institutes of Health (NIH), Bethesda, Maryland, U.S.A.*
Yuko Ito / *Aichi Prefectural Institute of Public Health, Nagoya, Japan*
Yusuke Iwasaki / *Department of Analytical Chemistry, Faculty of Pharmaceutical Sciences, Hoshi University, Tokyo, Japan*
Eshwar Jagerdeo / *Federal Bureau of Investigation Laboratory, Quantico, Virginia, U.S.A.*
Josef Janca / *Department of Chemistry, University of La Rochelle, La Rochelle, France*
J. Jancar / *BIA Separations d.o.o., Ljubljana, Slovenia*
Pavel Jandera / *Department of Analytical Chemistry, University of Pardubice, Pardubice, Czech Republic*
A. Jardy / *Analytical Chemistry Department, City of Paris Industrial Physics and Chemistry Higher Educational Institution (ESPCI), Paris, France*
Dennis R. Jenke / *Technology Resources Division, Baxter Healthcare Corporation, Round Lake, Illinois, U.S.A.*
Alfonso Jiménez / *Department of Analytical Chemistry, Nutrition and Food Sciences, University of Alicante, Alicante, Spain*
Kiyokatsu Jinno / *Department of Materials Science, Toyohashi University, Toyohashi, Japan*
Harald John / *Bundeswehr Institute of Pharmacology and Toxicology, Munich, Germany*
Brian Jones / *Selerity Technologies, Inc., Salt Lake City, Utah, U.S.A.*
Krzysztof Kaczmarski / *Faculty of Chemistry, Technical University of Rzeszów, Rzeszów, Poland*
Adnan A. Kadi / *Department of Pharmaceutical Chemistry, King Saud University, Riyadh, Saudi Arabia*
Huba Kalász / *Department of Pharmacology and Pharmacotherapy, Semmelweis University of Medicine, Budapest, Hungary*
John Kapolos / *Department of Agricultural Products Technology, Technological Educational Institute of Kalamata, Kalamata, Greece*
George Karaiskakis / *Physical Chemistry Laboratory, Department of Chemistry, University of Patras, Patras, Greece*
Jan Kás / *Department of Biochemistry and Microbiology, Institute of Chemical Technology, Prague, Czech Republic*
Galina Kassalainen / *Department of Chemistry and Geochemistry, Colorado School of Mines, Golden, Colorado, U.S.A.*
Sindy Kayillo / *Center for Biostructural and Biomolecular Research, University of Western Sydney, Sydney, New South Wales, Australia*
Sarah Kazmi / *Department of Chemistry, Northeastern University, Boston, Massachusetts, U.S.A.*
Ernst Kenndler / *Institute for Analytical Chemistry, University of Vienna, Vienna, Austria*
Eileen Kennedy / *Novartis Crop Protection, Inc., Greensboro, North Carolina, U.S.A.*
Tabrez A. Khan / *Department of Chemistry, Jamia Millia Islamia (A Central University), New Delhi, India*
Yuriko Kiba / *Department of Medicinal Chemistry, University of Tokushima, Tokushima, Japan*
Peter Kilz / *Polymer Standards Service GmbH, Mainz, Germany*

Chong-Kook Kim / *Research Institute of Pharmaceutical Sciences, Seoul National University, Seoul, and Department of Pharmaceutical Engineering, Inje University, Gyeongnam, Korea*
Peter T. Kissinger / *Chairman and CEO, Bioanalytical Systems, Inc., West Lafayette, Indiana, U.S.A.*
Eiichi Kitazume / *Faculty of Humanities and Social Sciences, Iwate University, Iwate, Japan*
Thorsten Klein / *Postnova Analytics, Munich, Germany*
Oliver Klett / *Institute of Chemistry, Uppsala University, Uppsala, Sweden*
Athanasia Koliadima / *Physical Chemistry Laboratory, Department of Chemistry, University of Patras, Patras, Greece*
B.L. Kolte / *Department of Chemical Technology, Dr. Babasaheb Ambedkar Marathwada University, Aurangabad, India*
Fumio Kondo / *Aichi Prefectural Institute of Public Health, Nagoya, Japan*
Vadim L. Kononenko / *Institute of Biochemical Physics, Russian Academy of Sciences, Moscow, Russia*
Teresa Kowalska / *Institute of Chemistry, Silesian University, Katowice, Poland*
Anna Kozak / *Department of Biochemistry and Microbiology, Institute of Chemical Technology, Prague, Czech Republic*
Ira S. Krull / *Department of Chemistry, Northeastern University, Boston, Massachusetts, U.S.A.*
Ján Krupcik / *Institute of Analytical Chemistry, Slovak University of Technology, Bratislava, Slovakia*
Svetlana Kulevanova / *Institute of Pharmacognosy, Faculty of Pharmacy, Sts. Cyril and Methodius University, Skopje, Republic of Macedonia*
Silvia Lacorte / *Department of Environmental Chemistry, Chemical and Environmental Research Institute of Barcelona (IIQAB), Barcelona, Spain*
Vaishali Soneji Lafita / *Abbott Laboratories, Inc., Abbott Park, Illinois, U.S.A.*
Fernando M. Lanças / *Institute of Chemistry of São Carlos (USP), University of São Paulo, São Carlos, Brazil*
James P. Landers / *Department of Chemistry, University of Virginia, Charlottesville, Virginia, U.S.A.*
David Y.W. Lee / *McLean Hospital, Harvard Medical School, Belmont, Massachusetts, U.S.A.*
Seungho Lee / *Department of Chemistry, Hannam University, Taejon, Korea*
Jozef Lehotay / *Institute of Analytical Chemistry, Slovak University of Technology, Bratislava, Slovakia*
Luciano Lepri / *Department of Chemistry, University of Florence (UNIFI), Florence, Italy*
James Lesec / *National Center for Scientific Research (CNRS), City of Paris Industrial Physics and Chemistry Higher Educational Institution (ESPCI), Paris, France*
Vera Leshchinskaya / *Bristol-Myers Squibb Co., Princeton, New Jersey, U.S.A.*
Chenchen Li / *College of Chemistry and Molecular Engineering, Peking University, Beijing, China*
Wilna Liebenberg / *Research Institute for Industrial Pharmacy, North-West University, Potchefstroom, South Africa*
Xiuli Lin / *Department of Chemistry, Wake Forest University, Winston-Salem, North Carolina, U.S.A.*
Cheng-Ming Liu / *Department of Medical Technology, Institute of Biomedical Technology, Taipei Medical University, Taipei, Taiwan*
Huwei Liu / *Institute of Analytical Chemistry, Peking University, Beijing, China*
Rosario LoBrutto / *Merck Research Laboratories, Rahway, New Jersey, U.S.A.*

E.S.M. Lutz / *Bioanalytical Chemistry Department, AstraZeneca R&D Mölndal, Mölndal, Sweden*
Ying Ma / *National Heart, Lung, and Blood Institute (NHLBI), National Institutes of Health (NIH), Bethesda, Maryland, U.S.A.*
Mohamed E. Mahmoud / *Medical Chemistry Department, King Abdullaziz University, Jeddah, Saudi Arabia*
Edward Malawer / *International Specialty Products, Wayne, New Jersey, U.S.A.*
Abul K. Mallik / *Department of Applied Chemistry and Biochemistry, Kumamoto University, Kumamoto, Japan*
P. Manesiotis / *Department of Materials Science, University of Patras, Patras, Greece*
M.L. Marín / *Department of Analytical Chemistry, University of Alicante, Alicante, Spain*
Wojciech Markowski / *Department of Inorganic and Analytical Chemistry, Medical University of Lublin, Lublin, Poland*
J. Martin-Villacorta / *Physical Chemistry Department, University of León, León, Spain*
C. Marutoiu / *Department of Chemistry, Lucian Blaga University of Sibiu, Sibiu, Romania*
T. Maryutina / *Vernadsky Institute of Geochemistry and Analytical Chemistry, Russian Academy of Sciences, Moscow, Russia*
Kazuhiro Matsuda / *Pharmacology Division, National Cancer Center Research Institute, Tokyo, Japan*
Sachie Matsuda / *Department of Dermatology, Horikiri Central Hospital, Tokyo, Japan*
Kiichi Matsuhisa / *Asahikawa National College of Technology, Asahikawa, Japan*
Maria T. Matyska / *Department of Chemistry, San Jose State University, San Jose, California, U.S.A.*
Andrei Medvedovici / *Department of Analytical Chemistry, University of Bucharest, Bucharest, Romania*
Gregorio R. Meira / *National Scientific and Technical Research Council (CONICET), Santa Fe, Argentina*
R. Mendez / *Physical Chemistry Department, University of León, León, Spain*
Raniero Mendichi / *Institute of Macromolecular Chemistry, National Research Council (CNR), Milan, Italy*
Jean-Michel Menet / *Aventis Pharma, Vitry-sur-Seine, France*
Damián Mericko / *Institute of Analytical Chemistry, Slovak University of Technology, Bratislava, Slovakia*
Rajmund Michalski / *Institute of Environmental Engineering, Polish Academy of Science, Zabrze, Poland*
Ivan Miksík / *Institute of Physiology, Academy of Sciences of the Czech Republic, Prague, Czech Republic*
Toshiaki Miura / *College of Medical Technology, Hokkaido University, Sapporo, Japan*
Emi Miyamoto / *Department of Health Science, Kochi Women's University, Kochi, Japan*
N. Montes / *Physical Chemistry Department, University of León, León, Spain*
Myeong Hee Moon / *Department of Chemistry, Kangnung National University, Kangnung, South Korea*
J.J.S. Moreira / *Chromatography Laboratory, University of São Paulo, São Carlos, Brazil*
Sadao Mori / *PAC Research Institute, Mie University, Nagoya, Japan*
Mark Moskovitz / *Dynamic Adsorbents, Inc., Atlanta, Georgia, U.S.A.*
Tomasz Mroczek / *Department of Pharmacognosy, Medical University of Lublin, Lublin, Poland*
Muhammad Mulja / *Faculty of Pharmacy, Airlangga University, Surabaya, Indonesia*

D. Muller / *Galilee Institute, University of North Paris, Villetaneuse, France*
Subra Muralidharan / *Chemistry Department, Western Michigan University, Kalamazoo, Michigan, U.S.A.*
Roy A. Musil / *Althea Technologies, Inc., San Diego, California, U.S.A.*
Ron Myers / *Wyatt Technology Corp., Santa Barbara, California, U.S.A.*
Noh-Hong Myoung / *Seoul Metropolitan Government, Institute of Health and Environment, Seoul, South Korea*
Monica J.S. Nadler / *Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, Massachusetts, U.S.A.*
Tim Nadler / *Applied Biosystems, Inc., Framingham, Massachusetts, U.S.A.*
Shoji Nagaoka / *Kumamoto Industrial Research Institute, Kumamoto, Japan*
Hiroyuki Nakazawa / *Department of Analytical Chemistry, Faculty of Pharmaceutical Sciences, Hoshi University, Tokyo, Japan*
A. Negro / *Analytical Chemistry Section, Faculty of Biological and Environmental Sciences, University of León, León, Spain*
Tuan Q. Nguyen / *Department of Materials Science, Polymer Laboratory, Swiss Federal Institute of Technology, Lanne, Switzerland*
Boryana Nikolova-Damyanova / *Institute of Organic Chemistry, Bulgarian Academy of Sciences, Sofia, Bulgaria*
Tadashi Nishio / *Division of Pharmaceutical Sciences, Graduate School of Natural Science and Technology, Kanazawa University, Kanazawa, Japan*
Hisao Oka / *Food-Related Chemistry, Laboratory of Chemistry, Aichi Prefectural Institute of Public Health, Nagoya, Japan*
Beatriz Oliveira / *Requimte, Bromatology Service, Faculty of Pharmacy, University of Porto, Porto, Portugal*
Jerzy Oszczudlowski / *Institute of Chemistry, Jan Kochanowski University, Kielce, Poland*
Koji Otsuka / *Department of Material Science, Himeji Institute of Technology, Hyogo, Japan*
Anders Palm / *Cell and Molecular Biology, Astra Zeneca, Lund, Sweden*
Irene Panderi / *School of Pharmacy, Division of Pharmaceutical Chemistry, University of Athens, Athens, Greece*
Ioannis N. Papadoyannis / *Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece*
Elias Papapanagiotou / *Laboratories of Food Hygiene, Faculty of Veterinary Medicine, Aristotle University of Thessaloniki, Thessaloniki, Greece*
D.M. Pereira / *Requimte, Department of Pharmacognosy, Faculty of Pharmacy, University of Porto, Porto, Portugal*
Joseph J. Pesek / *Department of Chemistry, San Jose State University, San Jose, California, U.S.A.*

Foreword

The collection of techniques known as chromatography may be the world's most prevalent and useful analytical methodology. In the pharmaceutical industry alone, HPLC is the second most prevalent instrument, after the pH meter. Thus, it is not surprising that the *Encyclopedia of Chromatography* is one of the most authoritative and best-selling scientific encyclopedias that have been published. This *Third Edition* is a three-volume set containing over 500 entries. The entries vary from the short and concise definition of terms to more extensive tomes on specific methods, background, optimization, practice, and theory. The majority of the entries have been updated and there are over 100 new entries. Many of these were edited and reviewed after being published online. Hence, the *Third Edition* contains the very latest information on this most important analytical technique, in addition to all relevant background material.

Given the size and extent of coverage of the *Encyclopedia of Chromatography*, *Third Edition*, a considerable effort was made by the Editor, Dr. Jack Cazes, to make sure the information is crisp, clear, and easy to access. Indeed, in response to reader feedback, there are two tables of contents: one in alphabetical order and the other by category of chromatography. This encyclopedia contains essential information for both the novice and the experienced scientist. If you don't have access to an entire university library and considerable excess time, then the *Encyclopedia of Chromatography*, *Third Edition*, is essential.

Prof. Daniel W. Armstrong, Ph.D.
University of Texas at Arlington, Arlington, Texas, U.S.A.

February 6, 2009

Foreword

Years ago, it was said that the difference between scientific research done in academia and that done in industry or government was that those involved in the former had lots of time but little money, while those involved in the latter had little time but lots of money. As the economic and technological realities of the twenty-first century unfold, it has become clear that such differences are no longer operative. In whatever setting it is performed, the goal of scientific research must be to give accurate information in the shortest possible time at the least possible expense. Recent advances in chromatography research have been consistent with this goal.

Since the publication of the first full edition of the *Encyclopedia of Chromatography* eight years ago, a myriad of existing methods have been improved and numerous new methods have been developed that achieve the goal of reducing both time and costs. Additionally, limits of detection have been reduced to previously unimaginable levels and new applications of chromatographic techniques have emerged in areas as diverse as chemical biology, materials science, and nanotechnology. As the first decade of this century comes to an end, it is therefore fitting that this new revised and updated edition be published.

While retaining the basic information on the theory and practice of all the realms of chromatographic science in the first edition, this new version includes updated material on all the advances that have occurred in the past several years. Therefore, it is a useful resource both for novices who are interested in learning basic chromatographic techniques and for experienced experts who are exploring new methods and applications. Most of all, this encyclopedia will stimulate the imagination and creativity of all who read it, thereby assisting in the progression of new advances that will surely come in the next decade and beyond.

Prof. Jerome E. Haky, Ph.D.
Florida Atlantic University, Boca Raton, Florida, U.S.A.

February 9, 2009

Preface for the Third Edition

The thoroughly revised and expanded third edition of the *Encyclopedia of Chromatography* is an authoritative source of information for practitioners and researchers in chemistry, biology, physics, engineering, and materials science. It is a quick reference source and a clear guide to specific chromatographic techniques and theory, providing a basic introduction to the science and technology of the method, as well as leading key references dealing with the theory and methodology for analysis of specific chemicals and applications in industry.

The third edition provides an abundance of updated topics, applications, and references from the literature, many discussions on emerging technologies and applications in chromatography, including numerous tables and figures to illustrate and clarify technical points presented in the entries—showcasing modern applications and instrumentation in use today—and detailed discussions on the methodology, with authoritative coverage of the instrumentation and theoretical aspects of chromatography.

The third edition will doubtless continue to serve as a valuable, reader-friendly reference for all practitioners of analytical chemistry and materials science, as well as for those who employ chromatographic methods for analysis of complex mixtures of substances.

Acronyms

AAS	Atomic Absorption Spectrometry
ACE	Affinity Capillary Electrophoresis
ADC (A/D)	Analog to Digital Converter
AES	Atomic Emission Spectroscopy
AMD	Automated Multiple Development
ANOVA	Analysis of Variance (a statistical term)
APCI	Atmospheric Pressure Chemical Ionization
APPI	Atmospheric Pressure Photo-Ionization
BGE	Background Electrolyte
BHT	Butylated Hydroxytoluene
CAE	Capillary Array Electrophoresis
CCC	Countercurrent Chromatography
CCD	Charge Coupled Device
CD	Compact Disk
CD	Cyclodextrin
CE	Capillary Electrophoresis
CEC	Capillary Electrochromatography
CF-FAB	Continuous-Flow Fast Atom Bombardment
CGE	Capillary Gel Electrophoresis
CIEF	Capillary Isoelectric Focusing
CITP	Capillary Isotachophoresis
CPC	Coil Planet Centrifuge or Centrifugal Partition Chromatography
CPU	Central Processing Unit
CSF	Cerebrospinal Fluid
CSP	Chiral Stationary Phase
CTAB	Hexadecyltrimethylammonium Bromide
CV	Coefficient of Variation
CZE	Capillary Zone Electrophoresis
DAD	Diode-Array Detection
DELFIA	Dissociation-Enhanced Lanthanide Fluoroimmunoassay
DHPLC	Denaturing High-Performance Liquid Chromatography
DNA	Desoxyribonucleic Acid
DOC	Dissolved Organic Carbon
DVD	Digital Video Disk
ECD	Electrochemical Detector or Electron Capture Detector
EDXRF	Energy-Dispersive X-ray Fluorescence
EI-MS	Electron Impact Mass Spectrometry
ELISA	Enzyme-Linked Immunosorbent Assay
ELSD	Evaporative Light Scattering Detector
EMIT	Enzyme Multiplied Immunoassay Technique
EOF	Electro-osmotic Flow
EPS	Extra-cellular Polymeric Secretions
ESI	Electrospray Ionization
FAAS	Flame Atomic Absorption Spectrometry
FFF	Field-Flow Fractionation
FID	Flame Ionization Detection (Detector)
FlFFF	Flow Field-Flow Fractionation
FPLC	Fast Protein Liquid Chromatography
FTIR	Fourier Transform Infrared
GC	Gas Chromatography
GFC	Gel Filtration Chromatography
GI	Gastrointestinal
GLC	Gas Liquid Chromatography
HIC	Hydrophobic Interaction Chromatography
HIV	Human Immunodeficiency Virus
HPLC	High-Performance Liquid Chromatography
HPSEC	High-Performance Size-Exclusion Chromatography
HPTLC	High-Performance Thin-Layer Chromatography
HSCCC	High-Speed Countercurrent Chromatography
HTAB	Hexadecyltrimethylammonium Bromide
ICP	Inductively Coupled Plasma
ICP-MS	Inductively Coupled Plasma-Mass Spectrometry
IEC	Ion-Exchange Chromatography
IEF	Isoelectric Focusing
γ-IFN	Gamma Interferon
IgG	Immunoglobulin G
IMAC	Immobilized Metal Affinity Chromatography; Immobilized Ion Metal Affinity Chromatography
I/O	Input/Output
IR	Infrared
IRMA	Immuno-Radiometric Assay
LC	Liquid Chromatography
LC-FTIR	Liquid Chromatography-Fourier Transform Infrared
LCD	Liquid Crystal Display
LIF	Laser-Induced Fluorescence
LIMS	Laboratory Information Management System
LLE	Liquid–Liquid Extraction
LOD	Limit of Detection
LOQ	Limit of Quantitation
LSER	Linear Solvation Energy Relationship
MALDI	Matrix-Assisted Laser Desorption Ionization
MALLS	Multiangle Laser Light Scattering
MDLC	Multidimensional Liquid Chromatography

MEEKC	Microemulsion Electrokinetic Chromatography
MEKC	Micellar Electrokinetic Chromatography
MEPS	Microextraction in a Packed Syringe
MFFF	Magnetic Field-Flow Fractionation
MIBK	Methyl Isobutyl Ketone
MIP	Molecularly Imprinted Polymer
MIP-OES	Microwave Induced Plasma Optical Emission Spectroscopy
MISP	Molecularly Imprinted Stationary Phase
pMMA	Poly-methylmethacrylate
MS	Mass Spectrometry
MSPD	Matrix Solid-Phase Dispersion
MTase	Methyl Transferase
MW	Molecular Weight
NACE	Non-Aqueous Capillary Electrophoresis
NARP	Non-Aqueous Reverse Phase
NIC	Network Interface Card
NIR	Near Infrared
NMR	Nuclear Magnetic Resonance
NSAID	Non-Steroidal Anti-Inflammatory Drug
OD	Optical Density
OPTLC	Over-Pressured Thin-Layer Chromatography
PAD	Pulsed Amperometric Detection
PAH	Polynuclear Aromatic Hydrocarbon
PAS	Photoacoustic Spectroscopy
PCB	Polychlorinated Biphenyl
PCR	Polymerase Chain Reaction
PDA	Photodiode Array
PITC (PTC)	Phenyl Isothiocyanate
PIXE	Proton-Induced X-ray Emission
RNA	Ribonucleic Acid
RP-HPLC	Reverse-Phase HPLC
RRHT	Rapid Resolution High Throughput
RRLC	Rapid Resolution Liquid Chromatography
RSD	Relative Standard Deviation
SATP	Salicylideneamino-2-thiophenol
SCSI	Small Computer System Interface
SD	Standard Deviation
SdFFF	Sedimentation Field-Flow Fractionation
SEC	Size-Exclusion Chromatography
SELDI	Surface-Enhanced Laser Desorption Ionization
SEM	Scanning Electron Microscopy
SFC	Supercritical Fluid Chromatography
SFE	Supercritical Fluid Extraction
SIMS	Secondary Ion Mass Spectrometry
SPE	Solid-Phase Extraction
SPME	Solid-Phase Microextraction
TB	Tuberculosis
TFA	Trifluoroacetic Acid
THF	Tetrahydrofuran
TLC	Thin-Layer Chromatography
TOC	Total Organic Carbon
TOF-MS	Time-of-Flight-Mass Spectrometry
TSP	Thermospray
UV	Ultraviolet
VIS, Vis	Visible
XPS	X-ray Photoelectron Spectroscopy

About the Editor

Jack Cazes is a world-renowned expert and consultant in chromatography and analytical instrumentation and is a Visiting Scholar at Florida Atlantic University, Boca Raton, Florida. The author, co-author, and editor of numerous books and research papers in these disciplines, he is Editor of the *Journal of Liquid Chromatography & Related Technologies, Instrumentation Science & Technology, Preparative Biochemistry & Biotechnology, and Journal of Immunoassay and Immunochemistry*, and the Editor of the *Chromatographic Science Series* books *and* the *Encyclopedia of Chromatography*.

Dr. Cazes has been at the forefront of liquid chromatography for over 45 years, during which time he pioneered the development of liquid chromatography. Dr. Cazes was previously Professor-in-Charge of the ACS Short Course and the ACS Audio Course on Gel Permeation Chromatography, and has taught organic chemistry at Rutgers University and Queens College (CUNY) and a special topics graduate-level course at Florida Atlantic University.

He was CEO of Sanki Laboratories, a company that developed and manufactured instruments for Centrifugal Partition Chromatography.

Dr. Cazes is a member Emeritus of the American Chemical Society and is featured in *Who's Who and American Men of Science*.

Absorbance Detection in CE

Robert Weinberger
CE Technologies, Inc., Chappaqua, New York, U.S.A.

INTRODUCTION

Most forms of detection in high-performance capillary electrophoresis (HPCE) employ on-capillary detection. Exceptions are techniques that use a sheath flow such as laser-induced fluorescence[1] and electrospray ionization mass spectrometry.[2]

In high-performance liquid chromatography (HPLC), postcolumn detection is generally used. This means that all solutes are traveling at the same velocity when they pass through the detector flow cell. In HPCE with on-capillary detection, the velocity of the solute determines the residence time in the flow cell. This means that slowly migrating solutes spend more time in the optical path and thus accumulate more area counts.[3]

Because peak areas are used for quantitative determinations, the areas must be normalized when quantitating without standards. Quantitation without standards is often used when determining impurity profiles in pharmaceuticals, chiral impurities, and certain DNA applications. The correction is made by normalizing (dividing) the raw peak area by the migration time. When a matching standard is used, it is unnecessary to perform this correction. If the migration times are not reproducible, the correction may help, but it is better to correct the situation causing this problem.

LIMITS OF DETECTION

The limit of detection (LOD) of a system can be defined in two ways: the concentration limit of detection (CLOD) and the mass limit of detection (MLOD). The CLOD of a typical peptide is about 1 μg/ml using absorbance detection at 200 nm. If 10 nl are injected, this translates to an MLOD of 10 pg at three times the baseline noise. The MLOD illustrates the measuring capability of the instrument. The more important parameter is the CLOD, which relates to the sample itself. The CLOD for HPCE is relatively poor, whereas the MLOD is quite good, especially when compared to HPLC. In HPLC, the injection size can be 1000 times greater compared to HPCE.

The CLOD can be calculated using Beer's Law:

$$\text{CLOD} = \frac{A}{ab} = \frac{5 \times 10^{-5}}{(5000)(5 \times 10)^{-3}} = 2 \times 10^{-6}\,M \quad (1)$$

where A is the absorbance (AU), a is the molar absorptivity (AU/cm/M), b is the capillary diameter or optical path length (cm), and CLOD is the concentration (M). The noise of a good detector is typically 5×10^{-5} AU. A modest chromophore has a molar absorptivity of 5000. Then in a 50 μm inner diameter (I.D.) capillary, a CLOD of 2×10^{-6} M is obtained at a signal-to-noise (S/N) ratio of 1, assuming no other sources of band broadening.

DETECTOR LINEAR DYNAMIC RANGE

The noise level of the best detectors is about 5×10^{-5} AU. Using a 50 μm I.D. capillary, the maximum signal that can be obtained while yielding reasonable peak shape is 5×10^{-1} AU. This provides a linear dynamic range of about 10^4. This can be improved somewhat through the use of an extended path-length flow cell. In any event, if the background absorbance of the electrolyte is high, the noise of the system will increase regardless of the flow cell utilized.

CLASSES OF ABSORBANCE DETECTORS

Ultraviolet/visible absorption detection is the most common technique found in HPCE. Several types of absorption detectors are available on commercial instrumentation, including the following:

1. Fixed-wavelength detector using mercury, zinc, or cadmium lamps with wavelength selection by filters.
2. Variable-wavelength detector using a deuterium or tungsten lamp with wavelength selection by a monochromator.
3. Filter photometer using a deuterium lamp with wavelength selection by filters.
4. Scanning ultraviolet (UV) detector.
5. Photodiode array detector.

Each of these absorption detectors have certain attributes that are useful in HPCE. Multiwavelength detectors such as the photodiode array or scanning UV detector are valuable because spectral as well as electrophoretic information can be displayed. The filter photometer is invaluable for low-UV detection. The use of the 185 nm mercury line becomes practical in HPCE with phosphate buffers

because the short optical path length minimizes the background absorption.

Photoacoustic, thermo-optical, or photothermal detectors have been reported in the literature.[4] These detectors measure the non-radiative return of the excited molecule to the ground state. Although these can be quite sensitive, it is unlikely that they will be used in commercial instrumentation.

OPTIMIZATION OF DETECTOR WAVELENGTH

Because of the short optical path length defined by the capillary, the optimal detection wavelength is frequently much lower into the UV compared to HPLC. In HPCE with a variable-wavelength absorption detector, the optimal S/N ratio for peptides is found at 200 nm. To optimize the detector wavelength, it is best to plot the S/N ratio at various wavelengths. The optimal S/N is then easily selected.

EXTENDED PATH-LENGTH CAPILLARIES

Increasing the optical path length of the capillary window should increase S/N simply as a result of Beer's Law. This has been achieved using a z cell (LC Packings, San Francisco California, U.S.A.),[5] bubble cell (Agilent Technologies, Wilmington, Delaware, U.S.A.), or a high-sensitivity cell (Agilent Technologies). Both the z cell and bubble cell are integral to the capillary. The high-sensitivity cell comes in three parts: an inlet capillary, an outlet capillary, and the cell body. Careful assembly permits the use of this cell without current leakage. The bubble cell provides approximately a threefold improvement in sensitivity using a 50 μm capillary, whereas the z cell or high-sensitivity cell improves things by an order of magnitude. This holds true only when the background electrolyte (BGE) has low absorbance at the monitoring wavelength.

INDIRECT ABSORBANCE DETECTION

To determine ions that do not absorb in the UV, indirect detection is often utilized.[6] In this technique, a UV-absorbing reagent of the same charge (a co-ion) as the solutes is added to the BGE. The reagent elevates the baseline, and when non-absorbing solute ions are present, they displace the additive. As the separated ions migrate past the detector window, they are measured as negative peaks relative to the high baseline. For anions, additives such as trimellitic acid, phthalic acid, or chromate ions are used at 2–10 m*M* concentrations. For cations, creatinine, imidazole, or copper(II) are often used. Other buffer materials are either not used or added in only small amounts to avoid interfering with the detection process.

It is best to match the mobility of the reagent to the average mobilities of the solutes to minimize electrodispersion, which causes band broadening.[7] When anions are determined, a cationic surfactant is added to the BGE to slow or even reverse the electro-osmotic flow (EOF). When the EOF is reversed, both electrophoresis and electro-osmosis move in the same direction. Anion separations are performed using reversed polarity.

Indirect detection is used to determine simple ions such as chloride, sulfate, sodium, and potassium. The technique is also applicable to aliphatic amines, aliphatic carboxylic acids, and simple sugars.[8]

Acids: Derivatization for GC Analysis

Igor G. Zenkevich
Chemical Research Institute, St. Petersburg State University, St. Petersburg, Russia

Abstract
The class *acids* includes various types of chemical compounds with active hydrogen atoms usually having $pK_a < 7$. The most important group of organic acids is the compounds with carboxyl fragment –COOH. The simplest monofunctional carboxylic acids retain their boiling points at standard atmospheric pressure without undergoing decomposition and, hence, can be analyzed directly by gas chromatography (GC). However, owing to the high polarities of carboxyl compounds, these compounds yield broad non-symmetrical chromatographic peaks on non-polar phases, which leads to poor detection limits and unsatisfactory reproducibility of their retention indices. The application of polar polyethylene glycols for analysis of free carboxylic acid is restricted by less thermal stability of such phases. The general approach in the (GC) analysis of acids is their derivatization, preferably esterification with the formation of alkyl or silyl esters. Many types of polyfunctional carboxylic acids (hydroxy-, mercapto-, amino-, etc.) cannot be analyzed in free, underivatized form owing to non-volatility and/or absence of thermal stability. These features are the principal reasons for the conversion of carboxylic acids into less polar derivatives without active hydrogen atoms in their molecules before their GC analysis.

INTRODUCTION

The class *acids* includes various types of chemical compounds with active hydrogen atoms usually having $pK_a < 7$. The most important group of organic acids is the compounds with carbonyl fragment $-CO_2H$. Some other compounds can be classified not only as O acids (e.g., hydroxamic acids, $-CONHOH \rightleftharpoons -C(OH)=NOH$), but also as C–H acids [with the presence of structural fragments $-CH(NO_2)_2$, $-CH(CN)_2$, $-CHF_2$, etc.]. Well-known compounds belonging to this class that can be subjected to GC analysis are semivolatile fatty acids of triglycerides and lipids,[1] numerous non-volatile polyfunctional biogenic compounds (including phenol carboxylic acids like gallic, vanillic, syringic), plant hormones (gibberellins), different acidic herbicides (e.g., 2,4-D, 2,4,5-T, MCPB, MCPA, fenoprop, haloxyfop), and many other substances. Strong inorganic acids like volatile hydrogen halides (HHal) and non-volatile H_2SO_4, H_3PO_4 can be objects of GC analysis too.

The simplest monofunctional carboxylic acids retain their boiling points at standard atmospheric pressure without undergoing decomposition and, hence, can be analyzed directly by GC. However, owing to the relatively high polarities of carbonyl compounds, a typical problem of their GC analysis with standard non-polar phases is the non-linear sorption isotherm. As a result, these compounds yield broad non-symmetrical peaks, which lead to poor detection limits and unsatisfactory reproducibility of their retention indices. The recommended stationary phases for direct analysis of free carboxylic acids are polar polyethylene glycols (Carbowax 20M, DBWax, SP-1000, FFAP, etc.). However, these phases have lower thermal stability as compared with polydimethyl siloxanes (~225–250°C vs. 300–350°C). This implies that the upper limit of the retention index (RI) is not more than 2500–3000 i.u. for these polar phases. High homologues of monocarboxylic acids cannot be eluted within this RI window (this is confirmed by the absence of RI data for palmitic acid, $C_{15}H_{31}CO_2H$, on the mentioned type of polar phases). Owing to this, thermally stable polar cyanoalkyl polysiloxanes (OV-225, OV-275, etc.) are preferable for direct analysis of carboxylic acids.

Large standard deviations of RIs of arenecarboxylic acids (benzoic, phenylacetic, etc.) on standard non-polar phases are explained by the high asymmetry of their chromatographic peaks. This effect cannot be eliminated by the use of inert chromatographic systems, special techniques of injection, or the application of modern WCOT columns. It depends on the typical non-linear sorption isotherm *polar sorbate–non-polar phase* and, hence, the conversion of these polar analytes into less polar derivatives is strongly recommended.

Some aliphatic dicarboxylic acids can also be distilled without decomposition under reduced pressures. Their direct GC analysis is at least theoretically possible. However, there have been very few successful attempts as these analytes require *on-column* injection of samples and chromatographic systems that are extremely inert. Most polyfunctional carboxylic acids (hydroxy, mercapto, amino, etc.) cannot be analyzed in free, underivatized form because they are non-volatile and/or lack thermal stability. That is why these carboxylic acids are converted into less polar derivatives without active hydrogen atoms before their GC analysis is undertaken.

The pH of samples containing acids should not be more than their pK_a values, i.e., not less than 4–4.5 for organic

Table 1 The comparison of key physicochemical and chromatographic properties of some aliphatic and aromatic carboxylic acids.

Acid	pK_a	T_b, °C	$RI_{non\text{-}polar}$	RI_{polar}
Acetic	4.75	118	638 ± 10	1428 ± 30
Palmitic	4.9	351.5	1966 ± 7	No data
Benzoic	4.2	250	1201 ± 24	2387 ± 15
Phenylacetic	4.2	266	1290 ± 44	No data

carboxylic acids, as non-volatile salts might be formed with organic or inorganic bases. Any attempts to analyze these salts by increasing the temperature of the injector and GC column usually lead to their thermal decomposition and should be avoided.

METHODS OF ACID DERIVATIZATION

The common method for derivatizing is by carboxylic acids their esterification with the formation of alkyl (arylalkyl, halogenated alkyl) or silyl esters:[2–5]

$$XCO_2H + RY \rightarrow XCO_2R + YH$$
$$XCO_2H + ZSi(CH_3)_3 \rightarrow XCO_2Si(CH_3)_3 + ZH$$

Some of the most widely used reagents for the esterification of acids are listed in Table 2. The general method for the silylation of mono- and polyfunctional carboxylic acids by forming for trimethylsilyl (TMS)[6,7] or the more stable *tert*-butyldimethylsilyl (TBDMS)[8,9] derivatives is similar to that for the silylation of other hydroxy-containing compounds (see *Hydroxy Compounds: Derivatization for GC Analysis*, p. 1165).

Table 2 Physicochemical and gas chromatographic properties of some alkylating derivatization reagents for carboxylic acids.

Reagent	Abbreviation	MW	T_b, °C	$RI_{non\text{-}polar}$	By-products ($RI_{non\text{-}polar}$)
Methanol/BCl_3, BF_3, HCl, DCC, etc.	—	32	64.6	381 ± 15	H_2O
Diazomethane (in diethyl ether solution)	—	42	–23	None (unstable)	N_2
Methyl iodide/DMFA, K_2CO_3	—	142	42.8	515 ± 7	CH_3OH (381 ± 15)
Dimethyl sulfate/base	—	126	188.5	853 ± 22	CH_3OH (381 ± 15)
1-Iodopropane/DMFA, K_2CO_3	—	170	102	711 ± 11	C_3H_7OH (552 ± 13), $(C_3H_7)_2O$ (680 ± 6)
2-Bromopropane	—	122	59.4	571 ± 5	*iso*-C_3H_7OH (486 ± 9), (*iso*-$C_3H_7)_2O$ (598 ± 5)
Ethyl orthoformate	—	148	145	870 ± 9	C_2H_5OH (452 ± 18)
Diethyl carbonate	—	118	126	761 ± 4	CO_2, C_2H_5OH (452 ± 18)
Methyl chloroformate	—	94	71	582 ± 17	CH_3OH (381 ± 15)
Ethyl chloroformate	—	108	—	640 ± 12	C_2H_5OH (452 ± 18)
Butyl chloroformate	—	136	—	832 ± 10	C_4H_9OH (658 ± 12)
Pentafluorobenzyl bromide	PFB-Br	260	174–175	991 ± 11[a]	$C_6F_5CH_2OH$ (934 ± 16)[a]
3,5-*bis*-Trifluoromethylbenzyl bromide	BTB-Br	306	—	1103 ± 9[a]	$(CF_3)_2C_6H_3CH_2OH$ (1046 ± 15)[a]
Tetramethylammonium hydroxide (25% aqueous solution)	TMAH	74	—	Non-volatile	$(CH_3)_3N$ (418 ± 9)
Trimethylanilinium hydroxide (0.2 *M* methanol solution)	TMPAH	136	—	Non-volatile	$C_6H_5N(CH_3)_2$ (1065 ± 9)
3,5-*bis*-Trifluoromethylbenzyl dimethylanilinium fluoride	BTBDMA-F	258	—	Non-volatile	$(CF_3)_2C_6H_3CH_2N(CH_3)_2$, $C_6H_5N(CH_3)_2$ (1065 ± 9)
2-Bromoacetophenone (phenacyl bromide)	—	198	260	1321 ± 4	$C6H_5COCH_2OH$ (1118)[a]
Dimethylformamide dimethylacetal	DMF-DMA	119	107–108	726 ± 4	$(CH_3)_2NCHO$ (749 ± 16), CH_3OH (381 ± 15)
Dimethylformamide diethylacetal	DMF-DEA	147	134–136	826[a]	$(CH_3)_2NCHO$ (749 ± 16), C_2H_5OH (452 ± 18)

[a]Estimated RI values.

In general, the simplest methyl esters of carboxylic acids are more stable to hydrolysis than are TMS-esters and, hence, they are the preferable derivatives for GC analysis.[10,11] The commonly available esterification reagents are the corresponding alcohols, ROH, themselves. Different esters have been used as the analytical derivatives of carboxylic acids: Me, Et, Pr, *iso*-Pr, isomeric Bu (excluding *tert*-Bu esters owing to their poorer synthetic yields), and so forth. This method requires an excess of dry alcohol and acid catalysis by BCl_3, BF_3, CH_3COCl, $SOCl_2$, etc. Otherwise, the alcohol used might become saturated with gaseous HCl, which must then be removed by heating the reaction mixtures after completion of the reaction. However, instead of easily volatile acid catalysts, completely non-volatile acids like H_2SO_4 can be used in this reaction.[12]

The treatment of polyfunctional acids by alcohols in the presence of strong inorganic acids as catalysts can simultaneously be accompanied by the derivatization of other functional groups. For example, carbonyl groups in ketocarboxylic acids are converted into dialkylketal fragments in the presence of in ketocarboxylic acids.[13,14]

Also, 2-chloroethyl ($RCO_2CH_2CH_2Cl$), 2,2,2-trifluoroethyl ($RCO_2CH_2CF_3$), 2,2,2-trichloroethyl ($RCO_2CH_2CCl_3$), and hexafluoroisopropyl esters [$RCO_2CH(CF_3)_2$] can be synthesized for GC analysis with selective detection in a similar manner. Instead of acids, some other reagents, namely, 1,1′-carbonyldiimidazole (I) and 1,3-dicyclohexylcarbodiimide (DCC, II), are recommended, as catalysts for this reaction.

The application of any additive reagents usually leads to the appearance of additional peaks on the chromatograms [including the peaks of by-products, e.g., imidazole from (I), $RI_{non\text{-}polar}$ 1072 ± 17], which must be reliably identified and excluded from data interpretation. The by-product from compound (II)—1,3-dicyclohexylurea—is non-volatile for GC analysis.

Another class of esterification reagents are halogenated compounds (alkyl iodides, substituted benzyl,[15] and phenacyl bromides), which need basic media for their reaction [K_2CO_3 or DMFA (dimethyl formamide) is normally used for the neutralization of HHal as acid by-product]. For methylation of carboxylic acids, some tetra-substituted ammonium hydroxides or halides can be used, e.g., tetramethylammonium hydroxide (in aqueous solutions) or trimethylanilinium hydroxide (in methanol solution). The intermediate ammonium carboxylates are thermally unstable and produce methyl alkanoates when the reaction mixtures are heated or when the carboxylates are introduced into the hot injector of the gas chromatograph (flash or on-column methylation):

$$RCO_2H + XNMe_3^+OH^{\&} \rightarrow [RCO_2^{\&}XNMe_3^+] \rightarrow RCO_2Me + XNMe_2 (X = Me, Ph, PhCH_2)$$

The possible by-products of these reactions are the corresponding amines (Me_3N, $PhNMe_2$). A similar method has been proposed for the butylation of organic acids.[16] Besides tetra-substituted ammonium hydroxides, more *exotic* reagents, e.g., trimethylsulfonium hydroxide, $(CH_3)_3S^+ OH^-$, in methanol solution, were recommended as the donors of methyl groups.[17]

If the appearance of any volatile by-products is undesirable, carboxylic acids can be methylated by diazomethane (CH_2N_2) (the single gaseous by-product is N_2). This reagent (*warning*: highly volatile and toxic) should by synthesized by the alkaline cleavage of *N*-methyl-*N*-nitrosourea, *N*-methyl-*N*-nitrosotoluenesulfamide, or (latest recommendations) *N*-methyl-*N*′-nitro-*N*-nitrosoguanidine (MNNG); however, owing to its low boiling point (–23C) it can be used only in diethyl ether solutions prepared immediately before use.

In the absence of acid catalysis, diazomethane reacts only with carboxylic acids (pK_a 4–5) and phenols (pK_a 9–10), but has no influence on aliphatic OH groups. Besides CH_2N_2, some more complex diazocompounds (diazoethane, diazotoluene) have been recommended for the synthesis of ethyl and benzyl esters, respectively. For the synthesis of benzyl (or substituted benzyl) esters, some special reagents have also been proposed, e.g., *N*,*N*′-dicyclohexyl-*O*-benzylurea and 1-(4-methylphenyl)-3-benzyltriazene.

However, reactive diazocompounds are not very selective as compared to carboxy groups, and the formation of numerous artifacts has been reported. For example, the reaction of sorbic (2,4-hexadienoic) acid with CH_2N_2 besides leading to the formation of methyl ester, methylated homologues (the result of interaction of diazomethane through the C–H bonds), and two isomeric 2-pyrazolines,[18] which makes this mode inappropriate in practice.

The esterification of carboxylic acids can also be accomplished using synthetic equivalents of acetals of alkanols $RCH(OR')_2$ (by acid catalysis), *ortho*-esters $RC(OR')_3$ (by acid catalysis), and dialkylcarbonates $CO(OR)_2$ (by base catalysis). A series of bifunctional reagents of this type—dimethylformamide dialkylacetals $(CH_3)_2N–CH(OR')_2$—are available at present. These compounds also react with primary amino groups, that is used in derivatization of amino acids for GC analysis (Fig. 1).

A *sandwich* injection technique (flash methylation) can also be used for derivatization. It implies the injection of the sample and reagent in the same syringe into the gas chromatographic column, e.g., successively placed 1 μl of derivatization reagent, 1 μl of pyridine with internal standard, and 1 μl of the solution of analytes in the same solvent.

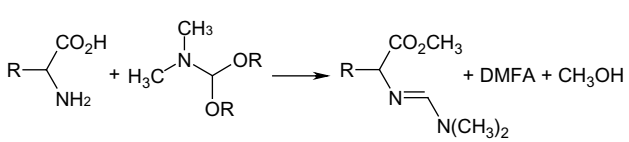

Fig. 1 One-step derivatization of amino acids by dimethylformamide dialkylacetals.

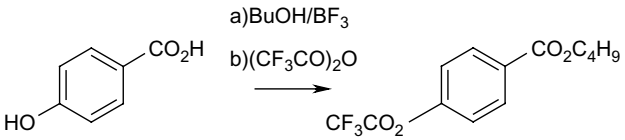

Fig. 2 Two-step derivatization of hydroxyarenecarboxylic acids.

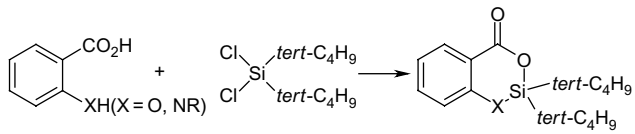

Fig. 4 One-step derivatization of hydroxy- or aminoarenecarboxylic acids by dichlorosilane reagents.

Alkyl chloroformates, $ClCO_2R$ (R = Me, Et, Bu), have been proposed as convenient alkylation reagents for carboxylic acids:[19]

$$RCO_2H + ClCO_2R' + B \rightarrow RCO_2R' + CO_2 + BH^+Cl$$

Two-stage single-pot derivatization of carboxylic acids (with intermediate formation of chloroanhydrides with thionyl chloride followed by their conversion into amides) was recommended preferably for HPLC analysis, but the simplest dialkylamides and even anilides[20] are volatile enough for GC analysis also (the mixture of Ph_3P and CCl_4, instead of $SOCl_2$, can be used in this reaction). Moreover, the same procedure is used for the synthesis of diastereomeric derivatives of enantiomeric carboxylic acids (see below):

$$RCO_2H + SOCl_2 + B \rightarrow RCOCl + SO_2 + BH^+Cl^-$$
$$RCOCl + R'R''NH + B \rightarrow RCONR'R'' + BH^+Cl^-$$

Derivatives of carboxylic acids such as amides are relatively stable to hydrolysis and can exist in aqueous solutions, at least at pH $\approx$ 7. However, the important modification of this reaction, namely rapid one-step formation of amides in aqueous media at room temperature, has been proposed only in 2007.[21] Besides the selected amine, 2,2,2-trifluoroethylamine hydrochloride (TFEA), special catalyst should be used: ethyl-[3-(dimethylamino)propyl]carbodiimide, C_2H_5–N=C=N–$(CH_2)_3$–$N(CH_3)_2$ (EDC, used as hydrochloride also).

The reactivities of carboxy and hydroxy groups in the polyfunctional hydroxy carboxylic acids are different. This indicates the possibility of an independent two-stage derivatization of these compounds (Fig. 2).

If these functional groups are located in *vic* (aliphatic series) or *ortho* positions (substitutes arenecarboxylic acids), methyl, butyl, or phenyl boronic acids are convenient reagents for their one-step derivatization with the formation of cyclic methyl(butyl, phenyl) boronates (Fig. 3).

A similar method for simultaneous derivatization of two functional groups is the formation of cyclic silylene derivatives for the same types of compounds (Fig. 4).[22]

A special type of carbonyl group derivatization is aimed at GC–MS determination of C=C double-bond positions in unsaturated long-chain acids. The analytical derivatives for the solution of this problem are nitrogen-containing heterocycles. These compounds can be synthesized by high-temperature condensation of carboxylic acids with 2-amino-2-methyl-1-propanol (2-substituted 4,4-dimethyloxazolines), 2-aminophenol (2-substituted benzoxazoles), and so forth (Fig. 5).

This reaction is so important in the analytical practice of carboxylic acids that their 4,4-dimethyloxazoline derivatives have been denoted with special abbreviations: DMOX derivatives. They have been used for a long time, but the optimization of reaction conditions, namely by in situ activation of carboxyl group, remains the actual problem up to the present. Numerous additional reagents have been proposed for these purposes, including those utilized in peptide syntheses: 2-chloro- and/or 2-bromo-1-methylpyridinium iodide (CMPI, BMPI), benzotriazol-1-yl-*N*-oxy-*tris*(dimethylamino)phosphonium hexachlorophosphate (BOP), and so forth. The latest recommendations permit us to carry out one-pot direct synthesis of amides and oxazolines with the use of such reagents as *bis*(2-methoxyethyl)aminosulfur trifluoride (Deoxo-Fluor) or diethylaminosulfur trifluoride (DAST).[23] Both of these compounds of general formula R_2NSF_3 belong to the group of fluorinating reagents and convert carboxylic acids in situ into more

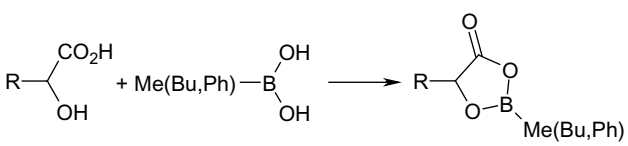

Fig. 3 One-step derivatization of α-hydroxyalkanecarboxylic acids by substituted boronic acids.

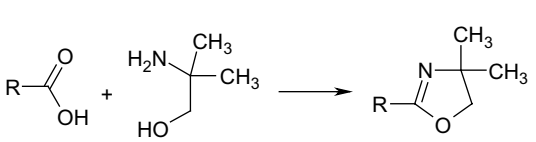

Fig. 5 An example of the formation of oxazoline derivatives from carboxylic acids.

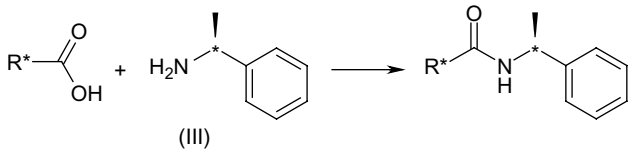

Fig. 6 An example of the formation of diastereomeric amides from chiral carboxylic acids and (S)-α-methylbenzenemethanamine.

reactive acyl fluorides, followed by their interaction with amino alcohols.

Methyl esters of carboxylic acids can be used for the formation of oxazolines, but this also requires the heating of reaction mixtures up to 180°C[24] and, hence, seems less convenient in analytical practice.

GC separation of enantiomeric carboxylic acids on non-chiral phases is based on the formation of their esters or amides with optically active alcohols (e.g., stereochemically pure (–)-menthol), or amines [(*S*)-α-methylbenzenemethaneamine, III], usually through the intermediate chloroanhydrides. These diastereomeric products are not as volatile as other acid derivatives, but, owing to the presence of two chiral centers (*) in the molecule, can be separated on non-chiral phases (Fig. 6).

A problem closely related to the derivatization of free carboxylic acids is the determination of their composition in biogenic triglycerides, lipids, and so forth. The sample preparation includes the re-esterification (preferably with formation of methyl esters) of these compounds in acidic ($MeOH/CH_3COCl$, $MeOH/BF_3$, etc.) or basic [MeOH/MeONa, $(MeO)_2SO_2$/NaOH, etc.] media. Methyl esters of fatty acids are a group of compounds well characterized by both standard mass spectra and GC retention indices on standard phases. The combination of these analytical parameters facilitates their reliable identification. Moreover, as the variety of biogenic carboxylic acids is very large,[1] it is important to mention the possibility of the theoretical prediction of their retention indices with the use of contemporary methods of chemometrics.[25] For the determination of the positions of C=C double bonds in the carbon skeleton of unsaturated fatty acids, different adducts with specific mass spectrometric fragmentation are recommended.[26]

Numerous derivatives of polyfunctional carboxylic acids important for analytical practice are characterized by GC RIs and mass spectra. As an example of this information, the data for 3 compounds from 136 known natural gibberellins are presented in Table 3. Commonly accepted

Table 3 An example of analytical data for some gibberellins (methyl ester TMS-ethers).

Gibberellin	Structural formula	$RI_{non\text{-}polar}$	$MW/(m/z)^{100}$
A2		2,741	508/130
A61		2,409	418/296
A106		2,421	416/282

Table 4 Gas chromatographic retention indices of volatile TMS derivatives of some inorganic acids.

Anion	TMS derivative	$RI_{non\text{-}polar}$
Borate	$B(OTMS)_3$	1,010
Carbonate	$CO(OTMS)_2$	1,048
Phosphite	$P(OTMS)_3$	1,115
Sulfate	$SO_2(OTMS)_2$	1,148
Arsenite	$As(OTMS)_3$	1,149
Phosphate	$PO(OTMS)_3$	1,273
Vanadate	$VO(OTMS)_3$	1,301
Arsenate	$AsO(OTMS)_3$	1,353

derivatives of these compounds are the methyl esters of TMS-ethers.[27] Even restricted GC–MS information (namely, molecular weight (MW), mass number of maximal peak in mass spectrum, $(m/z)^{100}$, and GC RI) is enough for reliable identification of all analogues of this group.

The general method for GC analysis of anions of inorganic acids is their silylation. The values of the retention indices on standard non-polar phases are known for TMS derivatives of the most important among them[4] (Table 4).

CONCLUSIONS

Both strong inorganic and weak organic acids usually need derivatization prior to GC analysis. The existence of active hydrogen atoms in the molecules explains the significant contribution of ionic structures, which are responsible for the high polarity and low volatility of these substances.

Most universal methods of derivatization of acids are silylation (TMS or TBDMS) and alkylation (the simplest methyl esters with minimal retention parameters are preferable among all possible derivatives). Other methods involve an auxiliary predetermination and can be recommended for the solution of special analytical problems.

Adsorption Chromatography

Robert J. Hurtubise
Department of Chemistry, University of Wyoming, Laramie, Wyoming, U.S.A.

INTRODUCTION

In essence, the original chromatographic technique was adsorption chromatography. It is frequently referred to as liquid–solid chromatography. Tswett developed the technique around 1900 and demonstrated its use by separating plant pigments. Open-column chromatography is a classical form of this type of chromatography, and the open-bed version is called thin-layer chromatography (TLC).

Adsorption chromatography is one of the more popular modern high-performance liquid chromatography (HPLC) techniques today. However, open-column chromatography and TLC are still widely used.[1] The adsorbents (stationary phases) used are silica, alumina, and carbon. Although some bonded phases have been considered to come under adsorption chromatography, these bonded phases will not be discussed. By far, silica and alumina are more widely used than carbon. The mobile phases employed are less polar than the stationary phases, and they usually consist of a signal or binary solvent system. However, ternary and quaternary solvent combinations have been used.

Adsorption chromatography has been employed to separate a very wide range of samples. Most organic samples are readily handled by this form of chromatography. However, very polar samples and ionic samples usually do not give very good separation results. Nevertheless, some highly polar multifunctional compounds can be separated by adsorption chromatography. Compounds and materials that are not very soluble in water or water–organic solvents are usually more effectively separated by adsorption chromatography compared to reversed-phase liquid chromatography.

When one has an interest in the separation of different types of compound, silica or alumina, with the appropriate mobile phase, can readily accomplish this. Also, isomer separation frequently can easily be accomplished with adsorption chromatography; for example, 5,6-benzoquinoline can be separated from 7,8-benzoquinoline with silica as the stationary phase and 2-propanol : hexane (1 : 99). This separation is difficult with reversed-phase liquid chromatography.[1]

STATIONARY PHASES

Silica is the most widely used stationary phase in adsorption chromatography.[2] However, the extensive work of Snyder[3] involved investigations with both silica and alumina. Much of Snyder's earlier work was with alumina. Even though the surface structures of the two adsorbents have distinct differences, they are sufficiently similar. Thus, many of the fundamental principles developed for alumina are applicable to silica. The general elution order for these two adsorbents is as follows:[1] saturated hydrocarbons (small retention time), olefins, aromatic hydrocarbons, aromatic hydrocarbons ≈ organic halides, sulfides, ethers, nitrocompounds, esters ≈ aldehydes ≈ ketones, alcohols ≈ amines, sulfones, sulfoxide, amides, carboxylic acids (long retention time). There are several reasons why silica is more widely used than alumina. Some of these are that a higher sample loading is permitted, fewer unwanted reactions occur during separation, and a wider range of chromatographic forms of silica are available.

Chromatographic silicas are amorphous and porous and they can be prepared in a wide range of surface areas and average pore diameters. The hydroxyl groups in silica are attached to silicon, and the hydroxyl groups are mainly either free or hydrogen-bonded. To understand some of the details of the chromatographic processes with silica, it is necessary to have a good understanding of the different types of hydroxyl groups in the adsorbent.[1,3] Chromatographic alumina is usually γ-alumina. Three specific adsorption sites are found in alumina: (a) acidic, (b) basic, and (c) electronacceptor sites. It is difficult to state specifically the exact nature of the adsorption sites. However, it has been postulated that the adsorption sites are exposed aluminum atoms, strained Al–O bonds, or cationic sites.[4] Table 1 gives some of the properties of silica and alumina.

The adsorbent water content is particularly important in adsorption chromatography. Without the deactivation of strong adsorption sites with water, non-reproducible retention times will be obtained, or irreversible adsorption of solutes can occur. Prior to using an adsorbent for open-column chromatography, the adsorbent is dried, a specified amount of water is added to the adsorbent, and then the adsorbent is allowed to stand for 8–16 hr to permit the equilibration of water.[3,4] If one is using a high-performance column, it is a good idea to consider adding water to the mobile phase to deactivate the stronger adsorption sites on the adsorbent. Some of the benefits are less variation in retention times, partial compensation for lot-to-lot differences in the adsorbent, and reduced band tailing.[1] However, there can be some problems in

Table 1 Some adsorbents used in adsorption chromatography.

Type	Name	Form	Average particle area size (μm)	Surface area (m^2/g)
Silica[a]	BioSil A	Bulk	2–10	400
	μPorasil	Column	10	400+
Silica[b]	Hypersil	Bulk	5–7	200
	Zobax Sil	Bulk or column	6	350
Alumina[a]	ICN Al-N	Bulk	3–7, 7–12	200
	MicroPak Al	Bulk or column	5, 10	79
Alumina[b]	Spherisorb AY	—	5, 10, 20	95

adding water to the mobile phase, such as how much water to add to the mobile phase for optimum performance. Snyder and Kirkland[1] have discussed several of these aspects in detail.

MOBILE PHASES

To vary sample retention, it is necessary to change the mobile-phase composition. Thus, the mobile phase plays a major role in adsorption chromatography. In fact, the mobile phase can give tremendous changes in sample retention characteristics. Solvent strength controls the capacity factor's values of all the sample bands. A solvent strength parameter (ε^0), which has been widely used over the years, can be employed quantitatively for silica and alumina. The solvent strength parameter is defined as the adsorption energy of the solvent on the adsorbent per unit area of solvent.[1,3] Table 2 gives the solvent strength values for selected solvents that have been used in adsorption chromatography. The smaller values of ε^0 indicate weaker solvents, whereas the larger values of ε^0 indicate stronger solvents. The solvents listed in Table 2 are single solvents. Normally, solvents are selected by mixing two solvents with large differences in their ε^0 values, which would permit a continuous change in the solvent strength of the binary solvent mixture. Thus, some specific combination of the two solvents would provide the appropriate solvent strength. In adsorption chromatography, the solvent strength increases with solvent polarity, and the solvent strength is used to obtain the proper capacity factor values, usually in the range of 1–5 or 1–10. It should be realized that the solvent strength does not vary linearly over a wide range of solvent compositions, and several guidelines and equations that allow one to calculate the solvent strength of binary solvents have been developed for acquiring the correct solvent strength in adsorption chromatography.[1,3] However, it frequently happens that the solvent strength is such that all of the solutes are not separated in a sample. Thus, one needs to consider solvent selectivity, which is discussed below.

Table 2 Selected solvents used in adsorption chromatography.

	Solvent strength (ε^0)	
	Silica	**Alumina**
Solvent		
n-Hexane	0.01	0.01
1-Chlorobutane	0.20	0.26
Chloroform	0.26	0.40
Isopropyl ether	0.34	0.28
Ethyl acetate	0.38	0.58
Tetrahydrofuran	0.44	0.57
Acetonitrile	0.50	0.65

Source: From Adsorption chromatography, in J. Chromatogr. A.[11]

To change the solvent selectivity, the solvent strength is held constant and the composition of the mobile phase is varied. It should be realized that because the solvent strength is directly related to the polarity of the solvent and polarity is the total of the dispersion, dipole, hydrogen-bonding, and dielectric interactions of the sample and solvent, one would not expect that solvent strength alone could be used to fine-tune a separation. A trial-and-error approach can be employed by using different solvents of equal ε^0. However, there are some guidelines that have been developed that permit improved selectivity. These are the "B-concentration" rule and the "hydrogen-bonding" rule.[1] In general, with the B-concentration rule, the largest change in selectivity is obtained when a very dilute or a very concentrated solution of B (stronger solvent) in a weak solvent (A) is used. The hydrogen-bonding rule states that any change in the mobile phase that results in a change in hydrogen-bonding between sample and mobile-phase molecules usually results in a large change in selectivity. A more comprehensive means for improving selectivity is the solvent-selectivity triangle.[1,5] The solvent-selectivity triangle classifies solvents according to their relative dipole moments, basic properties, and acidic properties. For example, if an initial chromatographic experiment does not separate all the components with a binary mobile phase, then the solvent-selectivity triangle can be used to choose another solvent for the binary system that has properties that are very different than one of the

solvents in the original solvent system. A useful publication that discusses the properties of numerous solvents and also considers many chromatographic applications is Ref.[6]

MECHANISTIC ASPECTS IN ADSORPTION CHROMATOGRAPHY

Models for the interactions of solutes in adsorption chromatography have been discussed extensively in the literature.[7–9] Only the interactions with silica and alumina will be considered here. However, various modifications to the models for the previous two adsorbents have been applied to modern high-performance columns (e.g., amino-silica and cyano-silica). The interactions in adsorption chromatography can be very complex. The model that has emerged which describes many of the interactions is the displacement model developed by Snyder.[1,3,4,7,8] Generally, retention is assumed to occur by a displacement process. For example, an adsorbing solute molecule X displaces n molecules of previously adsorbed mobile-phase molecules M:[8]

$$X_n + nM_a \rightleftharpoons X_a + nM_n$$

The subscripts n and a in the above equation represent a molecule in a non-sorbed and adsorbed phase, respectively. In other words, retention in adsorption chromatography involves a competition between sample and solvent molecules for sites on the adsorbent surface. A variety of interaction energies are involved, and the various energy terms have been described in the literature.[7,8] One fundamental equation that has been derived from the displacement model is

$$\log\left(\frac{k_1}{k_2}\right) = \alpha' A_S(\varepsilon_2 - \varepsilon_1)$$

where k_1 and k_2 are the capacity factors of a solute in two different mobile phases, α' is the surface activity of the adsorbent (relative to a standard adsorbent), A_S is the cross-sectional area of the solute on the adsorbent surface, ε_1 and ε_2 are the solvent strengths of the two different mobile phases. This equation is valid in situations where the solute and solvent molecules are considered non-localizing. This condition is fulfilled with non-polar or moderately polar solutes and mobile phases. If one is dealing with multisolvent mobile phases, the solvent strength of those solvents can be related to the solvent strengths of the pure solvents in the solvent system. The equations for calculating solvents strengths for multisolvent mobile phases have been discussed in the literature.[8]

As the polarities of the solute and solvent molecules increase, the interactions of these molecules become much stronger with the adsorbent, and they adsorb with localization. The net result is that the fundamental equation for adsorption chromatography with relatively non-polar solutes and solvents has to be modified. Several localization effects have been elucidated, and the modified equations that take these factors into consideration are rather complex.[7,8,10] Nevertheless, the equations provide a very important framework in understanding the complexities of adsorption chromatography and in selecting mobile phases and stationary phases for the separation of solutes.

APPLICATIONS

There have been thousands of articles published on the application of adsorption chromatography over the decades. Today, adsorption chromatography is used around the world in all areas of chemistry, environmental problem solving, medical research, and so forth. Only a few examples will be discussed in this section. Gogou et al.[11] developed methods for the determination of organic molecular markers in marine aerosols and sediment. They used a one-step flash chromatography compoundclass fractionation method to isolate compound-class fractions. Then, they employed GC/MS and/or GC/flame ionization detection analysis of the fractions. The key adsorption chromatographic step prior to the GC was the one-step flash chromatography. For example, an organic extract of marine aerosol or sediment was applied on the top of a 30×0.7 cm column containing 1.5 g of silica. The following solvent systems were used to elute the different compound classes: (a) 15 ml of *n*-hexane (aliphatics); (b) 15 ml toluene : *n*-hexane (5.6 : 9.4) (polycyclic aromatic hydrocarbons and nitropolycyclic aromatic hydrocarbons); (c) 15 ml *n*-hexane: methylene chloride (7.5 : 7.5) (carbonyl compounds); (d) 20 ml ethyl acetate: *n*-hexane (8 : 12) (*n*-alkanols and sterols); (e) 20 ml (4%, v/v) pure formic acid in methanol (free fatty acids). This example illustrates very well how adsorption chromatography can be used for compound-class separation.

Hanson and Unger[12] have discussed the application of non-porous silica particles in HPLC. Non-porous silica packings can be used for the rapid chromatographic analysis of biomolecules because the particles lack pore diffusion and have very effective mass-transfer capabilities. Several of the advantages of non-porous silica are maximum surface accessibility, controlled topography of ligands, better preservation of biological activity caused by shorter residence times on the column, fast column regeneration, less solvent consumption, and less susceptibility to compression during packing. The very low external surface area of the non-porous supports is a disadvantage because it gives considerably lower capacity compared with porous materials. This drawback is

counterbalanced partially by the high-packing density compared to porous silica. The smooth surface of the non-porous silica offers better biocompatibility relative to porous silica. Well-defined non-porous silicas are now commercially available.

Adsorption Studies by FFF

Niem Tri
Ronald Beckett
Water Studies Centre, Monash University, Melbourne, Victoria, Australia

INTRODUCTION

Adsorption is an important process in many industrial, biological, and environmental systems. One compelling reason to study adsorption phenomena is because an understanding of colloid stability depends on the availability of adequate theories of adsorption from solution and of the structure and behavior of adsorbed layers. Another example is the adsorption of pollutants, such as metals, toxic organic compounds, and nutrients, onto fine particles and their consequent transport and fate, which has great environmental implications. Often, these systems are quite complex and it is often favorable to separate these into specific size for subsequent study.

BACKGROUND INFORMATION

A new technique able to separate such complex mixtures is field-flow fractionation.[1–3] Field-flow fractionation (FFF) is easily adaptable to a large choice of field forces (such as gravitational, centrifugal, fluid cross-flows, electrical, magnetic and thermal fields or gradients) to effect high-resolution separations. Although the first uses for FFF were for sizing of polymer and colloidal samples, recent advances have demonstrated that well-designed FFF experiments can be used in adsorption studies.[4,5]

Although the theory of FFF for the characterization and fractionation of polymers and colloids has been outlined elsewhere, two important features of FFF need to be emphasized here. The first is the versatility of FFF, which is partly due to the diverse range of operating fields that may be used and the fact that each field is capable of delivering different information about a colloidal sample. For example, an electrical field separates particles on the basis of both size and charge, whereas a centrifugal field (sedimentation FFF) separates particles on the basis of buoyant mass (i.e., size and density). The second important feature is that this information can usually be measured directly from the retention data using rigorous theory. This is in contrast to most forms of chromatography (size-exclusion chromatography exempted), where the retention time of a given component must be identified by running standards.

In 1991, both Beckett et al.,[4] and Li and Caldwell[5] published articles demonstrating novel but powerful uses for sedimentation FFF in probing the characteristics of adsorbed layers or films on colloidal particles. Beckett et al., article demonstrated that it is possible to measure the mass of an adsorbed coating down to a few attograms (10^{-18} g), which translates to a mean coating thickness of human γ-globulin, ovalbumin, RNA, and cortisone ranging from 0.1 to 20 nm. A discussion of the theory and details of the experiment is beyond the scope of this entry. However, it is possible to appreciate how such high sensitivities arise by considering the linear approximation of retention time, t_r, of an eluting particle in sedimentation FFF with the field-induced force on the particle, F.

$$t_r = t_0 \frac{Fw}{6kT} \tag{1}$$

where w is the thickness of the channel (typically 100–500 μm), k is the Boltzmann constant, and T is the temperature in Kelvin. F is the force on the individual particle and is the product of the applied field and the buoyant mass of the particle (relative mass of the particle in the surrounding liquid medium).

The highest sensitivity of retention time to changes in the surface coating was found to occur when the density of the core particle was equal to that of the surrounding medium (i.e., the buoyant mass diminishes to zero and no retention is observed for the bare particle). If a thin film of a much denser material is adsorbed onto the particles, then the small increment in mass due to the adsorbed film causes a significant change in the particle's buoyant mass (see Fig. 1a). Consequently, the force felt by the particle is now sufficient to effect retention by an observable amount. Incidentally, analogous behavior is also possible if the coatings are less dense than the carrier liquid. If the diameter of the bare particle is known (from independent experiments) so that the surface area can be estimated, then it is also possible to calculate the thickness of the adsorbed film, provided the density of the film is the same as the bulk density of the material being adsorbed (i.e., no solvation of the adsorbed layer). In some systems, it may be possible to alter the solvent density to match the core particle density by the addition of sucrose or other density modifiers to the FFF carrier solution.

Using the above approach with experimental results from centrifugal FFF, adsorption isotherms were constructed by

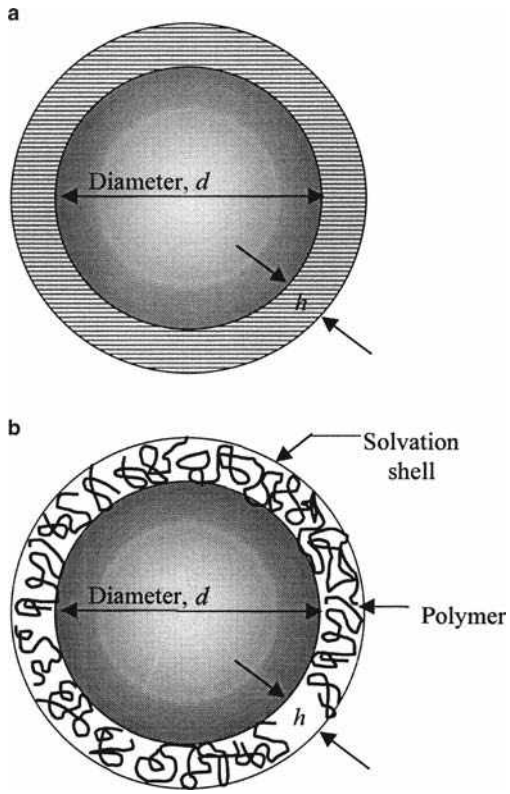

Fig. 1 Schematic representation of the adsorption complex proposed by (a) Beckett et al.,[4] showing the core particle with a dense non-hydrated adsorbed film and by (b) Li and Caldwell[5] showing the core particle with an adsorbed polymer and the associated solvation shell.

directly measuring the mass of adsorbate deposited onto the polymer latex particle surface at different solution concentrations. It was found that for human globulin and ovalbumin adsorbates, Langmuir isotherms were obtained. The measured limiting adsorption density was found to agree with values measured using conventional solution uptake techniques.

The model used in the above studies ignores the departure from the bulk density of the adsorbate brought about by the interaction of the two interfaces. Li and Caldwell's article addresses this issue by introducing a three-component model consisting of a core particle, a flexible macromolecular substance with affinity toward the particle, and a solvation shell (see Fig. 1b).

In this model, the buoyant mass is then the sum of the buoyant mass of the three components, assuming that these are independent of the mass of solvent occupied in the solvation shell. Thus, the mass of the adsorbed shell can be calculated if information about the mass and density of the core particle and the density of the macromolecule and solvent are known. Photon correlation spectroscopy, electron microscopy, flow FFF, or other sizing techniques can readily provide some independent information on the physical or hydrodynamic particle size, and pycnometry can be used to measure the densities of the colloidal suspension, polymer solution, and pure liquid.

The above measurements were combined to estimate the mass of the polymer coating, a surface coverage density, and the solvated layer thickness. These results showed good agreement with the adsorption data derived from conventional polymer radiolabeling experiments.

Another approach for utilizing FFF techniques in the study of adsorption processes is to use the following general protocol:

1. Expose the suspension to the adsorbate.
2. Run the sample through an FFF separation and collect fractions at designated elution volume intervals corresponding to specific size ranges.
3. Analyze the size fractions for the amount of adsorbate.

It must be emphasized that only strongly adsorbed material will be retained on the particles as the sample is constantly washed by the carrier solution during the FFF separation. Unless adsorbent is added to the carrier, these experiments will not represent the reversible equilibrium adsorption situation.

This approach was first outlined by Beckett et al.,[6] where radiolabeled pollutants (^{32}P as orthophosphate, ^{14}C in atrazine, and glyphosate) were adsorbed to two Australian river colloid samples. Sedimentation FFF was used to fractionate the samples and the radioactivity of each fraction was measured. From this, it was possible to generate a surface adsorption density distribution (SADD) across the size range of the sample. The SADD is a plot of the amount of compound adsorbed per unit particle surface area as a function of the particle size. It was shown that the adsorption density was not always constant, indicating perhaps a change in particle mineralogy, surface chemistry, shape, or texture as a function of particle size.

The above method is currently being extended to use other sensitive analytical techniques such as inductively coupled plasma–mass spectrometry (ICP–MS), graphite furnace atomic absorption (GFAAS), and inductively coupled plasma–atomic emission spectrophotometry (ICP–AES). With multielement techniques, it is not only possible to measure the amount adsorbed but changes in the particle composition with size can be monitored,[7] which is most useful in interpreting the adsorption results.[8] Hassellov et al.,[9] showed that using sedimentation FFF coupled to ICP–MS, it was possible to study both the major elements Al, Si, Fe, and Mn but also the Cs, Cd, Cu, Pb, Zn, and La. It was shown that it was possible to distinguish between the weaker and stronger binding sites as well as between different adsorption and ion-exchange mechanisms.

In electrical FFF, samples are separated on the basis of surface charge and even minute amount of adsorbate will

significantly be reflected in electrical FFF data, as demonstrated by Dunkel et al.[10] However, this technique is severely limited by the generation of polarization products at the channel wall due to the applied voltages.

In conclusion, the versatility and power of FFF are not restricted to its ability to effect high-resolution separations and sizing of particles and macromolecules. FFF can also be used to probe the surface properties of colloidal samples. Such studies have great potential to provide detailed insight into the nature of adsorption phenomena.

Affinity Chromatography

David S. Hage
Department of Chemistry, University of Nebraska-Lincoln, Lincoln, Nebraska, U.S.A.

Abstract
The history and basic principles of affinity chromatography are discussed in this entry. Affinity chromatography is a liquid chromatographic technique that uses a biologically related agent as a ligand for the purification or analysis of sample components. Affinity chromatography is a valuable tool in areas such as biochemistry, biotechnology, pharmaceutical science, clinical chemistry, and environmental testing, where it has been used for both the purification and analysis of compounds in complex sample mixtures. The various components of an affinity chromatographic method, including the types of affinity ligands, support materials, immobilization methods, and application or elution conditions that are employed in this technique, are discussed in this entry. Several specific types of affinity chromatography, including bioaffinity chromatography, immunoaffinity chromatography, lectin affinity chromatography, dye–ligand affinity chromatography, immobilized metal-ion affinity chromatography (IMAC), boronate affinity chromatography, weak affinity chromatography, and analytical affinity chromatography, are also described.

INTRODUCTION

Affinity chromatography is a liquid chromatographic technique that uses a biologically related agent as a stationary phase for the purification or analysis of sample components.[1,2] The retention of solutes in this method is based on the specific reversible interactions that occur in many biological systems, such as the binding of an enzyme with a substrate or of an antibody with an antigen. These interactions are exploited in affinity chromatography by placing one of a pair of interacting molecules onto or within a solid support and using this immobilized agent as a stationary phase. This immobilized agent is known as the *affinity ligand* and is what gives an affinity column the ability to bind to particular compounds in a sample.[2]

Affinity chromatography is a valuable tool in areas such as biochemistry, proteomics, pharmaceutical science, clinical chemistry, and environmental testing, where it has been used for both the purification and analysis of compounds in complex sample mixtures.[3–11] The strong and relatively specific binding that characterizes many affinity ligands allows solutes to be measured or purified by these ligands with little or no interference from other sample components. Often the solute of interest can be isolated in one or two steps, with purification yields of one hundred to several thousandfold being common.[3,6,7] This entry will first examine the history of affinity chromatography and the different ways in which affinity chromatography is performed. The various features of an affinity chromatographic method, including the types of affinity ligands, support materials, immobilization methods, and application or elution conditions that are employed in this technique, will then be discussed. Several specific types of affinity chromatography will be described next.

HISTORY OF AFFINITY CHROMATOGRAPHY

The earliest known use of affinity chromatography was in 1910 when Emil Starkenstein examined the binding of insoluble starch to the enzyme α-amylase.[12] Similar work with starch and other insoluble ligands (acting as both binding agents and supports) was conducted in the 1920s through the 1940s. Most of these early studies involved the use of affinity supports for the purification of enzymes. However, work on the selective purification of antibodies with biological ligands through the use of immunoprecipitation also began at this time.[2]

In the 1940s and 1950s, synthetic techniques became available for placing a broader range of ligands on insoluble materials that could be used as supports. These efforts began by employing solids that contained a non-covalently adsorbed layer of ligand, followed later by the development of methods for chemically bonding a ligand to solid supports. A covalent technique for ligand attachment to a support was first used by Landsteiner and van der Sheer in 1936, when they adapted the diazo-coupling technique to attach a number of haptens to a material based on chicken erythrocyte stroma.[13] Another significant development in this area occurred in 1951, when Campbell and coworkers used an activated form of cellulose (*p*-aminobenzylcellulose) for immobilizing the protein serum albumin, which was then employed in the isolation of antialbumin antibodies from rabbit serum.[14]

The modern era of affinity chromatography began in the late 1960s with the creation of beaded agarose supports by Hjerten[15] and the use of the cyanogen bromide immobilization method by Axen, Porath, and Ernback.[16] These two methods were combined in 1968 by Cuatrecasas, Wilchek, and Anfinsen to create immobilized nuclease inhibitor columns. These columns were then used for purifying the enzymes staphylococcal nuclease, α-chymotrypsin, and carboxypeptidase A. It was at this time that the name *affinity chromatography* was first used to describe this separation technique.[17] This was followed by a significant increase in the use of affinity chromatography in the 1970s up to the present time, with over 1000 entries per year appearing on this method.[2–7]

AFFINITY CHROMATOGRAPHY: METHODS

The most common method for performing affinity chromatography is to use a step gradient for elution, as shown in Fig. 1. This approach involves injecting a sample onto the affinity column in the presence of a mobile phase that has the right pH and solvent composition for solute–ligand binding. This solvent, which represents the weak mobile phase of the affinity column, is called the *application buffer*. In the presence of this buffer, compounds that are complementary to the affinity ligand bind as the sample is carried through the column by the application buffer. However, because of the high selectivity of the solute–ligand interaction, the other sample components tend to pass through the column without being retained. After the non-retained components have been completely washed from the column, the retained solutes can be eluted by applying a solvent that displaces them from the column or that promotes dissociation of the solute–ligand complex. The second solvent represents the strong mobile phase for the column and is known as the *elution buffer*. As the solutes of interest elute from the column, they are either measured or collected for later use. The column is then regenerated by re-equilibrating it with the application buffer before the injection of the next sample.[3,7]

Even though the *step gradient*, or *on/off*, *elution method* is the most common way of performing affinity chromatography, it is possible to use affinity methods under isocratic conditions. Isocratic elution can be employed if the retention of a solute is sufficiently weak to allow elution on the minute-to-hour timescale and if the kinetics for binding and dissociation with the ligand are fast enough to allow a large number of solute–ligand interactions to occur as the solute travels through the column. This approach is called *weak affinity chromatography* and is best performed if a solute binds to the ligand with an association equilibrium constant less than or equal to about 10^4–10^6 M^{-1}.[18–20]

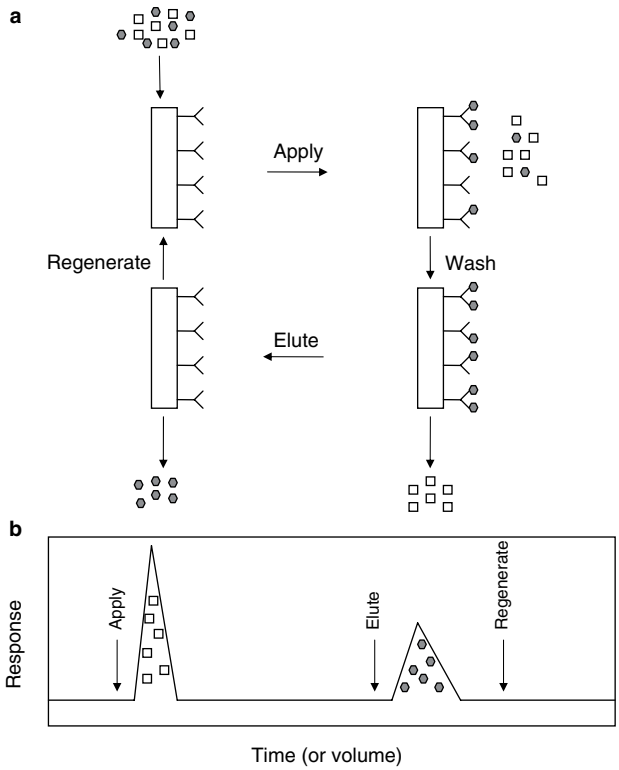

Fig. 1 a, Typical separation scheme and b, chromatogram for affinity chromatography. The filled circles represent the test analyte and the open squares represent other non-retained sample components.

TYPES OF AFFINITY LIGANDS

The most important factor that determines the success of any affinity separation is the type of ligand that is used within the column. A number of ligands that are commonly used in affinity chromatography are listed in Table 1. Most of these ligands are of biological origin, but a wide range of natural and synthetic molecules of non-biological origin have also been used in affinity separations. Regardless of their origin, all of these ligands can be placed into one of two categories: high-specificity ligands or general ligands.[2,6,7]

The term *high-specificity ligand* refers to a compound that binds to only one or a few closely related molecules. This type of ligand is used in affinity separations where the goal is to analyze or purify a specific solute. Examples include antibodies (for binding antigens), substrates or inhibitors (for separating enzymes), and single-stranded nucleic acids (for the retention of a complementary sequence). As this list suggests, most high-specificity ligands tend to be of biological origin. High-specificity ligands also tend to have large association equilibrium constants for their targets.

General, or *group-specific*, *ligands* are agents that bind to a family or class of related targets. These ligands are

Table 1 Common ligands used in affinity chromatography.

Type of ligand	Examples of retained targets
High-specificity ligands	
Antibodies	Drugs, hormones, peptides, proteins, viruses
Enzyme inhibitors and cofactors	Enzymes
Nucleic acids	Complementary nucleic acid strands and DNA/RNA-binding proteins
General ligands	
Lectins	Small sugars, polysaccharides, glycoproteins, and glycolipids
Protein A and protein G	Intact antibodies/immunoglobulins and F_c fragments
Boronates	Catechols and compounds that contain sugar residues, such as polysaccharides and glycoproteins
Synthetic dyes	Dehydrogenases, kinases, and various proteins
Metal chelates	Metal-binding amino acids, peptides, or proteins

used when the goal is to isolate a class of structurally related compounds. General ligands can be of either biological or non-biological origin and include agents such as protein A or protein G, lectins, boronates, biomimetic dyes, and immobilized metal chelates. This class of ligands usually exhibits weaker binding for targets than is seen with high-specificity ligands. However, some general ligands like protein A and protein G do have association equilibrium constants that rival those of high-specificity ligands.

SUPPORT MATERIALS

Another important factor to consider in affinity chromatography is the material used to hold the ligand within the column. Ideally, this support should have low non-specific binding for sample components, it should be easy to modify for ligand attachment, and it should be stable under the flow rate, pressure, and solvent conditions that will be employed in the analysis or purification of samples. Depending on what type of support material is being used, affinity chromatography can be characterized as being either a low- or a high-performance technique.[7,21,22]

In *low-performance* (or *column*) *affinity chromatography*, the support is usually a large-diameter, non-rigid material, such as a carbohydrate-based gel, or one of several synthetic organic-based polymers. The low back pressures that are produced by these supports means that these materials can often be operated under gravity flow or with a peristaltic pump, making them relatively simple and inexpensive to use for affinity purification or sample pretreatment. Disadvantages of these materials include their slow mass transfer properties and their limited stabilities at high flow rates and pressures. These factors tend to limit the direct use of these supports in analytical applications, where both rapid and efficient separations are usually desired.[7,21]

High-performance affinity chromatography (*HPAC*) is characterized by a support that consists of small, rigid particles that are capable of withstanding high flow rates and/or pressures.[7,21,22] Examples of affinity supports that are suitable for work under these conditions include modified silica or glass, azalactone beads, and hydroxylated polystyrene media. The stability and efficiency of these supports allows them to be used with standard high-performance liquid chromatography (HPLC) equipment. Although the need for HPLC instrumentation does make HPAC more expensive to perform than low-performance affinity chromatography, the better speed and precision of HPAC makes it the method of choice for many analytical applications.

Although porous, particulate materials like agarose, polymethacrylate, and silica are used in most current applications of affinity chromatography, there are several other types of supports that have recently become available for affinity separations.[21] Materials that fall in this category include non-porous supports, membranes, flow-through beads, continuous beds, and expanded bed particles. The good mass transfer properties of non-porous beads with diameters of 1–3 μm make them appealing for fast analytical or micropreparative separations, as well as for quantitative studies of affinity interactions. Similar properties are obtained using flow-through beads or continuous beds. An example is the use of monolithic supports with affinity ligands in a method known as affinity monolith chromatography (AMC).[23] The flat geometry and shallow bed depth of affinity membranes allow their use at high flow rates, making them well suited for capturing proteins from dilute feed streams. Similarly, the presence of low back pressures makes expanded bed particles attractive for use in isolating proteins from cell culture samples while allowing solid contaminants like cells and cell debris to pass through, thereby avoiding column clogging.[21]

IMMOBILIZATION METHODS

An additional factor to consider in affinity chromatography is the way in which the ligand is attached to the solid

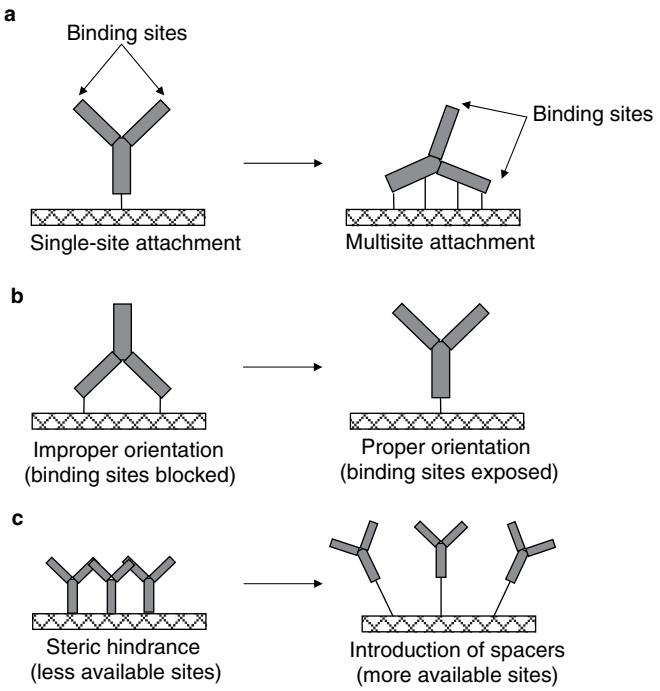

Fig. 2 Common immobilization effects during the coupling of affinity ligands to solid supports.
Source: From Immobilization methods for affinity chromatography, in *Handbook of Affinity Chromatography*.[24]

support, or the *immobilization method*. For a ligand that is a protein or peptide, immobilization generally involves coupling the ligand through free amine, carboxylic acid, or sulfhydryl residues in its structure. Immobilization of a ligand through other functional sites is also possible (e.g., the use of aldehyde groups produced by mild oxidation of the carbohydrate chains on a glycoprotein). All covalent immobilization methods involve at least two steps: 1) an *activation step*, in which the support is converted to a form that can be chemically attached to the ligand; and 2) a *coupling step*, in which the affinity ligand is attached to the activated support.[7,24] Occasionally, a third step is necessary to remove remaining activated groups and to minimize non-specific binding to the final support.[24]

The method by which an affinity ligand is immobilized is important because it can affect the actual or apparent activity of the final affinity column.[7,24] If the correct procedure is not used, a decrease in ligand activity can result from multisite attachment, improper orientation, or steric hindrance (Fig. 2). *Multisite attachment* refers to the coupling of a ligand to the support through more than one functional group, which can lead to distortion of the active region in a ligand and a loss of activity. This effect can be avoided by using a support with a limited number of activated sites or by using a method that couples through groups that are present in only a few places in the structure of the ligand. *Improper orientation* can lead to a loss in activity by coupling the ligand to the support through its active region; this effect can be minimized by coupling through functional groups that are distant from the active region. *Steric hindrance* refers to the loss of ligand activity due to the presence of a nearby support or neighboring ligands that interfere with solute binding. This effect can be avoided through the use of a spacer arm or by using supports that contain a relatively low coverage of the ligand.[7,24]

It is possible to place an affinity ligand within a column through means other than covalent immobilization.[24] The simplest of these alternative approaches is to use physical adsorption of the ligand onto a surface through ionic or non-specific interactions. In addition, a ligand can be held non-covalently on a column by means of a secondary ligand. A common example of the latter technique is the use of immobilized protein A or protein G to adsorb antibodies for use in immunoaffinity chromatography.[25,26] It is also possible to entrap or encapsulate a ligand within a support if the size of the entrapped ligand is larger than the pores of the support material (e.g., as occurs in the use of sol gels for protein entrapment).[24] Finally, there are instances in which the ligand itself can be used as both the support and stationary phases. Insoluble starch was used as both the support and the ligand for isolation of the enzyme amylase when affinity chromatography was first used.[12]

APPLICATION AND ELUTION CONDITIONS

The effect of application and elution buffers must be taken into consideration in affinity chromatography. Most application buffers in affinity chromatography are solvents that mimic the pH, ionic strength, and polarity experienced by the solute and ligand in their natural environment. These conditions give the solute its highest

association equilibrium constant for the ligand and, thus, its highest degree of retention on the column. The application buffer should be chosen so that it minimizes non-specific binding due to other sample components.[20]

Elution conditions in affinity chromatography are usually chosen so that they promote either the fast or gentle removal of solute from the column. The two most common approaches used for this purpose are *biospecific elution* and *non-specific elution*.[7,20] Biospecific elution is based on the addition of a competing agent that gently displaces a solute from the column. This type of elution is done by adding an agent that either competes with the ligand for the target solute (i.e., *normal role elution*) or competes with the target solute for binding sites on the ligand (i.e., *reversed role elution*). Although it is a gentle method, biospecific elution does result in long elution times and broad solute peaks that can be difficult to detect and measure. Non-specific elution uses a solvent that directly promotes weak solute–ligand binding. For instance, non-specific elution is carried out by changing the pH, ionic strength, or polarity of the mobile phase or by adding a denaturing agent or chaotropic substance to the elution buffer. Non-specific elution tends to be much faster than biospecific elution and results in sharper peaks that help provide lower limits of detection. However, care must be exercised when utilizing non-specific elution to avoid using a buffer that is too harsh and may cause denaturation of the target solute or a loss of ligand activity.

TYPES OF AFFINITY CHROMATOGRAPHY

There are many types of affinity chromatography that are in common use. *Bioaffinity chromatography* is the broadest category and includes any affinity separation method that uses a biological molecule as the ligand.[4–7,27] *Immunoaffinity chromatography* (*IAC*) is a special subcategory of bioaffinity chromatography in which the affinity ligand is an antibody or antibody-related agent.[25,26,28] This combination creates a highly specific method that is ideal for use in affinity purification or in analytical methods that involve complex samples. *Immunoextraction* is a subcategory of IAC in which an affinity column is used to isolate compounds from a sample before analysis by a second method. IAC can also be used to monitor the elution of analytes from other columns, giving rise to a scheme known as *postcolumn immunodetection*.[25,28,29]

Another common type of bioaffinity method is a technique that uses bacterial cell wall proteins like protein A or protein G for antibody purification. This approach is sometimes categorized as a subset of immunoaffinity chromatography but it is more appropriate to consider it under bioaffinity methods.[26–29] In *lectin affinity chromatography*, another type of bioaffinity chromatography, immobilized lectins like concanavalin A or wheat germ agglutinin are used for binding to targets that contain certain sugar residues.[27] Additional types of bioaffinity chromatography are those that make use of ligands that are enzymes, inhibitors, cofactors, nucleic acids, hormones, or cell receptors.[4–7,27] Examples of these methods include *receptor affinity chromatography*[30] and *DNA affinity chromatography*,[31] the latter of which can include the use of aptamers as binding agents.[32,33]

There are many types of affinity chromatography that use ligands that are of non-biological origin. For instance, the closely related methods of *dye–ligand affinity chromatography* and *biomimetic affinity chromatography* can use an immobilized synthetic dye (e.g., Fig. 3) to mimic a target that will bind to the active site of a protein or enzyme, making these methods popular tools for enzyme and protein purification.[32–35] *Immobilized metal-ion affinity chromatography* (*IMAC*) is an affinity technique in which the ligand is a metal ion that is complexed with an immobilized chelating agent.[36–38] IMAC is used to separate proteins and peptides that contain amino acids with electron donor groups and has become a popular tool for isolating recombinant proteins that contain histidine tags.[38] *Boronate affinity chromatography* employs boronic acid or a boronate as the affinity ligand. Boronate-related ligands are useful in binding to targets that contain *cis*-diol groups, such as catecholamines and glycoproteins.[39,40]

There are a number of other chromatographic methods that are closely related to traditional affinity chromatography. For instance, affinity chromatography can be adapted as a tool for studying solute–ligand interactions. This application is known as *analytical affinity chromatography*, *quantitative affinity chromatography*, or *biointeraction*

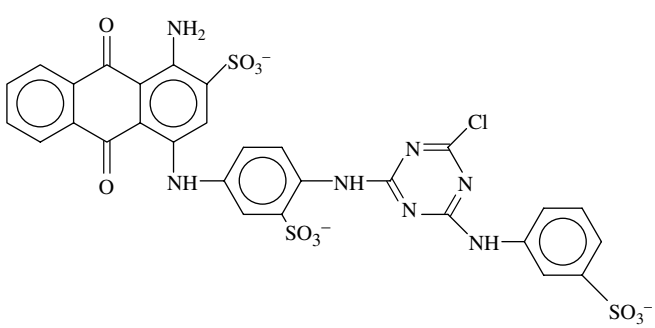

Fig. 3 Cibacron Blue 3GA, a triazine dye that is commonly used as a ligand for protein and enzyme purification in the method of dye–ligand affinity chromatography.

chromatography.[41–44] Methods that have been developed for this field can be used to acquire information regarding the equilibrium and rate constants for biological interactions, as well as the number and type of binding sites that are involved in these interactions. This method can also be used to examine the competition between two solutes for binding sites on a ligand (as is common in *frontal affinity chromatography*)[45] and to study both direct and allosteric effects during such competition.[41–43]

Other methods that are related to affinity chromatography include *hydrophobic interaction chromatography* (*HIC*) and *thiophilic adsorption*.[2,7] HIC is based on the interactions of proteins, peptides, and nucleic acids with short non-polar chains, such as those that were originally used as spacer arms on affinity supports. Thiophilic adsorption, also known as *covalent* or *chemisorption chromatography*, makes use of immobilized thiol groups for solute retention. Applications of this method include the analysis of sulfhydryl-containing peptides or proteins and mercurated polynucleotides.

Many types of *chiral liquid chromatography* can be considered affinity methods because they are based on binding agents that are of biological origin. Examples include columns that use cyclodextrins or immobilized proteins for chiral separations.[27,46,47] The growing use of molecularly imprinted polymers as stationary phases can also be considered to be a subset of affinity chromatography, because such materials are designed to mimic the multiple interactions and selectivity that are characteristic of many biological ligands.[48,49] Another area of growth in recent years has been the combined use of affinity columns (e.g., those containing antibodies) with other analytical methods, such as mass spectrometry,[42,45,50] liquid chromatography,[25,29,42] or capillary electrophoresis.[25,51]

CONCLUSION

In summary, affinity chromatography is a selective separation method that has numerous applications in the purification and analysis of compounds, especially targets that are related to biological systems. The wide variety of available ligands makes it possible to design affinity separations for a large range of target compounds. Some of these ligands are of biological origin while others are man-made. It is also possible to perform affinity chromatography with support materials that allow its use as either a preparative tool or an analytical method. In addition, affinity chromatography can be used as a tool to study biological interactions. These features have made affinity methods valuable in a number of fields, including biotechnology, biochemistry, clinical analysis, pharmaceutical science, and environmental testing. In recent years there has been considerable improvement in the use of affinity chromatography in combination with other methods, such as mass spectrometry and capillary electrophoresis.

Georgios A. Theodoridis
Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece

Abstract
Since the first reports in the early 1970s, molecular imprinting has evolved as a powerful technique with a variety of applications, ranging from trace analysis and sample pre-concentration to molecularly imprinted sensing devices and online extraction systems. In this entry, the authors outline the principles of molecular imprinting and the main approaches toward synthesis of such materials and discuss their most common applications, including the use of imprinted polymers for the recognition of biological macromolecules, as potential alternative media for affinity chromatography stationary phases.

INTRODUCTION

Molecular imprinting, in a primitive form, was first presented by Polyakov in 1931 when he attributed the differences he observed in the pore structure of silica to the differences in size and shape of the solvent used, namely benzene, toluene, or xylene. Several years later, in 1949, Dickey prepared silica gels in the presence of different dyes that showed selectivity for the latter over similar compounds. Wulff and coworkers were the first to report molecular imprinting in organic polymers in 1972, introducing the so-called covalent technique. Finally, Mosbach and coworkers, in 1981, reported on a "host-guest" polymerization used for the imprinting of dyes, thus introducing the non-covalent approach. Since the foundations of molecular imprinting technology were laid, it has evolved as an elegant technique for the generation of synthetic media with predetermined selectivity, the latter being a major parameter in separation science. Optimization of a chromatographic separation is often based on the enhancement of the selectivity of the separation system for a given analyte. This optimization procedure can aim at: 1) mobile-phase composition; 2) stationary phase choice; and 3) simultaneous optimization of both mobile and stationary phases. The first approach was for years (and still remains, but to a lesser extent) the subject of extensive research and development. Recent years, however, have seen tremendous increase in the drive toward the optimization of the selectivity of the chromatographic stationary phase. Affinity chromatography utilizing immobilized antibodies, receptors, or other proteinaceous recognition elements is an important development in contemporary separation science.

Molecular imprinting is now established as a powerful technique for producing artificial receptors. The drive toward selective stationary phases is indicated by the more than 4500 published papers and 500 filed patents related to molecular imprinting, since the mid-1990s. The imprinting process is based on the production of a polymeric network in the presence of a template molecule. The latter is subsequently removed from the polymer, thus leaving an active site, a "cavity" exhibiting molecular recognition toward the template molecule. Such cavities are complementary to the template molecule in terms of stereochemistry, shape, and chemical interactions. When at a later stage, a sample containing the template is administered to the polymer, selective binding of the template molecule will occur (Fig. 1). Such polymers are called molecularly imprinted polymers (MIPs) and have been used in separations, binding assays, sensors, and catalysis.

MOLECULAR IMPRINTING—PRINCIPLES

The principal idea behind MIP synthesis is the generation of solution state complexes between the template ligand in hand and appropriate functional monomers, followed by subsequent "freezing" of these complexes by copolymerization of the above with an excess of a cross-linking monomer. These monomer–template complexes are stabilized by non-covalent interactions, reversible covalent interactions, or metal ion-mediated interactions. The types of interactions that are usually exploited in molecular imprinting are: 1) cleavable covalent bonds; 2) π–π interactions; 3) hydrogen bonds; 4) hydrophobic van der Waals interactions; 5) crown-ether/cyclodextrin type interactions; 6) metal–ligand

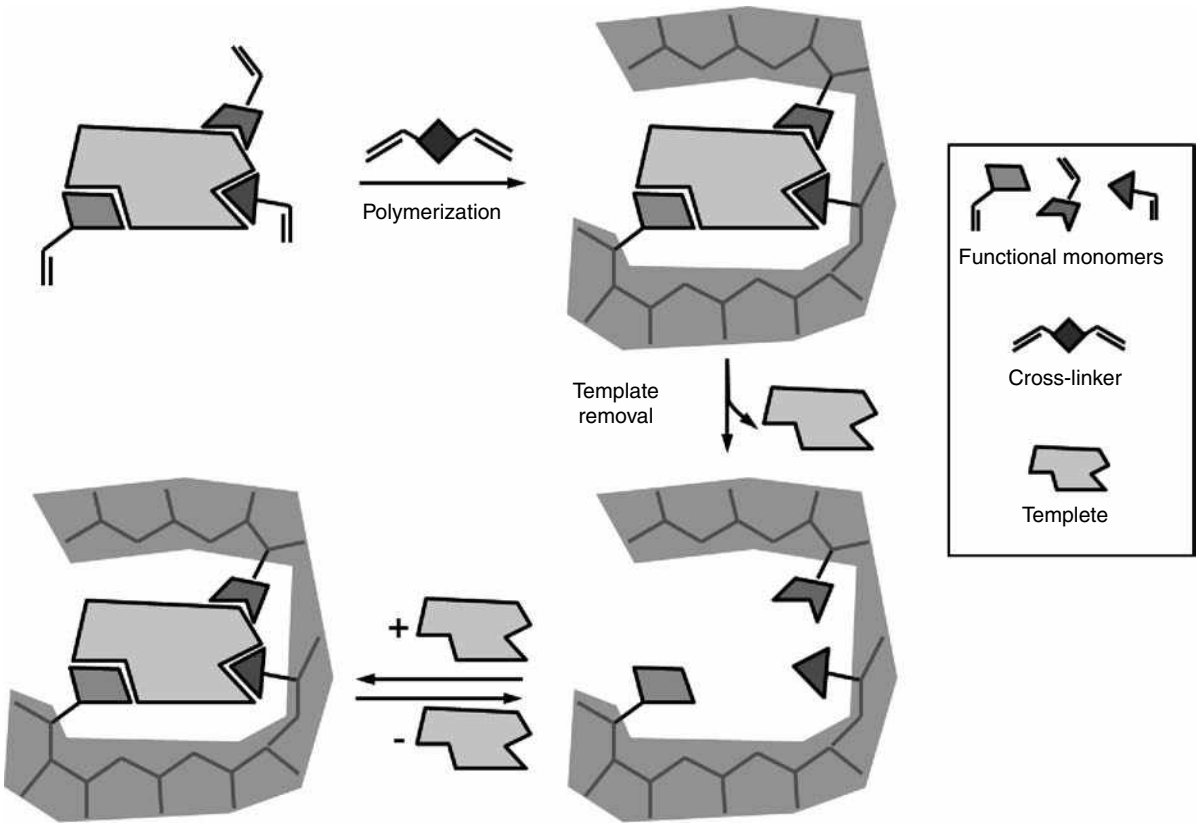

Fig. 1 Schematic representation of the imprinting process.

bonds; and 7) ionic forces. The imprinting effect is maximized when the template interacts with more than one binding site and when the interactions involved have directional or spatial determination.

NON-COVALENT APPROACH

The non-covalent or "self-assembly" approach was pioneered by K. Mosbach and coworkers and is now the most widely applied mode in molecular imprinting. The template is mixed with monomers and cross-linkers in an appropriate solvent. In this prepolymerization mixture, complexes of the template with the monomers are formed as a result of polar interactions such as hydrogen bonds, ionic interactions, van der Waals forces, etc. The strength of these interactions and the resulting complexes is of vital importance for the templating effect in the final polymer. Hence, "selective" interactions, such as the spatially determined hydrogen bonds, are preferred in contrast to more generic forces (hydrophobic interactions, van der Waals forces). Aprotic solvents allow polar interactions (hydrogen bonds) and are usually chosen, provided that they can dissolve the template molecule and the monomers. On the contrary, polar protic solvents suppress the formation of hydrogen bonds, whereas they promote hydrophobic and ionic interactions between the template and the monomers. Typical polymerization solvents are chloroform, acetonitrile, and tetrahydrofuran. Protic solvents like methanol have found limited use in specific cases. The role of the solvent is not only to provide the environment for the polymerization reaction, but also to produce a porous structure in the resulting polymer. Meso-/macroporous structure is necessary to ensure reasonable operating flow and pressure in liquid chromatographic applications and, most of all, good accessibility to the imprinted binding sites. Hence, the choice of the polymerization solvent determines the rigidity and the pore size of the MIP.

Monomers used for non-covalent molecular imprinting include methacrylic acid (MAA), 2- and 4-vinylpyridine (2- and 4-VP), trifluoromethacrylic acid (TFMAA), acrylamide and 2-hydroxyethyl methacrylate (HEMA). Ethyleneglycol dimethacrylate (EGDMA) is the most common cross-linker whereas divinylbenzene (DVB) and trimethylolpropane trimethacrylate (TRIM) have been used to a lesser extent. The cross-linker is added in excess concentrations (up to 80–90% of the molar ratio in the polymerization mixture), in order to obtain a rigid, highly dense polymeric network. This enables the imprinted sites to retain their shape and size and tolerate different environments, "resisting" shrinkage and swelling. Most researchers base their work on the above-mentioned monomers or combinations of them (cocktail of

monomers). In this approach, the formation of the template–monomer complex is expected to occur via selected functionalities of the corresponding molecules. Lately, the development of novel monomers specific for a given template has opened new ways in molecular imprinting. To achieve this, existing monomers are modified or totally new entities are prepared, aiming at a multipoint association with the template molecule. It is expected that such complexes will be stronger and more specific for the template molecule, thus the resulting MIP will exhibit higher affinity/avidity toward the template.

COVALENT AND SEMICOVALENT APPROACH

Covalent imprinting was first described in 1972 by G. Wulff and coworkers as a method of manufacturing enzyme analogue built polymers. This work is considered by many researchers as a major breakthrough, the actual initiation of molecular imprinting. In covalent imprinting, the template molecule is modified in order to incorporate a polymerizable functional group in it. Typically the template is bound to an appropriate monomer by labile covalent bonds. The monomers frequently used are 4-vinylphenylboronic acid and 4-vinylbenzylamine. During polymerization, the template is fixed in spatial arrangement within the polymer network. To recover the polymer, the labile bonds are cleaved, releasing the active binding sites.

The advantage of this technique is the predetermined stoichiometry between the template and the functional monomer. As a result covalent imprinting results in a high density of well-defined sites. Disadvantages of this approach is the synthetic effort that is required to come up with specific bonds that will tolerate the polymerization conditions and additionally can be easily cleaved in order to recover the template and free the active sites. Rebinding occurs by the formation of either covalent bonds or by formation of other types of interactions, as in the non-covalent approach. In the first case, an additional drawback is the slow kinetics of bond formation. The latter method of covalent imprinting with non-covalent rebinding, so-called semicovalent imprinting, is an ingenious hybrid technique that combines attractive features of the two modes. The template molecule is bound to the functional monomer via a sacrificing spacer (e.g., a carbonate ester). Following polymerization, the ester is cleaved with the loss of CO_2, leaving the functional monomer in appropriate position for interaction with the template.

SYNTHESIS OF MOLECULARLY IMPRINTED POLYMERS

After the template–monomer complexes have been formed in the prepolymerization solution, an azo initiator (e.g., azo-*N,N′*-bis-isobutyronitrile, AIBN) is added in the polymerization mixture. Free radical polymerization is initiated by heating at 40–60°C or photochemical homolysis by UV radiation (0–15°C). MIPs prepared at lower temperatures (0°C) by photopolymerization have been found to exhibit better molecular recognition due to the destabilizing effect of elevated temperatures to the monomer–template complexes.

Polymerization is allowed to take place for 10–24 hr. Next, the polymer is further processed in order to extract the template molecule and remove unreacted components from the polymer matrix. This step is of great importance for the successful future use of the MIP. Typical extraction solvents are mixtures of protic solvents with acids (e.g., methanol with 10% acetic acid). Such mixtures suppress polymer–template interactions and extract the template from the polymer core almost quantitatively. Soxhlet extraction, extensive washing, or alternative acid–base washing are the main experimental protocols used. Quantitative removal of the template is essential for two reasons: 1) the more template is removed, the higher the number of active sites revealed in the MIP and 2) it has been repeatedly reported that leakage or so-called bleeding of the remaining template from the MIP may occur. In such a case, even a minimal amount of template added as an artifact in a sample may interfere with the results of the analysis to a great extent. An elegant solution to this problem is the utilization of an analyte analogue, a "dummy template," during polymerization. By this approach even if leakage of the "dummy template" occurs, this will not interfere with the analysis, provided a separation step capable of separating the two analogue molecules is used.

Bulk polymerization is the dominant synthetic method in molecular imprinting. Polymerization occurs in sealed tubes resulting to a rigid highly cross-linked polymeric monolith exhibiting macroporous and mesoporous structure. Following template removal, the polymer is processed by grinding and sieving in order to reduce the size of the polymer particles. Grinding is performed manually by mortar and pestle or in a mechanical mill and results in irregularly shaped particles and a large quantity of fine particles ($<$20 μm). Extreme care should be taken during the removal of fine particles as they may severely hinder further analytical work by blocking the frits or tubing and thus building high pressure. Fines, however, may be used ideally for binding assays. Typically, MIP particles of 25–36 μm are used as a chromatographic material in high-performance liquid chromatography (HPLC) columns; 50–100 μm particles are used for solid-phase extraction media. Depending on the care taken during grinding and sieving about 50–60% of the produced MIPs are recovered for use as chromatographic material.

Alternative polymerization methods such as suspension polymerization, dispersion polymerization, and precipitation polymerization have been shown to produce spherical particles of a determined size; however, their use is limited.

Finally, the production of monolithic polymeric imprinted materials is a straightforward method of producing MIP rods inside a stainless-steel or a PEEK column and has drawn significant interest in the past few years.

MIPs AS CHROMATOGRAPHIC MEDIA

The use of MIPs as chromatographic stationary phases is their most studied application. This method is in fact the best way to rapidly and efficiently validate the performance of a developed MIP. To achieve this, the MIP is packed in an HPLC column and retention characteristics of the template and/or analogue molecules are collected in various selected mobile phases. From the collected data, useful parameters such as capacity factor, imprinting factor, and peak asymmetry are calculated and used to evaluate polymer affinity, cross-selectivity, and other features of the MIP.

Another attractive usage of MIPs is as chiral stationary phases (CSPs). Molecular imprinting offers a very efficient way of producing receptors against an enantiomer within a stationary phase. A major advantage of the use of MIPs is the predetermined selectivity. Hence, by preparing an MIP against an optically pure *R*-template, chiral separations of remarkable selectivity are easily achieved. The *R*-enantiomer will preferentially bind to the MIP and thus elute late, whereas the *S*-enantiomer will elute much earlier. Pharmaceuticals were the majority of the template molecules studied, given that the pharmaceutical industry's needs in chiral separations are still massive. MIP-based chiral separations of various types of drugs, peptides, protected amino acids, alkaloids, and other chiral compounds exhibited enantio-selectivities higher than conventional CSPs. "Enantio-polishing" is a useful application in that direction. In this approach, a synthetic product is assayed in an MIP-based CSP manufactured against an enantiomer. Optical impurities elute fast, leading to a purification of the desired enantiomer.

Despite these attractive features, MIP-based CSPs exhibit limitations, the dominant being the heterogeneity of the active binding sites. During the polymerization process active sites of high and lower affinity are both produced. High-affinity sites are produced where the best-defined interactions occur; sites of one-point interaction or other sites in the polymer network that exhibit non-selective interaction are responsible for lower affinity. This heterogeneity may result in peak asymmetry and tailing, and greatly decrease separation efficiency. As a result, multibinding site adsorption isotherms are typically observed for the template molecule. Another limitation of MIPs is capacity, which is in general lower than for other CSPs. Finally, the achievement of molecular recognition in an aqueous environment remains a challenge for MIP technologies. This challenge however, is to be exploited not only in chiral separations but also in sensing, catalysis, and any other application area. The use of tailored "designer" monomers specifically binding to the template in hand has shown significant promise to overcome these limitations.

Apart from HPLC, MIPs have also been used as media for capillary electrochromatography (CEC) and thin-layer chromatography (TLC). CEC is a hybrid separation technique that utilizes a stationary phase as in liquid chromatography and an electro-osmotic flow (EOF) as in capillary electrophoresis (CE). MIPs have been successfully employed as stationary phases of predetermined selectivity for CEC. In fact, high efficiency of CEC may potentially overcome the efficiency problems encountered with MIP chromatographic media. Mass transfer and kinetic limitations in MIP-based liquid chromatography could be addressed by the enhanced flow dynamics of CEC. A problem to be overcome is the introduction and immobilization of the polymer particles in packed capillaries. Usual techniques are the employment of a plug of polyacrylamide as a retaining frit or fusion of the silica capillary at both ends of the polymer bed to create a porous silica frit. Alternatively, in situ polymerization is used to produce monolithic MIP rods inside the column or coating of the inner walls of the capillary with thin-imprinted polymeric films. Additional obstacles include the known problems of capillary techniques: the need for increased sensitivity and column/polymer's capacity.

To conclude, MIP technology has to overcome important issues such as the need for a significant amount of template molecule, the production of particles of reproducible size and shape, and the tedious grinding–sieving process in order to provide a viable and pragmatic alternative for the large-scale production of materials to be widely used as stationary phases in either electrochromatography or conventional liquid chromatography. Alternative polymerization protocols, such as precipitation polymerization, which overcome the need for mechanical processing of the material postsynthesis, have recently been successfully employed in molecular imprinting protocols.

MIPs IN EXTRACTION AND SAMPLE PRETREATMENT

The use of MIPs as media for selective solid-phase extraction (SPE) is the application area closest to viable completion and product commercialization. This combination is abbreviated either as MI–SPE or as MIP–SPE and is the most successful application of MIPs so far. SPE is now an established technique for sample preparation due to its advantages as compared to other extraction methods: ease and simplicity, automation capability, reduced consumption of organic solvents, and choice between several stationary phases (C8, C18, CN, NH_2, Ph, ion exchange, mixed mode, etc.). These generic phases are the first choice for the development of a number of SPE protocols since

they offer high capacity, interaction with a wide range of analytes, and good reproducibility. The mechanism involved in extraction is the same that governs chromatographic analysis; thus it is rather easily conceived, controlled, and optimized. This conventional mechanism may also be considered as a drawback; therefore in many cases the need for alternative separation mechanisms of higher selectivity is evident.

Extraction mechanisms that take advantage of molecular recognition interactions (immuno-extraction and MI–SPE) are increasingly being developed to cover this need. Advantages of MIPs vs. immunoaffinity sorbents are the low cost and ease of preparation, the elimination of the biological receptor (and thus the long and tedious immunization experiments), the robustness and long life of the MIP, and the compatibility with elevated temperatures, organic solvents, and environments of increased ionic strength.

MI–SPE has been applied in either online or off-line mode for several analytes. In the first case, the MIP is packed as an HPLC precolumn. Column switching and pulsed elution modes are employed in online MI–SPE. An advantage of this design is the automation capability and the direct coupling to HPLC or other separation modes. Despite these advantages, the off-line mode is the most common practice and has been applied successfully to bio and environmental and food analysis.

There are some critical issues to be taken into consideration for the successful application of MI–SPE. Sample loading may occur in conditions of molecular recognition. In this case the entrapment of the analytes is selective and the following elution will provide an enriched sample to be further analyzed. Usually this selective adsorption/entrapment occurs in the polymerization solvent. It is theorized that by mimicking the conditions of polymerization, the assembly of the template–monomers complex will recur between the MIP and the template. Therefore it is expected and has also been found experimentally that molecular recognition and selective retention of the template is enhanced in the polymerization solvent.

A second strategy is the entrapment of the analytes by non-selective sorption on the MIP. Usually this is achieved by loading in aqueous environment and trapping by hydrophobic interactions. Next, a selective washing step removes unwanted matrix compounds from the SPE cartridge, whereas it facilitates selective binding of the analyte on the MIP. Finally, a selective desorption/elution solvent step obstructs hydrogen bonds or other such specific interactions and recovers the analyte. This mode employs additional extraction steps, but offers the advantage of straightforward application of aqueous samples (biofluids or environmental samples). The two modes of analyte trapping mentioned above could be easily understood by chromatographers as binding in the two chromatographic modes: normal phase for selective binding and reversed phase for non-selective binding–selective desorption. Fig. 2 depicts the operation principles of off-line MIP–SPE.

MIPs IN SENSORS AND BINDING ASSAYS

MIPs are ideal media to be used in sensing devices. Typically, sensors include a substrate-selective element (a receptor or an enzyme) immobilized on an appropriate surface (a membrane or an electrode). Binding of a ligand causes a signal, which is translated by an appropriate transducer to a quantitative response. MIPs provide inherent molecular recognition properties with no need for tedious chemical modifications. Therefore it is not surprising that various sensors have been developed utilizing MIPs as the recognition element; quartz crystal microbalance, acoustic, piezoelectric odor, luminescent, fiber optics, electrochemical, conductometric, and surface plasmon resonance sensors have been used in the analysis of a diversifying range of analytes: polyaromatic hydrocarbons, propranolol, nitrate, pesticides, nerve agents, caffeine, nucleotides, fluorescent-labeled amino acids, chloramphenicol, cholesterol, and many others. The methods have been applied to the analysis of different samples and matrices (biological, environmental, and so forth). Molecular imprinting may prove a smooth way toward the effective and straightforward production of sensors. Virtually any low molecular mass compound can be imprinted. Lately, larger entities such as proteins, bacteria, and living cells were targeted by MIP-based sensors, increasing dramatically the applicability and prospects of MIP technologies.

MIPs have also been used alternatively to biological receptors in competitive binding assays. The assay principle is the same as in known biological assays such as radioimmunoassay (RIA) or enzyme-linked immunosorbent assay (ELISA), but instead of antibodies MIPs are utilized. The method is often called molecularly imprinted assay (MIA). Typically, in MIA methods a marker

molecule (a labeled analyte analogue) is incubated together with the sample and the MIPs. Analyte and marker molecules compete for the binding sites of the polymer. Provided that the number of polymer's binding sites is limited and within an optimum range of the assay, the amount of marker bound on the polymer will depend on the amount of analyte in the sample. Hence, in samples rich in analyte molecules the marker will not bind in the polymer. In contrast, in samples with no or minimal quantities of analyte, the lot of the marker molecule will bind on the MIP. MIA protocols have been developed so far mostly in heterogeneous format, meaning that a separation step follows in order to separate the MIP particles from the sample. Marker molecules are often radiolabeled, but lately fluorescence tagging tends to substitute radioassays.

The advantages of using MIPs instead of antibodies in binding assays are the same attractive features that drive the utilization of MIPs as affinity chromatographic media: ease of preparation, lower cost, tolerance to extreme chemical and thermal conditions, no need for animal immunization, and long shelf life. For example, MIA protocols employ organic solvents offering an attractive alternative to conventional immunoassays. Additionally, MIPs have been found to provide affinity/avidity and cross-reactivity comparable to antibodies.

IMPRINTING LARGER BIOMOLECULES

Although imprinting of low-molecular-weight compounds has evolved to a significant extent with great achievements as discussed so far, imprinting of larger molecules, such as biological macromolecules, has remained underdeveloped. This is mainly due to the accessibility limitation of conventional MIP formulations. Recent years have seen a significant drive to overcome this limitation by means of novel ingenious approaches, most important of which are surface and epitope imprinting. In the first case, the macromolecule of interest, usually a protein, is attached reversibly to a surface that will not compromise its integrity and conformation, and an MIP is synthesized above the protein layer. Removal of the binding surface and the template results in an imprinted surface with cavities complementary to the protein of interest (Fig. 3). However, this approach is characterized by low selectivity and high cross-reactivity, due to the variety of different interactions between the protein and the functional monomer, and low capacity.

Hence, building on this approach, part of the protein of interest, an epitope, has been surface imprinted, instead of the whole, and the resulting binding sites were successfully used to capture the whole protein by recognition of the imprinted part (Fig. 4). In both cases, silica beads, membrane pores, or nanowire surfaces have been used as sacrificial supports and were easily removed by dissolution after polymerization occurred.

CONCLUDING REMARKS

Molecular imprinting technologies have found a niche in separation science. MIPs offer a good alternative to proteinaceous receptors and have been successfully used in affinity-based separations. Furthermore, the polymeric nature of the MIPs bears attractive features for applications that could not be achieved by antibodies or enzymes: gas chromatography, solid phase microextraction, and so forth. The amount of fundamental research and application labor that has been invested in MIP technologies combined with the emergence of a number of spin-off companies developing commercial products has led to the recent appearance of MIPs in chemical catalogs available for purchase.

The number of research groups working in the field is expanding; thus significant advances are made and new targets are aimed at. Imprinting in aqueous environment, imprinting of large biomolecules, imprinting in different formats, and implementation of existing recognition elements (e.g., cyclodextrins) are some of the areas where

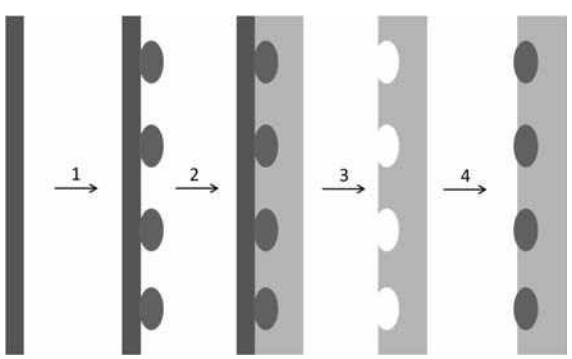

Fig. 3 Schematic representation of surface imprinting of a protein: 1, protein immobilization on the surface; 2, surface polymerization; 3, removal of initial surface and template; 4, protein rebinding.

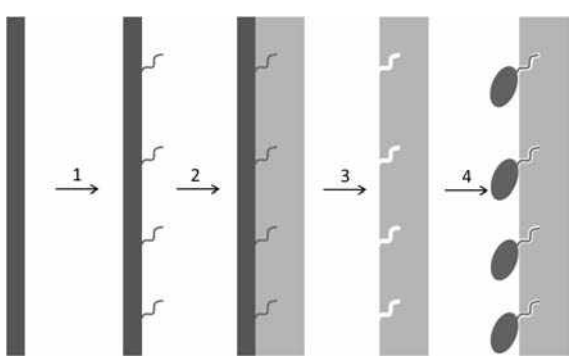

Fig. 4 Schematic representation of epitope imprinting: 1, epitope attachment on the surface; 2, surface imprinting of the epitope; 3, removal of the initial surface and template; 4, binding of the epitope-containing protein.

striking developments are expected. Parallel to these developments, antibody/receptor technologies spread out and become more robust. Techniques like solid phase peptide synthesis, recombinant protein technologies, and antibody engineering expand continuously. Taking into account the rapid growth in biotechnology and immunology, a central role of molecular recognition technologies is seen in many scientific disciplines: analytical chemistry, medicinal chemistry, drug and gene delivery, synthetic catalysis, and proteome research. In that direction MIPs could serve as a powerful tool complementary and/or alternative to biological receptors.

Affinity Chromatography: Spacer Groups

Terry M. Phillips
Ultramicro Analytical Immunochemistry Resource (UAIR), DBEPS, ORS, OD, National Institutes of Health, Bethesda, Maryland, U.S.A.

INTRODUCTION

A major problem arising in both affinity and immunoaffinity chromatography is the inefficiency of analyte recovery as a result of steric hindrance between the ligand (capture molecule) support and the analyte (molecule to be isolated), resulting in reduced or no recovery. This situation commonly occurs when low molecular weight ligands, such as pharmaceutical drugs, enzyme substrates, or receptor-binding ligands, are employed as the immobilized capture molecules. An accepted approach to rectify this situation is the employment of an accessory molecule or spacer arm to extend the capture molecule or ligand from the support surface.

USE OF SPACER ARMS

As a result of the popularity of affinity and immunoaffinity separation procedures, supports incorporating suitable spacer arms are commercially available (Table 1). The addition of even a short (4–6 carbon atoms) spacer arm will often ensure adequate clearance of the ligand from the support surface. This gives the analyte (molecule to be isolated) adequate access to the immobilized ligand.

A spacer molecule should be employed in cases where ligand attachment lies in close proximity to the analyte-binding site and interferes with analyte–ligand binding. In such cases, the length of the spacer arm is crucial and must be determined empirically, with six to eight carbon atoms often being the most successful. The spacer should be hydrophilic and not bind proteins nonspecifically, either because of its hydrophobicity or its charge. Some activation chemistries will automatically insert a suitable spacer between the support and the ligand, e.g., bis-oxirane, although the simplest technique for introducing a spacer arm is to directly derivatize a long carbon chain onto the surface itself. Many supports can be modified to accept a suitable carbon-based spacer arm and a convenient approach is to condense the spacer onto the support surface using carbodiimides. During the coupling stage, the carbodiimide reacts with carboxyl groups to form *O*-cylisourea at pH 4–5. The activated carboxyl group then condenses with an amino group on the support surface to form a peptide-bond-generating urea, a by-product that has to be removed from the reaction mixture. Two water-soluble carbodiimides are commercially available: 1-ethyl-3-(3-ethylamino-propyl) carbodiimide (EDC) or 1-cyclohexyl-3-(2-morpholinoethyl) carbodiimide metho-*p*-toluene sulfonate (CMC). Both of these agents have been successfully used to couple spacer arms to any support that has free amino groups.

Spacer arms can be attached directly to the support surface by linking them to reactive side chains present on the support itself, the ligand being attached to a reactive group positioned at the end of the spacer farthest away from the support surface. Pimplikar and Reithmeier[1] described a technique for the affinity isolation of a specific protein from solubilized erythrocyte ghosts using hydrophilic spacer arms of four or greater atoms in length. The support was prepared by reacting 4-acetamido-4′-*iso*-thiocyanostilbene-2,2′-disulfonate with Affi-Gel 102. The incorporation of the spacer arm was found to be essential for protein binding, removing steric hindrance of the support and allowing the protein to bind via its stilbene disulfonate-binding site. In a similar manner, Ivanov et al.[2] covalently immobilized the small blood group B antigenic molecule, trisaccharide-beta-aminopropyl glycoside, to poly-*N*-(2-hydroxyethyl) acrylamide-modified porous glass. This affinity support was then used to isolate anti-blood group B monoclonal antibodies. The incorporation of a short (4–6 atom) spacer arm was found to be essential in order to project the affinity ligand away from the support surface.

Affinity Chromatography: Weak

David S. Hage
Department of Chemistry, University of Nebraska-Lincoln, Lincoln, Nebraska, U.S.A.

Abstract
The general principles of weak affinity chromatography (WAC) are discussed in this entry. WAC is a subset of affinity chromatography that makes use of weak interactions for the separation or analysis of chemicals. These conditions create a situation in which isocratic elution can be used to pass an analyte through the column. The theory of WAC is discussed and examples are given of ligands that can be used in this technique. Examples of applications that have made use of WAC are also presented.

INTRODUCTION

Weak affinity chromatography (WAC) is a subset of affinity chromatography that makes use of weak interactions for the separation or analysis of chemicals.[1–4] This method is also referred to as *dynamic affinity chromatography*. Like traditional affinity chromatography, this is a liquid chromatographic technique that uses a selective binding agent as the stationary phase. This agent, which is known as the affinity ligand, might be a biological substance like a serum protein, a lectin, a low affinity antibody, or a carbohydrate.[1–10] The affinity ligand might also be a substance that mimics a biological system or uses specific interactions for retention, such as is found for certain dyes, biomimetic ligands, and boronates.[11–16]

Traditional affinity chromatography generally makes use of the on-off mode of elution. In this mode, a ligand with strong binding for the solute of interest is placed within the column.[4] A sample containing this solute is then injected onto this column in the presence of a mobile phase, known as the application buffer, which has a pH, ionic strength, and solvent composition that provide for strong and essentially irreversible solute–ligand binding. After non-retained sample components in this buffer have been washed from the column, a second solvent is applied for elution of the retained compounds. This second solvent is known as the elution buffer and acts to dissociate the retained substances from the affinity ligand by either disrupting their interactions with this stationary phase or displacing them with another chemical that binds to the ligand or analyte. This is usually performed with a step gradient, but other types of gradient elution schemes can also be used.

A different elution approach is used in WAC. In this case, a ligand is used within the column that has only weak-to-moderate binding to the target solutes. This approach involves the use of a system that has an association equilibrium constant of 10^5–10^6 M^{-1} or lower, as well as relatively fast association and disassociation kinetics. Under these conditions, a solute can take part in many binding and dissociation events with the ligand as it passes through the column. This also makes it possible for a solute to elute in the presence of the original application buffer, eliminating the need for a separate elution buffer. This process is usually conducted under isocratic conditions rather than with gradient elution.[1–4]

THEORY OF WAC

For a simple 1:1 interaction between an injected analyte (A) and an immobilized affinity ligand (L), the following equations can be used to describe the binding that occurs between A and L within an affinity column:

$$A + L \overset{K_a}{\rightleftharpoons} A - L \tag{1}$$

$$K_a = \frac{k_a}{k_d} = \frac{\{A - L\}}{[A]\{L\}} \tag{2}$$

In this equation, K_a is the association equilibrium constant for the binding of A with L, k_a is the association rate constant for this reaction, and k_d is the corresponding dissociation rate constant. The terms [A], {L}, and {A–L} represent the concentration of the analyte in a solution at equilibrium and the surface concentrations of the ligand and analyte–ligand complex under these same conditions.[4]

The reaction between the analyte and the ligand in this system can also be related to the retention of A on an affinity column that is operated under linear elution conditions (i.e., when a small amount of analyte is injected).

$$k = \frac{(t_R - t_M)}{t_M} \quad (3)$$

In this relationship, t_R is the average retention time measured for the analyte in the mobile phase and t_M is the void time of the system (i.e., the observed elution time for a totally non-retained solute).

The retention factor for an analyte can also be related to its association equilibrium constant with the immobilized ligand in the affinity column. This is shown in Eq. 4,

$$k = \frac{K_a\, m_L}{V_M} \quad (4)$$

where m_L is the moles of active ligand in column, V_M is the column void volume, and the combined term m_L/V_M is the phase ratio (i.e., the relative amount of stationary phase vs. mobile phase in the column). According to Eq. 4, the retention factor for an analyte on an affinity column will depend on two factors. The first of these is the strength of analyte–ligand binding in the mobile phase, as represented by the association equilibrium constant. The second is the relative concentration of active ligand within the column, as represented by the binding capacity or phase ratio (m_L/V_M). An increase in either or these two factors will cause a proportional increase in a solute's retention factor, as well as in its retention time and retention volume.[4,17]

Many biological ligands have moderate-to-large equilibrium constants for their target solutes under physiological conditions. This gives these ligands strong retention and long elution times when they are used in affinity columns under normal sample application conditions. For instance, a typical polyclonal antibody with an association equilibrium constant of 10^8–$10^{10}\ M^{-1}$ for a target compound will give a retention factor of 100–10,000 when this antibody is present at a concentration of $10^{-6}\ M$ in an affinity column. This level of retention is much higher than the optimum range of $k = 1$–20 that should ideally be present for work under isocratic conditions. This is the reason why step changes in the mobile phase or gradients are usually required for elution with such columns. However, with a weaker ligand it is possible to use isocratic elution. As an example, a ligand with an association constant of $10^6\ M^{-1}$ for an analyte will give a retention factor of $k = 1$ when this ligand is present at an effective concentration of $10^{-6}\ M$ in an affinity column, or $k = 10$ when the ligand is present at a concentration of $10^{-5}\ M$.[4]

APPLICATIONS OF WAC

All binding agents used in affinity chromatography can be placed into one of two categories. These are high-specificity ligands and general, or group-specific, ligands. High-specificity ligands bind to only one or a few closely related molecules. These tend to be biological compounds (e.g., antibodies) with large association equilibrium constants and high retention for their solutes. As a result, they are usually not used in WAC because they require step or gradient elution to dissociate their adsorbed solutes. It is possible for certain types of antibodies to be used as ligands in WAC if they have relatively weak binding for a target.[1–3,17–19] For instance, monoclonal antibodies with association equilibrium constants of 10^2–$10^4\ M^{-1}$ for carbohydrates have been used in several studies examining the theory and behavior of WAC (see Fig. 1).

General ligands are agents that bind to a family or class of related molecules. These ligands can be of either biological or non-biological origin. Examples include lectins, triazine dyes, serum proteins, boronates, and cyclodextrins (see Fig. 2). These ligands tend to have lower association constants than high-specificity ligands, making them more useful for work in WAC.[5–16] There are, however, some exceptions to this. Two examples of exceptions are protein A and protein G, which are general ligands commonly used in antibody isolation and which have association equilibrium constants of 10^7–$10^8\ M^{-1}$ for some types of antibodies.[5]

Two other types of biological ligands that can be used in WAC are enzymes and lectins.[5,9] As an example, the enzyme α-chymotrypsin has weak interactions with many of its inhibitors, which has allowed the separation of these inhibitors under isocratic conditions on an immobilized α-chymotrypsin column. Lectins are non-immune system proteins that bind carbohydrates with low-to-moderate association constants, allowing these agents to be used

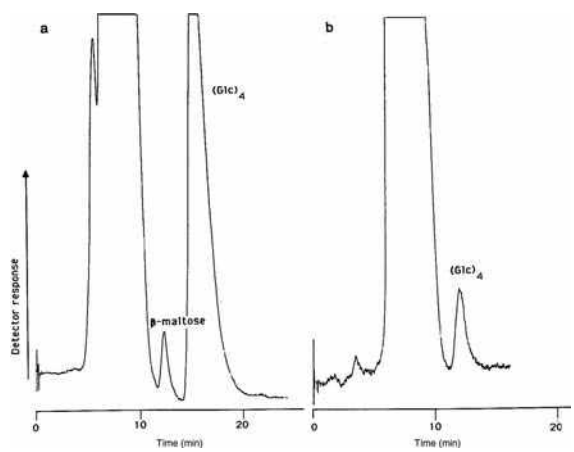

Fig. 1 Analysis of the oligosaccharide $(Glc)_4$ in (a) human urine and (b) serum by weak affinity chromatography. The affinity column was 5 × 100 mm I.D. and contained immobilized monoclonal antibodies against $(Glc)_4$. Elution was carried out under isocratic conditions at a flow rate of 0.2 ml/min using a pH 7.5, 0.02 *M* phosphate buffer that contained 0.1 *M* sodium sulfate.

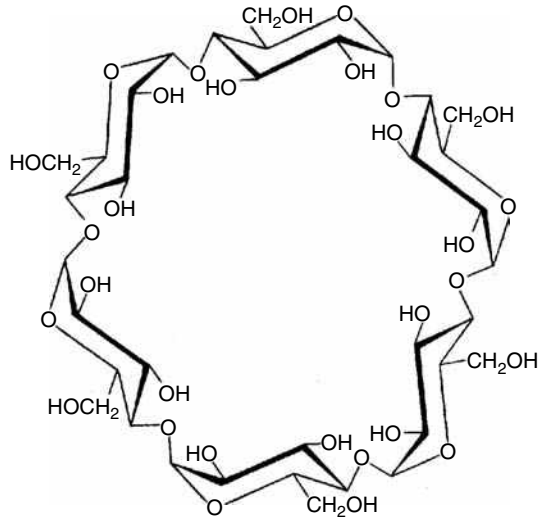

Fig. 2 Structure of α-cyclodextrin.

as affinity ligands under isocratic conditions. Wheat germ agglutinin has been used in an affinity column under such conditions for separating *N*-acetyl derivatives of mono-, di-, tri-, and tetrasaccharides.[7] Lectins have also been used as ligands for WAC coupled with mass spectrometry in proteomic studies examining protein modifications that involve O-linked *N*-acetyloglucosamine residues.[20]

Additional biological ligands that have been used in weak affinity separations include human serum albumin, bovine serum albumin, α_1-acid glycoprotein, and β-cyclodextrin.[5,9,10] These ligands have been particularly useful as chiral stationary phases for the separation of drugs and other agents (Fig. 3).[9] It is common with these immobilized ligands to use a mobile phase that contains a small amount of an organic modifier or a displacing agent to reduce analyte retention times and improve peak shapes. These ligands can also be used under physiological conditions as tools for studying the interactions with such binding agents in the body.

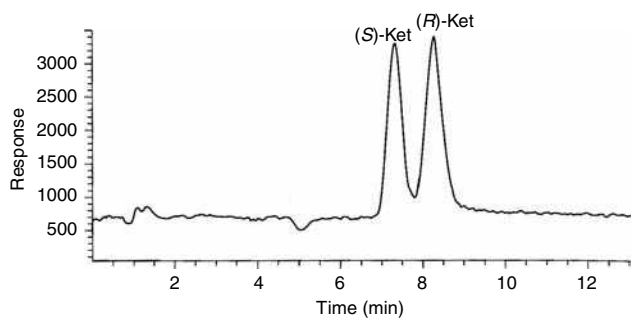

Fig. 3 Separation and determination of the enantiomers of ketamine in human plasma by using weak affinity chromatography and a column containing α_1-acid glycoprotein as the stationary phase with detection by mass spectrometry.
Source: From Affinity-based chiral stationary phases, in *Handbook of Affinity Chromatography*.[9]

Several non-biological ligands can be utilized in WAC, such as those used in *dye–ligand affinity chromatography*.[11–13] In this method, a synthetic triazine or a triphenylmethane dye acts as the immobilized ligand. *Biomimetic affinity chromatography* is a closely related method that can also be used in WAC. This uses a ligand that has been designed or selected to mimic the binding of a substance to a natural ligand. Synthetic dyes produced by combinatorial techniques might be utilized for this purpose, as well as binding agents that have been created through phage display or ribosome libraries.[11]

Boronic acid and its derivatives are another class of non-biological ligands that have weak binding and are often used under isocratic conditions. These are used in the method of *boronate affinity chromatography*, which makes use of the ability of such ligands to form covalent bonds with compounds that contain *cis*-diol groups. Such a property has made boronate ligands useful for the purification and analysis of many compounds that contain sugar residues, such as polysaccharides, glycoproteins, ribonucleic acids, and catecholamines.[14–16]

CONCLUSION

WAC involves the use of ligands in affinity chromatography that have relatively weak interactions with their target compounds. This feature allows the affinity column to be used under isocratic conditions. Ligands that have been used in WAC methods have included biological agents such as monoclonal antibodies, serum proteins, lectins, and carbohydrates such as cyclodextrins.[1–3,5–16,18–20] Additional binding agents such as dyes, biomimetic ligands, and boronates have also been used for this purpose.[11–16] This range of ligands has made WAC useful in applications that have ranged from chiral separations to proteomics and the study of solute–protein interactions in the body.[1–3,5–16,20]

Alcoholic Beverages: GC Analysis

Fernando M. Lanças
Institute of Chemistry of São Carlos (USP), University of São Paulo, São Carlos, Brazil

M. de Moraes
Chromatography Laboratory, University of São Paulo, São Carlos, Brazil

INTRODUCTION

Alcoholic beverages have been consumed by a significant range of worldwide population since the beginning of civilization until the present time. Therefore, there should be a great interest on consumption of beverages quality and, consequently, the usage of a suitable analytical technique to verify and control this desirable quality.

Alcoholic beverages are classified, in a general way, in fermented beverages (such as beer, wine, sake, etc.) and distilled ones (vodka, whisky, aguardente, tequila, cognac, liquors, etc.). The main volatile substances present in most alcoholic beverages belongs to the following chemical classes: alcohols (including ethanol, methanol, isobutanol, 3-methyl butan-2-ol, etc.), esters (such as ethyl acetate, methyl acetate, ethyl isobutyrate, isoamyl acetate, etc.), aldehydes (propanal, isobutanal, acetal, furfural, etc.), acids (acetic acid, propionic acid, butyric acid, etc.), and ketones (acetone, diacetyl, etc.).

Some of the substances are of greater concern than the others due to its relative quantities or to its flavored characteristic.[1] As an example, ethanol is the major compound in the group of alcohols being responsible for the formation of various other substances, such as acetaldehyde, resulting from ethanol oxidation, and it is the most abundant of the carbonylic compounds in distilled beverages. For the same reason, acetic acid is the major compound within its group, the carboxylic acids. Fusel alcohols (e.g., 1-propanol and 3-methyl butan-2-ol) as well as ethanol are also important substances in the alcohols group contributing to the flavor of distilled beverages because their odor is very distinctive and characteristic. There is an enormous variety of substances in small concentrations belonging to the esters group. Even so, ethyl acetate corresponds to more than 50% of the esters within this group.

These compounds are responsible to important characteristics as smell and taste, in which the large fraction of these substances originates from fermentation or during beverages storage.[1]

Because gas chromatography (GC) is an analytical technique in which separation and identification of volatile compounds occurs, it might be considered the best technique for this kind of sample.[2]

ANALYSIS BY GC

Analysis of alcoholic beverages by GC have as their main objectives to investigate flavoring compounds and contaminants which might be intentional or occasional. Whereas the former ones (the flavors) are analyzed to control their favorable characteristics to the beverage, the adulterants have to be controlled due to their deleterious contribution. Adulteration includes the addition of certain compounds to enhance a desirable flavor. Because these compounds are usually added as a racemic mixture, their presence can be verified using a suitable chiral column for enantiomer separation.[3] On the other hand, occasional contaminants are substances originating in small quantities during beverage production and might be carcinogenic. The main source might be raw materials like grape, sugar-cane, and so forth contaminated with pesticides[4] or as a result of the fermentation process itself.[5,6]

Comments in each major part of the GC instrumentation as used for beverage analysis are presented.

SAMPLE INTRODUCTION

Distilled Beverages

Generally, samples are injected in the chromatographic system without any dilution or pretreatment step, using the split mode (i.e., with sample division), which is suitable for the analysis of the major compounds in beverages.When the objective of analysis is the determination of compounds present in small quantities (μg/L), some extraction and/or concentration step is necessary, followed by the sample injection in the splitless mode (without sample division). This last sample introduction mode is usually combined with extraction techniques such as liquid–liquid extraction (LLE), solid-phase extraction (SPE),[4] and solid-phase microextraction (SPME).[7,8]

Fermented Beverages

Sample introduction is basically the same compared to the distilled one. Nevertheless, in many complex samples

(i.e., some kind of wines), it is not advisable to inject them into the chromatograph without a pretreatment step.

Recently, SPME has provided many improvements as the cleanup step of complex samples, particularly for the analysis of volatile compounds by *headspace* techniques.[8] SPME is a solventless extraction and concentration technique which has advantages as a simple and economic technique that reduces health hazards and environmental issues.

COLUMNS

Until 1960, all commercial chromatographic columns were packed in wide-bore tubing and separations had low resolution and low efficiency, taking a long time for a run to be completed. Since then, there have been significant improvements with the introduction of wall-coated open tubular (WCOT) columns, whose inner diameter was smaller than the packed ones are coated with a thin film of the liquid phase.[9]

When capillary fused-silica columns arose, a large number of separations of complex samples have obtained success as a result of the higher number of plates (about 30 times over the packed columns in average).

Despite the efficient separations, it has been noticed that some low-boiling compounds of alcoholic beverages coeluted because of the use of a polar stationary phase. This column separates mainly based on the boiling temperatures of chemical substances, but separation becomes very difficult if there are some compounds with similar boiling temperatures. A polar stationary phase like poly(ethylene glycol) (PEG) is a better choice for this sort of problem because these separations are based on compound structures. In all cases, cross-linked or immobilized phases are recommended because they are more thermolabile and also resistant to most solvents. This is particularly important when splitless injection is used in combination with PEG-type phases because otherwise a severe column bleeding might be observed after ~220°C.

Detection Systems

The flame ionization detector (FID) is one of the most commonly used detectors in beverage analysis by GC, as it is suitable to most groups of compounds investigated in alcoholic beverages.[9] This occurs because almost all compounds of interest in such samples are able to burn in the flame, forming ions and producing a potential difference measured by a collector electrode.

In trace analysis of contaminant substances, one can use specific detectors for certain compounds, such as a nitrogen–phosphorus detector (NPD), thus gaining detection ability for nitrogenated and phosphorylated compounds; the electron-capture detector (ECD) shows excellent

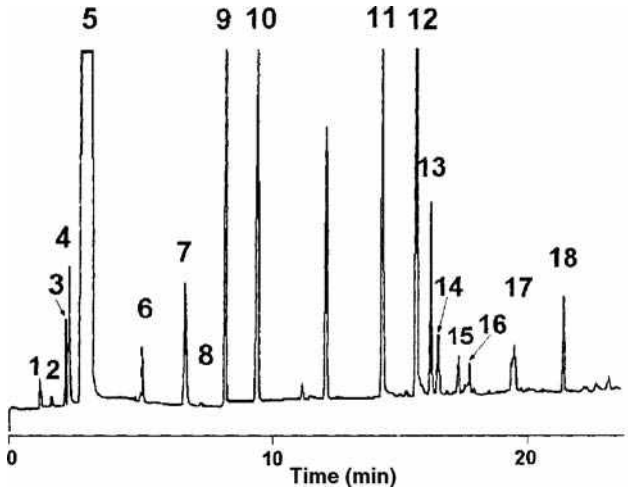

Fig. 1 GC analysis of white wine sample by fused-silica column poly(ethylene glycol) type (15.00 m × 0.53 mm × 1.00 μm). Chromatographic conditions: carrier gas: hydrogen (3.6 ml/min); column temperature: 40°C (4 min) → 8°C/min → 270°C; injector port temperature: 250°C; detector temperature: 300°C. Identity of the selected peaks: (1) acetaldehyde, (2) acetone, (3) ethyl acetate, (4) ethanol, (5) ethanol, (6) propanol, (7) isoamyl acetate, (8) *n*-butanol, (9) heptanone, (10) isoamyl alcohol, (11) acetic acid, (12) propionic acid, (13) isobutyric acid, (14) 2,3 butanediol, (15) 1,2 propanediol, (16) butyric acid, (17) isovaleric acid, (18) valeric acid.

performance for chlorinated substances and the flame photometric detector (FPD) is the most widely used for sulfur-containing compounds.

GC–mass spectrometry (MS) combination has become one of the most important coupling in analytical chemistry used for the confirmation of results obtained by other detectors.[9] This technique is based on the fragmentation of the molecules that arrives into the detector. Ion formation occurs and they are separated by the mass/charge (*m/z*) ratio generally detected by a electron multiplier. Quantitative analysis can be realized through the single-ion monitoring (SIM) mode, where some characteristic ions are selected and monitored increasing the detection sensibility and selectivity. Another qualitative technique, GC–sniffing[10] is very much used for flavor analysis, despite discordance among researchers. In this case, the volatile substances from a extract are separated by GC, and as they leave the equipment through a specially designed orifice, a trained analyst is able to smell some of the substances and tentatively identify them (Fig. 1).

More than 500 compounds have been found in concentrated flavor extracts in distilled beverages.[1] For this reason, there is an obvious necessity to find and optimize analytical techniques capable of investigating and to keep trading control of the alcoholic beverages. Among them, GC has been far from any other preferred tool for the analysis of alcoholic beverages.

Alkaloids: CCC Separation

Fuquan Yang
Yoichiro Ito
National Heart, Lung, and Blood Institute (NHLBI), National Institutes of Health (NIH), Bethesda, Maryland, U.S.A.

INTRODUCTION

Alkaloids are an important class of compounds that have pharmacological effects on various tissues and organs of humans and other animal species. More than 16,000 are known and most are derived from higher plants. Alkaloids have also been isolated from microorganisms, from marine organisms such as algae, dinoflagellates, and puffer fish, as well as from terrestrial animals, such as insects, salamanders, and toads.

Pelletier[1] defines an alkaloid as "a cyclic compound containing nitrogen in a negative oxidation state which is of limited distribution in living organisms." This definition includes both alkaloids with nitrogen as part of a heterocyclic system and the many exceptions with extracyclic bound nitrogen. From the viewpoint of analytical chemistry, the most important trait of alkaloids is their basicity, arising from a heterocyclic tertiary nitrogen atom. Many alkaloids are complex components which are biosynthetically derived from various amino acids, such as phenylalanine, tyrosine, tryptophan, ornithine, and lysine. The biogenesis of alkaloids is used for their classification, as this is directly linked with their molecular skeleton, e.g., the two largest groups are indole alkaloids and isoquinoline alkaloids. Other important groups are tropane alkaloids, pyridine, and pyrrolizidine alkaloids. In the past 10 years, there has been an increasing interest in the isolation and determination of alkaloids in plant materials, in pharmaceutical products, and in other samples of biological interest. Currently, much work is being carried out to discover new alkaloid molecules for different applications, such as new antiviral and antitumor treatments. So the separation and analysis of alkaloids are of great importance.[2,3] But the problem is that extensive tailing and irreversible adsorption may occur due to the interaction between the basic alkaloids and acidic silanol groups when alkaloids are separated by conventional column chromatography with silica gel or chemically bonded C_{18} on silica as the stationary phase.

OVERVIEW

Countercurrent chromatography (CCC), as a support-free liquid–liquid partition chromatographic separation technique, eliminates various complications such as irreversible adsorption loss, denaturation of sample, tailing of solute peaks, contamination, etc. that sometimes arise from the interaction between solute molecules and the solid support matrix present in most other chromatographic methods. Countercurrent chromatography utilizes an immiscible two-phase solvent system, one phase as the stationary phase and the other as the mobile phase. The chromatographic process in CCC is based on the partition of a solute between the stationary and mobile phases. The partition coefficient (K), being one of the most important parameter in CCC, is defined as the ratio of the concentration of a solute in the stationary phase (C_s) to that in the mobile phase (C_m). In the past, various CCC systems, such as droplet CCC, rotation locular CCC, and centrifugal partition chromatography, have been used for the final or partial separation of alkaloids from a crude sample. The high-speed CCC (HSCCC) technique developed in the early 1980s[4] improved in both the partition efficiency and separation speed, and has been successfully applied to the separation of alkaloids.

pH-Zone-refining CCC was developed for the large-scale separation of ionizable compounds, including alkaloids and organic acids in the mid-1990s by Ito.[5,6] It uses a retainer base (or acid) in the stationary phase to retain the solutes in the column and an eluter acid (or base) to elute the solutes according to their pK_a values and hydrophobicities, and produces a succession of highly concentrated rectangular solute peaks with minimum overlap while impurities are concentrated at the peak boundaries. This technique has been successfully used for large-scale separation of alkaloids.

SEPARATION OF ALKALOIDS BY STANDARD COUNTERCURRENT CHROMATOGRAPHY

The standard CCC separation is solely based on the difference in the partition coefficients of solutes between the two phases of a solvent system. Most alkaloids have basic properties with pK_a values ranging from 6 to 12, but usually 7 to 9. Although the free base is soluble only in organic solvents, protonation of the nitrogen in the free base usually results in a water-soluble compound. This behavior serves as the basis for the selective extraction or isolation of alkaloids by liquid–liquid partitioning

processes. On the other hand, quaternary alkaloids are poorly soluble in organic solvents, but they are soluble in water, regardless of its pH.

Generally, a systematic search for the two-phase solvent systems for CCC is focused on the hydrophobicity of the solvent system for providing a proper range of partition coefficients of solutes. For the separation of ionizable compounds such as alkaloids, however, an additional adjustment is required with respect to the pH and ionic strength of the solvent system.

Halogen-containing organic solvents, such as chloroform and dichloromethane, have been widely used in alkaloid separation because of their relatively strong proton-donor character. The chloroform-containing, two-phase solvent systems (chloroform–aqueous phosphate or citrated buffer and chloroform–methanol–dilute inorganic acid) have been widely used for the separation of alkaloids by CCC (Table 1).

Cai et al. first used a chloroform–0.07 *M* sodium phosphate buffer (pH 6.4–6.5) solvent system for the separation of matrine and oxymatrine from *Sophora flavescens*, atropine, scopolamine, and hyoscyamine from *Datura mete* L. by HSCCC.[7] Cooper et al. successfully used chloroform–0.2 *M* potassium phosphate buffer with an

optimum pH value of each at 5.0, 5.6, 6.0, and 7.4 for the separation of pyrrolizidine alkaloids from various sources of *Senecio douglasii* var. *longilobus*, *Trichodesma incanum*, *Symphytum* spp. and *Amsinckia tessellata*, respectively.[8]

A two-phase solvent system composed of chloroform–methanol–dilute inorganic acid has been used for the separation of a variety of alkaloids including isoquinoline alkaloids, naphthyl-tetrahydroisoquinoline alkaloids, flavonoid alkaloids, pentacyclic aromatic alkaloids, diterpenoid alkaloids, aporphine alkaloids, etc. The following example illustrates a typical systematic solvent selection for the separation of palmatine, berberine, epiberberine, and coptisine from the crude alkaloids of *Coptis chinensis* Franch by analytical HSCCC.[9] In Fig. 1, nine chromatograms are arranged in such a way that the effects of the concentration of HCl (0.3–0.1 *M*) and the relative volumes of methanol (4 : 3 : 2–4 : 1.5 : 2, v/v) on the separation of alkaloids from *C. chinensis* Franch are each readily observed. As the concentration of HCl is reduced from 0.3 to 0.1 *M* in the solvent system, the retention time of alkaloids and their peak resolution are increased. A similar effect is also produced by decreasing the relative volumes of methanol in the solvent system from 4 : 3 : 2 to 4 : 1.5 : 2). Among those, the solvent system composed of $CHCl_3$–MeOH–0.2 *M* HCl (4 : 1.5 : 2) produced the best separation of all four major alkaloids components. The optimum solvent system thus obtained led to the successful separation of alkaloids from *C. chinensis* Franch by preparative HSCCC. A similar method was also used for the separation of diterpenoid alkaloids, including lappaconitine, ranaconitine, *N*-deacetyllappaconitine, and *N*-deacetylranaconitine from *Aconitum sinomontanum*.[10]

More than 10 kinds of neutral two-phase solvent systems have been successfully used for the separation of alkaloids by CCC.[11] Most of the alkaloids from marine sponge—including acridine, pyrroloquinoline, imidazole, β-carboline alkaloids, etc.—were separated with neutral two-phase solvent systems by HSCCC in the final or middle step of separation (Table 1).

SEPARATION OF ALKALOIDS BY H-ZONE-REFINING COUNTERCURRENT CHROMATOGRAPHY

Fig. 2 shows a typical separation of 3 g of three alkaloids from a crude extract of *Crinum moorei* using a binary

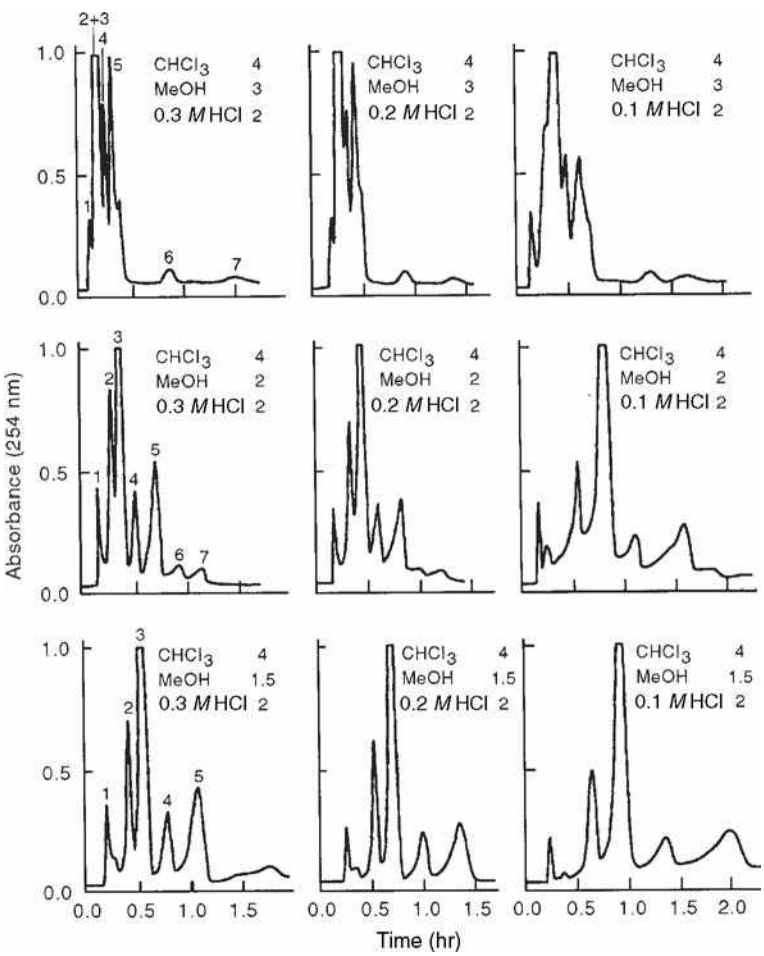

Fig. 1 Chromatograms of the crude alkaloids from *C. chinensis* Franch by analytical HSCCC. Nine chromatograms are arranged in such a way that the effects of methanol and HCl concentrations on the alkaloid separation are each clearly visualized. Experimental conditions: apparatus: analytical HSCCC instrument equipped with a multilayer coil of 0.85 mm I.D. and 30 ml capacity; sample: 2.5 mg of crude alkaloid extract of *C. chinensis* Franch; solvent system: shown above each chromatogram; mobile phase: lower organic phase; flow rate: 1 ml/min; revolution: 1500 rpm. Retention of the stationary phase was as follows: $CHCl_3$–MeOH–(0.1–0.3 *M* HCl) (4 : 3 : 2), 77%; $CHCl_3$–MeOH–(0.1–0.3 *M* HCl) (4 : 2 : 2), 80%; and $CHCl_3$–MeOH–(0.1–0.3 *M* HCl) (4 : 1.5 : 2), 77%.

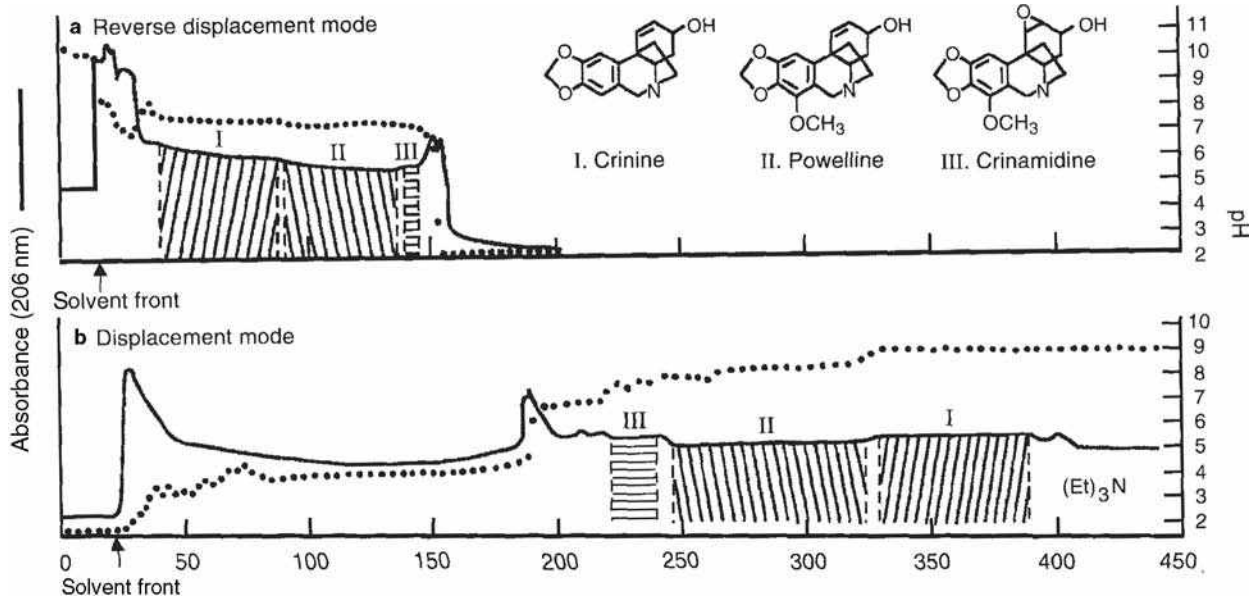

Fig. 2 Chromatograms of the crude alkaloid extract of *Crinum moorei* obtained by pH-zone-refining CCC. Experimental conditions were as follows: apparatus: high-speed CCC centrifuge equipped with a multiplayer coil of 1.6 mm I.D. and about 300 ml capacity; solvent system: methyl-*tert*-butyl ether–water; stationary phase: (a) upper phase (5 m*M* triethylamine) and (b) lower phase (10 m*M* HCl); mobile phase: (a) lower phase (5 m*M* HCl) and (b) upper phase (10 m*M* triethylamine); flow rate: 3.3 ml/min; sample: crude alkaloid extract of *C. moorei*, 3 g dissolved in 30 ml of each phase; revolution: (a) 800 rpm (600 rpm until 66 ml of mobile phase was eluted) and (b) 600 rpm throughout.

solvent system composed of methyl-*tert*-butyl ether–water where triethylamine (5–10 m*M*) was added to the organic phase and HCl (5–10 m*M*) was added to the aqueous phase.[12] In Fig. 2a, where the aqueous phase was used as the mobile phase and HCl as the eluter, the alkaloids were eluted as HCl salts, while in Fig. 2b, where the organic phase is used as mobile phase and triethylamine as the eluter, the alkaloids were eluted as free bases. The same binary solvent system was also used for the separation of alkaloids from the root of *S. flavescens* Ait.[13] In order to increase the solubility of the alkaloids in methyl-*tert*-butyl ether–water solvent system, this solvent system was modified to methyl-*tert*-butyl ether–tetrahydrofuran–water (2 : 2 : 3, v/v), while triethylamine (10 m*M*) was added to the upper organic stationary phase as a retainer and hydrochloric acid (10 m*M*) to the aqueous mobile phase as an eluter. This solvent system was applied to the separation of diterpenoid alkaloids from a crude prepurified sample containing lappaconitine at about 90% purity. Up to 10.5 g of the sample loading yielded 9.0 g of lappaconitine at a high purity of over 99% as determined by HPLC.[14] As most alkaloids have a high solubility in chloroform, a binary solvent system composed of chloroform–water is suitable for a large-scale preparative separation when 18–24 m*M* HCl was added to the aqueous stationary phase as a retainer and 0.1% triethylamine (TEA) to the organic mobile phase as an eluter. This system was successfully used for the separation of berberine chloride, canadaline, canadine, β-hydrastine, and isocorypalmine from a methanolic extract of Goldenseal by pH-zone-refining CCC.[15] The separation of alkaloids by pH-zone-refining CCC is summarized in Table 2.

Table 2 Separation of alkaloids by pH-zone-refining CCC.

Alkaloids	Source	Solvent systems[a]	Retainer[b]	Eluter[c]
Amaryllis alkaloids	*Crinum moorei*	M*t*BE–H_2O (1 : 1)	TEA (5 m*M*/SP)	HCl (5 m*M*/MP)
		M*t*BE–H_2O (1 : 1)	HCl (10 m*M*/SP)	TEA (10 m*M*/MP)
Vinca alkaloids	*Vinca minor*	M*t*BE–H_2O (1 : 1)	TEA (5 m*M*/SP)	HCl (5 m*M*/MP)
Matrine, sophocarpine	*Sophora flavescens*	M*t*BE–H_2O (1 : 1)	TEA (10 m*M*/SP)	HCl (5–0 m*M*/MP)
Diterpenoid alkaloids	*Aconitum sinomontanum*	M*t*BE–THF–H_2O (2 : 2 :7 : 3)	TEA (10 m*M*/SP)	HCl (10 m*M*/MP)
Isoquinoline alkaloids	*Hydrastis canadensis rhizomes*	$CHCl_3$–H_2O (1 : 1)	18–24 m*M* HCl	TEA (0.1%/MP)

[a]M*t*BE = methyl-*tert*-butyl ether; THF = tetrahydrofuran.
[b]TEA = triethylamine; SP = stationary phase.
[c]MP = mobile phase.

CONCLUSIONS

Countercurrent chromatography overcomes all of the problems caused by solid support matrix present in most other chromatographic methods. Countercurrent chromatography can purify alkaloids with high recovery and reproducibility.

pH-Zone-refining CCC extends the preparative capacity of HSCCC and provides many important advantages over the conventional CCC method, including an over 10-fold increase in sample loading capacity, high concentration of fractions with very high purity, concentration of minor impurities, etc.

Alumina-Based Supports for LC

Esther Forgács
Tibor Cserháti
Institute of Chemistry, Chemical Research Center, Hungarian Academy of Sciences, Budapest, Hungary

INTRODUCTION

Various liquid chromatography (LC) techniques offer a unique possibility for the separation and quantitative determination of a large variety of organic, metalloorganic, and inorganic compounds with highly similar molecular structures. These methods are indispensable in medical practice and research, pharmaceutical chemistry, food science and technology, environmental pollution control, legislation procedures, etc. The rapid development of the theory of the retention processes in chromatography have made it obvious that the efficient separation of various compounds (selection of the best separation method, support and mobile phase, and any other parameter influencing the efficacy) requires a profound knowledge of the impact of molecular characteristics of solutes, stationary and mobile phases, and their interplay at the molecular level on retention. The expert application of such knowledge will highly facilitate the rational design of optimal separation methods. As the chemistry and physicochemistry of the surface of the support determines the retention characteristics of stationary phases, physical methods such as nuclear magnetic resonance (NMR), Fourier transform infrared (FTIR), etc. have been frequently used to study the stationary phases in LC.

The overwhelming majority of LC separations are carried out in silica or in silica-based, reversed-phase (mainly octadecylsilica, ODS) stationary phases. Although the retention characteristics of silica and surface-modified silica supports are excellent, and they can be used for the successful separation of a wide variety of solutes, they also have some drawbacks. Thus, the acidic character of the free silanol groups exert a considerable impact on the retention behavior of both silica and silica-based supports; basic solutes are more strongly bonded onto the silica surface than neutral or acidic substances, resulting in unpredictable retention behavior. Moreover, silica and silica derivatives are not stable at alkaline pHs, making the separation of strongly basic compounds difficult. The objectives of the newest developments in LC are the development and practical application of more stable supports than silica and modified silicas, with different separation capacities (alumina, zirconia, titania, mixed oxides, and their modified derivatives, porous graphitized carbon, various polymer supports, etc.). Although these new supports show excellent separation characteristics, they are not well known, not frequently used, and the molecular basis of retention has not been elucidated in detail.

The objectives of this entry are the enumeration and critical evaluation of the recent results obtained in the assessment of the relationship between the physicochemical characteristics and retention behavior of a wide variety of solutes on alumina stationary phases and the elucidation of the efficacy of various multivariate mathematical–statistical methods for the quantitative description of such relationships.

ALUMINA

Alumina offers another alternative to silica because of its inherent higher pH stability. However, in contrast to its extensive use as a medium in column chromatography for purification purposes, or for separations in the normal-phase mode, there are still relatively few reports concerning alumina-based materials in the reversed-phase mode.

The chromatographic aspects of the surface characteristics of alumina stationary phases have not been studied as profoundly as zirconia supports; however, the presence of hydroxyl and oxide ions on the surface has been reported.[1]

Crystalline alumina may exist in various forms; the τ-form is generally used in chromatography. Alumina strongly adsorbs water molecules, as depicted in Fig. 1. The two different hydroxyl groups show acidic or alkaline properties, resulting in amphoteric characteristics and ion exchange behavior of the alumina surface, as demonstrated in Fig. 2.[2] It has been further shown that the simultaneous interaction of pH, the composition of buffer and that of the mobile phase modifier governs the retention on alumina surfaces in ion exchange chromatography.[3,4] The good separation characteristics of alumina stationary phase were exploited, not only in the ion-exchange mode, but also in the adsorption (direct phase) chromatographic mode. Alumina supports have been frequently used in thin-layer chromatography (TLC), and the separation of inorganic and organometallic solutes on alumina layers was reviewed.[5] Non-ionic surfactants (α-(1,1,3,3-tetramethylbutyl)phenyl ethylene oxide oligomers) were also

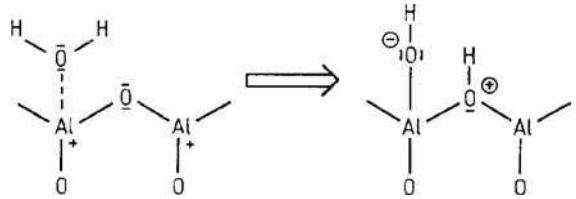

Fig. 1 Chemisorption of water on bare alumina.
Source: From The use of organic modifiers in ion exchange chromatography on alumina. The separation of basic drugs, in Chromatographia.[2]

separated on alumina layers using *n*-hexane mixed with ethyl acetate, dioxane, and tetrahydrofurane (THF), and the data were evaluated by spectral mapping technique. Surfactants were separated according to the number of ethylene oxide groups in the molecule; surfactants with longer ethylene oxide chain were eluted later. This finding indicates that the polar ethylene oxide units turn toward the stationary phase and that they are bonded to the adsorption sites on the alumina surface. Calculations proved that the solvent strength of THF was the highest, followed by dioxane and ethyl acetate. The selectivity of ethyl acetate differed considerably from the selectivities of THF and dioxane.[6] Other nonionic surfactants (nonylphenyl[7] and tetrabutylphenyl[8] ethyleneoxide oligomers) were

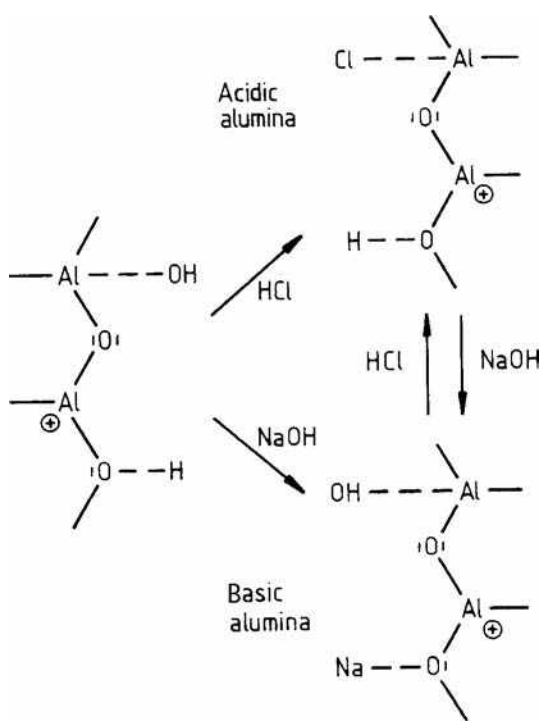

Fig. 2 Surface behavior of alumina in basic and acidic media, respectively.
Source: From The use of organic modifiers in ion exchange chromatography on alumina. The separation of basic drugs, in Chromatographia.[2]

successfully separated on an alumina HPLC column using *n*-hexane-ethyl acetate mixtures as mobile phases. Significant linear correlations were found between the molecular parameters of the solutes and their retention characteristics:

$$\log k_0' = 3.61 + (0.37 \pm 0.03)n_e \quad r = 0.9911 \tag{1}$$

$$b = 3.54 + (1.18 \pm 0.03)n_e \quad r = 0.9991 \tag{2}$$

where k_0' is the capacity factor of nonylphenyl ethyleneoxide oligomer surfactants, extrapolated to zero concentration of ethyl acetate in the mobile phase; b is the slope value of the linear relationship between the log k' values of surfactants and the concentration of ethyl acetate in the eluent $\pm$ standard deviation; and n_e is the number of ethylene oxide groups per molecule.

$$\log k_0' = 3.41 + (0.36 \pm 0.01)n_e + (0.13 \pm 0.03)\text{PI} \quad F = 217.65 \tag{3}$$

$$b = 3.56 + (0.78 \pm 0.07)n_e + (0.52 \pm 0.13)\text{PI} \quad F = 64.65 \tag{4}$$

where PI characterizes the position of the butyl substituents, other symbols are the same as in Eqs. 1 and 2.

The data entirely support the previous conclusions concerning the retention mechanism of surfactants on alumina. Moreover, Eqs. 3 and 4 indicate that alumina is an excellent support for the separation of tetrabutylphenyl ethylene oxide oligomers according to the number of ethylene oxide groups and the position of the alkyl substituents in one run. The efficiency of alumina support for the separation of positional isomers was also established with HPLC–mass spectrometry (HPLC–MS).[9]

MODIFIED ALUMINA

Polymers have also been used for the coating of alumina. Thus, maleic acid adsorbed onto the alumina surface was, in situ, polymerized with 1-octadecene and cross-linked with 1,4-divinylbenzene.[10] It was assumed that the polymer forms a monolayer on the alumina, forming a reversed-phase surface. This assumption was substantiated by results showing that the retention order of model compounds was the same as on an ODS column. The lower separation capacity of the new stationary phase was tentatively explained by the lower surface porosity of alumina. Principal component analysis was employed for the elucidation of the relationship between the retention behavior of non-homologous series of solutes on polybutadiene (PBD)-coated alumina and their physicochemical parameters.[11] Calculations revealed significant relationships

between the capacity factor extrapolated to pure water (k_w') and the physicochemical parameters:

$$\log k_w' = 0.052 + 0.208(\log P) \quad (5)$$

$n = 21;\ s = 0.279;\ r = 0.9711;\ F = 314$

$$\log k_w' = 1.618 + 0.089\text{bonrefr } 2.505\text{delta} \quad (6)$$

$n = 21;\ s = 0.500;\ r = 0.9090;\ F = 42.8$

$$\log k_w' = 1.272 + 0.089\text{bonrefr } 2.648\text{delta } 0.598\text{ind} \quad (7)$$

$n = 21$; $s = 0.394$; $r = 0.9476$; $F = 49.8$ where $\log P$ is the hydrophobicity, "bondrefr" is the molecular refractivity, "delta" is the submolecular polarity parameter, "ind" indicator variable (0 for heterocyclics and 1 for benzene derivatives). Calculations indicated that PBD-coated alumina behaves as an RP stationary phase, the bulkiness and the polarity of the solute significantly influencing the retention. The separation efficiency of PBD-coated alumina was compared with those of other stationary phases for the analysis of *Catharanthus* alkaloids. It was established that the pH of the mobile phase, the concentration and type of the organic modifier, and the presence of salt simultaneously influence the retention. In this special case, the efficiency of PBD-coated alumina was inferior to that of ODS.[12] The retention characteristics of polyethylene-coated alumina (PE-Alu) have been studied in detail using various non-ionic surfactants as model compounds.[13] It was found that PE-Alu behaves as an RP stationary phase and separates the surfactants according to the character of the hydrophobic moiety. The relationship between the physicochemical descriptors of 25 aromatic solutes and their retention on PE-coated silica (PE-Si) and PE-Alu was elucidated by stepwise regression analysis.[14]

$$\log k_{\text{PE-Alu}}' = 0.144(\pm 0.092) + 0.9325(\pm 0.0505)\log k_{\text{PE-Si}}' \quad (8)$$

$n = 25;\ r = 0.968;\ s = 0.333;\ F = 340$

$$\log k_{\text{PE-Alu}}' = 1.474(\pm 0.376) + 0.5976(\pm 0.2990)R_2 + 0.9162(\pm 0.3025)\pi_2{}^{*}0.8279(\pm 0.2624) \times \sum \beta_2{}^{\text{H}} + 3.206(\pm 0.304)V_x \quad (9)$$

$n = 24;\ r = 0.958;\ s = 0.397;\ F = 53$

$$\log k_{\text{PE-Si}}' = 1.670(\pm 0.373)0.9167(\pm 0.2120)\pi_2{}^{*} + 3.842(\pm 0.267)V_x \quad (10)$$

$n = 24;\ r = 0.956;\ s = 0.398$

$$\log k_{\text{PE-Alu}}' = 2.122(\pm 0.549)2.068(\pm 0.798)\delta_{\max} + 0.3283(\pm 0.0897)\mu + 0.00940(\pm 0.00111)V_{\text{aq}} \quad (11)$$

$n = 25;\ r = 0.926;\ s = 0.525;\ F = 42$

$$\log k_{\text{PE-Si}}' = 2.401(\pm 0.456)2.424(\pm 0.662)\delta_{\max} + 0.2821(\pm 0.0746)\mu + 0.01057(\pm 0.00092)V_{\text{aq}} \quad (12)$$

$n = 25$; $r = 0.953$; $s = 0.436$; $F = 69$ where μ is the total dipole moment, $\delta_{\max}$ is the maximum electron excess charge (electron deficiency) on an atom in the solute molecule, V_{aq} is the solvent (water) accessible molecular volume. Calculations proved that both stationary phases behave as RP supports, with the retention strength of PE-Si being higher. The retention can be successfully related to the molecular parameters included in the calculations.

The differences observed may be attributed to free silanol groups on the silica surface not covered by the polyethylene coating.

Various synthetic methods were developed for the covalent binding of hydrophobic ligands to the surface of alumina.[15,16] These methods generally resulted in real RP stationary phases with higher pH stability than the silica-based stationary phase. The retention of 33 commercial pesticides was determined on OD alumina, ODS, and on alumina support.[17] Stepwise regression analysis proved that the retention of pesticides on OD alumina does not significantly depend on the lipophilicity of pesticides determined on a silica-based RP support. This discrepancy was tentatively explained by the different binding characteristics of the adsorption centers on the surfaces of silica and alumina not covered by the hydrophobic ligand. Using another set of solutes, the similarities of the retention order on both OD alumina and ODS was observed.[18]

The spectral mapping technique, combined with cluster analysis and non-linear mapping, was used for the comparison of the retention behaviors of RP silica and RP alumina columns using tributylphenol ethylene oxide oligomers as model compounds.[19] The columns included in the experiments were C_1, C_2, C_6, C_8, and C_{18} silica, Pe-Si, alumina, and C_{18} alumina. The retention strengths of RP-HPLC columns showed considerable variations, the strongest and the weakest being C_{18} silica and PE-Si, respectively. The retention strength of alkyl-modified silicas depended linearly on the carbon load. The two-dimensional selectivity map and the cluster dendogram of the column selectivities are depicted in Figs. 3 and 4, respectively. From the results, it is clear that both the strength and the selectivity of retention show high variations. C_1, PE-Si, and PE-Alu exhibited similar retention selectivity.

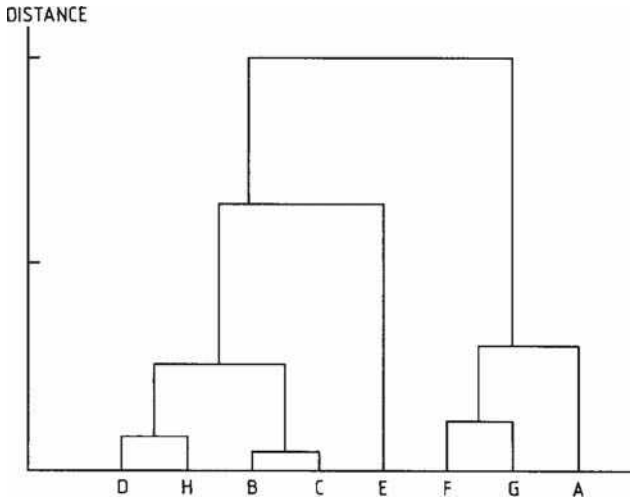

Fig. 3 Two-dimensional non-linear selectivity map of reversed-phase HPLC columns. Number of iterations: 377. Maximum error: 2.1×10^{-3}. (A) C_1 silica; (B) C_2 silica; (C) C_6 silica; (D) C_8 silica; (E) C_{18} silica; (F) polyethylene coated silica; (G) polyethylene-coated alumina; (H) C_{18} alumina.
Source: From Determination of retention behaviour of some non-ionic surfactants on reversed-phase high-performance liquid chromatography supports by spectral mapping in combination with cluster analysis or non-linear mapping, in J. Chromatogr. A.[19]

This result may be attributed to the fact that polyethylene chains lie parallel to the surface of the support, with the end groups being anchored to the polar adsorption centers. According to this model, only the surface of the polyethylene coating pointing toward the mobile phase is available to the solutes in the mobile phase. This apolar polymeric layer is similar in thickness to the C_1 coating but differs markedly from the longer alkyl chains that are more or less immersed in the mobile phase and are providing more CH_2 groups for the binding of apolar solutes. The conclusions drawn from the two-dimensional non-linear mapping and cluster analysis are similar, suggesting that both methods can be used for the reduction of the dimensionality of a multidimensional spectral map.

CONCLUSIONS

The development of new non-silica-based stationary phases was mainly motivated by the poor stability of silica and modified silicas at extreme pH values. It was shown that alumina supports can be used successfully for the solution of a wide variety of analytical problems concerning the separation of natural products, pharmaceuticals, and xenobiotics at any mobile phase pH. Moreover, alumina shows different retention characteristics than silica (i.e., it shows higher separation capacity for positional isomers). The data may facilitate not only the solution of various practical separation problems in LC, but will also promote a better understanding of the underlying physicochemical principles governing retention.

Amines, Amino Acids, Amides and Imides: Derivatization for GC Analysis

Igor G. Zenkevich
Chemical Research Institute, St. Petersburg State University, St. Petersburg, Russia

Abstract

The amines are an extensive class of organic compounds of general formula RNH_2 (primary), RR′NH (secondary), and RR′R″N (tertiary). The chemical and chromatographic properties of these compounds are determined by the presence of a basic functional group and active hydrogen atom(s) in the molecule. Amides are derivatives of carboxylic acids with structural fragments –CO–N < , > PO–N <, or $–SO_2^-$ N, while imides have two acyl fragments connected through a nitrogen atom, e.g., –CO–NR–CO–, or –CO–NR–SO_2^-. The compounds with structural fragment > C=N–, "imines", have the trivial name "Schiff bases." As these compounds have no active hydrogen atoms, they need no derivatization and, moreover, they themselves are the derivatives of both amines and carbonyl compounds.

The simplest members of the amine class usually are volatile enough for their direct gas chromatography (GC) analysis. Nevertheless, the principal reason for the derivatization of amines and related compounds is the high sensitivity of amino compounds to various chemical agents. Among the multitude of organic substances, only amines in acidic media reversibly form nonvolatile salts, which can make their GC analysis impossible. Besides that, these compounds are very sensitive to the action of various electrophilic reagents; their exhaustive alkylation gives nonvolatile quaternized ammonium salts, which cannot be restored to the initial analytes. Finally, amino compounds are easily oxidized. Owing to the above-mentioned facts, the principal goal of derivatization of amines and related substances is to protect these compounds from chemical transformations prior to GC analysis by their conversion to more stable derivatives.

INTRODUCTION

Amides are an extensive class of organic compounds of general formula RNH_2 (primary), RR′NH (secondary), and RR′R″N (tertiary). Their chemical and chromatographic properties are determined by the presence of a basic functional group and (for *prim* and *sec* amines) active hydrogen atoms in the molecule. The basicity is very different for aliphatic amines (pK_a 10.5 ± 0.8) and substituted anilines (pK_a 4.9 ± 0.3) owing to the p–π conjugation N–Ar. Amides are derivatives of carboxylic acids with structural fragments -CO–N<, >PO–N<, or $–SO_2–$N< (including cyclic structures), while imides have two acyl fragments connected through a nitrogen atom, e.g., –CO–NR–CO–, as in the molecule of saccharine. Some other groups of nitrogen-containing compounds should also be mentioned here: compounds with structural fragment >C = N– (the so-called Schiff bases), which also have the synonym *imines*. As the last-mentioned compounds have no active hydrogen atoms they need no derivatization, and, moreover, they themselves are the derivatives of both amines and carbonyl compounds.

The simplest members of the amine class are usually volatile enough for direct gas chromatography (GC) analysis. For example, the comparison of simple tertiary amines with the structurally analogous isoalkanes indicates that both the boiling point at atmospheric pressure and the gas chromatographic retention indices (RIs) for the tertiary amines are slightly lower (!) than for the corresponding alkanes (Table 1).

A similar comparison of physicochemical and chromatographic properties of amides (first, the primary amines, $RCONH_2$) indicates that these compounds are highly polar, the polarity exceeding that of the corresponding carboxylic acids, RCO_2H. This is because of the high polarity of the CO–NH bond, which is reflected by the dipole moments (μ): about 1.7 D for acids and ~3.7 D for amides. Moreover, the difference in the boiling point (T_b) of simplest amides and acids exceeds 100°C. The measure of chromatographic polarity is the difference in RI in the standard polar and non-polar

Table 1 Comparison of physicochemical (boiling points) and chromatographic (retention indices) properties of some tertiary amines and structurally related alkanes.

Compound	T_b, °C	$RI_{non\text{-}polar}$
tert-Amine R_3N		
Et_3N	89.4	677 ± 8
Pr_3N	156.5	933 ± 8
Hydrocarbon analog R_3CH		
Et_3CH	93.4	687 ± 3
Pr_3CH	157.5	936 ± 15

Table 2 Comparison of physicochemical (boiling points) and chromatographic (retention indices on non-polar and polar phases) properties of some carboxylic acids and their primary amides.

Acid	Tb, °C	$RI_{non\text{-}polar}$	RI_{polar}	Amide	Tb, °C	$RI_{non\text{-}polar}$	RI_{polar}
CH_3CO_2H	118	638 ± 10	1428 ± 30	CH_3CONH_2	221	711 ± 19	1759 ± 26
$C_2H_5CO_2H$	141	725 ± 18	1524 ± 23	$C_2H_5CONH_2$	222	808 ± 6	1815 ± 12

phases (ΔRI): about 800 i.u. for acids and above 1000 i.u. for amides (Table 2).

However, high polarity is not the principal reason why amines and related compounds can be derivatized easily. More important is the high sensitivity of amino compounds to various chemical agents. Among the multitude of organic substances, only amines in acidic media form non-volatile salts, which can make their GC analysis impossible. Of course, these salts can be recovered as free bases by treating them with other (more basic) amines or with excess of ammonia.[1] Besides, these compounds are very sensitive to various electrophilic reagents; their exhaustive alkylation yields non-volatile quaternized ammonium salts $(R_4N)^+X^-$, which cannot be restored to the initial analytes by the action of bases. Owing to their non-volatility, these salts cannot be the objects of GC analysis, but their injection into hot parts of chromatographic systems can lead to the formation of some volatile products (artifacts). Also, some of the amino compounds are easily oxidized. Hence, the principal goal of derivatization of amines and related substances is to protect these compounds from chemical transformations prior to GC analysis by converting them to more stable derivatives.

Also, as per the general principles of derivatization, when other polar functional groups with active hydrogen atoms are present in molecules, the derivatization of one or (better) all of them becomes necessary. This is typical in the case of amino acids, which exist in the form of inner-molecular salts $RCH(NH_3^+)CO_2^-$ in the solid state.

DERIVATIZATION OF AMINES

The principal methods of amino compound derivatization for GC analysis include the following types of chemical reactions:[2–5]

- Acylation: $RR'NH + R''COX + B \rightarrow RR'NCOR'' + BH^+X^-$
- Formation of Schiff bases (only for primary amines): $RNH_2 + R'R''CO \rightarrow RN = CR'R'' + H_2O$
- Alkylation: $RR'NH + R''X + B \rightarrow RR'NR'' + BH^+X^-$
- Silylation: $RR'NH + XSi(CH_3)_3 \rightarrow RR'NSi(CH_3)_3 + XH$

Acylation is the most common method as amides are preferred over other kinds of derivatives. Their basicity is significantly less than that of amines and, hence, the pH of samples indicates that the influence is not as strong as on initial amines. Schiff bases and especially *N*-trimethylsilyl (TMS) derivatives are sensitive to postreaction hydrolysis.

A number of recommended acylating reagents are listed in Table 3, and they belong to two classes of chemicals: anhydrides (X = OCOR″) and chloroanhydrides (X = Cl). The most widely used among them are acetic, trifluoroacetic (TFA), pentafluoropropanoic (PFP), and heptafluorobutanoic (HFB) anhydrides, as well as pentafluorobenzoyl chloride (PFB-Cl).[6] The by-products of acylation in all cases are acids; these reactions need basic media (additives of pyridine or tertiary amines) to prevent the formation of non-volatile salts from the analytes. The technique of derivatization is extremely simple: sample mixtures are allowed to stand with acylating reagents for some minutes prior to analysis.

The anhydrides and chloroanhydrides of chlorinated acetic acids and PFB-Cl (electrophoric reagents) are used for the synthesis of chlorinated amides for GC analysis with selective detectors [e.g., electron-capture detector (ECD)]. Diethylpyrocarbonate converts primary and secondary amines (including NH_3) into *N*-substituted carbamates:

$$RR'NH + O(CO_2C_2H_5)_2 \rightarrow RR'NCO_2C_2H_5 + CO_2 + C_2H_5OH$$

The next group of derivatization reactions is the formation of Schiff bases from primary amines with carbonyl compounds. Some recommended reagents are listed in Table 4. Aromatic aldehydes (including pentafluorobenzaldehyde as electrophoric reagent[7]) are much more reactive in this condensation as compared with ketones and aliphatic compounds (of the latter, only low-boiling acetone and cyclohexanone have been used in GC practice). The synthetic analogs, primarily acetals and ketals, of carbonyl compounds can be made to react with amines. Thus dimethylformamide dialkylacetals, $(CH_3)_2N–CH(OR)_2$, react with primary amines, $R'NH_2$ forming *N*-dimethylaminomethylene derivatives, $R'–N = CH–N(CH_3)_2$. As long as these reagents catalyze the esterification of carboxyl groups, they can be used for single-stage derivatization of amino acids (see below).

Table 5 Comparison of retention indices for *N*-trimethylsilyl derivatives of simplest primary amines and corresponding isothiocyanates.

R	$RI_{non\text{-}polar}$ [$RNHSi(CH_3)_3$]	$RI_{non\text{-}polar}$ (RNCS)
Me	689 ± 21	689 ± 16
Et	756 ± 11	736 ± 5

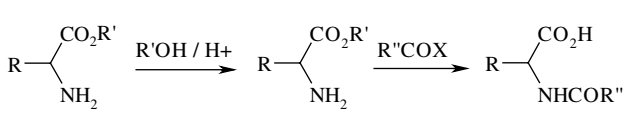

Fig. 1 "Classical" two-step scheme for derivatization of amino acids.

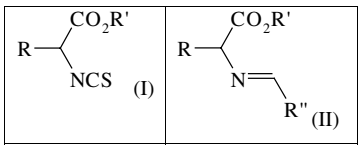

Fig. 2 Some alternative to *N*-acylated derivatives of amino acids.

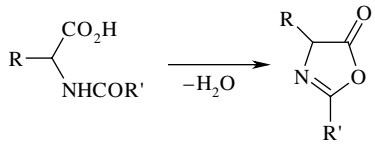

Fig. 4 Dehydration of *N*-acyl derivatives of amino acids with formation of azlactones.

Carbon disulfide as the thio-analog of carbonyl compounds reacts with primary amines, resulting in the formation of alkyl isothiocyanates, which have slightly lower RIs than those of other derivatives of primary amines, including *N*-trimethylsilylated amines (Table 5). The sole product of this reaction is gaseous hydrogen sulfide:

$$RNH_2 + CS_2 \rightarrow RNCS + H_2S$$

The alkylation of amines was a highly popular method of derivatization in peptide chemistry before the practice of contemporary mass spectrometric techniques for the analysis of non-volatile compounds. Direct alkylation of amines by alkyl halides (Hoffman reaction) can finally lead to non-volatile ammonium salts and, hence, other *soft* reagents should be used. For example, exhaustive methylation without quaternization can be provided by the mixtures $CH_2O/NaBH_4/(H^+)$ or CH_2O/formic acid.

At present silylation of amines is a well-investigated,[8] but relatively rarely used, method for their derivatization owing to the facile hydrolysis of the resultant *N*-TMS compounds. It leads to the formation, in the reaction mixtures, of both *mono*-(RNHTMS) and *bis*-[RN(TMS)$_2$] derivatives. This multiplicity of products from the same precursor presents some difficulties in data interpretation. The *N*-(*tert*-butyldimethylsilyl) (TBDMS) derivatives are more resistant to hydrolysis, and their formation is unambiguous (only *N*-monosubstituted compounds are formed) because of steric reasons.[9–11] It is interesting to note that one of the numerous silylating agents (see Table 3 in *Hydroxy Compounds: Derivatization for GC Analysis*, p. 1165)—trimethylsilyl imidazole—possesses a unique selectivity, because it is inert in relation to amines.

Some special derivatization methods are recommended for amines for optimizing their determination in dilute water samples, especially in combination with preconcentration of analytes. This explains the choice of conversion of primary aromatic amines by iodine into the corresponding iodoarenes:[12]

$$ArNH_2 + 1.5I_2 \rightarrow ArI + 2HI + 0.5N_2$$

In the example of amines it is interesting to note an *exotic* derivatization reaction, where a single reagent provides double functionalization of the protected group by different structural fragments. This reagent is trimethylsilylketene, $(CH_3)_3Si–CH = C = O$, which reacts with primary amines giving their TMS-acetyl derivatives:[13]

$$RNH_2 + Me_3SiCHCO \rightarrow [R - N(COCH_3) - SiMe_3] \rightarrow R - N = C(CH_3) - OSiMe_3$$

Because there were no obvious advantages, this method was not modified; however, it illustrates the specific chemical properties of an interesting reagent.

Tertiary amines have no active hydrogen atoms, and their derivatization is not required in the generally accepted sense. The reactions of these compounds do not imply the substitution of active hydrogen atoms, but the cleavage of N–C bonds. If necessary (for GC analysis with selective detectors), N–CH_3 bonds can be cleaved by chloroformates:

$$R'R''N - CH_3 + CCl_3CH_2OCOCl \rightarrow R'RN - CO_2CH_2CCl_3$$

DERIVATIZATION OF AMINO ACIDS

Mixtures of amino acids, R–CH(NH_2)CO_2H, produced by the hydrolysis of polypeptides are important for chromatographic analysis. Some dozens of methods have been proposed for derivatization of these compounds for their GC

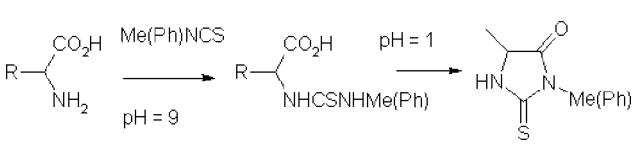

Fig. 3 Formation of *N*-carbamoyl derivatives of amino acids, followed by their cyclization to phenylthiohydantoines.

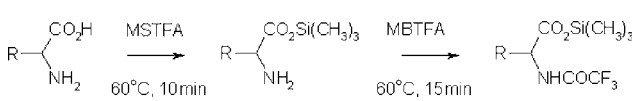

Fig. 5 Two-stage *O*-silylation-*N*-acylation of amino acids.

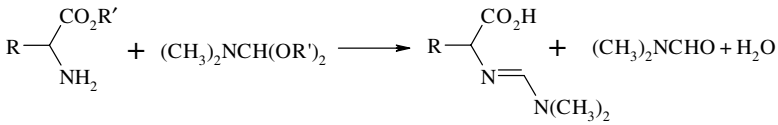

Fig. 6 One step formation of *N*-dimethylaminomethylene derivatives of amino acids *O*-esters.

determination. The most widely used can be subdivided into two types:

1. Separate derivatization of functional groups CO_2H and NH_2 by different reagents.
2. Protection of both groups by only one reagent.

Typical derivatives of the first type are the various esters (Me, Et, Pr, *iso*-Pr, Bu, *iso*-Bu, *sec*-Bu, Am, *iso*-Am, etc.) of *N*-acyl (acetyl, TFA, PFP, HFB, etc.) amino acids. The butyl esters of *N*-TFA amino acids owing to the frequency of their use even have a special abbreviation: TAB derivatives. The two-stage process includes the esterification of amino acids by an excess of the corresponding alcohol in the presence of HCl and, after the evaporation of volatile compounds, the treatment of the non-volatile hydrochlorides of alkyl esters by acylating reagents (Fig. 1).

Some variations of this process are known. Instead of *N*-acylation, intermediate esters can be treated with CS_2/Et_3N and CH_3OCOCl, which leads to the formation of 2-alkoxycarbonyl isothiocyanates (I), or with carbonyl compounds, which leads to formation of Schiff bases (II, see Fig. 2), but the analytical advantages of these derivatives are not obvious.

Similar *N*-acyl-*O*-alkyl derivatives can also be used for GC analysis of the simplest oligopeptides (at least dipeptides and tripeptides). The GC analysis of oligopeptides involving multistep sequences including their reduction into polyaminoalcohols by $LiAlH_4$, followed by their secondary derivatization, is outdated.

A typical example of single-stage derivatization of amino acids is based on their reaction with methyl or phenyl isothiocyanates with the formation of 3-methyl (phenyl) thiohydantoins. The optimal analytical method for the analysis of semivolatile organic compounds of this class is RP HPLC, but derivatives of the simplest amino acids can be objects of GC analysis as well (Fig. 3).

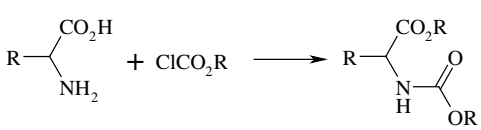

Fig. 7 One-step derivatization of both carboxy and amino groups of amino acids in reaction with chloroformates.

The stable non-volatile intermediate phenyl thiocarbamoyl derivatives are formed in basic media and can be analyzed directly only by RP HPLC. Their cyclization into thiohydantoins requires acid catalysis. This mode of derivatization is an important supplement to the Edman's method of *N*-terminated sequencing of polypeptides. Before GC analysis, all thiohydantoins can be further converted into *N*-TFA or enol-*O*-TMS derivatives, which increases the selectivity of their determination in complex matrices.

N-acylated amino acids in the presence of water-coupling reagents [dicyclohexylcarbodiimide (DCC) or an excess of trifluoroacetic anhydride] form other cyclic derivatives—so-called azolactones (2,4-disubstituted oxazolin-5-ones) (Fig. 4).

The known disadvantage of TMS derivatives of amino acids is the easy postreaction hydrolysis of N–Si bonds in the formed derivatives, which leads to uncertainty regarding the formed products. At the same time, silylation of carboxylic acids is the most popular method for their derivatization (see *Acids: Derivatization for GC Analysis*, p. 3). Hence, it seems reasonable to combine the silylation of CO_2H groups in amino acids with the formation of other derivatives of amino groups, e.g., amides. This method of derivatization was realized only in 2007.[14] The first step is the formation of *O*-TMS derivatives under mild conditions (with MSTFA as reagent), followed by trifluoroacetylation of amino groups by MBTFA (Fig. 5).

One of the most popular methods of single-stage amino acid derivatization at present is their conversion into *N*,*O*(*S*)-*tert*-butyldimethylsilyl (TBDMS) derivatives by the treatment of *tert*-butyldimethylsilyl trifluoroacetamide (MTBSTFA) or its *N*-methyl analog.[9–11,15] Another method was proposed at the beginning of the 1970s and is based on amino acid interaction with dimethylformamide dialkylacetals, $(CH_3)_2NCH(OR')_2$ (R = Me, Et, Pr, *iso*-Pr, Bu, Am), with the formation of

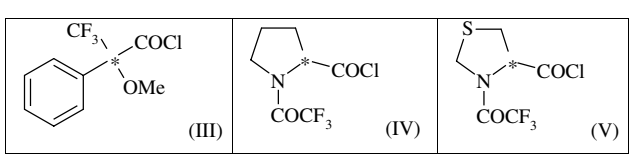

Fig. 8 Some examples of chiral reagents used for separation of chiral amines in the form of diastereomers.

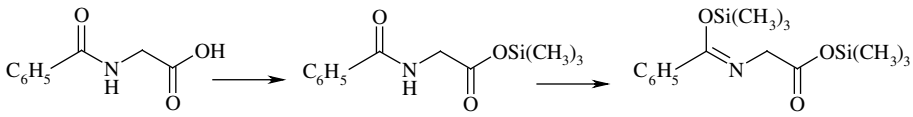

Fig. 9 Consequent formation of mono- and *bis*-TMS derivatives from *N*-acylated amino acids.

N-dimethylaminomethylene derivatives of amino acids alkyl esters (Fig. 6).[16]

An alternative method for the simultaneous derivatization of both carboxylic and amino fragments in amino acids known since the 1990s implies the interaction of these analytes with chloroformates. It leads to the esterification of carboxy groups together with the formation of *N*-ethoxycarbonyl derivatives (Fig. 7).[17]

The GC separation of enantiomeric D- and L-amino acids with non-chiral phases needs their conversion into diastereomeric derivatives. The second chiral center in the molecule [asterisk (*) in Fig. 8] arises after their *O*-esterification by stereochemically pure alcohols [(*R*)- or (*S*)-2-butanol, 2-pentanol, pinacolol, menthol, etc.] or acylation of NH_2 groups by chiral reagents, e.g., α-methoxy-α-trifluoromethylphenylacetyl chloride [MTPAC (III)],[18] *N*-trifluoroacetyl-L-prolyl chloride [*N*-TFA-L-Pro-Cl (IV)], or the corresponding anhydride[19] *N*-trifluoroacetylthiazolidine-4-carbonyl chloride (V).

DERIVATIZATION OF AMIDES AND IMIDES

The derivatization methods available for amides and imides is not so vast as for other classes of amino compounds (remember that numerous amides themselves are used as the target analytical derivatives of amino compounds). The active hydrogen atoms in the structural fragments –CO–NH– or SO_2–NH– are rather acidic and, hence, sometimes the recommended acetyl or TFA derivatives of these compounds (with additional acidic protection groups) are unstable with respect to hydrolysis.

Trimethylsilyl derivatives of amides seem to be more appropriate for GC analysis.[20] However, the molecules of amides contain two nucleophilic centers (*N* and *O*) and, depending on their chemical origin, they can form *N*-TMS or *O*-TMS derivatives. The latter prevails in the case of arylamides, like *N*-aroyl amides [e.g., *N*-benzoyl glycine (hippuric acid)], owing to the formation of conjugate systems (usually both *mono*- and *bis*-TMS derivatives are registered on the chromatograms) (Fig. 9).

The preferable derivatization method for amides is their exhaustive alkylation (e.g., methylation), because permethylated amides and imides are volatile enough for GC analysis. This can be illustrated by the retention data of methylated derivatives of the simplest diamide, namely urea, $CO(NH_2)_2$. Both the initial compound and its mono and two dimethyl homologues cannot be analyzed by GC owing to their non-volatility (contain active hydrogen atoms). The RI of trimethyl urea (one active hydrogen) on standard non-polar polydimethyl siloxanes is 976 ± 28, whereas for tetramethyl urea it is 956 ± 5 (see the better interlaboratory reproducibility of the latter RI value as compared with the previous one).

The exhaustive methylation of amides can be realized with rather high yields by their reactions with dimethyl sulfate in the presence of bases [(*iso*-Pr)$_2$NEt],[21] by CH_3I in acetone solution, with CH_3I in the presence of K_2CO_3 or (less convenient) LiH in DMSO (high-boiling solvent), in heterophase *water–organic solvent* systems (together with the extraction of derivatives from matrices), and directly in the injector of a gas chromatograph (flash methylation) by $PhNMe_3^+OH^-$ (TMPAH). These modes of derivatization precede the GC determination of numerous diuretics (acetazolamide, ethacrinic acid, clopamide, etc.),[22] some barbiturates and their metabolites, xanthines (theophylline, theobromine), different urea and carbamate pesticides (monuron, fenuron, linuron, and their metabolites), and so forth.

CONCLUSIONS

The main reason for the derivatization of amines and related compounds is their chemical lability. Compared with other classes of organic compounds, only amines can reversibly form non-volatile salts with acids. Besides, these compounds are very sensitive to the action of electrophilic reagents, which can irreversibly convert amines into non-volatile ammonium salts. This explains the necessity for derivatization of different amines to prevent chemical transformation of analytes prior to their GC analysis.

Amino Acids and Derivatives: TLC Analysis

Luciano Lepri
Alessandra Cincinelli
Department of Chemistry, University of Florence (UNIFI), Florence, Italy

Abstract
The best operative conditions to separate the 20 natural amino acids by using a wide variety of commercially available stationary phases used both in normal and in reversed-phase chromatography and by two-dimensional (2D) chromatography technique are described. Resolution of amino acids derivatives, which play a fundamental role in the peptide and protein sequence structures, is also reported.

INTRODUCTION

Amino acids are carboxylic acids in which a hydrogen atom in the side chain (usually on the α-carbon) has been replaced by an amino group. Hence, they are amphoteric. In weak acid solution, the carboxyl group of a neutral amino acid (with one amino group and one carboxyl group) is dissociated, and the amino group binds a proton to give a dipolar ion (zwitterion). The pH at which the concentration of the dipolar ion is maximum is called the isoelectric point (pI), which is calculated using the relation

$$\mathrm{p}I = \frac{1}{2}(\mathrm{p}K_1 + \mathrm{p}K_2)$$

where pK_1 and pK_2 refer to the dissociation of the carboxyl group and the protonated amino group, respectively (most neutral aliphatic amino acids with a non-polar side chain have pI 6.0, which corresponds to pK_{a1} 2.3 and pK_{a2} 9.7).

Amino acids constitute the basic units of all proteins. The number of α-amino acids obtained from various proteins is about 40, but only 20 are present, in varying amounts, in all proteins. Thin-layer chromatography (TLC) is one of the most promising separation methods for these compounds, for which gas chromatographic (GC) analysis is not suitable.

PREPARATION OF TEST SOLUTIONS

Amino acids should be as free from impurities as possible, since they exhibit a pronounced capacity for binding metal ions. The analysis of amino acids in natural fluids or extracts requires the removal of interfering compounds prior to chromatographic separation, in order to prevent tailing and deformation of the spots (e.g., high salt concentrations are found in urine samples and hydrolysates of proteins or peptides).

Salts can be conveniently removed by passing the sample through a cation-exchange resin column. Free amino acids from sanguine plasma can be obtained after centrifugation of the suspension resulting from the addition of a $Na_3(PW_{12}O_{40})$ solution to the samples for removing proteins.

Enrichment of amino acids in urine (10 ml) can be performed by extracting the lyophilized sample with 1 ml of a methanol–1 *M* HCl mixture (4:1 v/v) and applying an aliquot of supernatant liquid to the plate after centrifugation.

Multivitamin syrups and energy drinks are diluted with an appropriate aqueous–alcoholic mixture (80% ethanol), and the resulting solution is applied to plates for the determination of taurine and lysine.

CHROMATOGRAPHIC TECHNIQUES FOR AMINO ACID SEPARATION

Untreated Amino Acids

Standard solutions of amino acids are usually prepared in water or in aqueous–alcoholic solvents (70% ethanol), with the addition of hydrochloric acid (0.1 *M*) for the dissolution of relatively insoluble amino acids (e.g., tyrosine and cystine). Detection is generally performed with ninhydrin reagent by heating the plates at about 100°C for 5–10 min. After color development with the ninhydrin, treatment of the layer with a complex-forming cation (e.g., Cu^{II}, Cd^{II}, Ni^{II}) causes the color to change from blue to red and increases color fastness considerably. More specific coloration of amino acids can be achieved by adding bases such as collidine and cyclohexylamine to the detecting agent solution, or by using 4-hydroxybenzaldehyde–ninhydrin as spray reagent. For the location of tryptophan and its

derivatives, a 1% solution of *p*-dimethylaminobenzaldehyde in ethanol–hydrochloric acid (1:1 v/v) can be used.

Distinguishable and stable colors of amino acids can be obtained by spraying first with 0.25% 2,3-dichloro-1,4-naphthaquinone and, successively, with 0.4% isatin in ethanol and heating at 110°C for 10 min.

Amino acids have been separated on layers of a wide variety of inorganic and organic adsorbents, ion exchangers, and impregnated plates. The two most commonly used adsorbents are silica gel and cellulose.

Separation on Silica Gel and Cellulose Layers

It is interesting to note that by using neutral eluents such as ethanol or *n*-propanol–water, the acidic amino acids (e.g., Glu, Asp) travel much faster on silica gel than basic amino acids (e.g., Lys, Arg, His), which, indeed, show very small R_f values. The difference is likely due to cation exchange between the protonated amino groups of basic amino acids and the acidic groups present on silica gel. The strong retention observed for these compounds when eluting with acidic solvents (Table 1) confirms this hypothesis. A similar phenomenon is also observed on cellulose plates and may be for the cellulose carboxyl groups.

Furthermore, it is seen that the presence of a hydroxyl group in the molecule does not necessarily reduce the R_f value, as the chromatographic behavior of serine with respect to glycine on layers of silica gel and cellulose shows (Table 1). Some of the numerous eluents that have been used for the separation of amino acids on silica gel are acetone–water–acetic acid–formic acid (50:15:12:3), ethylacetate–pyridine–acetic acid–water (30:20:6:11), 96% ethanol–water–diethylamine (70:29:1), chloroform–formic acid (20:1), chloroform–methanol (9:1), isopropanol–5% ammonia (7:3), and phenol–0.06 *M* borate buffer pH 9.30 (9:1). On cellulose plates, ethylacetate–pyridine–acetic acid–water (5:5:1:3), *n*-butanol–acetic acid–water (4:1:1 and 10:3:9), *n*-butanol–acetone–acetic acid–water (35:35:7:23), *n*-butanol–acetone–ammonia–water (20:20:4:1), collidine–*n*–butanol–acetone–water (2:10:10:5), phenol–methanol–water (7:10:3), ethanol–acetic acid–water (2:1:2), and cyclohexanol–acetone–diethylamine–water (10:5:2:5) have also been used as eluents.

Recently, amino acids used in medical practice as drugs for parenteral and per os feeding, in cattle breeding, and in poultry raising were separated and determined on silica plates.[1] Quantitative determination of serine, threonine, phenylalanine, tryptophan, lysine, ornithine, arginine, valine, and leucine was effected by videodensitometric scanning after selection of the optimum conditions for visualization of the spots on chromatograms by using the plate-immersion technique.

Separation efficiency can be increased by multiple developments or two-dimensional (2D) chromatography.

Table 1 R_f values of the 20 common amino acids in different experimental conditions (ascending technique).

Amino acid and abbreviation	Silica gel G[a]	Microcrystalline cellulose[b]	Fixion 50-X8 (Na+)[c]	Silanized silica gel + 4% HDBS[d]	p*I*
Glycine (Gly)	18	15	56	83	6.0
Alanine (Ala)	22	29	51	74	6.0
Serine (Ser)	18	16	67	85	5.7
Threonine (Thr)	20	21	67	83	6.5
Leucine (Leu)	44	64	22	26	6.0
Isoleucine (Ile)	43	60	28	31	6.1
Valine (Val)	32	48	43	54	6.0
Methionine (Met)	35	23	28	42	5.8
Cysteine (Cys)	7	3	56	–	5.0
Proline (Pro)	14	34	–	63	6.3
Phenylalanine (Phe)	43	55	14	21	5.5
Tyrosine (Tyr)	41	36	12	45	5.7
Tryptophan (Trp)	47	36	2	13	5.9
Aspartic acid (Asp)	17	15	72	86	3.0
Asparagine (Asn)	14	–	–	85	5.4
Glutamic acid (Glu)	24	27	35	83	3.2
Glutamine (Gln)	15	–	–	–	5.7
Arginine (Arg)	6	11	2	28	10.8
Histidine (His)	5	7	11	40	7.6
Lysine (Lys)	3	7	8	47	9.8

[a]Eluent: *n*-butanol–acetic acid–water (80 + 20 + 20 v/v/v).
[b]Eluent: 2-butanol–acetic acid–water (3:1:1 v/v/v).
[c]Eluent: 84 g citric acid + 16 g NaOH + 5.8 g NaCl + 54 g ethylene glycol + 4 ml concentrated HCl (pH = 3.3).
[d]Eluent: 0.5 *M* HCl + 1 *M* CH_3COOH in 30% methanol (pH = 0.7).

Several solvent systems are suitable for 2D separation, and the combination of chloroform–methanol–17% ammonium hydroxide (40 + 40 + 20) and phenol–water (75 + 25) separates all protein amino acids, except leucine and isoleucine, on silica plates.

Multiple development techniques [unidimensional multiple development (UMD) and incremental multiple development (IMD)] were also used to separate the components of a reference solution of amino acids in blood plasma on cellulose plates eluted with acetonitrile–water (8:2 v/v).[2]

Separation on Ion Exchangers and Impregnated Plates

Cellulose ion exchangers (e.g., diethylaminoethyl cellulose) and ion-exchange resins have been widely used as stationary phases for TLC separation of untreated amino acids. Fixion 50-X8 commercial plates, which contain Dowex 50-X8 type resin, have been tested on both Na^+ and H^+ forms for 30 amino acids, and the results obtained for the 20 common protein amino acids are reported in Table 1. The isomer pair of leucine and isoleucine is well separated by this method. In addition, the hydroxyl group notably increases the R_f values owing to the hydrophobic properties of the resin, and the pairs serine/glycine and threonine/alanine can be resolved.

Many studies have focused on impregnated plates. The methods used for impregnation depend on whether the plates are homemade or commercially available. In the first case, the impregnation reagent is usually added to a slurry of the adsorbent, whereas ready-to-use plates are dipped in the solution of the reagent.

The resolution of amino acids has been affected by using different metal ions as impregnating agents at various concentrations. On silica gel impregnated with Ni^{II} salts, the results indicate a predominant role of the partitioning phenomenon when eluting with acidic aqueous and non-aqueous solutions (e.g., *n*-butanol–acetic acid–water and *n*-butanol–acetic acid–chloroform in the 3:1:1 v/v/v ratio). The impregnation of silanized silica gel with 4% dodecylbenzenesulfonic acid (HDBS) solution on both homemade and ready-to-use plates is particularly useful in resolving amino acids.[3] The parameters affecting the retention of amino acids on these layers are the type of adsorbent, the concentration and properties of the impregnating agent, the percentage and kind of organic modifier, pH, and the ionic strength of the eluent.

The data in Table 1 show that complete resolution of basic amino acids (Arg, His, Lys) and of neutral amino acids that differ in their side-chain carbon atom number (i.e., Gly, Ala, Met, Val, Leu, and Ile) is possible on homemade plates of silanized silica gel (C_2) impregnated with a 4% solution of HDBS in 95% ethanol. More compact spots can be obtained on RP-18 ready-to-use plates dipped in the same solution of the surfactant agent.

RESOLUTION OF AMINO ACID DERIVATIVES

The identification of N-terminal amino acids in peptides and proteins is of considerable practical importance because it constitutes an essential step in the process of sequential analysis of peptide structures. Many N-amino acid derivatives have been proposed for this purpose and the ones most commonly studied by TLC are 2,4-dinitrophenyl (DNP)- and 5-dimethylaminonaphthalene-1-sulfonyl (dansyl, Dns)-amino acids, and 3-phenyl-2-thiohydantoins (PTH-amino acids). Recently, 4-(dimethylamino)azobenzene-4′-isothiocyanate (DABITC) and phenyl-isothiocyanate (PITC) have also been investigated as derivatizing agents of amino acids.

DNP-Amino Acids

The dinitrophenylation of amino acids, peptides, and proteins and their separation by 1D and 2D TLC have been reviewed by Rosmus and Deyl.[4]

DNP-amino acids are divided into those that are ether extractable and those that remain in the aqueous phase. Water-soluble α-DNP-Arg, α-DNP-His, ε-DNP-Lys, bis-DNP-His, *O*-DNP-Tyr, DNP-cysteic acid ($CySO_3H$), and DNP-cystine $(Cys)_2$ have been identified on silica gel plates in the *n*-propanol–34% ammonia (7:3 v/v) system. Although separation of DNP-Arg and ε-DNP-Lys is incomplete (R_f values 0.43 and 0.44, respectively), both of them can be detected because of the color difference produced in the ninhydrin reaction.

Ether-soluble DNP-amino acids have been investigated by 1D and 2D chromatography. The latter technique offers the possibility of almost complete separation of the two groups of derivatives.

The yellow color of DNP-amino acids deepens upon exposure to ammonia vapor, and it is sufficiently intense for visualizing even 0.1 μg. The detection limit is lower (about 0.02 μg) under UV light (360 nm with dried plates and 254 nm with wet ones), but it increases for 2D chromatography (about 0.5 μg). At present, the applications of DNP-amino acids are limited.

PTH-Amino Acids

The formation of PTH-amino acids by the Edman degradation[5] of peptides and proteins or by successive modifications of the method constitutes the most commonly used technique for the study of the structure of biologically active polypeptides today. Identification of PTH-amino acids in mixtures may be successfully achieved by TLC. Quantitative determination is based on UV adsorption (detection limit: 0.1 μg at 270 nm). An alternative is offered by the chlorine/toluidine test, which is very useful since the minimal amount required for detection is about 0.5 μg.

When 1D chromatography on alumina, polyamide, and silica gel is used, difficulties are encountered in resolving Leu/Ile and Glu/Asp pairs as well as other combinations

of PTH-amino acids (e.g., Phe/Val/Met/Thr). The most common solvents used on polyamide plates are *n*-heptane–*n*-butanol–acetic acid (40:30:9), toluene–*n*-pentane–acetic acid (60:30:35), ethylene chloride–acetic acid (90:16), and ethylacetate–*n*-butanol–acetic acid (35:10:1), and those employed on silica gel are *n*-heptane–methylene chloride–propionic acid (45:25:30), xylene–methanol (80:10), chloroform–ethanol (98:2), chloroform–ethanol–methanol (89.25:0.75:10), chloroform–*n*-butylacetate (90:10), diisopropyl ether–ethanol (95:5), methylene chloride–ethanol–acetic acid (90:8:2), *n*-hexane–*n*-butanol (29:1), *n*-hexane–*n*-butylacetate (4:1), pyridine–benzene (2.5:20), methanol–carbon tetrachloride (1:20), and acetone–methylene dichloride (0.3:8). The complete resolution of specific mixtures is possible with 2D chromatography by the use of certain solvent systems mentioned.

The characteristic colors of PTH-amino acids following ninhydrin spray and the colored spots observed under UV light on polyamide plates containing fluorescent additives are very useful in identifying those amino acids that have nearly identical R_f values. TLC of PTH-amino acids has been reviewed by Rosmus and Deyl.[4]

Dns-Amino Acids

Dansylation in 0.2 *M* sodium bicarbonate solution is widely used for the identification of N-terminal amino acids in proteins, and it is the most sensitive method for the quantitative determination of amino acids, since dansyl derivatives are highly fluorescent under a UV lamp (254 nm). Much research has focused on silica gel and polyamide plates using both 1D and 2D chromatography.

No solvent system resolves all the Dns-amino acids by 1D chromatography. Also, 2D chromatography requires more than two runs for a complete resolution. The eluents most commonly used on polyamide layers are benzene–acetic acid (9:1), toluene–acetic acid (9:1), toluene–ethanol–acetic acid (17:1:2), water–formic acid (200:3), water–ethanol–ammonium hydroxide (17:2:1 and 14:15:1), ethylacetate–ethanol–ammonium hydroxide (20:5:1), *n*-heptane–*n*-butanol–acetic acid (3:3:1), chlorobenzene–acetic acid (9:1), and ethylacetate–acetic acid–methanol (20:1:1). On silica plates, acetone–isopropanol–25% aqueous ammonia (9:7:1), chloroform–benzyl alcohol–ethyl acetate–acetic acid (6:4:5:0.2), chloroform–ethyl acetate–acetic acid (38:4:2.8 or 24:4:5), and dichloromethane–methanol–propionic acid (21:3:2) are used.

A widely employed chromatographic system is the one based on polyamide plates eluted with water–formic acid (200:3 v/v) in the first direction and benzene–acetic acid (9:1 v/v) in the second direction. A third run with 1 *M* ammonia–ethanol (1:1 v/v) or ethylacetate–acetic acid–methanol (20:1:1 v/v/v) in the direction of solvent 2 resolves especially basic Dns-amino acids or Glu/Asp and Thr/Ser pairs.

DABTH-Amino Acids

These compounds are obtained in acid medium via dimethylaminoazobenzenethiocarbamyl (DABTC) derivatives formed by the reaction in basic medium of DABITC with the primary amino group of N-terminal amino acids in peptides. The color differences among DABITC, DABTC derivatives, and dimethylaminoazobenzenethiohydantoin (DABTH)-amino acids facilitate identification on TLC. These derivatives are colored compounds and, because of their stability and sensitivity, are usually used for qualitative and quantitative analyses of amino compounds such as amino acids and amines.

All DABTH-amino acids, except the Leu/Ile pair, can be separated by 2D chromatography on layers of polyamide, with water–acetic acid (2:1 v/v) and toluene–*n*-hexane–acetic acid (2:1:1 v/v/v) being solvents 1 and 2, respectively. Resolution of the DABTH-Leu/Dns-Ile pair on polyamide is possible with formic acid–ethanol (10:9 v/v) and on silica plates using chloroform–ethanol (100:3 v/v) as eluent.

PTC-Amino Acids

Phenylthiocarbamyl (PTC) derivatives[6] were obtained at pH 12 by in situ reaction for 15 min or in a tube of phenylisothiocyanate with the amino group of amino acids and separated on silica gel 60 F_{254} and RP-18 F_{254} plates with 2D and 1D chromatography, respectively.

In normal-phase chromatography the 2D technique was used to resolve two mixtures of 10 and 11 PTC-amino acids, by eluting with ethanol–chloroform (2:1 v/v) in the first direction and methanol–dioxane–chloroform (1:1:1 v/v/v) in the second direction.

The PITC zone does not interfere with the spots of amino acids since the derivatizing agent migrates toward the solvent front in such experimental conditions

Detection was performed by exposing the plates sprayed with a sodium azide and starch solution to iodine vapor. White spots on a violet-gray background appeared.

In reversed-phase chromatography, the separations of three mixtures of seven PTC- amino acids were effected by eluting with acetonitrile–4% sodium azide + 2% starch solution (pH = 6.5) (2:8 v/v).

Detection was effected by exposing the plates to iodine vapor for 5 sec. The groups of PTC-Leu, PTC-Ile, and PTC-Phe were not resolved. PITC remains near origin.

Cbo AND BOC-AMINO ACIDS

Carbobenzoxy (Cbo) and *tert*-butyloxycarbonyl (BOC) amino acids are very useful in the synthesis of peptides, and consequently their separation from each other and from unreacted components used in their preparation is

very important. For this separation, various mixtures of *n*-butanol–acetic acid–5% ammonium hydroxide and of *n*-butanol–acetic acid–pyridine with or without the addition of water have been used on silica gel.

The BOC-amino acids give a negative ninhydrin test; however, if the plates are heated at 130°C for 25 min and immediately sprayed with a 0.25% solution of ninhydrin in butanol, a positive test is obtained.

RESOLUTION OF ENANTIOMERIC AMINO ACID AND THEIR DERIVATIVES

Amino acids are optically active and the separation of the enantiomeric pairs is an important objective. (The topic is discussed in the entry *Enantiomeric Separations by TLC*.)

Amino Acids, Peptides, and Proteins: CE Analysis

Danilo Corradini
Institute of Chromatography, Rome, Italy

INTRODUCTION

Amino acids, peptides, and proteins are analyzed by a variety of modes of capillary electrophoresis (CE) which employ the same instrumentation, but are different in the mechanism of separation. A fundamental aspect of each mode of CE is the composition of the electrolyte solution. Depending on the specific mode of CE, the electrolyte solution can consist of either a continuous or a discontinuous system. In continuous systems, the composition of the electrolyte solution is constant along the capillary tube, whereas in discontinuous systems, it is varied along the migration path.

Capillary zone electrophoresis (CZE), micellar capillary electrokinetic chromatography (MECC), capillary gel electrophoresis (CGE), and affinity capillary electrophoresis (ACE) are CE modes using continuous electrolyte solution systems. In CZE, the velocity of migration is proportional to the electrophoretic mobilities of the analytes, which depends on their effective charge-to-hydrodynamic radius ratios. CZE appears to be the simplest and, probably, the most commonly employed mode of CE for the separation of amino acids, peptides, and proteins. Nevertheless, the molecular complexity of peptides and proteins and the multifunctional character of amino acids require particular attention in selecting the capillary tube and the composition of the electrolyte solution employed for the separations of these analytes by CZE.

DISCUSSION

The various functional groups of amino acids, peptides, and proteins can interact with a variety of active sites on the inner surface of fused-silica capillaries, giving rise to peak broadening and asymmetry, irreproducible migration times, low mass recovery, and, in some cases, irreversible adsorption. The detrimental effects of these undesirable interactions are usually more challenging in analyzing proteins than peptides or amino acids, owing to the generally more complex molecular structures of the larger polypeptides. One of the earliest, and still more adopted, strategy to preclude the interactions of peptides and proteins with the wall of bare fused-silica capillaries is the chemical coating of the inner surface of the capillary tube with neutral hydrophilic moieties.[1] The chemical coating has the effect of deactivating the silanol groups by either converting them to inert hydrophilic moieties or by shielding all the active interacting groups on the capillary wall. A variety of alkylsilane, carbohydrate, and neutral polymers can be covalently bonded to the silica capillary wall by silane derivatization.[2] Polyacrylamide (PA), poly(ethylene glycol) (PEG), poly(ethylene oxide) (PEO), and polyvinylpyrrolidone (PVP) can be successfully anchored onto the capillary surface treated with several different silanes, including 3-(methacryloxy)-propyltrimethoxysilane, 3-glycidoxypropyltrimethoxysilane, trimethoxyallylsilane, and chlorodimethyloctylsilane. Alternatively, a polymer can be adsorbed onto the capillary wall and then cross-linked in situ. Other procedures are based on simultaneous coupling and cross-linking. Alternative materials to fused silica such as polytetrafluorethylene (Teflon) and poly(methyl methacrylate) (PMMA) hollow fibers has found limited application.

The deactivation of the silanol groups can also be achieved by the dynamic coating of the inner wall by flushing the capillary tube with a solution containing a coating agent. A number of neutral or charged polymers with the property of being strongly adsorbed at the interface between the capillary wall and the electrolyte solution are employed for the dynamic coating of bare fused-silica capillaries. Modified cellulose and other linear or branched neutral polymers may adsorb at the interface between the capillary wall and the electrolyte solution with the main consequence of increasing the local viscosity in the electric double layer and masking the silanol groups and other active sites on the capillary surface. This results in lowering or suppressing the electro-osmotic flow and in reducing the interactions with the capillary wall.

Polymeric polyamines are also strongly adsorbed in the compact region of the electric double layer as a combination of multisite electrostatic and hydrophobic interactions. The adsorption results in masking the silanol groups and the other adsorption active sites on the capillary wall and in altering the electroosmotic flow, which is lowered and, in most cases, reversed from cathodic to anodic. One of the most widely employed polyamine coating agents is polybrene (or hexadimetrine bromide), a linear hydrophobic polyquaternary amine polymer of the ionene type.[3] Alternative choices are polydimethyldiallylammonium

chloride, another linear polyquaternary amine polymer, and polyethylenimine (PEI). Very promising is the efficient dynamic coating obtained with ethylenediamine-derivatized spherical polystyrene nanoparticles of 50–100 nm diameter, which can be successively converted to a more hydrophilic diol coating by in situ derivatization of the free amino groups with 2,3-epoxy-1-propanol.[4]

In most cases, the electrolyte solution employed in CZE consists of a buffer in aqueous media. Although all buffers can maintain the pH of the electrolyte solution constant and can serve as background electrolytes, they are not equally meritorious in CZE. The chemical nature of the buffer system can be responsible for poor efficiency, asymmetric peaks, and other untoward phenomena arising from the interactions of its components with the sample. In addition, the composition of the electrolyte solution can strongly influence sample solubility and detection, native conformation, molecular aggregation, electrophoretic mobility, and electroosmotic flow. Consequently, selecting the proper composition of the electrolyte solution is of paramount importance in optimizing the separation of amino acids, peptides, and proteins in CZE. The proper selection of a buffer requires evaluating the physical–chemical properties of all components of the buffer system, including buffering capacity, conductivity, and compatibility with the detection system and with the sample.

Non-buffering additives are currently incorporated into the electrolyte solution to enhance solubility, break aggregation, modulate selectivity, improve resolution, and allow detection, which is particularly challenging for amino acids and short peptides. In addition, a large number of amino compounds, including monovalent amines, amino sugars, diaminoalkanes, polyamines, and short-chain alkylammonio quaternary salts are successfully employed as additives for the electrolyte solution to aid in minimizing interactions of peptides and proteins with the capillary wall in bare fused-silica capillaries. Other additives effective at preventing the interactions of proteins, peptides, and amino acids with the capillary wall include neutral polymers, zwitterions, and a variety of ionic and non-ionic surfactants.[5] Less effective at preventing these untoward interactions are strategies using electrolyte solutions at extreme pH values, whether acidic, to suppress the silanol dissociation, or alkaline, to have both the analytes and the capillary wall negatively charged.

Selectivity in CZE is based on differences in the electrophoretic mobilities of the analytes, which depends on their effective charge-to-hydrodynamic radius ratios. This implies that selectivity is strongly affected by the pH of the electrolyte solution and by any interaction of the analyte with the components of the electrolyte solution which may affect its charge and/or hydrodynamic radius.

Additives can improve selectivity by interacting specifically, or to different extents, with the components of the sample. Most of the additives employed in amino acid, peptide, and protein CZE are amino modifiers, zwitterions, anionic or cationic ion-pairing agents, inclusion complexants (only for amino acids and short peptides), organic solvents, and denaturing agents.

The capability of several compounds to ion-pair with amino acids, peptides, and proteins is the basis for their selection as effective additives for modulating the selectivities of these analytes in CZE.[5] Selective ion-pair formation is expected to enlarge differences in the effective charge-to-hydrodynamic radius ratio of these analytes, leading to enhanced differences in their electrophoretic mobilities, which determine improved selectivity. Several diaminoalkanes, including 1,4-diaminobutane (putrescine), 1,5-diaminopentane (cadaverine), 1,3-diaminopropane, and *N*,*N*,*N*′,*N*′-tetramethyl-1,3-butanediamine (TMBD) can be successfully employed as additives for modulating the selectivity of peptides and proteins (Figs. 1 and 2). Moreover, several anions, such as phosphate, citrate, and borate, which are components of the buffer solutions employed as the background electrolyte, may also act as ion-pairing agents influencing the electrophoretic mobilities of amino acids, peptides, and proteins and, hence, selectivity and resolution. Other cationic ion-pairing agents include the ionic polymers polydimethyldiallylammonium chloride and polybrene, whereas myoinositol hexakis-(dihydrogen phosphate), commonly known as phytic acid, is an interesting example of a polyanionic ion-pairing agent.

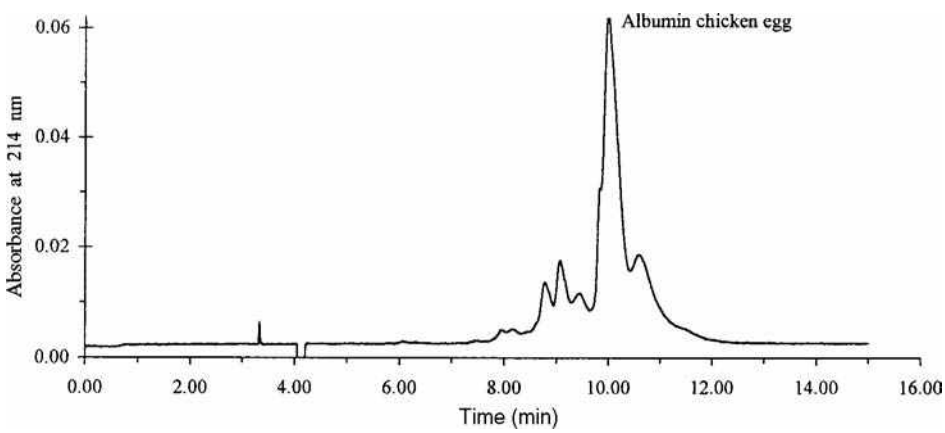

Fig. 1 Detection of microheterogeneity of albumin chicken egg by capillary zone electrophoresis. Capillary, bare fused-silica (50 μm × 37 cm, 30 cm to the detector); electrolyte solution, 25 m*M* Tris-glycine buffer containing 0.5% (v/v) Tween-20 and 2.0 m*M* putrescine; applied voltage, 20 kV; UV detection at the cathodic end.

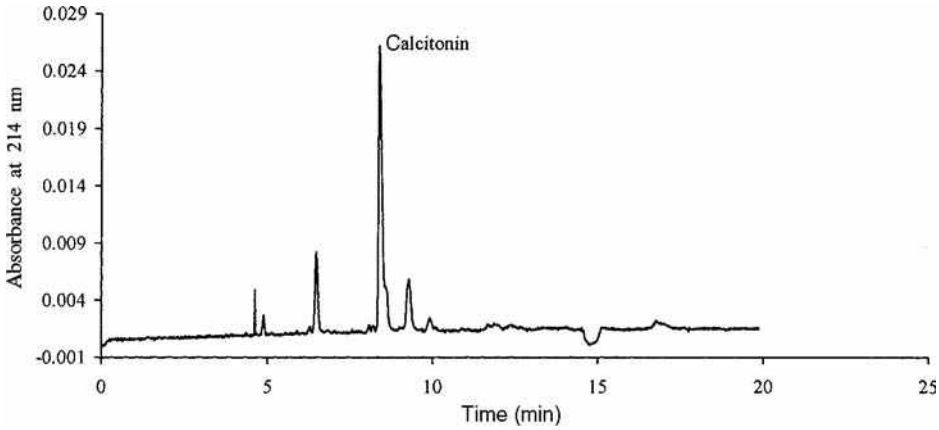

Fig. 2 Separation of impurities from a sample of synthetic human calcitonin for therapeutic use by CZE. Capillary, bare fused-silica (50 μm × 37 cm, 30 cm to the detector); electrolyte solution, 40 m*M* *N*,*N*,*N*′,*N*′-tetramethyl-1,3-butanediamine (TMBD), titrated to pH 6.5 with phosphoric acid; applied voltage, 15 kV; UV detection at the cathodic end.

Surfactants have been investigated extensively in CE for the separation of both charged and neutral molecules using a technique based on the partitioning of the analyte molecules between the hydrophobic micelles formed by the surfactant and the electrolyte solution, which is termed micellar electrokinetic capillary chromatography (MECC or MEKC). This technique is widely used for the analysis of a variety of peptides and amino acids,[6] but it is less popular for protein analysis.[7] The limited applications of MECC to protein analysis may be attributed to several factors, including the strong interactions between the hydrophobic moieties on the protein molecules and the micelles, the inability of large proteins to penetrate into the micelles, and the binding of the monomeric surfactant to the proteins. The result is that, even though the surfactant concentration in the electrolyte solution exceeds the critical micelle concentration, the protein–surfactant complexes are likely to be not subjected to partitioning in the micelles, as do amino acids, peptides, and other smaller molecules.

However, surfactants incorporated into the electrolyte solution at concentrations below their critical micelle concentration (CMC) may act as hydrophobic selectors to modulate the electrophoretic selectivity of hydrophobic peptides and proteins. The binding of ionic or zwitterionic surfactant molecules to peptides and proteins alters both the hydrodynamic (Stokes) radius and the effective charges of these analytes. This causes a variation in the electrophoretic mobility, which is directly proportional to the effective charge and inversely proportional to the Stokes radius. Variations of the charge-to-hydrodynamic radius ratios are also induced by the binding of non-ionic surfactants to peptide or protein molecules. The binding of the surfactant molecules to peptides and proteins may vary with the surfactant species and its concentration, and it is influenced by the experimental conditions such as pH, ionic strength, and temperature of the electrolyte solution. Surfactants may bind to samples, either to the same extent [e.g., protein–sodium dodecyl sulfate (SDS) complexes], or to a different degree, which can enlarge differences in the electrophoretic mobilities of the separands.

In CGE, the separation is based on a size-dependent mechanism similar to that operating in polyacrylamide gel electrophoresis (PAGE), employing as the sieving matrix either entangled polymer solutions or gel-filled capillaries.[8] This CE mode is particularly suitable for analyzing protein complexes with SDS. The separation mechanism is based on the assumption that fully denatured proteins hydrophobically bind a constant amount of SDS (1.4 g of SDS per 1 g of protein), resulting in complexes of approximately constant charge-to-mass ratios and, consequently, identical electrophoretic mobilities. Therefore, in a sieving medium, protein–SDS complexes migrate proportionally to their effective molecular radii and, thus, to the protein molecular weight. Consequently, SDS–CGE can be used to estimate the apparent molecular masses of proteins, using calibration procedures similar to those employed in SDS–PAGE.

Continuous electrolyte solution systems are also employed in ACE,[9] where the separation depends on the biospecific interaction between the analyte of interest and a specific selector or ligand. The molecules with bioaffinity for the analyte (the selector or ligand) can be incorporated into the electrolyte solution or can be immobilized, either to an insoluble polymer filled into the capillary or to a portion of the capillary wall. ACE is a useful and sensitive tool for measuring the binding constant of ligands to proteins and characterizing molecular properties of peptides and proteins by analyzing biospecific interactions. Examples of biospecific interactions currently investigated by ACE include molecular recognition between proteins or peptides and low-molecular-mass receptors, antigen–antibody complexes, lectin–sugar interactions, and enzyme–substrate complexes. ACE is also employed for the chiral separation of amino acids using a protein as the chiral selector.

Enantiomeric separations of amino acids and short peptides are performed using either a direct or the indirect approach.[10] The indirect approach employs chiral reagents for diasteromer formation and their subsequent

separation by various modes of CE. The direct approach uses a variety of chiral selectors that are incorporated into the electrolyte solution. Chiral selectors are optically pure compounds bearing at least one functional group with a chiral center (usually represented by an asymmetric carbon atom) which allows sterically selective interactions with the two enantiomers. Among others, cyclodextrins (CDs) are the most widely chiral selectors used as additives in chiral CE. These are cyclic polysaccharides built up from D-(+)-glucopyranose units linked by α-(1,4) bonds, whose structure is similar to a truncated cone. Substitution of the hydroxyl groups of the CDs results in new chiral selectors which exhibit improved solubility in aqueous solutions and different chiral selectivity. Other chiral selectors include crown ethers, chiral dicarboxylic acids, macrocyclic antibiotics, chiral calixarenes, ligand-exchange complexes, and natural and semisynthetic linear polysaccharides. Chiral selectors are also commonly employed in combination with ionic and non-ionic surfactants for enantiomeric separations of amino acids and peptides by MECC.

In discontinuous systems, the composition of the electrolyte solution is varied along the migration path with the purpose of changing one or more parameters responsible for the electrophoretic mobilities of the analytes. The discontinuous electrolyte solution systems employed in capillary isoelectric focusing (CIEF) have the function of generating a pH gradient inside the capillary tube in order to separate peptides and proteins according to their isoelectric points.[11] Each analyte migrates inside the capillary until it reaches the zone with the local pH value corresponding to its isoelectric point, where it stops moving as a result of the neutralized charge and consequent annihilated electrophoretic mobility. CIEF is successfully employed for the resolution of isoenzymes, to measure the isoelectric point (p*I*) of peptides and proteins, for the analysis of recombinant protein formulation, hemoglobins, human serum, and plasma proteins. Discontinuous electrolyte solution systems are also employed in capillary isotachophoresis (CITP), where the analytes migrate as discrete zones with an identical velocity between a leading and a terminating electrolyte solution having different electrophoretic mobilities. CITP finds large applications as an online preconcentration technique prior to CZE, MECC, and CGE. It is also employed for the analysis of serum and plasma proteins and amino acids.[12]

The majority of amino acids and short peptides have no, or only negligible, UV absorbance. Detection of these analytes often requires chemical derivatization using reagents bearing UV or fluorescence chromophores. High detection sensitivity, reaching the attomolar (10^{-21}) mass detection limit can be obtained using fluorescence labeling procedures in combination with laser-induced fluorescence detection.[13] A variety of fluorescence and UV labeling reagents are currently employed, including *O*-phthaldehyde (OPA), fluorescein isothiocyanate (FITC), 1-dimethylaminonaphthalene-5-sulfonyl chloride (dansyl chloride), 4-phenylspiro[furan-2(3H)-1′ phthalene (fluorescamine), and naphthalene dicarboxaldehyde (NDA). However, derivatization may reduce the charge-to-hydrodynamic radius ratio differences between analytes, making separations difficult to achieve. In addition, precolumn derivatization is not suitable for large peptides and proteins, due to the formation of multilabeled products. These problems can be overcome using postcolumn derivatization procedures.

Another, very attractive alternative is indirect UV detection.[14] This indirect detection procedure makes use of a UV-absorbing compound (or "probe"), having the same charge as the analytes, that is incorporated into the electrolyte solution. Displacement of the probe by the migrating analyte generates a region where the concentration of the UV-absorbing species is less than that in the bulk electrolyte solution, causing a variation in the detector signal. In the indirect UV detection technique, the composition of the electrolyte solution is of critical importance, because it dictates separation performance and detection sensitivity.

Probes currently employed in the indirect UV detection of amino acids include *p*-aminosalicylic acid, benzoic acid, phthalic acid, sodium chromate, 4-(*N*,*N*′-dimethylamino)-benzoic acid, 1,2,4,-benzenetricarboxylic acid (trimellitic acid), 1,2,4,5-benzenetetracarboxylic acid (pyromellitic acid), and quinine sulfate. Several of these probes are employed in combination with metal cations and cationic surfactants, which are incorporated into the electrolyte solution as modifiers of the electro-osmotic flow.

Coupling mass spectrometry (MS) to CE provides detection and identification of amino acids, peptides, and proteins based on the accurate determination of their molecular masses.[15] The most critical part of coupling MS to CE is the interface technique employed to transfer the sample components from the CE capillary column into the vacuum of the MS. Electrospray ionization (ESI) is the dominant interface which allows a direct coupling under atmospheric pressure conditions. Another distinguishing features of this "soft" ionization technique when applied to the analysis of peptides and proteins is the generation of a series of multiple charged, intact ions. These ions are represented in the mass spectrum as a sequence of peaks, the ion of each peak differing by one unit of charge from those of adjacent neighbors in the sequence. The molecular mass is obtained by computation of the measured mass-to-charge ratios for the protonated proteins using a "deconvolution algorithm" that transforms the multiplicity of mass-to-charge ratio signals into a single peak on a real mass scale. Obtaining multiple charged ions is actually advantageous, as it allows the analysis of proteins up to 100–150 KDa using mass spectrometers with an upper mass limit of 1500–4000 amu.

Concentration detection limits in CE/MS with the ESI interface are similar to those with UV detection. Sample sensitivity can be improved by using ion-trapping or time-of-flight (TOF) mass spectrometers. MS analysis can also

be performed off-line, after appropriate sample collection, using plasma desorption–mass spectrometry (PD–MS) or matrix-assisted laser desorption–mass spectrometry (MALDI–MS).

Amino Acids: HPLC Analysis

Ioannis N. Papadoyannis
Georgios A. Theodoridis
Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece

INTRODUCTION

Amino acids are small organic molecules that posses both an amino and a carboxyl group. Amino acids occur in nature in a multitude of biological forms, either free or conjugated to various types of compounds, or as the building blocks of proteins. The amino acids that occur in proteins are named α-amino acids and have the empirical formula $RCH(NH_2)COOH$. Only 20 amino acids are used in nature for the biosynthesis of the proteins, because only 20 amino acids are coded by the nucleic acids.

DISCUSSION

Amino acids show acid–base properties, which are strongly dependent on the varying R groups present in each molecule. The varying R groups of individual amino acids are responsible for specific properties: polarity, hydrophilicity–hydrophobicity.[1,2] Hence, the 20 α-amino acids could be categorized in the 4 distinct groups listed in Table 1.

Their dipolar (zwitterionic) behavior is a fundamental factor in any separation approach. At low pH, amino acids exist in their cationic form with both amino and carboxyl groups protonated. The ampholyte form appears at a pH of 6–7, whereas at higher values, amino acids are in their anionic form (carboxyl group dissociated). Another important parameter is that all α-amino acids (with the exception of Gly) are asymmetrical molecules exhibiting optical isomerization (L being the isomer found in nature). As can be seen in Table 1, amino acids are actually small [molecular weight (MW) ranging from 75 to 204] molecules, exhibiting pronounced differences in polarity and a few chromophoric moieties.

The determination of amino acids in various samples is a usual task in many research, industrial, quality control, and service laboratories. Hence, there is a substantial interest in the HPLC analysis of amino acids from many diverse areas like biochemistry, biotechnology, food quality control, diagnostic services, neuro-chemistry/biology, and so forth. As a result, the separation of amino acids is probably the most extensively studied and best developed chromatographic separation in biological sciences. The most known system is the separation on a cation-exchange column and postcolumn derivatization with ninhydrin, which was described in 1951 by Moore and Stein. With this approach, a sulfonated polystyrene column achieved a separation of the 20 naturally occurring amino acids within approximately 6 hr; modifications of the original protocol enhanced color stabilization of the derivatives and enabled the application of the method in various real samples. Since then, immense developments in instrumentation, column technologies, and automation established high-performance liquid chromatography (HPLC) as the dominant separation technique in chemical analysis. Numerous published reports described the HPLC analysis of amino acids in a great variety of samples. To no surprise, a two-volume handbook is entirely devoted to HPLC for the separation of amino acids, peptides and proteins.[3] Many of the initial reports employed soft resins or ion exchangers such as polystyrene or cellulose as stationary phases. These materials show some disadvantages (e.g., compaction under pressure, reduced porosity, and wide particle size distribution). The last decades' developments in manufacturing silica-based materials resulted in the domination of reversed-phase (RP) silica-based packing in liquid chromatography. As a result, RP-HPLC is, at present, widely used for the separation of amino acids, because it offers high resolution, short analysis time, ease in handling combined with low cost, and environmental impact per analysis circle.

In ligand-exchange chromatography (LEC), the separation of analytes is due to the exchange of ligands from the mobile phase with other ligands coordinated to metal ions immobilized on a stationary phase. LEC has been used successfully for the resolution of free amino acids, amino acid derivatives, and for enantiomeric resolution of racemic mixtures.[3]

Apart from ninhydrin, many other derivatization reagents have been used; both precolumn and postcolumn derivatization modes have been extensively employed.[3–5] Derivatization procedures offer significant advantages in both separation and detection aspects and, thus, will be discussed in further detail. The rest of the entry will be divided into two sections: separation of underivatized amino acids, where the determination of free amino acids and postcolumn derivatization procedures are described; and separation of derivatized amino acids, where precolumn derivatization approaches are discussed.

	Amino acid	Structure at pH 6-7	MW	pK_a
Hydrophobic Aminoacids (Non-polar R)	Alanine Ala		89	2.35, 9.69
	Leucine Leu		131	2.36, 9.60

	Histidine His		155	1.82, 8.95, 10.53

SEPARATION OF UNDERIVATIZED AMINO ACIDS

The differing solubilities, polarities, and acid–base properties of free amino acids have been exploited in their separation by partition chromatography, ion-exchange chromatography, and electrophoresis. For example, the elution order obtained from a polystyrene ion-exchange resin with an acidic mobile phase corresponds to the amino acid classification depicted in Table 1: Acidic amino acids are eluted early, neutral between, and basic amino acids later. In this case, ionic interactions between the sample and the stationary phase are the driving force for the separation of the groups. However, hydrophobic van der Waals and π–π aromatic interactions are responsible for the separation of amino acids within the groups.[3]

The dominant stationary phase in HPLC is modified silica and, to be more specific, octadecyl silica (ODS). It should be pointed out that there could be great differences between various types of ODS materials or even between different batches of the same material. Carbon load, free silanol content, endcapping, type of silica, and coupling chemistry to the C_{18} moiety, not to mention the several physical characteristics of the packing material all involve the behavior of an ODS column. However, a rather safe generalization is that, in such material, hydrophobic interactions are a dominant mechanism of separation.[3–7]

In typical ODS materials, polar amino acids are very weakly retained on column; thus, they are insufficiently resolved. In contrast, non-polar amino acids are stronger retained and adequately separated. To overcome the poor resolution of polar amino acids, two strategies are the most promising:

1. Derivatization (as discussed in the next section).
2. Modification of the mobile phase with the addition of ion-pairing reagents.

Alkyl sulfates/sulfonates added to the mobile phase form a micellar layer interacting with both the stationary phase and the amino acids (which under these conditions are protonated). A mixed mechanism (ion-pairing and dynamic ion exchange) is observed. Furthermore, the ion-pairing reagent masks underivatized silanols of the ODS material, reducing non-specific unwanted interactions. Sodium dodecyl sulfate (SDS) is the most often used ion-pairing reagent. Gradient elution is often required to achieve reasonable analysis time for non-polar amino acids. Despite the above-mentioned advantages, ion-pairing shows some disadvantages, such as irreproducibility (especially in gradient runs), long equilibration times, and difficulties in ultraviolet (UV) detection.

Another possibility is the use of alternative stationary phases. A strong trend of the last decade is the employment of specialty phases in challenging and complex separations. Thus, newer C_8, NH_2, CN, mixed mode phases (materials incorporating both ion exchange and reversed-phase moieties), new polymeric phases, and zirconia-based materials offer attractive stationary-phase selectivities.

POSTCOLUMN DERIVATIZATION

The non-derivatized amino acids, following their chromatographic separation, can either be directly detected as free amino acids, online derivatized, or by postcolumn derivatization. Derivatization with ninhydrin, the classical amino acid analysis, was the first reported postcolumn derivatization method. Modern postcolumn derivatization protocols employ sophisticated instrumentation and achieve high resolution and sensitivity. In such configurations, derivatization occurs in a reaction coil placed between the analytical column and the detector. Additional pumps and valves are required; thus, such systems typically run fully automated and controlled by a computer. The major disadvantages of postcolumn derivatization are the need for sophisticated and complex instrumentation and the band broadening occuring in the reactor. *O*-phthaldialdehyde (OPT) is the most common reagent in postcolumn derivatization. OPT reacts with primary amino acids under basic conditions, forming a fluorescent derivative (OPA derivative) that allows detection at femtomole levels. Disadvantages of OPA derivatization are the instability of the resultant derivatives and the fact that secondary amino acids are not detected.

If no derivatization takes place, detection is preferably accomplished by UV at a low wavelength (200–210 nm) in order to enhance detection sensitivity. However, detection selectivity is sacrificed at such low wavelengths. Electrochemical detection, when applied to the analysis

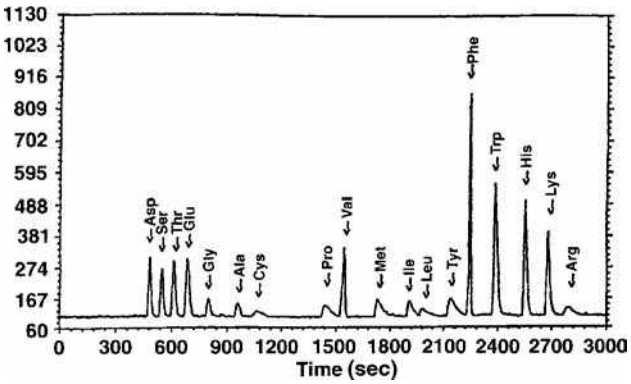

Fig. 1 HPLC analysis of 18 common amino acids. Conditions: stationary phase: CS-10 cation exchange; mobile phase: gradient of aqueous 0.01% TFA and ammonium acetate; detection at the ELSD.
Source: From Amino acid analysis of peptides using HPLC with evaporative light scattering detection, in J. Liq. Chromatogr. Relat. Technol.[11]

of free amino acids, offers higher selectivity but suffers from a small linearity range. Furthermore, most amino acids (with the excepion of tryptophan, tyrosine, and cysteine) are not intrinsically electrochemically active within the current useful potential range.[5] Lately, the development of the evaporative light-scattering detector (ELSD) offers an attractive alternative for the determination of non-derivatized amino acids (Fig. 1).

SEPARATION OF DERIVATIZED AMINO ACIDS

Precolumn derivatization is the generally accepted approach for the determination of amino acids, because it offers significant advantages: increased detection sensitivity, enhanced selectivity, enhanced resolution, and limited needs for sophisticated instrumentation (in contrast with postcolumn derivatization techniques).

In modern instrument configurations, derivatization can take place in a conventional autosampler; the resultant derivatives are separated on the analytical column. Detection limits at the femtomole level are achieved, and the resolution of polar amino acids is greatly enhanced.

The most common derivatization reagents are as follows:

- Dimethylamino azobenzene isothiocyanate (DABITC).
- 4-(Dimethylamino)azobenzene-4-sulfonyl chloride (dabsyl chloride or DABS-Cl) [dabsyl derivatives].
- 1-*N*-*N*-Dimethylaminonaphthalene-5-sulfonyl chloride [dansyl derivatives].
- Fluorodinitrobenzene (DNP derivatives).
- Fluorescamine.
- 9-Fluorenylmethyl chloroformate (FMOC-Cl).
- 4-Chloro-7-nitro-2,1,3-benzoxadiazole (NBD-Cl).
- Phenylisothiocyanate (PITC) [phenylthiohydantoin (PTH) derivatives].
- Methylisothiocyanate (MITC) [methylthiohydantoin (MTH) derivatives].

Fig. 2 illustrates the structure of the product resulting from the derivatization of an amino acid with the above-mentioned reagents. Mixtures of derivatives with the most commonly used reagents (dansyl, DNP, PTH) are readily provided in kits, to be directly used as reference standards in HPLC analysis.

Phenylthiohydantoin derivatization offers a special value because it is actually performed during Edman degradation, the sequencing technique mostly used for the determination of the primary structure of proteins and peptides. PTH derivatives are separated in many different stationary phases, in either normal- or reversed-phase mode and are mostly detected at 254 nm.[8–9] Using radiolabeled proteins, sequencing of proteins down to the 1–100 pmol range can be achieved. The formed derivatives are basic and thus interact strongly with base silica materials. RP separations are mostly carried out in acidic conditions with the addition of appropriate buffers (sodium acetate mostly, but also phosphate, perchlorate, etc). Failings of PTH derivatization are the lengthy procedure and the higher detection limits obtained (compared to fluorescent derivatives). Potent advantages of the method are its robustness and reproducibility, and the extensive research literature that covers any possible requirement. An alternative to PTH is MTH derivatization, a method well suited for solid-phase sequencing.[3]

Dimethylamino azobenzene isothiocyanate microsequencing results in red–orange derivatives, which exhibit their absorbance maximum at 420 nm with $\varepsilon = 47.000$, in other words offering threefold higher sensitivity compared to PTH derivatives. DABITC derivatives are separated in C_8 or C_{18} columns in acidic environment, within 20 min.

Dabsyl chloride is an alternative to DABITC as a derivatization reagent to be used for manual sequencing. Dabsyl chloride reacts with primary and secondary amino acids forming red–orange derivatives that are stable for months. The method offers excellent sensitivity, ease, and speed of preparation and high-resolution capabilities. However, it suffers from interferences with ammonia present in biological samples. Furthermore, it results in a relatively reduced column lifetime due to the utilization of excess of Dabsyl chloride.[9]

The dansyl derivatization has been extensively studied to label α- or ε-amino groups. DNS derivatives are formed within 2 min and are detected by either UV or fluorescence. A typical example of a separation of dansyl amino acids is illustrated in Fig. 3.

The FMOC derivatization offers high fluorescent detection sensitivity, but it requires an extraction step to remove unreacted FMOC and by-products. This step is a potential cause of analyte losses. Furthermore, it not suitable for

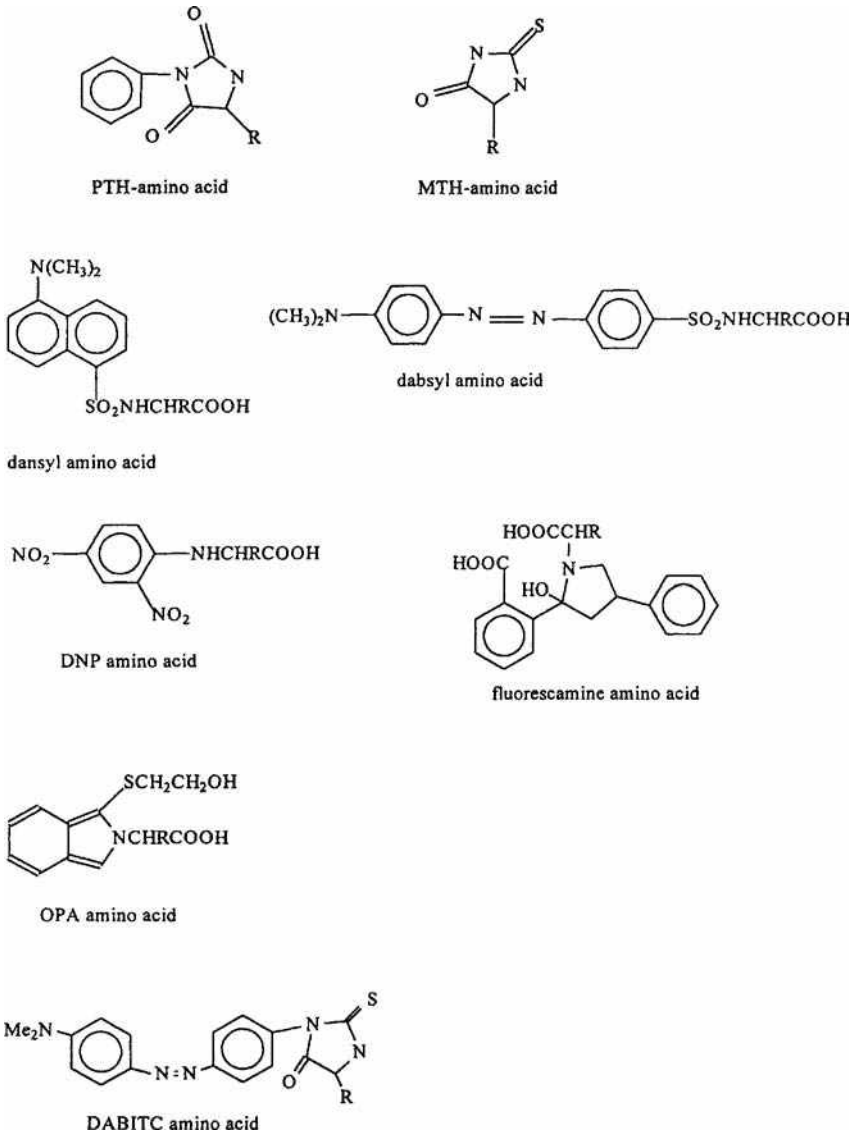

Fig. 2 Structures of the most common amino acid derivatives.

Trp and Cys, because the corresponding derivatives exhibit a lower response due to intramolecular quenching of fluorescence.

The DNP derivatives are analyzed either in normal or reversed phase. Disadvantages of this method are the lower detection sensitivity (60 times less sensitive compared to dabsyl detection) and the lower separation resolution. However, this approach has proven useful for the determination of lysine in food materials.

Finally, the incorporation of an electroactive functionality into a chromatographic label is an attractive alternative for the HPLC of amino acids. Reagents like p–*N* and *N*-dimethylaminosothiocyanate have been used to facilitate amperometric detection of the derivatives.

CHIRAL SEPARATION OF AMINO ACIDS

The importance of chirality has rapidly evolved the last decade. Both analytical and preparative separations are needed for biochemical, pharmaceutical, and alimentary purposes. Amino acids are asymmetrical molecules. L is the form appearing in proteins; however the D form is also present in nature. Enantiomeric separation of amino acids has been achieved in various stationary phases, such as polystyrene and polyacrylamide to which chiral ligands were covalently bound. Metal ions, in conjunction with chiral ligands, have also been utilized in the mobile phase in the reversed-phase and ligand-exchange mode. Novel stationary chiral phases developed for enantiomeric analysis incorporate chiral ligands (e.g., cyclodextrins or even amino acids) immobilized on silica. Generally, L-amino acid-bonded phases retain L-amino acids stronger than the D species.[3,5,10]

Recently, a strong trend in molecular recognition is the development of molecular imprinting polymers (MIP). MIPs have been used as synthetic antibodies in immunoassays and biosensors, but also as catalysts and separation media (employed both in analysis and extraction). One of

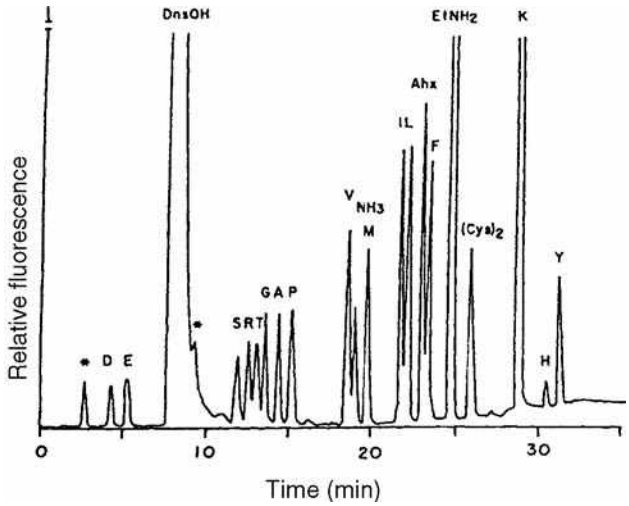

Fig. 3 RP–HPLC analysis of a mixture of dansyl amino acids. Conditions: stationary phase: 4 μm Nova Pak C_{18}; mobile phase: gradient of methanol and tetrahydrofuran versus aqueous phosphate buffer; detection in a fluorescent detector; excitation 338 nm, emission 455 nm. Amino acids are abbreviated by the one-letter system.

the first applications of MIPs in separations was the enantiomeric separation of amino acids derivatives.

CONCLUSIONS

High-performance liquid chromatography, when compared to other instrumental methods [thin-layer chromatography (TLC), gas chromatography (GC), automated amino acid analyzer], offers significant advantages in the analysis of amino acids: high resolution, high sensitivity, low cost, time saving (one-third of the analysis time of an amino acid analyzer), and a multivariate optimization scheme offering versatility and flexibility. Furthermore, optimization of HPLC determination enables the practitioner to overcome typical problems of other methods (e.g., the well-known interferences of ammonia in amino acid analyzer). An additional advantage of HPLC is its direct compatibility with mass spectrometry. The widespread use of liquid chromatography–mass spectrometry (LC–MS) in proteomic analysis, which at present utilizes state of the art mass spectrometers (e.g., matrix-assisted laser desorption ionization–time-of-flight—mass spectrometry), is seen as a potent future trend.

The variety of instrumentation and experimental conditions (columns, buffers, organic modifiers, derivatization procedures, etc.) reported in the vast literature may hinder the novice from pinpointing the best method to use. The choice of the appropriate method depends on the specific needs of each analytical problem and the nature of the sample to be analyzed. Aspects such as specificity and speed of the derivatization reaction should always be considered. Furthermore, in such multivariate dynamic systems, precision, accuracy, and linearity of the chosen method is a very important factor. The practitioner should carefully follow the developed protocol; the use of automated systems, especially in derivatization procedures, could greatly enhance the reproducibility of the method.

Amino Acids: HPLC Analysis Advanced Techniques

Susana Maria Halpine
STArt! teaching Science Through Art, Playa del Rey, California, U.S.A.

INTRODUCTION

Amino acid analysis (AAA) is a classic analytical technique that characterizes proteins and peptides based on the composition of their constituent amino acids.[1,2] It provides qualitative identification and is essential for the accurate quantification of proteinaceous materials.

Amino acid analysis is widely applied in research, clinical facilities, and industry. It is a fundamental technique in biotechnology, used to determine the concentration of peptide solutions, to confirm protein binding in antibody conjugates, and for end-terminal analysis following enzymatic digestion. Clinical applications include diagnosing metabolic disorders in newborns. In industry, it is used for quality control of products ranging from animal feed to protein pharmaceuticals.

The analysis of a polypeptide typically involves four steps: hydrolysis (or deproteination with physiological samples), separation, derivatization, and detection. Hydrolysis breaks the peptide bonds and releases free amino acids, which are then separated by side-group using column chromatography. Derivatization with a chromogenic reagent enhances the separation and spectral properties of the amino acids, and is required for sensitive detection. A data processing system compares the resulting chromatogram, based on peak area or peak height, to a calibrated standard (Fig. 1a). The results, expressed as mole percent and micrograms of residue per sample, determine the percentage composition of each amino acid as well as the total amount of protein in the sample. Unknown proteins may be identified by comparing their amino acid composition with those in protein databases. Successful identification of unknown proteins may be achieved using internet search programs.[3]

Other techniques, such as capillary electrophoresis (CE) and matrix-assisted laser desorption ionization (MALDI) mass spectrometry, provide qualitative analyses–often with greater speed and sensitivity.[1] Nevertheless, AAA by high-performance liquid chromatography (HPLC) complements other structural analysis techniques, such as peptide sequencing, and remains indispensable for quantifying the composition and absolute content of proteinaceous materials.[2]

PEPTIDE HYDROLYSIS

Acid hydrolysis of proteins and peptides yields 16 of the 20 DNA-coded amino acids; tryptophan is destroyed, cysteine recovery is unreliable, and asparagine and glutamine are converted to aspartic acid and glutamic acid, respectively.[1,2,4,5] Furthermore, some side-groups, such as the hydroxyl in serine, promote the breakdown of the residue, while aliphatic amino acids such as valine and leucine, protected by stearic hindrance, require longer hydrolysis time. This variation in yield can be overcome by hydrolyzing samples for 24, 48, and 72 hr and extrapolating the results to zero time point.

Conventional hydrolysis exposes the polypeptide to 6 *M* HCl under vacuum at 110°C for 20–24 hr. Protective agents, such as 0.1% phenol, are added to improve recovery. Gas-phase hydrolysis, in which the acid is delivered as a vapor, gives comparable results to liquid-phase hydrolysis. Additionally, the gas phase minimizes acid contaminants and allows parallel hydrolysis of standards and samples within the same chamber.

The reaction rate doubles with every 10°C increase, so that hydrolysis at 145°C for 4 hr gives results comparable to those from the conventional method. Microwave hydrolysis reduces analysis time to 30–45 min. Alternative hydrolysis agents include methane sulfonic acid, which often gives better recovery but is non-volatile, and alkaline hydrolysis, used in the analysis of tryptophan, proteoglycans, and proteolipids.

Careful sample preparation and handling during the hydrolysis step are critical for maintaining accurate and reproducible results.[1,2,4–6] Salts, metal ions, and other buffer components remaining in a sample may accelerate hydrolysis, producing unreliable quantification. The Maillard reaction between amino acids and carbohydrates results in colored condensation products (humin) and decreased yield.[7] Routine method calibration with proteins and amino acid standards, use of an internal standard (1 nmol norleucine is used for sensitive analysis), and control blanks are strongly recommended, along with steps to minimize background contaminants (Fig. 1b). Attention to housekeeping details, such as cleaning glassware and baking in a muffle furnace, can minimize background contaminants. The practical limit for high sensitivity hydrolysis is 10–50 ng of sample; below this amount, background contaminants and losses during hydrolysis begin to play a larger role.

DERIVATIZING REAGENTS FOR ANALYSIS OF AMINO ACIDS BY HPLC

The first automated analyzer was developed by Moore, Stein, Spackman, and Hamilton in the 1950s. Hydrolysates

were separated on an ion-exchange column, followed by postcolumn reaction with ninhydrin. Although this system remains the standard method, especially for physiological amino acids, its major drawback is low sensitivity, typically at the nanomole level. Several methods have since been developed offering high sensitivity and faster analyses without sacrificing reproducibility.[1–5,7–9] The choice of an optimal derivative technique depends on factors such as specific application requirements, sample size, sample preparation time, and equipment maintenance.[10] Amino acid derivatives based on ultraviolet (UV) light detection provide accurate analysis at the picomole level and derivatives requiring fluorescence detection are accurate at the femtomole level.

Amino acids react with many reagents to form stable derivatives and strong chromophores (Table 1). Derivatization can precede (precolumn) or follow (in-line postcolumn) the chromatographic separation. Both pre- and postcolumn systems are currently employed: ninhydrin and phenylisothiocyanate (PITC) analyzers are widely used, while 6-aminoquinolyl-*N*-hydroxysuccinimidyl carbamate (AQC), *O*-phthalaldehyde (OPA), and OPA/9, fluorenylmethylchloro-formate (FMOC) systems provide the highest sensitivity.

Postcolumn systems typically use cation-exchange columns with either sodium citrate (for hydrolysates) or lithium citrate (for physiological samples) as the mobile phase. Contaminating salts and detergents are better tolerated because the samples are "cleaned up" before reaction with the reagent. The additional pump for the reagent, however, may lead to sample dilution, peak broadening, baseline fluctuations, and longer analysis time (30–90 min). Fluorescent reagents are compatible with a wider range of buffers, but the buffers must be amine-free if used with precolumn methods.

Since the 1980s, precolumn derivatization methods have gained wider acceptance due to simpler preparation,

Table 1 Amino acid derivatization reagents.

Reagent	Chromophore	Detection limit	Separation time	Drawbacks	Advantages
AQC (6-aminoquinolyl-*N*-hyfroxysuccinimidyl carnamate)	Fluorescent (ex. 245 nm, em. 395 nm); UV 245 nm	160 fmol	35–50 min precolumn	Quaternary gradient elution required for complex, non-hydrolysate samples	Tolerates salts and detergents, rapid reaction, stable product, good reagent separation, high sensitivity and accurancy
Dansyl chloride(4-*N*, *N*-dimethylaminoazobenzene-4′-sulfonyl chloride)	Visible 436 nm	Low fmol	18–44 min precolumn	Multiple products, critical concentration	Stable product, good separation, high sensitivity
Dansyl chloride (5,*N*, *N*-dimethylaminonaphthalene-1-sulfonyl chloride)	Fluorescent (ex. 360–385 nm, em. 460–495 nm); UV 254 nm	Low pmol	60–90 min	Multiple products, critical concentration, difficult separation leads to long separation time	Stable product
Fluorescamine(4-phenyl-spiro[furan-2(3H), 1′-phthalan]-3,3′-dione)	Fluorescent (ex. 390 nm, em. 475 nm)	20–100 pmol	30–90 min postcolumn	Secondary amine pretreatment, critical concentraion, may give background interference	Rapid reaction, stable product, good reagent separation
FMOC (9-fluorenylmethylchloro formate)	Fluorescent (ex. 265 nm,1 pmol em, 320 nm); UV 265 nm	1 pmol	20–45 min precolumn	Multiple products, extraction of excess reagent	Stable product, used with OPA for detection of secondary amine
Ninhydrin (triketohydrindene hydrate)	Primary amine (440 nm), secondary amine (570 nm)	100 pmol	30 min postcolumn	Low sensitivity and resolution	Good reproducibility
OPA (*O*-phthalaldehyde)	Fluorescent (ex. 340 nm, em. 455 nm	50 fmol	90 min postcolumn, 17–35 precolumn	Secondary amine pretreatment, slow reaction, unstable derivative, background interference	Good reagent separation, high sensitivity and reproducibility with automated system
PITC (phenylisothiocyanate)	UV 254 nm	1 pmol	15–27 min precolumn	Salt interference, requires refrigeration, excess reagent removed under vacuum	Ease of use, flexibility, good separation, reproducibility enhanced with automation

Adapted from Cooper, Packer, & Williams[1] and Smith.[2]

faster analyses, and better resolution. The separation on reversed-phase C-8 or C-18 columns typically requires low-UV mobile phases, such as sodium phosphate or sodium acetate buffers, with acetonitrile or methanol as organic solvent. Separation times range from 15 to 50 min.

IMPROVED RECOVERY OF SENSITIVE AMINO ACIDS

Cysteine and tryptophan require special treatment for quantitative analysis.[1,11] Cystine/cysteine can be determined using three equally successful methods: oxidation, alkylation, and disulfide exchange. Oxidation to cysteic acid is commonly carried out by pretreatment with performic acid. Alkylation using pretreatment with 4-vinylpyridine or iodoacetate produces piridylethylcysteine (PEC) and carboxymethylcysteine (CMC), respectively. Disulfide exchange is achieved by adding reagents such as dithiodipropionic acid, dithiodiglycolic acid, or dimethylsulfoxide (DMSO) to the HCl during hydrolysis. The latter treatment offers ease of use as well as accurate yields.

The superior approach to tryptophan analysis involves the addition of dodecanethiol to HCl, especially when combined with automatic vapor-phase hydrolysis. Alternative hydrolysis agents such as methane sulfonic acid, mercaptoethanesulfonic acid, or thioglycolic acid can produce 90% or greater yields. Acid hydrolysis additives and alkaline hydrolysis using 4.2 *M* NaOH are also used with varying results.

Qualitative analysis of glycopeptides and phosphoamino acids is achieved through a separate, partial hydrolysis with 6 N HCl acid at 110°C for 1 and 1.5 hr, respectively.[1,12] Separation of cysteine, tryptophan, and amino sugars requires minimal chromatographic adjustments; phosphoamino acid separation is straightforward using reversed phase but cumbersome using ion exchange.

ANALYSIS OF FREE AND MODIFIED AMINO ACIDS

Blood, urine, and cerebrospinal and other physiological fluids contain a great number of post-translationally modified amino acids (approximately 170 have been studied to date) and in a wider range of concentrations than protein hydrolysates.[1,13,14] Additionally, plant sources produce about 500 non-protein amino acids, and in geological samples, highly unusual amino acids may indicate extraterrestrial origin.[15,16]

Although the free amino acids in these samples do not require hydrolysis, blood plasma and cerebrospinal fluid must be deproteinated before analysis. Otherwise, proteins may bind irreversibly to ion-exchange columns, resulting in loss of resolution. Furthermore, any peptide hydrolases must be inactivated. For ion-exchange analysates, a protein precipitant is added before centrifugation. Sulfosalicylic acid, a common precipitating agent, is added in solid form to avoid sample dilution. For reversed-phase analysates, ultrafiltration, SEC, or organic solvent extraction is recommended. Samples with low protein and high amino acid concentrations, such as urine and amniotic fluid, need only to be diluted before analysis.

Precolumn derivatives are more tolerant of lipid-rich samples.[1] Changing the guard column routinely is recommended to avoid column buildup, especially for reversed-phase systems.

AMINO ACID RACEMIZATION ANALYSIS

L-Amino acid enantiomers are the most prevalent in nature. However, D-forms are increasingly found in living organisms, fossils, and extraterrestrial samples. D-Amino acids resulting from post-translational modifications now appear to be fundamental components of bacterial cell walls and microbial antibiotics.[2]

Racemization, the interconversion of amino acid enantiomers, occurs slowly in biological and geological systems. The rate increases with extreme pH values, high temperature, and high-ionic strength. Rates also vary between amino acids: At 25°C, the racemization half-life of serine is about 400 yr, while that of isoleucine is 40,000 yr. Enantiomer analysis is used to confirm bioactivity of synthetic peptides and for geological dating.[1,2,7,16]

Hydrolysis itself accelerates racemization. Shorter acid exposure at higher temperatures, such as 160°C for 1 hr, decreases racemization by about 50% compared to conventional hydrolysis. Liquid-phase methanesulfonic acid, gas-phase microwave, conventional, and gas-phase microwave hydrolysis produce progressively higher rates of racemization. Additional phenol, however, significantly reduces racemization during microwave hydrolysis.[4]

The three general approaches to enantiomer separation entail a chiral stationary phase, a chiral mobile phase, or a chiral reagent. Tandem columns, with reversed and chiral stationary phases, were used to separate 18 D–L pairs of phenylthiocarbamyl (PTC)-amino acids in 150 min. OPA-amino acid enantiomers have been separated on both ion-exchange and reversed-phase columns using a sodium acetate buffer with an L-proline-cupric acetate additive. Chiral reagents, such as Marphey's reagent and OPA/IBLC (*N*-isobutyryl-L-cysteine), were successfully used for racemization analysis within 80 min.

CONCLUSIONS

Amino acid analysis continues to be an essential tool in protein chemistry. It has been described as "deceptively

difficult": Accurate results require attention to sophisticated instrumentation, sample handling, and consideration of the chemistry of specific amino acids under investigation.[17] When the "art and practice" are carefully addressed, however, AAA provides a fundamental understanding of peptides and proteins unmatched by other techniques.[6]

ACKNOWLEDGMENT

INTRODUCTION

Chromatographic separations are mainly used for analytical purposes and, as such, are termed analytical chromatography. Chromatography, however, is gaining increasing importance as a tool that enables isolation of preparative amounts of the desired substances. Such "preparative chromatography" is usually achieved with liquid chromatography (LC) and high-performance liquid chromatography (HPLC), but also occasionally with thin-layer chromatography (TLC).

Each separation occurs because of the different interactions of each species with a sorbent. To describe the partitioning process, knowledge of the isotherm involved is needed. In analytical chromatography, the concentration of a species in an analyzed sample is very low, so description of the retention process typically requires knowledge of the slope of the isotherm when the concentration is zero.

When chromatography is used in the preparative mode, the entire dependence of the equilibrium on the concentrations of adsorbed and non-adsorbed solute must be established. The equilibrium isotherm is usually non-linear and analysis of such isotherms is a necessary prerequisite to enable prediction of the retention mechanism.

OVERVIEW

Physicochemical description of retention processes in liquid chromatography (planar chromatography included) is far from complete and, therefore, new endeavors are regularly undertaken to improve existing retention models and/or to introduce the new ones. The excessive simplicity of already established retention models in planar chromatography is—among other reasons—because some types of intermolecular interaction in the chromatographic systems are disregarded. For example, none of the validated models focusing on prediction of solute retention takes into consideration so-called "lateral interactions," the term used to denote self-association of solute molecules.

The aim of this report is to give insight into the role of lateral interactions in TLC band formation.

THEORY OF CHROMATOGRAPHIC BAND FORMATION

Study of the mechanism of adsorption in TLC is more difficult than in column liquid chromatography. The nonlinear isotherm model in TLC can be designed in a qualitative way only, after investigation of chromatographic band shape and of the concentration distribution within this band; phenomena characteristic of TLC band formation can also have a major effect on the mechanism of retention.

Transfer Mechanism in TLC

In TLC, as most frequently practiced, transfer of mobile phase through the thin layer is induced by capillary flow. Solvents or solvent mixtures contained in the chromatographic chamber enter capillaries in the solid bed, attempting to reduce both their free surface area and their free energy. The free-energy gain ΔE_m of a solvent entering a capillary is given by the relationship:

$$\Delta E_m = -\frac{2\gamma V_n}{r} \quad (1)$$

where γ is the free surface tension, V_n denotes the molar volume of the solvent, and r is the capillary radius.

From Eq. l, it follows that the capillary radius r has a very important effect on capillary flow; a smaller radius leads to more efficient flow. The methods used for preparation of commercial stationary phases and supports cannot ensure all pores are of equal, ideal diameter; this results in side effects that contribute to the broadening of chromatographic spots. Other mechanisms of spot broadening are described below.

Broadening of Chromatographic Bands as a Result of Eddy Diffusion and Resistance to Mass Transfer

The most characteristic feature of chromatographic bands is that the longer the development time and the greater the distance from the start, the greater become their surface areas. This phenomenon is not restricted to planar chromatography—it occurs in all chromatographic techniques. Band broadening arises as a result of eddy and molecular diffusion, the effects of mass transfer, and the mechanism of solute retention.

Eddy diffusion of solute molecules is induced by the uneven diameter of the stationary phase or support capillaries, which automatically results in uneven mobile phase flow rate through the solid bed. Some solute molecules are thus displaced more quickly than the average rate of displacement of the solute, whereas others are retarded.

Molecular diffusion is the regular diffusion in the mobile phase, the driving force of each dissolving process and, therefore, needs no further explanation.

The effects of mass transfer are different in the stationary and mobile phases. The resistance to mass transfer in the mobile phase varies with the reciprocals of mobile phase velocity and the diffusivity of the species. The resistance to mass transfer inside the stationary phase varies with the reciprocal of diffusivity and is proportional to the radius of the adsorbent granules attached to the chromatography plate, or the structural complexity of the internal pores in chromatographic paper. For both types of mass-transfer resistance, band stretching is proportional in each direction, as measured from the geometrical spot center, and increases in magnitude the greater the resistance.

All the aforementioned phenomena, which contribute jointly to spot broadening, are used to be described as the effective diffusion. Effective diffusion is a convenient notion, which, apart from being concise and informative, emphasizes that all the contributory phenomena occur simultaneously.

Broadening of Chromatographic Bands as a Result of the Mechanism of Retention

Mechanisms of solute retention, which are also responsible for spot broadening, differ from one chromatographic technique to another, and their role in this process is far less simple than that of diffusion and mass transfer. Use of densitometric detection has, however, furnished insight into concentration profiles across the chromatographic band, enabling estimation of the role of solute retention in peak broadening and prediction of the retention mechanism. Fig. 1 shows three examples of such concentration profiles in the absence of mass overload.

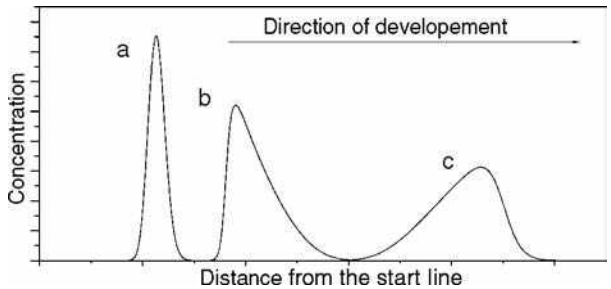

Fig. 1 Three examples of concentration profiles along the chromatographic stationary phase bed: a, symmetrical without tailing; b, skewed with tailing toward the mobile-phase front; and c, skewed with tailing toward the origin.

Numerous efforts have been made to describe the band broadening effect and the formation of the concentration profiles. The most interesting models are those that consider band broadening as a two-dimensional process.

Two models of two-dimensional band broadening were established by Belenky et al.[1,2] and by Mierzejewski.[3] In these models, non-linearity of the adsorption isotherm was neglected so that elliptical spots only, with symmetrically distributed concentration (as shown in Fig. 1a), could be modeled. We will now focus our attention on the effect of the adsorption mechanism on the concentration profiles of chromatographic bands.

ADSORPTION EQUILIBRIUM ISOTHERMS

Isotherm models reflect interactions between active sites on the sorbent surface and the adsorbed species and, simultaneously, interactions occurring exclusively among the adsorbed species. The dependence of isotherm shapes on concentration profiles in TLC is fully analogous to relationships between HPLC peak profiles and the isotherm models, which have been discussed in depth by Guiochon et al.[4]

Let us briefly recall several chromatographic models and analyze the correspondence between concentration profiles and types of isotherm. The simplest isotherm model is furnished by Henry's law.

$$q = HC \tag{2}$$

where q is the concentration of the adsorbed species, H is Henry's constant, and C is the concentration in the mobile phase. This isotherm is also called the linear isotherm, and

concentration profiles obtained with its aid are similar to that shown in Fig. 1a. It should be stressed that, for the linear isotherm, peak broadening results from eddy diffusion and from resistance of the mass transfer only; it does not depend on Henry's constant. In practice, such concentration profiles are observed only for analyte concentrations that are low enough for the equilibrium isotherm to be regarded as linear.

One of the simplest non-linear isotherm models is the Langmuir model.

$$q = \frac{q_s KC}{1 + KC} \tag{3}$$

where q_s is the saturation capacity and K the equilibrium constant. To make use of this isotherm, ideality of the liquid mixture and of the adsorbed phase must be assumed. Concentration profiles obtained with the aid of this isotherm are similar to that presented in Fig. 1c. The larger the equilibrium constant, the more stretched is the concentration tail (and the chromatographic band).

More complicated models take into account lateral interaction between the adsorbed molecules. One of these models was designed by Fowler and Guggenheim.[5] It assumes ideal adsorption on a set of the localized sites, with weak interactions among molecules adsorbed on neighboring sites. It also assumes that the energy of interactions between two adsorbed molecules is so small that the principle of random distribution of the adsorbed molecules on the sorbent surface is not significantly affected. For liquid–solid equilibria, the Fowler and Guggenheim isotherm is empirically extended and written in the form:

$$KC = \frac{\theta}{1 - \theta} e^{-\chi\theta} \tag{4}$$

where χ denotes the empirical interaction energy between two molecules adsorbed on nearest-neighbor sites, and θ is the degree of the surface coverage. For $\chi = 0$, the Fowler–Guggenheim isotherm simply becomes the Langmuir isotherm.

Another model, which takes into account lateral interaction and surface heterogeneity, is the Fowler–Guggenheim–Jovanovic isotherm.[6]

$$\theta = 1 - e^{-(aCe^{\chi\theta})^{\nu}} \tag{5}$$

where a is a constant and χ a heterogeneity term.

The next model, which assumes single-component localized monolayer adsorption with specific lateral interactions among all the adsorbed molecules, is the Kiselev model.[7–9] The final equation of this model is

$$\frac{\theta}{(1 - \theta)C} = \frac{K}{(1 - KK_a(1 - \theta)C)^2} \tag{6}$$

where $\theta = q/q_s$, K is the equilibrium constant for adsorption of analyte on active sites, and K_a is the association constant.

All these isotherms can generate the concentration profiles presented in Fig. 1b. The more pronounced the tailing, the stronger the lateral interactions. The concentration profiles presented in Fig. 1b could also be obtained if the adsorbed species formed multilayer structures.[10,11]

Multilayer isotherm models can be derived from the equations:

$$K_1 C(q_s - q_1 - q_2 - q_3 - \cdots - q_n) - q_1 = 0 \tag{7}$$

$$K_2 C q_1 - q_2 = 0 \tag{8}$$

$$K_3 C q_2 - q_3 = 0 \tag{9}$$

$$K_n C q_{n-1} - q_n = 0 \tag{10}$$

where the first equation describes the equilibrium between free active sites and adsorbed species, and subsequent equations depict equilibria between adjacent analyte layers. It is usually assumed that $K_2 = K_3 = \ldots = K_n = K_a$. This set of equations (i.e., Eqs. 7–10) results in the isotherm:

$$q = q_s \frac{KC(1 + 2K_p C + 3(K_p C)^2 \cdots)}{1 + KC + KCK_p C + KC(K_p C)^2 \cdots} \tag{11}$$

The Retention Model

Qualitative modeling of the experimentally observed densitometric profiles for any given adsorption isotherm has been presented in Refs.[11,12] on the basis of the model:

$$\frac{\partial C}{\partial t} + w\frac{\partial C}{\partial x} + \Phi\frac{\partial q}{\partial t} = D_x\frac{\partial^2 C}{\partial x^2} + D_y\frac{\partial^2 C}{\partial y^2} \tag{12}$$

with the assumed boundary conditions:

$$\frac{\partial C}{\partial x}\Big|_{x=0,x=x1} = \frac{\partial C}{\partial y}\Big|_{y=0,y=y1} = 0 \tag{13}$$

where Eq. 12 represents the differential mass balance for the mobile phase and the solid state, w is the average mobile-phase flow rate, C and q are, respectively, the concentrations (mol dm^{-3}) of the analyte in the mobile phase and on the sorbent surface, D_x and D_y are, respectively, the effective diffusion coefficients lengthwise (x) and in the direction perpendicular to this direction (y), Φ is the so-called phase ratio, and $x1$ and $y1$ are the plate length and width, respectively. It was assumed that at time $t = 0$,

analyte is concentrated in a rectangular spot at the start of the chromatogram.

The Role of Intermolecular Interactions: Multilayer Adsorption

When low-molecular–weight carboxylic acids are chromatographed on cellulose powder with a non-polar mobile phase, the densitograms obtained are similar to those presented in Fig. 2. Carboxylic acids form associative multimers by hydrogen bonding because of the presence of the negatively polarized oxygen atom from the carbonyl group and the positively polarized hydrogen atom from the hydroxyl group. Direct contact of these cyclic acidic dimers with a sorbent results in forced cleavage of most of the dimeric rings (e.g., because of inevitable intermolecular interactions by hydrogen bonding with hydroxyl groups of the cellulose), thus considerably shifting the equilibrium of self-association toward linear associative multimers.

The tendency of carboxylic acid analytes to form associative multimers can also be viewed as multilayer adsorption. Analysis of the concentration profiles presented in Fig. 2 reveals that for low concentrations of the analyte, peaks a and b are similar to the band profiles simulated by use of the Langmuir isotherm, whereas peaks c–f resemble profiles obtained by use of the anti-Langmuir isotherm (tailing toward the front of the chromatogram is more pronounced than tailing toward the start of the chromatogram.)

More spectacular results are obtained with some alcohols. Figs. 3 and 4 depict the densitometric profiles for 5-phenyl-1-pentanol chromatographed on Whatman No. 3 and Whatman No. 1 chromatography papers.

In this instance, very steep concentration profiles toward the start of the chromatogram are obtained; this is

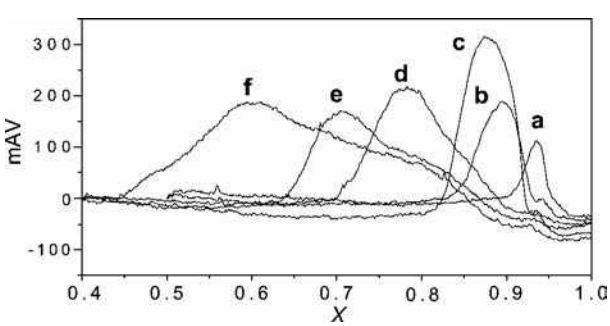

Fig. 2 Concentration profiles of 4-phenylbutyric acid on microcrystalline cellulose at 15°C with decalin as mobile phase. Concentrations of the analyte solutions in 2-propanol were (a) 0.1, (b) 0.2, (c) 0.3, (d) 0.4, (e) 0.5, and (f) 1.0 *M*. The volumes of sample applied were 3 μl.
Source: From Densitometric acquisition of concentration profiles in planar chromatography and its possible shortcomings. Part 1.4-Phenylbutyric acid as an analyte, in Acta Chromatogr.[13]

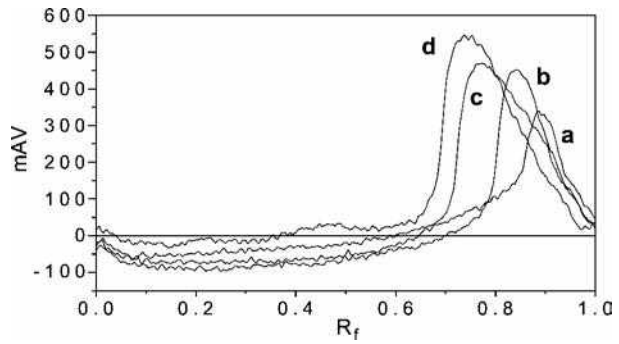

Fig. 3 Concentration profiles of 5-phenyl-1-pentanol obtained on Whatman No. 3 chromatography paper at ambient temperature with *n*-octane as mobile phase. Concentrations of the analyte solutions in 2-propanol were (a) 0.5, (b) 1.0, (c) 1.5, and (d) 2.0 *M*. The volumes of sample applied were 5 μl.
Source: From Densitometric comparison of the performance of Stahl-type and sandwich-type planar chromatographic chambers, in J. Liq. Chromatogr. Relat. Technol.[14]

indisputably indicative of some kind of interaction among the adsorbed molecules. The concentration profiles presented in Figs. 2–4 can be obtained theoretically from the model given by Eqs. 12 and 13 combined with the isotherm (Eq. 11), assuming three-layer adsorption as a maximum.

As an example, qualitative reproduction of the experimental concentration profiles shown in Figs. 3 and 4 is given in Fig. 5. The Eq. 11 constants of the adsorption isotherm, the mobile phase velocity, and effective diffusion coefficients were chosen to reproduce the shapes of the lengthwise cross sections of the chromatographic bands obtained in the experimental densitograms.

The calculations presented in graphical form in Fig. 5 were performed for $q_s = 1.5$, $K = 0.5$, $K_p = 5$, $w = 0.3$ cm/min,

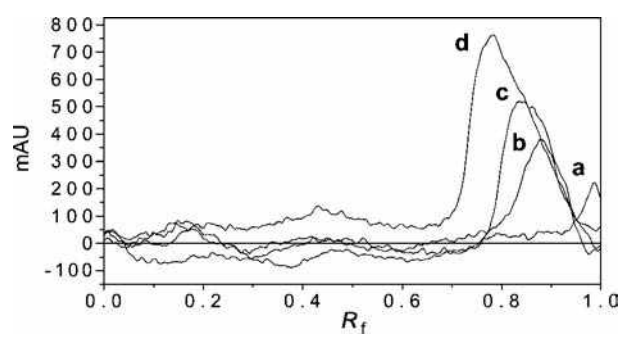

Fig. 4 Concentration profiles of 5-phenyl-1-pentanol obtained on Whatman No. 1 chromatography paper at ambient temperature with *n*-octane as mobile phase. Concentrations of the analyte solutions in 2-propanol were (a) 0.25, (b) 0.50, (c) 0.75, and (d) 1.0 *M*. The volumes of sample applied were 5 μl.
Source: From Densitometric comparison of the performance of Stahl-type and sandwich-type planar chromatographic chambers, in J. Liq. Chromatogr. Relat. Technol.[14]

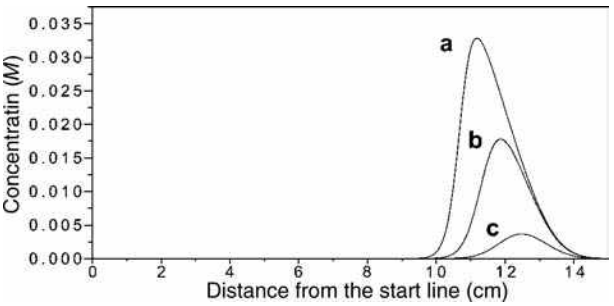

Fig. 5 The lengthwise cross section of the simulated chromatogram for a hypothetical alcohol or acid, according to the model given by Eqs. 12 and 13 in conjunction with the isotherm given by Eq. 11. Concentrations of the applied solutions were (a) 1.0, (b) 0.5, and (c) 0.1 *M*.

$D_x = 0.007$ cm^2/min, and an initial spot length of 0.06 cm. The phase ratio Φ was assumed to be 0.25.

From Fig. 5, it is apparent that the adsorption fronts are considerably less steep than the desorption fronts, and that the adsorption fronts simulated for different initial concentrations of the spots overlap. Similar behavior is apparent in the typical experimental densitograms, given in Figs. 3 and 4. In all these densitograms, the adsorption fronts for the different concentrations of acid also overlap.

CONCLUSIONS

Satisfactory qualitative agreement between experimental and theoretical concentration profiles for polar analytes suggests their retention is substantially affected by lateral interactions, which are probably even more complex than is assumed in this isotherm model. Overlapping of the adsorption fronts can be explained solely on the basis of the lateral interactions among the adsorbed molecules.

Antibiotics: CCC Separation

M.-C. Rolet-Menet
Analytical Chemistry Laboratory, Unit of Formation and Research (UFR) of Pharmaceutical and Biological Sciences, Paris, France

INTRODUCTION

Antibiotics are chemical compounds made either by living organisms or by chemical synthesis. They have the property to inhibit, in small amounts, some vital processes of viruses, micro-organisms (such as bacteria and fungi), and certain cells of multicellular organisms (cancerous cells, parasitic cells, etc.). The development of antibiotics made by micro-organisms requires isolation and purification of the desired compound from a complicated matrix such as a fermentation broth. These bioactive microbial metabolites are often produced in very small quantities and have to be removed from other secondary metabolites and non-metabolized media ingredients. Antibiotics are normally biosynthesized as mixtures of closely related congeners and many are labile molecules, thus requiring mild separation techniques with a high resolution capacity. Although recent advances in high-performance liquid chromatography (HPLC) technology using sophisticated equipment and refined adsorbents greatly facilitate the isolation of antibiotics, some drawbacks remain, related to various complications arising from the use of a solid support, such as adsorptive loss, deactivation, and contamination. Moreover, HPLC purification always requires sample preparation, prepurification, concentration, etc. Liquid–liquid partition techniques and particularly countercurrent chromatography (CCC) are suitable for the separation of antibiotics because they utilize a separation column free of solid support matrix, made of Teflon® channels or tubes. Raw material can be injected into the column without any previous sample treatment, which simplifies the purification procedure.

ANTIBIOTICS

Antibiotics differ widely in their polarities because their chemical structures are very variable. They are synthesized by various living materials like bacterial strains (such as *Streptomyces*[1] and *Bacillus*) and marine sponges. Oka et al.,[2] have gathered antibiotics purified by CCC from crude extract and fermentation broth. They have shown that CCC can be successfully applied to the separation of macrolides and of various other antibiotics, including various peptide antibiotics, which are strongly adsorbed to silanol groups on the silica gel used in the stationary phase in HPLC. Several CCC types are used, such as droplet CCC (DCCC)[3] and the more recent X-axis CCC, foam CCC, centrifugal partition chromatography (CPC), high-speed CCC (HSCCC), and Quattro CCC (QCCC). This discussion focuses on the separation of macrolides and polypeptide antibiotics by CCC.

Several separations of macrolide and polypeptide antibiotics by CCC are reported in the literature. Macrolides are heterosides in which the aglycone is a cyclic macrolactone with at least 14 atoms. They act by stopping protein synthesis. Polypeptide antibiotics are frequently cyclic molecules. They act by disorganizing the protein structure of the bacterial membrane. Figs. 1–5 show the structure of several molecules the purification of which is described subsequently. Sporaviridins[4] are produced by *Kutzneria viridogrisea*. They are very polar, water-soluble, basic glycoside antibiotics (Fig. 1). They consist of six components; each has a 34-membered lactone, seven monosaccharide units, a pentasaccharide (viridopentaose), and two monosaccharides. They are active against Gram-positive bacteria, acid-fast bacteria, and *Trichophyton*. WAP-8294A[5] complex (Fig. 2) is produced by *Lysobacter* sp. and consists of at least 19 closely related and very polar components. WAP-8294A2 is present as the major component and A1 and A4 are minor components. They show strong activity against Gram-positive bacteria, including methicillin-resistant *Staphylococcus aureus* (MRSA) and vancomycin-resistant enterococci. Ivermectins B1[6] are derived from avermectins B1, the natural fermentation products of *Streptomyces avermitilis*. The avermectins B1 have double bonds between carbon atoms 22 and 23, whereas the ivermectins B1 have single bonds in these positions (Fig. 3A). They have intermediate polarity. The ivermectins B1 are a mixture of two major homologs, ivermectins B1a (>80%) and ivermectins B1b (< 20%), but a crude ivermectin complex also contains various minor components. Ivermectins B1 are broad-spectrum antiparasitic agents used against *Onchocerca volvulus* in human medicine and for food animals such as cattle, swine, and horse. The bryostatins have been isolated from the marine bryozoan *Bugula neritina*[7] (Fig. 3B). They are macrolides with intermediate polarity. They show significant activity against lymphocytic leukemia in vitro, with ED_{50} values from 0.33 to 1.4 μg/ml, respectively. Ascomycin and related compounds[8] (Fig. 4) are macrolide antibiotics with intermediary polarity.

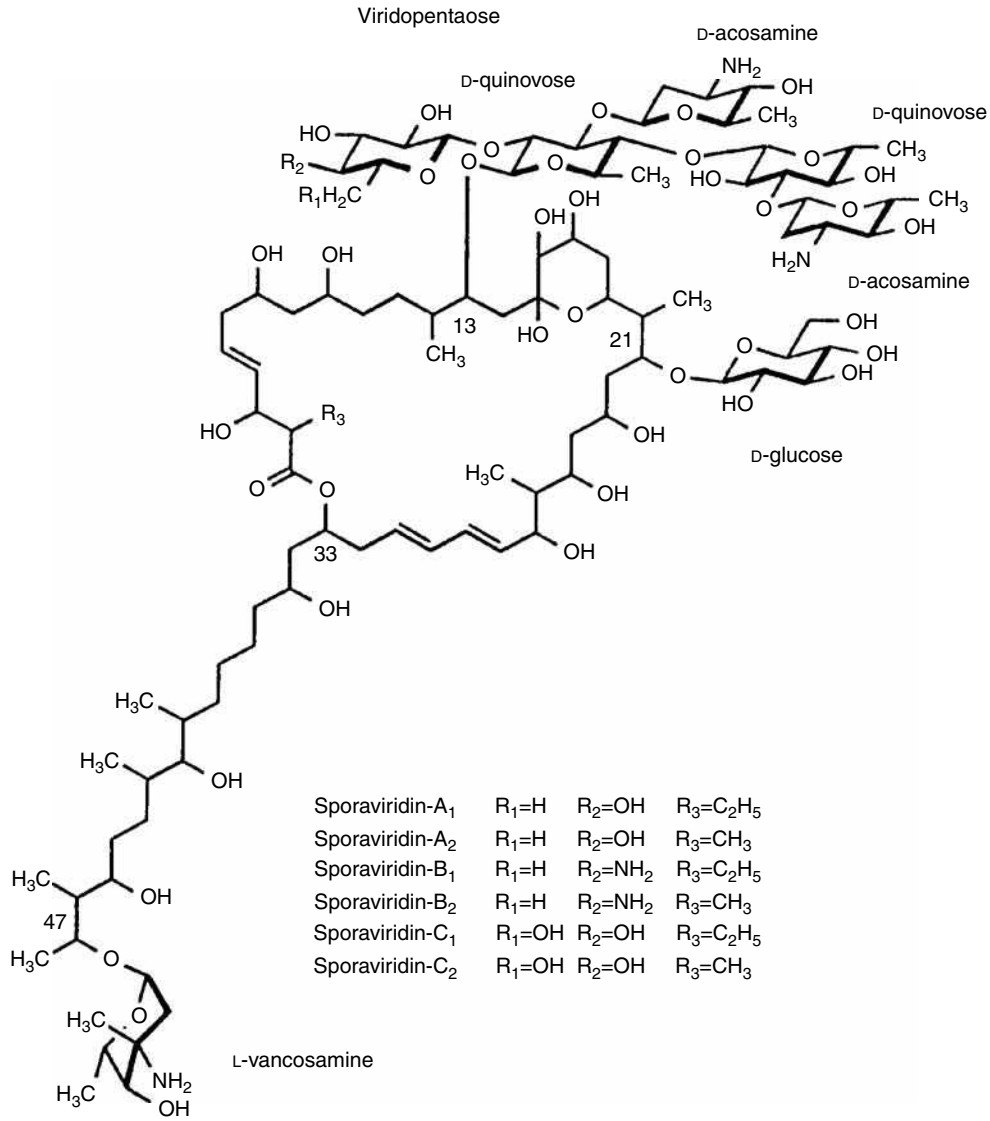

Fig. 1 Chemical structure of sporaviridins.

They have been identified from *Streptomyces tsukubaensis* and *S. hygroscopicus* and are reported as immunosuppressants with higher potency than cyclosporin A.

Finally, bacitracins[9] are peptide antibiotics produced by *Bacillus subtilis* and *Bacillus licheniformis*. Over 20 components are contained in the bacitracin complex medium, among which the major active components are bacitracin A and F (Fig. 5). They exhibit inhibitory activity against Gram-positive bacteria and are among the most commonly used antibiotics as animal feed additives.

SOLVENT SYSTEM

The polarity of the above-mentioned molecules is very variable according to the saccharide unit number contained in the chemical formula. Several procedures to choose a solvent system are described in the literature. Usual solvent systems are biphasic and made of three solvents, two of which are non-miscible. If the polarities of the solutes are known, the classification established by Ito[2] can be taken as a first approach. He classified solvent systems into three groups according to their suitability for non-polar molecules ("non-polar" systems, based on *n*-hexane), intermediate polarity molecules ("intermediary" system, based on chloroform), and polar molecules ("polar" system, based on *n*-butanol). The molecule must have a high solubility in one of the two non-miscible solvents. The addition of a third solvent enables a better adjustment of the partition coefficients (K). Oka, Oka, and Ito[10] propose a choice of various solvent systems to purify antibiotics. They have to fulfill various criteria. The settling time of the solvent system should be shorter than 30 sec to ensure satisfactory retention of the stationary phase. The partition coefficient of the target compounds should be close to 1, and the separation factor (α) between the compounds

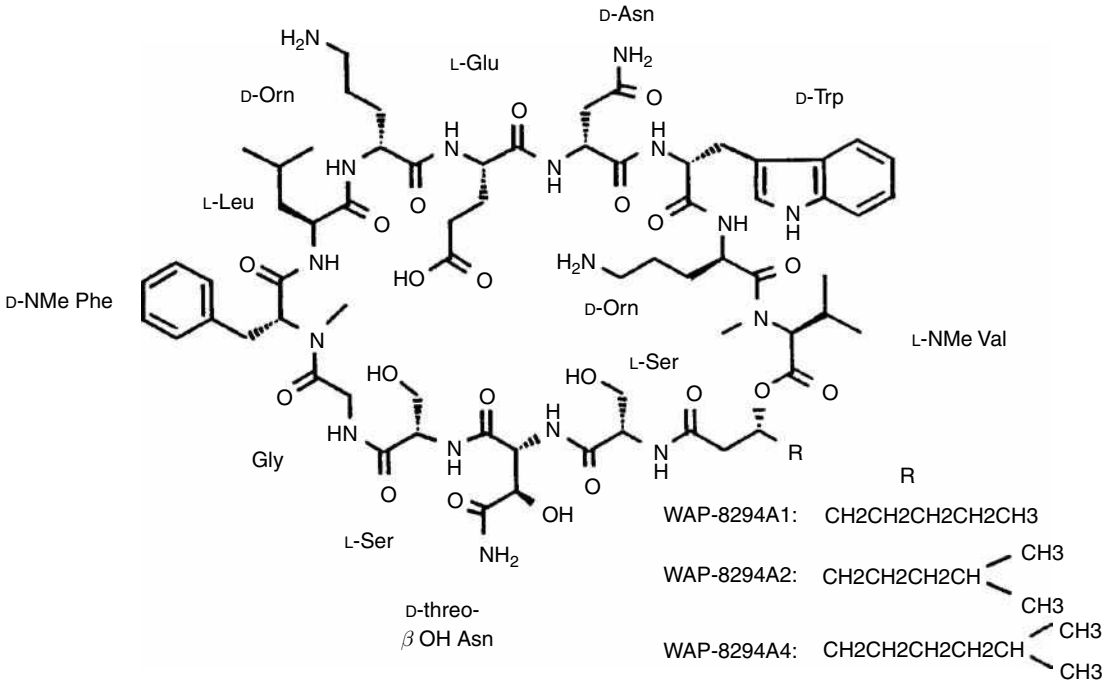

Fig. 2 Chemical structure of WAP-8294A complex.

should be larger than 1.5. Two series of solvent systems can provide an ideal range of K values for a variety of samples: *n*-hexane–ethylacetate–*n*-butanol–methanol–water and chloroform–methanol–water. These solvent series cover a wide range of hydrophobicity continuously from the non-polar *n*-hexane–methanol–water system to the more polar *n*-butanol–water system. To select the solvent system, Wang-Fan et al.[8] measured the solubility of macrolides in a series of common solvents, where the polarities were ranked with dielectric constants. The partition coefficients of solutes were compared in various ternary solvent systems selected according to the solubility studies. A ternary solvent system was selected based on suitable partition coefficients of the antibiotics. Finally, in the further optimization of composition proportions, the quaternary solvent systems showed the best solvent selectivities by giving the most prominent differences of partition coefficient.

COUNTERCURRENT CHROMATOGRAPHY FOR PURIFICATION OF ANTIBIOTICS

Several CCC devices are commonly used to purify antibiotics, such as the rotating coil instruments particularly used in HSCCC and the cartridge instruments used in CPC. A chapter of this encyclopedia is entirely devoted to the various CCC devices, so that only some indications about performances of CCC as compared to preparative HPLC are given here.

Menet and Thiébaut[11] have compared the performances of CCC and preparative HPLC regarding the separation of two antibiotics *X* and *Y*. The CCC apparatus used was a centrifugal partition chromatograph (CPC, Sanki* LLN) of 250 ml internal volume. For the purpose, classical parameters of preparative scale chromatography were calculated: experimental duration, including the sample preparation and separation time; solvent consumption, including the volume of the mobile phase, the stationary phase, and the injection solvent; and purity of the purest fraction in *Y*. The parameter "purity in *Y*" was chosen because *Y* is the solute that is the most difficult to purify because of its physical properties (particularly hydrophobicity), which are close to those of the main impurities. The hourly yield (g/hr) is defined as the ratio of the recovered quantity to the experimental duration. The volumic yield (g/L) is defined as the ratio of the recovered quantity to the solvent consumption. Table 1 summarizes the results of separations of *Y* by CCC and preparative HPLC. The solvent volume consumption is the volume of the stationary and mobile phases in CCC or the volume of the mobile phase used in HPLC and the samples. The injected sample in CCC was not prepurified to concentrate it in *Y* from 7% to 25%. So the injected quantity in *Y* in CCC is lower (0.28 g, as against 1.59 g in preparative HPLC). For similar volumic yields, i.e., 0.20 g/L in CCC and 0.15 g/L in preparative HPLC, the enrichment in *Y* is higher with CCC than with preparative HPLC. Indeed, starting from a crude extract at 7% in *Y* with CCC or from 25% in *Y* extract with preparative HPLC leads to the same 95% highest purity. These results demonstrate the advantage of CCC in directly purifying crude extracts. Moreover, no preliminary purification of the extract is required, in contrast to preparative HPLC, which requires a 1 day enrichment of the crude extract from 7% to 25% in *Y*.

EXAMPLES OF PURIFICATION

Separation of Sporaviridins[4]

The chemical structures of sporaviridins are described in Fig. 1. They are only soluble in polar solvents such as water, methanol, and *n*-butanol. Therefore, a two-phase solvent system containing *n*-butanol was examined. A non-polar solvent such as diethyl ether was added to the *n*-butanol–water system to decrease the solubility of molecules in *n*-butanol and to obtain partition coefficients close to 1. The partition coefficients *K* are defined as the ratio of the solute concentration in the upper phase (butanol rich) to its concentration in the lower one (water rich).

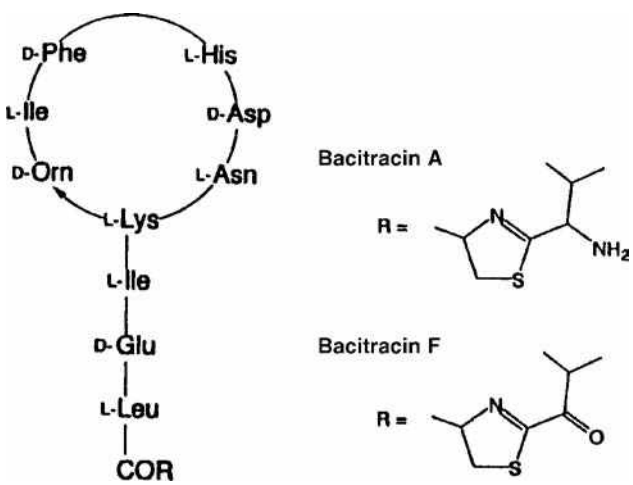

Fig. 5 Chemical structure of bacitracins.

Table 1 Comparison of CCC and HPLC performances.

	CCC	HPLC
Crude extract purity in *Y* (%)	7	25
Injected quantity of *Y* (g)	0.28	1.59
Experiment duration (hr)	6.2	2.2[a]
Solvent volume consumption (L)	1.4	10.8

Hourly yield (g/hr)	0.035	0.72
Volumic yield (g/L)	0.20	0.15

[a]1 hr for column equilibration at 90 ml/min flow rate +1 hr for separation.

A two-phase solvent system of *n*-butanol–diethylether–water (10 : 4 : 12, v/v/v) was selected because it allows one to obtain the almost equally dispersed partition coefficients among six components (C2, B2, A2, C1, B1, A1). The preparative separation of six components from sporaviridin complex by HSCCC was performed in 3.5 hr (500 ml elution volume). The six components were eluted in the order of their partition coefficients, yielding pure components A1 (1.4 mg), A2 (0.6 mg), B1 (0.7 mg), B2 (0.5 mg), C1 (1.1 mg), and C2 (1.4 mg) from 15 mg of the sporaviridin complex.

Separation of the Main Components of WAP-8294A Complex[5]

The chemical structures of WAP-8294A complex are described in Fig. 2. The structure of WAP- 8294A2 has been elucidated as a cyclic depsipeptide with a molecular mass of 1561. High-speed CCC (type J apparatus, total capacity 300 ml) was applied to the separation of the main components of the WAP-8294A complex. Due to the high polarity of these compounds, a hydrophilic two-phase solvent system composed of *n*-butanol–ethylacetate–aqueous 0.005 M trifluoroacetic acid (1.25 : 3.75 : 5, v/v/v) was used, providing a suitable range of partition coefficient values. The preparative separation of six components from the WAP-8294A complex was performed in 13.3 hr, with the lower phase as mobile phase at 0.5 ml/min. Pure fractions (1–6 mg) were obtained from 25 mg of WAP-8294A complex.

Separation of Ivermectins[6]

These molecules have an intermediary polarity (Fig. 3A). A two-phase solvent system composed of *n*-hexane, ethyl acetate, methanol, and water was selected. In this case, the partition coefficients *K* are defined as the ratio of the solute concentration in the upper phase to its concentration in the lower one. A solvent mixture of *n*-hexane–ethylacetate–methanol–water (19 : 1 : 10 : 10, v/v/v/v) yielded the best *K* values; from 0 to 3.25 mg of crude ivermectin was separated in 4.0 hr. This separation

yielded 18.7 mg of 99.0% pure ivermectin B1a, 1.0 mg of 96.0% pure ivermectin B1b, and 0.3 mg of 98.0% pure avermectin B1a.

Separation of Bryostatins[7]

An amount of 906.5 g of lymphocytic leukemia cell line active fraction was obtained by extraction from 1000 kg of *Bugula neritina*. Further purification was performed with HSCCC. Bryostatins have intermediary polarity, so that *n*-hexane–ethylacetate–methanol–water (3 : 7 : 5 : 5, v/v/v/v) was employed with the upper layer as mobile phase and lower layer as stationary phase. By this technique, from 300 mg to 3 mg of seven bryostatins have been isolated, including a new molecule, bryostatin 14 (Fig. 3B).

Separation of Ascomycin and Analogs[8,12]

Ascomycin and derivatives (Fig. 4) were purified by QCCC. The QCCC apparatus has four coils that are wound tightly on two separate bobbins on one rotor, each bobbin containing two concentrically wound coils. Optimization of solvent systems was based on solubility studies and measurements of partition coefficients for FK-506 and ascomycin. Hexane–*tert*-butylmethylether–methanol–water (1 : 3 : 6 : 5; v/v/v/v) showed the best solvent selectivity. Baseline separation of 25 mg of FK-506 and 50 mg of ascomycin was achieved in 6 hr.

Separation of Bacitracins[9]

Bacitracin complex (Fig. 5) was purified by foam CCC. The column design for foam CCC consists of a Teflon® tube. Simultaneous introduction of N_2 and the liquid phase through the respective flow tube produces a countercurrent between the gas and the liquid phase through the coil. The sample mixture injected through the middle portion of the column is separated according to the foaming capability: The foam active components travel through the coil with the gas phase and elute through the foam collection line, whereas the rest of components move with the liquid phase and elute through the liquid collection line.

After experiment, fractions from the foam and liquid outlets are collected and analyzed. The elution curve of bacitracin components from the foam outlet shows three major peaks, and the one from the liquid outlet, one peak. HPLC analysis of the fractions clearly indicates that the bacitracin components are separated in the order of hydrophobicity of the molecules in the foam fractions, and in increasing order of their hydrophilicity in the liquid fractions.

CONCLUSIONS

High-speed CCC successfully achieves preparative scale separations and purifications of numerous antibiotics from crude extracts. Moreover, the sample is directly analyzed without preliminary purification of the extract, as is required in preparative HPLC.

Antibiotics: TLC Analysis

Irena Choma
Department of Chemical Physics, Marie Curie-Sklodowska University, Lublin, Poland

INTRODUCTION

Antibiotics are an extremely important class of human and veterinary drugs. Chemically, they constitute a widely diverse group with different functions and ways of operation. They can be derived from living organisms or obtained synthetically. Nowadays, the term "antibiotics" is often extended to so-called chemotherapeutics, such as the sulfonamides and quinolones. However, all of them exhibit antibacterial properties, i.e., either inhibit the growth of or kill bacteria.

Antibiotics are used both in human and veterinary medicine as well as in animal husbandry. They enable prevention and control of many bacterial diseases. However, there are many side effects connected with their use, such as: toxicity, allergies, or intestinal disorder. Additionally, overuse and misuse of these drugs can lead to the emergence of antibiotic resistant bacteria. Analysis of antibiotics embraces their determination in pharmaceuticals, body fluids, feed, and food. The most popular analytical methods are the chromatographic techniques. Thin-layer chromatography (TLC) is usually used as a screening method preceding high-performance liquid chromatography (HPLC) analysis, but there are also many examples of quantitative TLC analysis. TLC is also applied in the purification of newly discovered antibiotics, analysis of antibiotic metabolites and impurities, search for new biologically active compounds, and studying interactions and retention behavior of antibiotics. Antibiotics can be also applied as stationary or mobile-phase additives for chiral separations.

BACKGROUND INFORMATION

Penicillin, the first natural antibiotic, produced by genus *Penicillium*, discovered in 1928 by Fleming, and sulfonamides, the first chemotherapeutic agents, discovered in the 1930s, start a long list of presently known antibiotics. Beside β-lactams (penicillins and cephalosporins) and sulfonamides, the list includes aminoglycosides, macrolides, tetracyclines, quinolones, peptides, polyether ionophores, rifamycins, lincosamides, coumarins, nitroheterocycles, amphenicols, and others.

In principle, antibiotics should eradicate pathogenic bacteria in the host organism without causing significant damage to it. Nevertheless, most antibiotics are toxic, some of them even highly so. The toxicity of antibiotics for humans is not only due to medical treatment but also due to absorption of those drugs through contaminated food. In modern agricultural practice, antibiotics are administered to animals both for treatment of diseases and for prophylaxis as well as to promote growth as feed or water additives. All of this results in the appearance of unsafe antibiotic residues or their metabolites in edible products, e.g., milk, eggs, and meat. Some of them, like penicillins, can cause allergic reactions in sensitive individuals. Therefore, monitoring antibiotic residues should be an important task for government authorities.

There are many analytical methods for determining antibiotics in pharmaceuticals, body fluids, and food. They can be based on microbiological, immunochemical, and physicochemical principles. The most popular methods belonging to the latter group are chromatographic ones, mainly liquid chromatography, including HPLC and TLC.[1,2]

HPLC offers high sensitivity and separation efficiencies. However, it requires sophisticated equipment and is expensive. Usually, before HPLC analysis, tedious sample pretreatment is necessary, such as protein precipitation, ultrafiltration, partitioning, metal chelate affinity chromatography (MCAC), matrix solid-phase dispersion (MSPD), or solid-phase extraction (SPE). Generally, the sample clean-up procedures used before TLC separation are the same as for HPLC. Still, they can be strongly limited in the case of screening TLC or when plates with concentrating zones are applied.

TLC is cheaper and less complicated than HPLC, provides high sample throughput, and usually requires limited sample pretreatment. However, the method is generally less sensitive and selective and gives poor resolution. Some of these problems can be solved by high-performance TLC (HPTLC) or forced flow planar chromatography (FFPC), i.e., rotation planar chromatography (RPC), overpressured-layer chromatography (OPLC), and electro-planar chromatography (EPC). Lower detection limits can also be achieved using an autosampler for injection, applying special techniques of development and densitometry as a detection method, or/and spraying the plate after development with appropriate reagents. There is also a possibility of coupling TLC with autoradiography, mass spectrometry (MS) or Fourier-transform infrared (FTIR). Then, TLC can reach selectivity, sensitivity, and resolution close to those of HPLC.

TLC stripped of the above-mentioned attributes may still serve as a screening method, i.e., one that establishes the presence or absence of antibiotics above a defined level

of concentration. Screening TLC methods show sensitivity similar to microbiological assays, which are the most popular screening methods, applied for controlling antibiotic residues in food in many countries. TLC/bioautography (TLC/B) is one of the TLC screening methods. The developed TLC plates are placed on or dipped in a bacterial growth medium seeded with an appropriate bacterial strain. The location of zones of growth inhibition gives information about antibiotic residues.[3,4]

In relation to the extremely diverse nature of antibiotics, a variety of different separation and detection modes are used in analytical practice. Characteristics in brief and some general rules of separation for the most popular classes of antibiotics are presented below.

PENICILLINS

The basic structure of penicillins is a thiazolidine ring linked to a β-lactam ring to form 6-aminopenicillanic acid, the so called "penicillin nucleus" (Fig. 1). This acid, obtained from *Penicillium chrysogenum* cultures, is a precursor for semisynthetic penicillins (ampicillin, amoxicillin, oxacillin, cloxacillin, dicloxacillin, and methicillin) produced by attaching different side chains to the "nucleus." Benzylpenicillin (penicillin G) and phenoxymethylpenicillin (penicillin V) are the naturally occurring penicillins.

The most widely used stationary phase for analysis of penicillins is silica gel, but silanized silica, cyano-silica, silica gel impregnated with tricaprylmethylammonium chloride, cellulose, and alumina plates are also employed. It is advantageous to add acetic acid to the mobile-phase and/or spotting acetic acid before the sample injection in order to avoid the decomposition of β-lactams on silica gel. Mobile phases in reversed-phase (RP) systems usually contain pH 5–6 buffer and organic solvent(s).[5] The most popular detection methods are bioautography and UV densitometry, often coupled with spraying with proper reagents. A review paper on chromatographic analysis of penicillins in animal tissues, included TLC, was written by Boison.[6]

CEPHALOSPORINS

Cephalosporins are derived from natural cephalosporin C produced by *Cephalosporium acremonium*. Chemically,

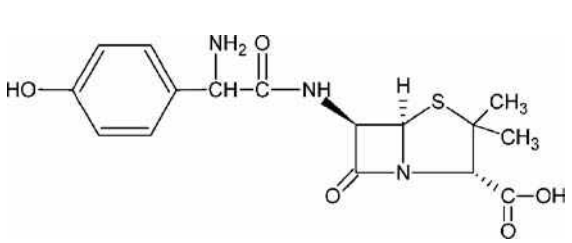

Fig. 1 Amoxicillin.

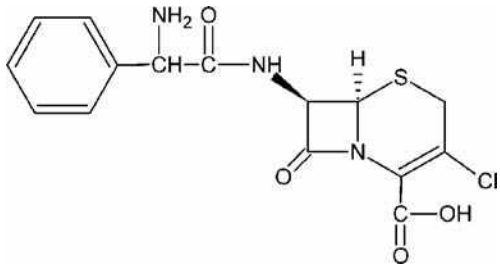

Fig. 2 Cefaclor.

they are derivatives of 7-aminocephalosporanic acid (cephem nucleus) (Fig. 2). Cephalosporins are closely related to penicillins and exhibit the same mechanisms of action, i.e., they inhibit bacterial cell wall synthesis and are used mainly for treating staphylococcal and streptococcal infections in patients who cannot use penicillins. They are commonly divided into three classes differing in the spectrum and toxicity. Cephalosporins can be analyzed by both normal-phase (NP) and RP TLC; however, more efficient separation is obtained on silanized gel than on bore silica gel.[7,8] Silica gel is sometimes impregnated with Na_2EDTA, tricaprylmethylammonium chloride, transition metal ions, or hydrocarbon. Inorganic ion exchangers (e.g., stannic oxide) or silica gel mixed with an exchanger (e.g., with Mg/Al layered double hydroxide) can be also used as stationary phases for cephalosporin analysis. The mobile phases are polar and similar to those used for penicillins. Acetic acid or acetates are very often components of solvents for NP TLC, and ammonium acetate/acetic acid buffer for RP TLC. All cephalosporins can be detected at 254 nm. Applying reagents such as ninhydrin, iodoplatinate, chloroplatinic acid, or iodine vapor can lower the detection limit. An alternative to UV detection is bioautography with, for instance, *Neisseria catarrhalis*.

AMINOGLYCOSIDES

Aminoglycosides consist of two or more amino sugars joined via glycoside linkage to a hexose nucleus (Fig. 3). Streptomycin was isolated in 1943 from *Streptomyces griseus*; then others were discovered in different *Streptomyces* strains. Aminoglycosides are particularly active against aerobic microorganisms and against the tubercle bacillus, but because of their potential ototoxicity and nephrotoxicity, they should be carefully administered. Aminoglycosides, due to their extremely polar, hydrophilic character, are analyzed mostly on silica gel, but C-18 plates can also be used. Polar organic solvents (methanol, acetone, chloroform) mixed with 25% aqueous ammonia are the most popular mobile phases. Because the majority of aminoglycosides lack UV absorption, they must be derivatized by spraying or dipping after development

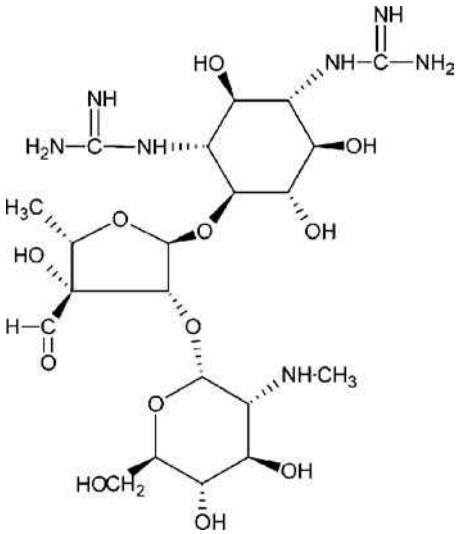

Fig. 3 Streptomycin.

with fluorescamine, vanillin, or ninhydrin solutions. They can be also detected by charring, treating with iodine vapor, or derivatization with 4-chloro-7-nitrobenzo-2-oxa-1,3-diazole (NBD-Cl) or with a mixture of diphenylboronic anhydride and salicylaldehyde. Bioautography with *Bacillus subtilis*, *Sarcina lutea*, and *Mycobacterium phlei* is also possible. Recently, a thorough review on aminoglycoside analysis appeared, embracing, among other methods, also TLC.[9]

MACROLIDES

Macrolides are bacteriostatic antibiotics composed of a macrocyclic lactone ring with one or more deoxy sugars attached to it (Fig. 4). The main representative of the class, erythromycin, was discovered in 1952 as a metabolic product of *Streptomyces erythreus*. Now, erythromycin experiences its renaissance because of its high activity against many dangerous bacteria such as *Campylobacter* and *Legionella*. The macrolide antibiotics group is still being expanded due to the search for macrolides with pharmacokinetic properties better than those of erythromycin. The separation of macrolides is performed on silica gel, kieselguhr, cellulose, and RP layers.[10] Silica gel and polar-mobile phases are extremely frequently applied, usually with the addition of methanol, ethanol, ammonia, sodium, or ammonium acetate. Because of the absence of chromophore groups, bioautography, derivatization, as well as charring are used, the last mainly by spraying with acid solutions (e.g., anisaldehyde/sulfuric acid/ethanol) and heating.

TETRACYCLINES

Tetracyclines, consisting of the octahydronaphthacene skeleton, are "broad-spectrum" antibiotics produced by *Streptomyces* or obtained semisynthetically (Fig. 5). They can be separated by both RP and NP TLC. Cellulose, kieselguhr, cyano-silica, or silica gel impregnated with EDTA or Na_2EDTA can be used. The last one is the most popular stationary phase in tetracycline analysis. Impregnation is necessary due to the very strong interaction of tetracyclines with hydroxyl groups and metal impurities. Also mobile phases, for both RP and NP TLC, should contain chelating agents such as Na_2EDTA, citric acid, or oxalic acid. Tetracyclines are amphoteric; thus, adjusting the pH of the mobile phases is very essential for their good separation. Tetracyclines give fluorescent spots, which can be detected by UV lamp, fixed at 366 nm or by densitometry. Spraying with reagents, for instance, with Fast Violet B Salt solution, provides lower detection levels. Tetracyclines can also be detected by MS (TLC/FAB/MS, TLC/MALDI/MS) as well as by bioautography. Many TLC separation methods are described in the review on the analysis of tetracyclines in food.[11]

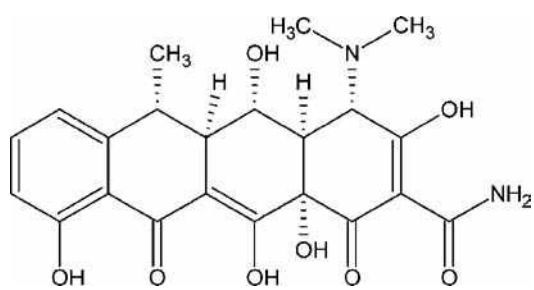

Fig. 5 Doxycycline.

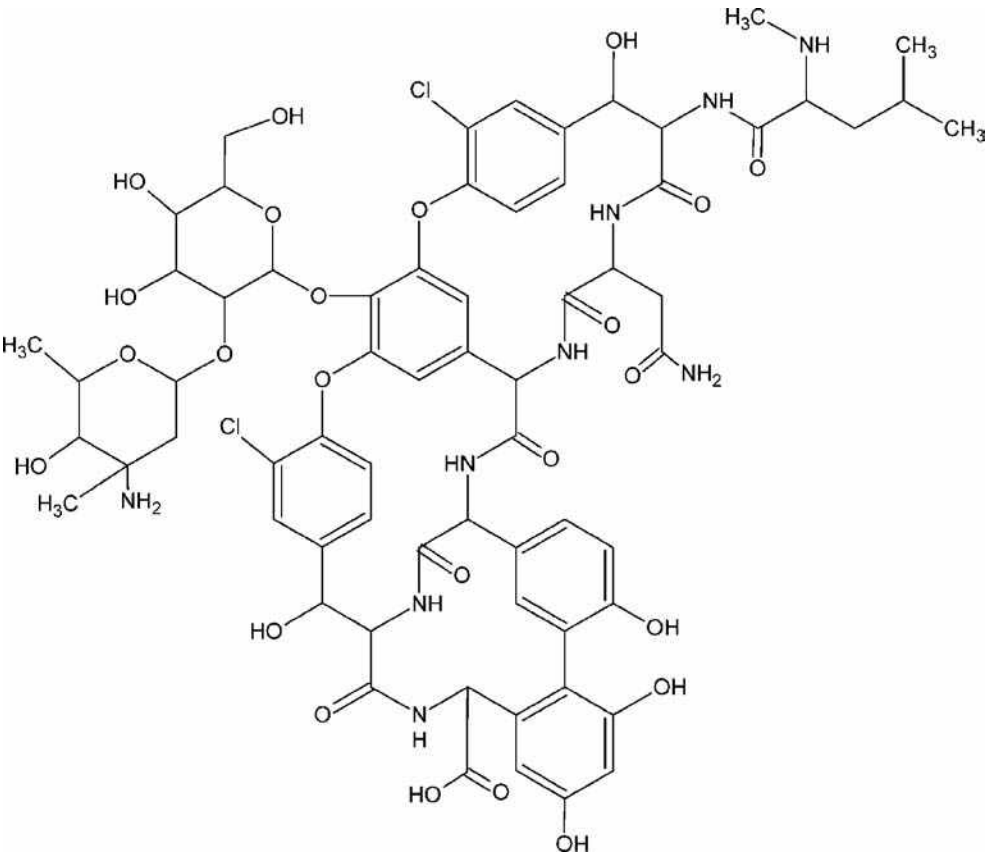

Fig. 6 Vancomycin.

MACROCYCLIC ANTIBIOTICS

Peptides

Peptide antibiotics are composed of a peptide chain of amino acids D and L covalently linked to other moieties (Fig. 6). Most peptides are toxic and have poor pharmacokinetic properties. Peptide antibiotics are difficult to analyze in biological and food samples, as they are similar to matrix components. They can be separated on silica gel, amino silica gel, polyamide, modified cellulose, and silanized silica gel plates.[12] A variety of mobile phases are applied, from simple ones like chloroform/methanol to multicomponent ones like *n*-butanol/butyl acetate/methanol/acetic acid/water. Bioautographic detection can be employed with *Bacillus subtilis* and *Mycobacterium smegmatis* as well as fluorescence densitometry or densitometry after spraying the plate with reagents such as ninhydrin or Fluram®.

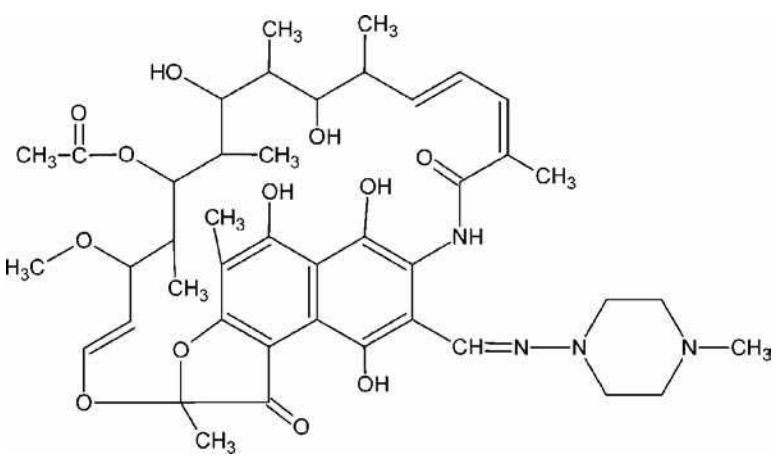

Fig. 7 Rifamycin.

Rifamycins

Rifamycins (ansamycins) are structurally similar macrocyclic antibiotics, produced by *Streptomyces mediterranei*. Their characteristic "ansa" structure consists of aromatic rings spanned by an aliphatic bridge (Fig. 7). Rifamycins are active against Gram-positive bacteria and are mainly used in treating tuberculosis. They can be analyzed using silica gel, polyamide, diphenyl, or C-18 plates and various mobile-phase systems from neat organic solvents, through binary non-aqueous solvents, to binary aqueous–organic solvents.[12] Rifamycins are colored compounds and do not require special detection methods.

POLYETHERS

Polyether or ionophore antibiotics, mainly produced by *Streptomyces* species, consist of cyclic ethers, a single carboxylic group, and several hydroxyl groups (Fig. 8). They are widely used anticoccidiosis agents for poultry. The main members of this class are salinomycin, monensin, narasin, and lasalocid. They can be analyzed on both silica gel and RP-18 plates with mixed organic phases. After derivatization with fluorescent pyrenacyl esters, they can be detected fluorodensitometrically at 360 nm. TLC/B with *Bacillus subtilis* can be used too.[13] There is also an example of coupling TLC with flame ionization detection.

AMPHENICOLS

Chloramphenicol is a highly effective broad-spectrum antibiotic originally isolated from *Streptomyces venezuelae* (Fig. 9). Nowadays, chloramphenicol is banned within the United States and the EC because it is believed to cause aplastic anemia. Other members of the amphenicol group are thiamphenicol and the recent one, florphenicol. These three antibiotics show strong UV absorption and can be determined directly, without any derivatization at 254 or 280 nm. Usually silica-gel plates and simple organic or aqueous–organic solvents are used.[14]

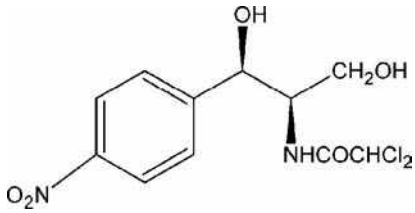

Fig. 9 Chloramphenicol.

SULFONAMIDES

Sulfonamide drugs are bacteriostatic synthetic compounds, the first chemotherapeutics used in human medicine. The progenitor of the class was a red azo dye, 2,4-diaminobenzene-4′-sulfonamide, called prontosil rubrum. The sulfonamides include sulfanilamide (4-amino-benzenesulfonamide) and numerous compounds related to it (Fig. 10).

Sulfonamide drugs are mainly used in veterinary practice and as growth promoters. They are used in the treatment of human infections to a lesser extent because they are toxic and some patients are hypersensitive to them.

Sulfonamides can be analyzed both by NP TLC (on silica gel, alumina, polyamide, and Florisil® layers) and by RP TLC (on silanized silica, RP-2, RP-8, and RP-18 layers).[15] Some sulfonamides have been separated by TLC on silica or polyamide impregnated with metal salts. Both aqueous and non-aqueous eluents are applied. Detection of sulfonamides can be performed on fluorescence layers at 254 nm and after derivatization with, for instance, fluorescamine solution at 366 nm.

NITROFURANS

Nitrofuran drugs are synthetic broad-spectrum chemotherapeutic agents, derivatives of nitrofuran (Fig. 11). Their application in human medicine is limited to some infections (e.g., nitrofurantoin is applied in treating urinary tract infections) or to external use. In veterinary practice, they are used as growth promoters and to prevent and treat diseases in poultry and swine.

Nitrofurans can be separated in NP systems on silica gel and can be detected as colored spots after spraying the plate with pyridine and illuminating with UV light at 366 nm.[16]

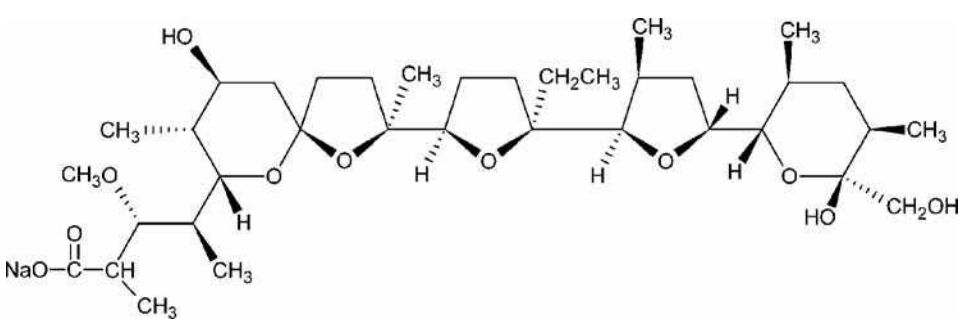

Fig. 8 Monensin.

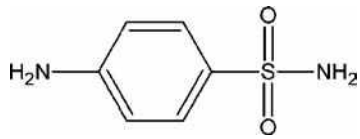

Fig. 10 Sulfanilamide.

QUINOLONES

Nalidixic acid, discovered serendipitously in 1962, was the first member of this class, though of rather minor importance. In the 1980s, synthetic fluoroquinolones were developed and became valid antibiotics with broad spectrum and of good tolerance (Fig. 12). Quinolones are polar, mostly amphoteric compounds. They are usually analyzed on silica gel plates, preferably impregnated with Na_2EDTA or K_2HPO_4 to avoid strong adsorption. Multicomponent organic-mobile phases are employed, usually with the addition of aqueous solutions of ammonia or acids to control pH. Micellar TLC with a cetyl trimethylammonium bromide/sodium dodecyl sulfate mixture as mobile phase and polyamide as stationary phase can also be applied. Densitometry or fluorescence densitometry is a detection method of choice, sometimes preceded by postchromatographic derivatization. Bioautographic detection can also be applied.[4]

ANALYSIS OF ANTIBIOTICS BELONGING TO VARIOUS CLASSES

The analysis of antibiotics belonging to various classes is much more complicated than the analysis of members of one group only. Generally, it is necessary to divide the analyzed antibiotics preliminarily into subgroups. This can be achieved by developing the plate with different mobile phases or using gradient elution.[17] Different stationary phases are sometimes used for different antibiotic classes.[18] It is also possible to use one plate and one mobile phase but various modes of detection for different groups of antibiotics or to combine various modes of development with various modes of detection.[19] Bioautography is very often applied in the multiclass screening.[20] Scanning densitometry at different wavelengths on a hydrocarbon-impregnated silica gel HPTLC plate without solvent elution for direct quantification of many different classes of antibiotics is also described.[21]

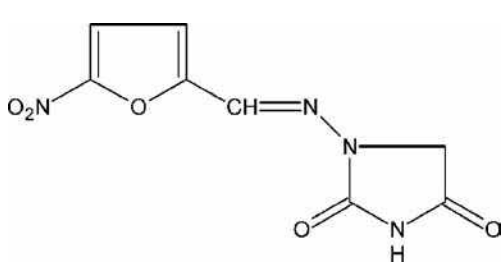

Fig. 11 Nitrofurantoin.

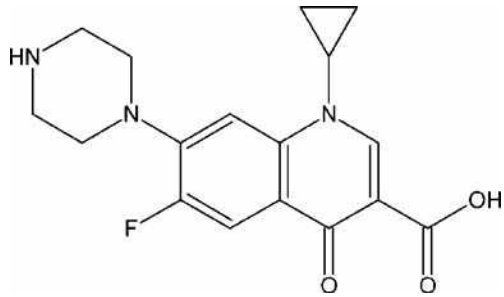

Fig. 12 Ciprofloxacin.

OTHER APPLICATIONS

Beside typical antibiotic analysis, focused on the separation of antibiotics belonging to one or various classes, there are many examples of diverse TLC applications such as the following:

1. Purity control of antibiotics.
2. Examining the stability and breakdown products of antibiotics in solutions and dosage forms.[22]
3. Analysis of antibiotic metabolites.
4. Separation of antibiotic derivatives, obtained in the process of searching for new antibiotics.
5. Purification of newly discovered antibiotics before further testing. Antimicrobial substances are isolated from culture broths or plants and purified by preparative TLC on silica-gel plates.
6. Chemical and biomolecular–chemical screening. Chemical screening is a systematic approach in the search for new biologically active compounds in extracts from microorganisms or plants. Their chromatographic parameters calculated from the TLC plate as well as their chemical reactivity toward staining reagents allow one to obtain a picture of a microbial metabolite pattern (fingerprint). Biomolecular–chemical screening combines the chemical screening strategy with binding behavior toward DNA.[23]
7. Studying interactions of antibiotics with biological matrices. The interactions of the antibiotics with various compounds, cell membranes, and proteins present in biological matrices modify the biological efficacy and stability of the drugs. The interaction of 13 antibiotics with human serum albumin (HSA) was studied by charge-transfer RP TLC in neutral, acidic, basic, and ionic conditions and the relative strength of interaction was calculated.[24]
8. Applying some antibiotics as stationary or mobile-phase additives for chiral separations. The macrocyclic antibiotics (ansamycins, glycopeptides, and

polypeptides) can be used as chiral selectors in TLC. They can be used both as mobile-phase additives (e.g., vancomycin) and for impregnation of TLC silica plates (e.g., erythromycin or vancomycin) for the separation of chiral compounds.[25]

9. Studying the retention behavior of antibiotics, e.g., determining the hydrophobicity parameters of antibiotics by RP TLC.

CONCLUSIONS

TLC is generally less sensitive and gives worse separation than HPLC. However, it predominates over HPLC in at least two aspects: It allows for the analysis of many samples at the same time, and it requires limited sample pretreatment. These features are very important in the analysis of antibiotics, which usually concerns controlling their level in many complicated matrices such as blood, urine, dietary products, and pharmaceuticals. Thus, TLC can be a very useful screening method preceding HPLC analysis. Nevertheless, there are also many examples of analytical applications of TLC, which can achieve selectivity and sensitivity comparable with those characteristic of HPLC. The future of the analytical option in antibiotic analysis is connected with progress in detection and the development of FFPC methods.

Antidiabetic Drugs: HPLC/TLC Determination

A. Gumieniczek
H. Hopkała
A. Berecka
Department of Medicinal Chemistry, Medical University of Lublin, Lublin, Poland

INTRODUCTION

A review of some chromatographic methods for determination of new oral antidiabetic drugs is presented: gliclazide, glimepiride, and glipizide from sulfonylureas; nateglinide and repaglinide from glinides; and pioglitazone and rosiglitazone from glitazones. This entry describes the selected methods for the analysis of these important drugs in pharmaceuticals and in biological materials. Two chromatographic techniques [High-performance liquid chromatography (HPLC), Thin-layer chromatography (TLC)] and various pretreatment modes are described. Sensitivities, linearities, and specificities of the presented methods are compared. The selected methods for determination of potential impurities in bulk drug substances and metabolites of the drugs in biological samples are described. Stability data concerning the mentioned drugs are also presented. Finally, suitable methods for separation of the drugs as well as their isomers (enantiomers and diastereoisomers) are presented.

DETERMINATION OF ANTIDIABETIC DRUGS

Currently, sulfonylureas are the oral agents most commonly used for the treatment of type II diabetes mellitus. They act by binding to receptors located on the membranes of beta cells of the islets of Langerhans. Binding of the ligand and receptor is followed by closure of the K^+-ATP channel, influx of Ca^{2+}, and depolarization of the cell membrane. These events induce degranulation of insulin-containing vesicles and are followed by a hypoglycemic effect.[1] In the past few decades, several generations of sulfonylureas have been developed for common use. Gliclazide (I), glimepiride (II), and glipizide (III) are the principal representatives from the latest generation.

Nateglinide (IV) and repaglinide (V) represent a new class of insulin secretagogues, chemically unrelated to sulfonylureas. Both nateglinide and repaglinide act by stimulating insulin secretion from the beta cells, but they bind to sites distinct from the sulfonylureas' binding sites. Importantly, insulin release takes place only in the presence of glucose. Therefore, they are highly physiologic mealtime glucose regulators.[1,2]

The advent of thiazolidinediones, pioglitazone (VI), and rosiglitazone (VII), which ameliorate insulin resistance and normalize blood glucose level, has revolutionized the treatment of type II diabetes mellitus. Their mechanism of action is quite different from that of established antidiabetic drugs. These compounds are high affinity ligands of peroxisome proliferator receptor gamma, a member of the nuclear receptor superfamily, which controls the expression of genes involved in lipid and carbohydrate metabolism.[2] Chemical structures of the mentioned antidiabetic drugs are presented in Fig. 1.

In addition to being the latest and most commonly prescribed drugs, the hypoglycemic agents selected for this review are more pharmacologically potent. Consequently, they are prescribed at low dosages. Because of the low drug levels in both plasma and urine, analytical methods for detection and quantification of these drugs must be very specific and sensitive. Chromatography plays a major role in the study of their pharmacokinetics in animals and humans. It is also applied for detection and quantification of potential impurities in bulk drug substances, and to determine the ratio of optically active enantiomers and diastereoisomers.

HPLC ANALYSIS

Determination of Sulfonylureas

Among the mentioned drugs, sulfonylureas are the compounds that are more extensively investigated. Some methods were elaborated for determination of gliclazide in human plasma, as a routine assay or to evaluate the bioequivalence of different formulations of the drug. The method of Park et al.,[3] with a semimicrochromatographic column, is fast and requires only a small amount of mobile phase, with a reasonable limit of quantification. The intraday and interday precision values are less than 5.9% and 8%, respectively. This HPLC method, with UV detection, is suitable for clinical monitoring and for pharmacokinetic study of the drug. The method of Igaki et al.[4] includes derivatization of gliclazide with 7-fluoro-4-nitro-benzene-1,3-diazole and fluorimetric detection. However, this method is not more sensitive

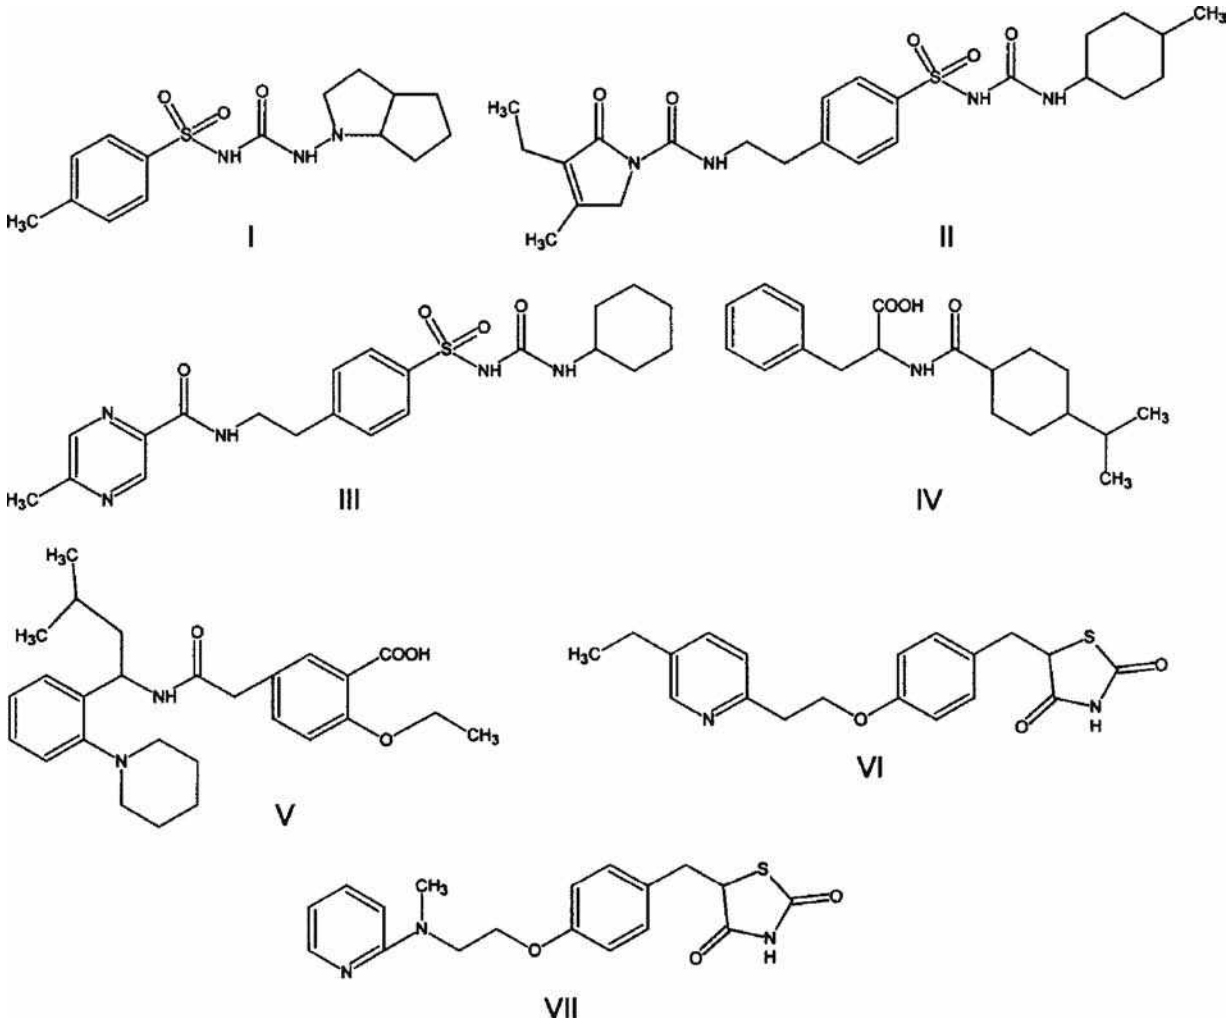

Fig. 1 (I) Chemical structures of gliclazide; (II) glimepiride; (III) glipizide; (IV) nateglinide; (V) repaglinide; (VI) pioglitazone; and (VII) rosiglitazone.

than HPLC–UV measurement. Rouini, Mohajer, and Tahami[5] described a simple assay of gliclazide, which needs a small sample volume (100 μl of serum) and minimal sample work-up. This method has many advantages such as increased sensitivity, high resolution, and economic aspects.

A sensitive method for quantitation of glimepiride in human plasma was established using electrospray ionization tandem mass spectrometry (ESI/MS/MS). Detection of glimepiride is accurate and precise with a quantitation limit of 0.1 ng/ml. This method was successfully applied to a pharmacokinetic study of glimepiride. No interferences of the analytes were observed because of high selectivity of the MS/MS technique.[6] The method of Song et al.[7] is also sufficiently sensitive, with a quantification limit lower than the minimum concentration recommended for plasma samples obtained after the administration of 2 mg glimepiride. This study indicates a reliable stability of glimepiride under the experimental conditions. The drug can remain in an autosampler for at least 24 hr, without showing significant loss in the quantified values. The analyte is also stable in plasma for three cycles of freeze-thaw, when stored at −20°C and thawed to room temperature.

A stress testing of drug substance can help to identify the likely degradation products and to provide important information on drug stability. Consequently, it can be a fundamental contribution to development and validation of stability indicating analytical methods. These methods can be used in quality monitoring of pharmaceutical products. Kovaríková et al. elaborated the study for determination of glimepiride in the presence of its degradation products. After acid hydrolysis, two additional peaks were detected, while alkaline conditions led to decomposition of glimepiride into three degradation products. Degradation of glimepiride in the solution of hydrogen peroxide resulted in formation

of two major peaks. The novelty of this work is based on the description of an analytical procedure that is suitable for monitoring the purity of glimepiride.[8]

The method of Emilsson was elaborated for determination of glipizide in plasma and urine. The utility of this assay for pharmacokinetic study is demonstrated by determining the drug in the samples from a diabetic subject receiving 5 mg of glipizide. The interassay precision is about 10%.[9] The method of Lin, Deasi-Krieger, and Shum was developed and validated for determining the fraction of free glipizide in plasma using equilibrium dialysis and tandem mass spectrometry. Equilibrium dialysis is frequently used to study protein binding and to determine free analyte in biological samples. The accurate determination of free (unbound) drug in plasma is essential for therapeutic monitoring of drugs. It is well known that only the unbound drug is available for distribution, elimination, and pharmacodynamic interaction with receptors. In the mentioned method, the intra-assay and interassay precision values are lower than 9% and 10%, respectively. Glipizide is stable throughout the equilibrium dialysis (37°C) up to six hours. The analytes are also stable when stock solutions of glipizide are stored at a temperature 4°C for one month, or at room temperature for six hours.[10]

Among these eight studies concerning sulfonylureas, six deal with plasma or serum,[3–7,10] and one study is performed on plasma and urine.[9] A study not dealing with biological samples is applied to a methanolic solution of glimepiride.[8] Most of the authors use solvent/buffered solutions as mobile phases in isocratic mode.[3,5,6,8,9] Solvent/unbuffered water or water may also be used.[4,10] The more frequently chosen columns are the C_{18} cartridges.[3,4,6–9] However, C_8 and phenyl cartridges may also be used.[5,10] Ultraviolet absorbance detection is commonly used, but in some cases MS/MS[6,10] or fluorescence detectors[4] are preferred.

Chromatographic techniques require various procedures to isolate the drugs from biological matrices. In the reviewed methods, two distinct approaches are applied: liquid–liquid extraction and direct injection into a chromatographic system. Diethyl ether and ethyl acetate,[6] chloroform,[3,4] toluene,[5] benzene,[9] methyl *t*-butyl ether, and *n*-butyl chloride[10] are used as solvents to obtain recoveries well over 80% for all considered compounds. However, manual sample preparation can be labor and time intensive. Therefore, direct injection is used as a highly automated methodology.[7] The direct injection of complex samples, however, may lead to contamination of columns, thereby impairing their performance. Contamination often persists, even when a precolumn is used to protect the analytical column. A summary of these chromatographic methods for determination of sulfonylureas is presented in Table 1.

Determination of Glinides

The method of Meng et al.[11] can be used for the quality control, stability study, and validity term of nateglinide tablets. In the linear range 0.2–2 μg/ml, the precision is 0.98%. The method of Ono, Matsuda, and Kanno[12] was elaborated for determining nateglinide and its seven metabolites in plasma and urine. However, this method requires an expensive column switching equipment.

A simple, precise, and rapid HPLC method was developed for determination of repaglinide in pharmaceutical dosage forms.[13] In this method, the intraday and interday precision values are 1.01% and 1.15%, respectively. The high efficacy of repaglinide is reflected in the low therapeutic dose of ~2 mg, which requires very sensitive assay for determination of its pharmacokinetics. The paper of Greischel et al.[14] describes a fully automated HPLC assay of repaglinide in plasma with electrochemical detection. The method was validated and applied to a routine analysis of therapeutic plasma levels of the drug. In this method, the interassay precision is 9.2% in 30 ng/ml. Repaglinide is stable in plasma at −20°C for at least six weeks, which is sufficient time for storage between blood sampling and analysis. It is also stable in plasma for over 24 hr at 30°C. A summary of these HPLC methods is shown in Table 2.

Determination of Glitazones

An HPLC method was elaborated for the purity assay of pioglitazone in tablets. This method is capable of detecting all process related compounds that may be present at trace levels in a finished product. This method is very useful for process monitoring during the production of pioglitazone. The relative standard deviation values of assay and recovery of impurities are below 1.0% and 2.7%, respectively. Accelerated degradation studies were also performed to demonstrate validity of the method. The samples of pioglitazone refluxed with HCl, subjected to high temperature or exposed to UV light, did not give any degradation products. The sample refluxed with NaOH completely decomposed to several degradation products.[15]

Some methods are adequate for determination of pioglitazone and its metabolites in biological material.[16,17] It is very important for interpretation of the results, as three of the metabolites of pioglitazone are pharmacologically active. Owing to the large differences in polarity between the parent compound and metabolites of pioglitazone, it is difficult to obtain high extraction recoveries for all of them. Thus, the emphasis is placed on the parent compound and the three active metabolites.[16] The method of Lin et al.[17] was validated for accuracy, precision, sensitivity, specificity, and reproducibility according to the Food and Drug Administration guidelines for bioanalytical methods, over the concentration range of pioglitazone 0.5–2000 ng/ml. Samples of pioglitazone remain stable for at least five

months when stored at −20°C. Extracted analytes are stable in mobile phase at an ambient temperature for 24 hr. Stock solutions of pioglitazone are also stable at 4°C for one month or at room temperature for six hours.[17]

The paper of Muxlow, Fowles, and Russell[18] describes a fully automated method for the quantitative analysis of rosiglitazone in plasma using online dialysis. Similarly, the method of Lin et al. describes a procedure employing equilibrium dialysis for separation of unbound rosiglitazone from plasma for simultaneous quantitation of the unbound and total drug. This is very important because rosiglitazone is known to be highly protein bound, mainly to serum albumin. For highly protein bound drugs, fluctuations in the free fraction can impact the interpretation of the total drug measurement. In the above method, interassay precision is less than 7.6% and intra-assay precision less than 8.9%. The method is linear in the range 1–2000 ng/ml.[10]

Because rosiglitazone is a fluorescent compound, the method with a fluorescence detector is presented with excitation at 247 nm and emission at 367 nm. The low limit of quantitation of rosiglitazone in plasma is 3 ng/ml. The interassay and intra-assay precision values are better than 10% at all concentrations.[18]

The method of Radhakrishna, Satyanarayana, and Satyanarayana was elaborated for determination of rosiglitazone and its related impurities in pharmaceutical formulations. The described method is linear over a range of 0.45–10 μg/ml for related impurities and 180–910 μg/ml for rosiglitazone. Precision values for determination of the drug and related compounds are below 1.0% and 3.6%, respectively. The samples of rosiglitazone refluxed with HCl, subjected to high temperature, and exposed to UV light gave small additional peaks. But the samples refluxed with NaOH or H_2O_2 were mostly converted to degraded products. The developed method was found to be selective, sensitive, and precise for determination of rosiglitazone and their process related impurities. Photodiode array detection (DAD) was used as evidence of the method specificity and to evaluate the homogeneity of the rosiglitazone peak.[19]

Among these six studies concerning glitazones, four deals with plasma or serum[10,16–18] and two with tablets.[15,19] As mobile phases, solvent/buffered solutions, solvent/unbuffered water, or water in isocratic mode are used. Two distinct approaches are applied to isolate the drugs from biological matrices: liquid–liquid extraction and solid-phase extraction (SPE). Solvents used to extract the drugs include methyl *t*-butyl ether and *n*-butyl chloride.[10,17] With the exception of two papers, in which serum extracts are chromatographed on C_8[16] and phenyl columns,[10] all other reviewed methods use C_{18} cartridges.

The HPLC techniques are capable of detecting most of the reported compounds using UV absorbance detection, although DAD detection provides more information in detecting some unknown peaks.[15,19] In the method of Zhong and Williams,[16] by using the wavelength 269 nm for pioglitazone and its metabolites, some interferences from human serum were eliminated. However, MS/MS detection can serve as a more reliable tool for determination of pioglitazone and its metabolites in human serum.[10,17] A summary of these chromatographic methods is shown in Table 3.

Separation of Oral Antidiabetics

The paper of Ho et al.[20] describes a convenient method for separation and simultaneous detection of 10 antidiabetic drugs, including gliclazide, glimepiride, glipizide, nateglinide, repaglinide, pioglitazone, and rosiglitazone in plasma and urine by LC–MS/MS with gradient programming. The compounds were isolated from the biological matrix by a simple liquid–liquid extraction with 1,2-dichloroethane. Confirmation of these drugs can be readily achieved by comparing the product-ion mass spectra, as well as the retention times, with those of their corresponding standards. The interday precision for the peak areas is about 20–30%. The targeted antidiabetics can be easily detected in plasma and urine at a concentration of 10 ng/ml. This method is clearly described in Table 4.

Determination of Enantiomers and Diastereoisomers

In the pharmaceutical industry, separation of enantiomers has been a field of growing interest because they often display quite different pharmacological activities and toxicity profiles. Resolution of enantiomers by liquid chromatography is very frequently used for determining the optical purity and for obtaining individual enantiomers of the drugs.

Only the D-enantiomer of nateglinide is approved to be used in clinical treatment because it is much more potent than the L-enantiomer. Some works were developed for determination of the L-enantiomer in bulk drug substance of nateglinide. The assay of Cao et al.[21] allows the accurate and precise measurement of D-nateglinide and its enantiomer during pharmacokinetic studies in humans. The interday precision values for both enantiomers in plasma and urine are about 7% and 10%, respectively.

Repaglinide has one asymmetric center. It is used for the treatment as a pure enantiomer because only the (+) form is active. Therefore, it is necessary to monitor the purity of the bulk drug substance to keep the level of inactive enantiomer under control. However, the method described in the literature is not adequate for selective determination of repaglinide enantiomers.[13,14]

Some authors propose HPLC methods for selective determination of *trans*-glimepiride and its *cis*-isomer impurity. The method of Wei et al.[22] can be applied to the assay of the *cis*-isomer of glimepiride in bulk drug substance and glimepiride tablets.

Table 5 Summary of the reviewed TLC methods.

Refs.	Matrix	Drug	Support	Mobile phase (v/v)	Detection	Linearity range (μg/ml)
[23]	Bulk	IV,VI, VII	Silica gel 60 F_{254} RP-18 F_{254}	Chloroform–ethyl acetate–acetic acid (5 : 5 : 0.1) MeCN-phosphate buffer at pH 4.4 (5 : 5)	UV 254	—
[24]	Tablets	VI	HPTLC CN F_{254}	1,4-Dioxane-phosphate buffer at pH 4.4 (5 : 5)	UV 266	40–240
[25]	Tablets	VII	HPTLC Silica gel 60 F_{254}	Chloroform–ethyl acetate-25% NH_4OH (5 : 5 : 0.1)	UV 240	20–100

These methods concerning the separation studies are presented in Table 4.

TLC ANALYSIS

Thin-layer chromatography can be successfully applied to separate the compounds, closely related in chemical structure, or used in combination therapy, as well as the metabolites from biological samples. Thin-layer chromatography may also be used to control the chemical purity of the compounds and to predict the HPLC behavior of the drugs and related metabolites. High performance TLC (HPTLC) can be used as an effective quantitative alternative to other chromatographic techniques. Its accuracy and precision are satisfactory for routine use in a pharmaceutical analysis.

The chromatographic behavior of repaglinide, pioglitazone and rosiglitazone, among four other antidiabetic drugs, was investigated on silica gel and RP-18 adsorbents. In the reversed-phase (RP) technique, the effects of different organic modifiers and pH of the buffers on the drugs retention were examined. For separation of these drugs, RP chromatography on RP-18 adsorbent was more effective than use of a normal phase technique on silica gel.[23] The TLC separation of repaglinide, pioglitazone, and rosiglitazone on cyanopropyl plates with mixtures comprising 1,4-dioxane with phosphate buffers was also elaborated. Finally, the best chromatographic conditions were applied for quantitative determination of pioglitazone in tablets. In this method, precision validated by replicate analyses of standard solutions is 4.99% and 2.57% for the lowest and the highest calibration levels, respectively.[24]

A simple, rapid HPTLC method was developed for determination of repaglinide in tablets. The effect of pH, temperature, and UV light on degradation of repaglinide was also investigated. No evidence of degradation was observed for samples subjected to alkaline and heat conditions, whereas the chromatograms of samples subjected to acid hydrolysis contained two additional peaks. Because this method can effectively separate the drug from its degradation products, it can be used as a stability-indicating procedure.[25] A summary of the reviewed TLC methods is shown in Table 5.

CONCLUSIONS

Because of their therapeutic advantages, the above-discussed oral antidiabetic drugs are more and more frequently used in therapy and are extensively examined by analytical procedures. Especially, the methods for pharmacokinetic studies and for quantification of potential impurities in bulk drug substances are continually being developed. Most favored, in terms of a number of publications, are the HPLC techniques, although TLC methods are also represented. In HPLC, a RP technique with C_{18} columns is more prevalent than the alternative phases. Isolation steps are almost evenly distributed between conventional liquid–liquid extraction and SPE procedures. The UV detection can serve as a reliable tool for determination of most of these antidiabetics. However, new prospects are represented by the MS/MS detection. Sensitive and automated HPLC techniques with column switching are also more and more frequently applied.

The TLC methods show higher interest in more recent publications. This technique may be used as an alternative quantitative procedure, especially in quality monitoring of pharmaceutical products.

Antioxidant Activity: Measurement by HPLC

Marino B. Arnao
Manuel Acosta
Antonio Cano
Department of Plant Biology (Plant Physiology), University of Murcia, Murcia, Spain

INTRODUCTION

The determination of antioxidant activity (capacity or potential) of diverse biological samples is generally based on the inhibition of a particular reaction in the presence of antioxidants. The most commonly used methods are those involving chromogenic compounds of a radical nature: the presence of antioxidant leads to the disappearance of these radical chromogens. They are either photometric or fluorimetric and can comprise kinetic or end-point measurements. Recently, there has been increasing interest in the adaptation of these methods for online determinations using liquid chromatography (LC). In this entry, we present the adaptation to high-performance liquid chromatography (HPLC) of our methods for the determination of the antioxidant activity in a range of samples. Advantages and disadvantages of these methods are discussed.

A biological antioxidant is a compound that protects biological systems against the potentially harmful effects of processes or reactions that cause excessive oxidation. Hydrophilic compounds, such as vitamin C, thiols, and flavonoids, as well as lipophilic compounds, such as vitamin E, vitamin A, carotenoids, and ubiquinols, are the best-known natural antioxidants. Many of these compounds are of special interest due to their ability to reduce the hazard caused by reactive oxygen and nitrogen species (ROS and RNS, some are free radicals), and have been associated with lowered risks of cardiovascular diseases and other illnesses related to oxidative stress.[1] Practically all the above-mentioned compounds are obtained through the ingestion of plant products such as fruits and vegetables, nuts, flours, vegetable oils, drinks, and infusions, taken fresh or as processed foodstuffs.[2] A common property of these compounds is their antioxidant activity. The activity of an antioxidant is determined by:

1. Its chemical reactivity as an electron or hydrogen donor in reducing the free radical.
2. The fate of the resulting antioxidant-derived radical and its ability to stabilize and delocalize the unpaired electron.
3. Its reactivity with other antioxidants present.

Thus, antioxidant activity is a parameter that permits quantification of the capacity of a compound (natural or artificial) and/or a biological sample (from a wide range of sources) to scavenge free radicals in a specific reaction medium.[1,3,4]

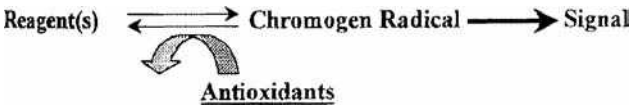
METHODS TO MEASURE ANTIOXIDANT ACTIVITY

Antioxidant activity can be measured in a number of different ways. The most commonly used methods are those in which a chromogenic radical compound is used to simulate ROS and RNS; it is the presence of antioxidants that provokes the disappearance of these chromogenic radicals, as shown in the reaction model given in Scheme 1. In order for this method to be effective, it is necessary to obtain synthetic metastable radicals that can easily be detected by photometric or fluorimetric techniques. Nevertheless, different strategies for the quantification of antioxidant activity have been utilized: e.g., decoloration or inhibition assays. Details of these strategies and commonly used methods have been presented and reviewed elsewhere.[3,4]

When chromogenic radicals are used to determine antioxidant activity, the simplest method is to:

1. Dissolve the radical chromogen in the appropriate medium.
2. Add antioxidant.
3. Measure the loss of radical chromogen photometrically by observing the decrease in absorbance at a fixed time.
4. Correlate the decrease observed in a dose–response curve with a standard antioxidant (e.g., trolox, ascorbic acid), expressing the antioxidant activity as equivalents of standard antioxidant, a well-established parameter in this respect being Trolox Equivalent Antioxidant Capacity (TEAC).[3]

2,2′-Azino-bis-(3-ethylbenzthiazoline-6-sulfonic acid (ABTS) (Fig. 1) and α,α′-diphenyl-β-picrylhydrazyl radical (DPPH) are the two most commonly used synthetic compounds in antioxidant activity determinations. ABTS, when oxidized by the removal of one electron, generates a metastable radical. The ABTS radical cation ($ABTS^{\cdot+}$) has a characteristic absorption spectrum with maxima at 411,



Scheme 1 Reaction model of antioxidant activity determination using chromogenic radicals.

414, 730, and 873 nm (Fig. 1), with extinction coefficients of 31 and 13 m*M*/cm at 414 and 730 nm, respectively.[5] In the reaction between $ABTS^{\cdot+}$ and antioxidants, the radical is neutralized by the addition of one electron (see the reaction presented in Scheme 1. This leads to the disappearance of the $ABTS^{+}$, which can be estimated by the decrease in absorbance (virtually any wavelength between 400 and 900 nm can be selected to avoid exogenous absorption interferences). Generally, $ABTS^{\cdot+}$ is generated directly from its precursor in aqueous media by a chemical reaction (e.g., manganese dioxide, ABAP, potassium persulfate) or by an enzymatic reaction (e.g., peroxidase, hemoglobin, met-myoglobin).[5]

Recently, we have developed a method based on $ABTS^{+}$ generated by horseradish peroxidase (HRP) that permits the evaluation of the antioxidant activity of pure compounds and plant-derived samples.[6] The method is easy, accurate, and fast to apply and presents numerous advantages because it avoids undesirable side reactions, does not require high temperatures to generate ABTS radicals, and allows for antioxidant activity to be studied over a wide range of pH values. This method is capable of determining both hydrophilic (in buffered media) antioxidant activity (HAA) and lipophilic (in organic media) antioxidant activity (LAA).[5] In the second case,

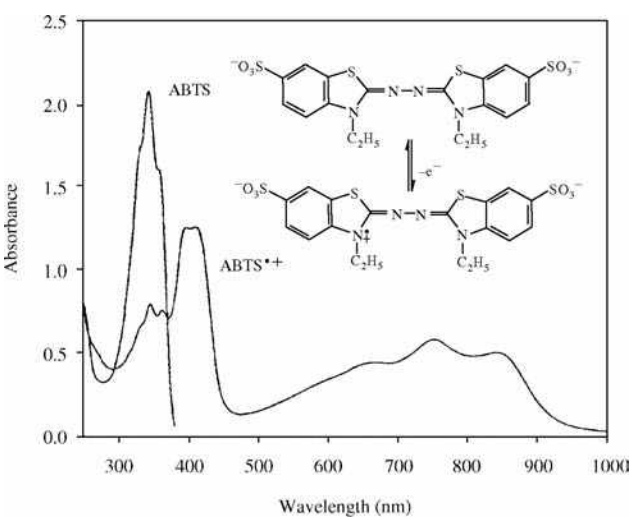


Fig. 1 Spectral characteristics of ABTS and its oxidation products, the ABTS radical ($ABTS^{\cdot+}$), showing absorbance of up to 1000 nm. The chemical structures show the nitrogen-centered radical cation of $ABTS^{\cdot+}$.

$ABTS^{\cdot+}$ is generated directly in ethanolic medium by HRP, which is a powerful oxidizing biocatalyst that can act in non-aqueous media—a capacity that has been widely used in biotechnological applications. Thus, it is possible to estimate the antioxidant activity of both antioxidant types in the same sample (HAA and LAA). The antioxidant capacities of natural compounds, such as ascorbic acid, glutathione, cysteine, phenolic compounds (resveratrol, gallic acid, ferulic acid, quercetin, etc.), or synthetic antioxidants, such as BHT, BHA, or trolox (a structural analog of vitamin E), have been estimated, as well those of plant extracts or samples from other sources. Different applications of the method have determined antioxidant activity in a range of foodstuffs.[7] The $ABTS^{\cdot+}$ chromogen used in our method has been compared with another widely used radical chromogen, $DPPH^{\cdot}$; it was concluded that in the determination of the antioxidant potential of citrus and wine samples, the $DPPH^{\cdot}$ method could significantly underestimate TEAC by up to 36% compared to $ABTS^{\cdot+}$.[8] Also, we have applied the method to study the total antioxidant activity of different vegetable soups, obtaining relevant data on the relative contribution of hydrophilic (ascorbic acid and phenols) and lipophilic (carotenoids) components to their total antioxidant activity.[9] On the other hand, our methods have been used in animal physiological studies on changes in the plasma antioxidant status caused by the hormone melatonin in rats[10] and by other authors on the effect of "in vivo" oxidant stress in the rat aorta.[11]

Under our assay conditions, $ABTS^{\cdot+}$ generation progresses quickly and only 1–5 min is necessary to reach maximum absorbance. This is a decisive factor in the easy and rapid application of the assay with minimal reagent manipulation. In contrast, other assays that use $ABTS^{\cdot+}$ to measure the activity of lipophilic antioxidants have certain drawbacks, among which are: lengthy time (up to 16 hr) to chemically generate and stabilize $ABTS^{\cdot+}$ via potassium persulfate;[12] a previous filtration step when manganese dioxide is used; or, in the case of the assay that uses ABAP, high temperatures (45–60°C) that tend to affect $ABTS^{\cdot+}$ stability. The advantage of enzymatic $ABTS^{\cdot+}$ generation, as opposed to chemical generation, is that the reaction can be controlled by the amount of H_2O_2 added, while the exceptional qualities of HRP in $ABTS^{\cdot+}$ generation is an important feature in both the aqueous and the organic system.[5–6] The most significant limiting factor in this type of strategy is the fact that the $ABTS^{\cdot+}$ must be stable during the analysis; we were able to optimize the conditions to ensure >99% stability. During optimization, it was verified that the concentration ratio between radical ($ABTS^{\cdot+}$) and substrate (ABTS) is a determining factor for the stability of $ABTS^{\cdot+}$, although pH and temperature are also important elements. With respect to the sensitivity of these methods, the calibration using L-ascorbic acid presented a detection limit of 0.15 nmol and a quantification limit of 0.38 nmol. For

lipophilic antioxidants, limit of detection (LOD) of 0.08 and limit of quantitation (LOQ) of 0.28 nmol of trolox were obtained. The LOD and LOQ of similar values were obtained for α-tocopherol and β-carotene.

ANTIOXIDANT ACTIVITY BY HPLC

The possibility of automating antioxidant activity determination and applying it to a large number of samples was an interesting objective. Previously, we have adapted our method as a microassay using a microplate reader to determine total antioxidant activity.[5] Recently, other authors have adapted radical chromogenic tests into methods that combine the advantages of rapid and sensitive chromogen radical assays with HPLC separation for the online determination of radical scavenging components in complex mixtures. Specifically, the $DPPH^{\cdot}$ method and the method of Rice-Evans, which uses $ABTS^{\cdot+}$ generated chemically with potassium persulfate, have been adapted as such.[13–14] Nonetheless, the chemical generation of $ABTS^{\cdot+}$ via potassium persulfate required 16–17 hr to complete. Our methods resulted in faster and better controlled generation of stable ABTS radical because $ABTS^{\cdot+}$ was generated enzymatically in only 2–5 min, with perfect control over the amount of $ABTS^{\cdot+}$ formed and its stability (ABTS/$ABTS^{\cdot+}$ ratios).[6] The speedy generation of $ABTS^{\cdot+}$ permitted quick acquisition of the absorbance value desired in the detector by the addition of aliquots of H_2O_2 to the ABTS solution.

The adaptation of the $ABTS^{\cdot+}$ method as an online test required that the chromogen radical should be stable for sufficient time in different solvents to permit the utilization of isocratic or gradient elution programs. The online reaction time between $ABTS^{\cdot+}$ and potential antioxidants was an additional potential limiting factor.

For online measurement of the antioxidant activity of samples using LC, it is first necessary to consider the basic equipment required. Thus, the determination of antioxidant activities in separate components of samples by HPLC in a postcolumn reaction of analytes with preformed $ABTS^{\cdot+}$ requires at least:

1. Two pumps, one for the mobile-phase solutions and another for the preformed $ABTS^{\cdot+}$ solution. A pulse dampener is recommended to minimize pulse oscillations.
2. A sample injector.
3. The chromatography column.
4. A reaction coil of adequate length to give the desired reaction time.
5. A UV–Visible (UV–Vis) detector.
6. An integration system (software) for data analysis.

Fig. 2 shows a schematic diagram of the equipment used in this study. In this case, because only one diode array detector was available, two injections of the sample were necessary: one to obtain the UV profile (at 250 nm) and another for the antioxidant activity profile at 600 nm (negative peaks). If two UV–Vis detectors had been used, only one injection would have been required to obtain the dual-HPLC profile but the chromatograms must be time-normalized.

In this type of analysis, a dual-HPLC profile was obtained. The UV profile (injection one) was of interest because all the main components of biological samples are absorbed in this wavelength range. The second injection detected absorbance changes at 600 nm or higher (see absorption spectrum of $ABTS^{\cdot+}$ in Fig. 1) to give the antioxidant activity profile. The photodiode array detector additionally recorded the absorption spectra of peaks and, consequently, could also provide data on the possible chemical nature of the analyzed compounds. The HPLC-ABTS method can be used to characterize hydrophilic (ascorbic acid, phenolic compounds, organic acids, etc.) or lipophilic antioxidants (trolox, a synthetic standard antioxidant analog of vitamin E or carotenoids such as β-carotene, lycopene, xanthophylls, etc.). Using standard antioxidants, the dual-HPLC profile as shown in Fig. 3 could be obtained. In Fig. 3A, the upper chromatogram (trolox detected at 250 nm) and the lower chromatogram

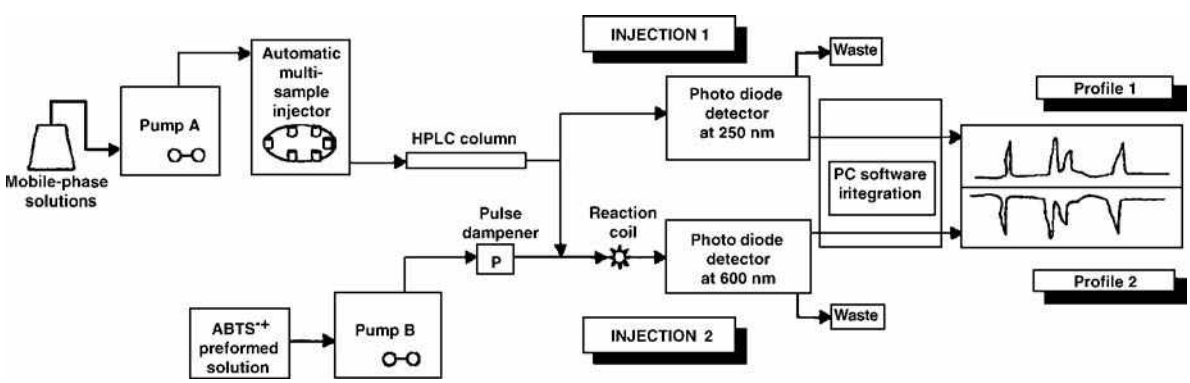

Fig. 2 Instrumental scheme for the determination of antioxidant activities by HPLC using $ABTS^{\cdot+}$ as chromogenic radical.

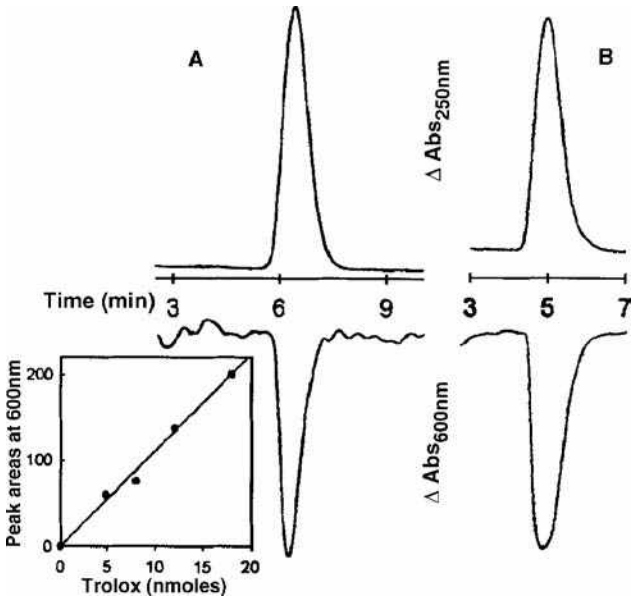

Fig. 3 Dual-HPLC plots of two antioxidants: trolox and resveratrol. Upper chromatograms show UV profiles registered at 250 nm and lower chromatograms $ABTS^{\cdot+}$ scavenging (antioxidant activity) profiles registered at 600 nm (negative peak). In (A), trolox was detected with a retention time of 6.2 min. Inset: Calibration curve of scavenging activity (peak areas at 600 nm) for different amounts of trolox. In (B), resveratrol was detected at 5.0 min.

(the scavenging activity of trolox vs. $ABTS^{\cdot+}$ measured at 600 nm) were correlated. A calibration curve relating the antioxidant concentration and the signal (600 nm, as peak areas) was obtained and used as standard to express all data as TEAC. Generally, a known amount of trolox was injected into HPLC in any chromatographic conditions (to analyze hydrophilic or lipophilic compounds) to quantify its antioxidant activity and obtain the calibration curve. Thus, antioxidant activity was calculated from the sum of the peak areas of the chromatogram profile at 600 nm (negative peaks) and expressed as trolox equivalents (TEAC) using the previously mentioned calibration curves. An example of another important antioxidant (resveratrol) is shown in Fig. 3B.

Another significant aspect was the stability of the radical chromogen $ABTS^{\cdot+}$ in different solvents, in isocratic or gradient elution programs. We found that in the mobile phases used in our determinations (saline solutions and mixtures of organic solvents in different proportions), the observed fall was less than 0.01 expressed as $-\Delta Abs_{730nm}/min$.[15] This stability is high enough to obtain accurate data, approximately 10 times greater than the data reported in Ref.[14]

It was very important to guarantee at least 1 min of online reaction time between $ABTS^{\cdot+}$ and the antioxidants because fast antioxidants, such as trolox or ascorbic acid, reacted with $ABTS^{\cdot+}$ almost immediately, but other antioxidants required more time. In our case, trolox and ascorbic acid presented TEAC values of 1.0 and 0.99, respectively, using the HPLC–ABTS method (Table 1); similar values were obtained using the ABTS end-point method or the method of Rice-Evans.[3,6] In the method of Koleva et al.,[14] ascorbic acid presented time dependence: at 30 sec, 60% of TEAC was expressed. In our system, and to guarantee sufficient online reaction time, a stainless steel reaction coil of 1 ml volume (2.5 m × 0.7 mm I.D.) coupled to a pump was connected to the chromatographic system (between the column and the diode detector) (Fig. 2). Thus, using a suitable elution program (0.5–0.7 ml/min of mobile phases) and introducing between 0.3 and 0.5 ml/min of the preformed $ABTS^{\cdot+}$ (0.2 m*M*), a total online reaction time of 1 min was obtained.

Table 1 Antioxidant activities of different compounds determined by the HPLC–ABTS and by the end-point method.

	Antioxidant activity (TEAC)	
Compound	**HPLC-ABTS method**	**End-point method**
L-Ascorbic acid	0.99	1.0
Trolox	1.0	1.0
Ferulic acid	0.87	1.94
Gallic acid	1.39	3.02
Resveratrol	1.32	2.34
Quercetin	2.83	4.30

Source: From Methods to measure the antioxidant activity in plant material. A comparative discussion, in Free. Radic. Res.[4]

Under these conditions, a study of the antioxidant potential of pure compounds could be carried out. Table 1 shows the values of antioxidant activity (expressed as TEAC) of different compounds of interest, determined by the online method (HPLC–ABTS method) and compared with the values obtained by our conventional photometric end-point method.[6] As can be observed, the two most important standard antioxidants, trolox and ascorbic acid, presented similar TEAC using either method. Thus, either can be used as reference to express antioxidant activity, except that trolox has the advantage because it can be used in both hydrophilic and lipophilic assays. The TEAC values of phenolic compounds were underestimated by approximately half when the HPLC–ABTS method was used as compared to the end-point method. This was due to the different reactivities of antioxidants with $ABTS^{\cdot+}$, and because, unfortunately, the time dependence of online scavenging activity determinations made it very difficult to obtain the total reaction for the slowest antioxidants resulting in a partial estimation of this activity. Nevertheless, the HPLC–ABTS method provided important additional information in the form of correlation between the different peaks of a sample and their antioxidant activities.

The HPLC–ABTS has been used in a study on the HAA and the LAA of fresh citrus and tomato juices.[15] The data

obtained showed a good correlation between vitamin C content and HAA and slight underestimations of LAA. We are currently applying this method to different plant materials with the aim of finding out which compounds apport significant antioxidant properties to the foodstuffs studied.

CONCLUSIONS

Determinations of antioxidant activity are widely used in phytochemistry, nutrition, food chemistry, clinical chemistry, as well as in human, animal, and plant physiology, etc. Methods adapted to HPLC have appeared only recently but can be expected to have multiple applications in the future. $ABTS^{\cdot+}$ is an excellent metastable chromogen for the detection and quantification of the HAA and LAA of biological samples. Thus, using a simple photometer (end-point method),[6] a microplate reader (multisample titration method),[5] or HPLC equipment, a broad range of possibilities are available for the characterization of diverse samples (animal- or plant-derived). Some applications of special interest could include:

1. Characterization of biological samples (e.g., plant extracts, foods).
2. Studies on the changes in the antioxidant activity of material during industrial or postharvest processing (e.g., thermal processes, Maillard reactions, and cold storage of foods, etc.).
3. The search for new natural antioxidants of vegetable or marine origin.
4. Clinical determinations.

Antiretroviral Drugs

Melgardt M. de Villiers
School of Pharmacy, University of Wisconsin, Madison, Wisconsin, U.S.A.

Wilna Liebenberg
Research Institute for Industrial Pharmacy, North-West University, Potchefstroom, South Africa

INTRODUCTION

When seeking chromatographic analytical methods for anti-retroviral drugs (ARVs), the approved methods published in national and international pharmacopoeias such as the United States Pharmacopeia,[1] British Pharmacopoeia,[2] European Pharmacopoeia,[3] and Japanese Pharmacopoeia[4] should be considered first. However, methods of analysis for many of the newer ARVs are not listed in these pharmacopoeias. In addition, when ARVs are combined into a single dosage form, or administered together, the analytical methods for single entities frequently do not apply. Since different classes of ARVs act at different stages of the HIV life cycle, combination of several (typically three or four) ARVs is usually more effective. Combination therapy is therefore known as highly active anti-retroviral therapy (HAART).[5] The preferred initial regimens are either: Efavirenz + Lamivudine or Emtricitabine + Zidovudine or Tenofovir; or Lopinavir boosted with Ritonavir + Zidovudine + Lamivudine or Emtricitabine.[6]

ARVs are broadly classified by the phase of the retrovirus life cycle that the drug inhibits. There are thus five broad classifications of ARVs retroviral drugs in development, though only the first three classes currently have licensed examples:[6]

1. Reverse transcriptase inhibitors (RTIs) target construction of viral DNA by inhibiting activity of reverse transcriptase. There are two subtypes of RTIs, nucleoside-analogue RTIs and non-nucleoside-analogue RTIs. Nucleoside/nucleotide analogues include: Abacavir, Didanosine, Emtricitabine, Lamivudine, Stavudine, Tenofovir, Zalcitabine (production discontinued), and Zidovudine. Non-nucleoside Reverse Transcriptase Inhibitors include: Delavirdine, Efavirenz, and Nevirapine.
2. Protease inhibitors (PIs) target viral assembly by inhibiting the activity of protease. Protease inhibitors include: Amprenavir, Atazanavir, Fosamprenavir, Indinavir, Lopinavir/Ritonavir, Nelfinavir, Ritonavir, Saquinavir, and Tipranavir.
3. Fusion inhibitors block HIV from fusing with a cell's membrane to enter and infect it. An example of a drug in this class is Enfuvirtide.
4. Integrase inhibitors inhibit the enzyme integrase, which is responsible for integration of viral DNA into the DNA of the infected cell.
5. Entry inhibitors block HIV-1 from the host cell by binding CCR5, a molecule on the viral membrane termed a co-receptor that HIV-1 normally uses for entry into the cell.

In Table 1, chromatographic methods of analysis for ARVs taken from pharmacopoeial and other reports are summarized. These methods represent tested analytical methods for determining the drugs, alone or in combination, using mainly high-performance liquid chromatography (HPLC) analysis with or without sample preparation. These methods can be used for analyzing the drugs in pharmaceutical dosage forms or biological fluids.

CONCLUSION

Although there are analytical methods for some ARV drugs available in official compendia because of the constant introduction of newer drugs and with the move toward combination therapy, it is difficult to quickly find these methods. This report is an attempt to summarize these methods, thereby providing a single source of published HPLC methods.

Table 1 Conditions for the chromatographic analysis of anti-retroviral drugs.

Drug	Analysis method	Refs.
 Abacavir	Mobile phase: Methanol : acetonitrile: 0.015 *M* KH_2PO_4 (36:2.6:61.4, v/v/v) adjusted to pH 6.9 with 5 N NaOH. Chromatographic system: The separation was carried out at ambient temperature on a reversed-phase Waters Spherisorb ODSI column (250 × 4.6 mm, 5 μm particle size). The chromatographic separation was performed isocratically. The UV detector was set at a wavelength of 284 nm. An injection volume of 20 μl was used. Ketoprofen was used as an internal standard. The retention times were 5.49 min for abacavir and 9.15 min for ketoprofen in the mobile phase, 5.46 min for abacavir and 9.24 min for ketoprofen in serum samples	[7]
	The standards and samples were chromatographed on a Kromasil octadecyl column at room temperature. Each set of study samples assayed with mobile phase containing 25 m*M* ammonium acetate buffer (pH 4.0 with acetic acid)–methanol (95:5, v/v) initially, and a linear gradient of acetonitrile increasing from 0% to 50% over 30 min. A 10 min HPLC column re-equilibration time followed each individual analysis. The mobile-phase flow rate 0.7 ml/min, and the total run time for each was 40 min. The analytes were quantitated following UV detection at 295 nm	[8]
 Didanosine	For the analysis of didanosine in drug substance and formulated products, tablets chromatography is carried out on a pre-packed, Lichrospher 100 Rp-8 (5.0 μm, 250 mm × 4.0 mm) column using 0.01 *M* sodium acetate solution : methanol (85:15, v/v) adjusted to pH 6.5 with acetic acid as mobile phase at a flow rate of 1.5 ml/min and a 248 nm detection. The assay was linear over the concentration range of 50–150 μg/ml ($R \approx 0.999$). The method was validated for accuracy and precision	[9]
 Emtricitabine	Separation of emtricitabine (FTC) enantiomers using an amylose *tris*[(*S*)-1-phenylethylcarbamate] coated onto APS-Nucleosil (7 μm particle size, 500 Å pore size, 20% w/w, 15 × 0.46 cm I.D.) chiral column under polar organic elution mode. Good enantioselectivity ($\alpha = 1.9$) with excellent enantioresolution (RS = 3.3) was achieved by the use of methanol with 0.02% of triethylamine acetate as mobile phase. The method allows the accurate determination of as low as 0.2% of each enantiomer as an impurity. The validated method proved to be reliable and sensitive for the quantification of both enantiomers as impurity in different batches of emtricitabine and b-D-(+)-FTC	[10]
 Lamivudine	Mobile phase: A filtered and degassed mixture of 0.025 *M* ammonium acetate solution (pH of 3.8 ± 0.2 adjusted with acetic acid) and methanol (95:5). Make adjustments if necessary. Chromatographic system: The liquid chromatograph must be equipped with a 277 nm detector and a 4.6 mm × 25 cm, C_{18} column. Flow rate 1.0 ml/min. Column temperature maintained at 35°C. The resolution, *R*, between lamivudine and lamivudine diastereomer is not less than 1.5 with the relative retention times about 1.0 for lamivudine and 0.9 for lamivudine diastereomer. The relative standard deviation for replicate injections must not be more than 2.0%	[1]
 Stavudine	Mobile phase: A filtered and degassed mixture of 0.01 *M* ammonium acetate and acetonitrile (95:5). Chromatographic system: A liquid chromatograph equipped with a 254 nm detector and a 4.6 mm × 3.3 cm, C_{18} column that contains 3 μm packing. Flow rate about 0.7 ml/min. The retention time of the stavudine peak is between 2.8 and 5.0 min; the column efficiency is not less than 800 theoretical plates; the tailing factor is less than or equal to 1.6–1.8; and the relative standard deviation for replicate injections is not more than 2.0%	[1]
	This method is also used for the analysis of the drug in tablets after employing a resolution solution prepared by dissolving accurately weighed quantities of thymine and thymidine in water, diluted with water to obtain a solution having a known concentration of 0.1 μg/ml of each component. The resolution, *R*, between thymine and thymidine is not less than 2.0, and thymine is resolved from the void volume	
	For the analysis of stavudine in solution, a mobile phase composed of two solutions is recommended. Solution A: A filtered and degassed mixture of 25 m*M* ammonium acetate and methanol (94:6). Solution B: A filtered and degassed mixture of 25 m*M* ammonium acetate and methanol (1:1). Chromatographic system: A liquid chromatograph equipped with a 268 nm detector and a 4.6 mm × 3.3 cm C_{18}column and a 4 mm × 20 mm C_{18} guard column. The flow rate is about 1 ml/min. The chromatograph is programed so that from 0 to 12 min, 100% of Solution A is eluted.	

(Continued)

Table 1 Conditions for the chromatographic analysis of anti-retroviral drugs. *(Continued)*

Drug	Analysis method	Refs.
	Then by a step gradient, the mobile phase is changed to 100% Solution B. From 12.1 to 17 min, 100% Solution B is eluted. From 17 to 17.1 min, the mobile phase is changed back to 100% Solution A. From 17.1 to 35 min, the chromatograph is recalibrated with 100% Solution A. Using the resolution solution used for the analysis of tablets, the resolution, *R*, between thymine and thymidine is not less than 8.4. The column efficiency is not less than 2000 theoretical plates; the tailing factor for the stavudine peak is not more than 2; and the relative standard deviation for replicate injections is not more than 2.0%	[1]
 Tenofovir	This method combines a solid–liquid extraction procedure with a reversed-phase HPLC system. The system requires a mobile phase containing Na_2HPO_4 buffer, tetrabutylammonium hydrogen sulfate, and acetonitrile for different elutions through a C_{18} column with UV detection. The method proved to be accurate, precise, and linear between 10 and 4,000 ng/ml. The method was applied to determine trough levels of tenofovir in 11 HIV-infected patients and for pharmacokinetic studies in HIV-infected patients with renal failure	[11]
 Zalcitabine	Mobile phase: A filtered and degassed mixture of phosphate buffer (6.8 g of monobasic potassium phosphate and 8.7 g of dibasic potassium phosphate in 2000 ml of water adjusted with dilute phosphoric acid or potassium hydroxide solution to a pH of 6.8 $\pm$ 0.05) and acetonitrile (97:3). Make adjustments if necessary. Chromatographic system: A liquid chromatograph equipped with a 270 nm detector and a 4.6 mm $\times$ 15 cm, C_{18} column. Flow rate is about 1 ml/min. The tailing factor for the zalcitabine peak is not greater than 1.5, and the relative standard deviation is not more than 2.0%. The resolution, *R*, between zalcitabine and a zalcitabine related compound is not less than 2	[1]
	The drug in tablets requires the following chromatographic conditions. Mobile phase: A filtered and degassed mixture of buffer solution and acetonitrile (85:15). The buffer solution is composed of 3.4g of monobasic potassium phosphate in sufficient water to make 1 L adjusted with phosphoric acid to a pH of 2.2. Chromatographic system: A liquid chromatograph is equipped with a 280 nm detector, a precolumn C_{18} cartridge and a 4.6 mm $\times$ 25 cm analytical C_{18} column that contains 5 μm packing. A flow rate of about 1.5 ml/min. The resolution, *R*, between the zalcitabine and zalcitabine related compound A peaks is not less than 1.1, and the tailing factor for the zalcitabine peak is not more than 1.5. The relative standard deviation for replicate injections is not more than 2%	[1]
 Zidovudine	Mobile phase: A filtered and degassed mixture of water and methanol (80:20). Make adjustments if necessary. Chromatographic system: A liquid chromatograph equipped with a 265 nm detector and a 4.0 mm $\times$ 25 cm C_{18} column and a 3.2 mm $\times$ 1.5 cm C_{18} guard column. The flow rate is about 1.0 ml/min. The relative retention times are about 0.25 for zidovudine related compound C (thymine), 1.0 for zidovudine, and 1.17 for zidovudine related compound B (3′-chloro-3′-deoxythymidine); the resolution, *R*, between zidovudine and zidovudine related compound B is not less than 1.4; the tailing factor is not more than 1.5; and the relative standard deviation for replicate injections is not more than 2.0%. In the USP, this method is also used for the analysis of the drug in injections and capsules	[1]
	For the analysis of zidovudine in oral solutions, the mobile phase is a filtered and degassed mixture of 0.040 *M* sodium acetate, methanol, acetonitrile, and glacial acetic acid (900:90:10:2). Chromatographic system: A liquid chromatograph equipped with a 240 nm detector and a 4.0 mm $\times$ 12.5 cm C_{18} column. The flow rate is about 1.0 ml/min. The relative retention times are about 0.12 for zidovudine related compound C (thymine) and 1.0 for zidovudine; the resolution, *R*, between zidovudine and zidovudine related compound C (thymine) is not less than 4.0; the tailing factor is not more than 2.0; and the relative standard deviation for replicate injections is not more than 2.0%	[1]

(Continued)

Table 1 Conditions for the chromatographic analysis of anti-retroviral drugs. *(Continued)*

Drug	Analysis method	Refs.
	For the analysis of zidovudine in tablets, the mobile phase suggested in the USP is 3.0 g of sodium acetate and 1.3 g of sodium 1-octanesulfonate in 900 ml of water. Add 90 ml of methanol and 40 ml of acetonitrile, and mix. Adjust with glacial acetic acid to a pH of 5.3, filter, and degas. Chromatographic system: A liquid chromatograph equipped with a 265 nm detector and a 4.6 mm × 15 cm C_{18} column. The flow rate is about 1.3 ml/min. The resolution, *R*, between zidovudine and a peak having a relative retention time of about 1.2 is not less than 2.5; the tailing factor for the zidovudine peak is not more than 2.0; and the relative standard deviation for replicate injections is not more than 2.0%	[1]
 Delavirdine	Mobile phase: A mixture of 10 m*M* potassium phosphate buffer, pH 6.0, with acetonitrile (2 : 1). The chromatographic system: Separation was affected on a Zorbax SB CN, 150 × 4.6 mm I.D., 5 μm analytical column along with a RP-CN 15 × 3.2 mm I.D., 7 μm precolumn. The column effluent was monitored using a Waters Model 470 scanning fluorescence detector operated with 18 nm slit widths at 302 nm excitation and 425 nm emission. Typical injection intervals were about 11 min at a flow rate of 1.5 ml/min. Retention times were approximately 3 min for the metabolite, 7.5 min for the internal standard, and 9 min for delavirdine. Typical system performance was approximately 10,000 plates/m for the metabolite, 19,000 plates/m for the internal standard, and 31,000 plates/m for delavirdine with a minimum resolution of 1.7 between the internal standard and delavirdine	[12]
 Efavirenz	Mobile phase: A mixture of 10 m*M* phosphate buffer pH 2.4 (adjusted with 1 N HCl) and acetonitrile (55:45, v/v). Chromatographic system: The analytical column was a C_{18}, 150 × 4.6 mm I.D., 5 μm particle size (Lichrospher 100 RP-18e) protected by a compatible guard column. The UV detector was set at 245 nm. 20 μl samples were injected and the chromatogram was run for 10 min at a flow rate of 2.4 ml/min at ambient temperature	[13]
 Nevirapine	Mobile phase: A filtered and degassed mixture of 0.025 *M* ammonium phosphate buffer (pH about 5) and acetonitrile (4:1). Chromatographic system: A liquid chromatograph equipped with a 220 nm detector and a 4.6 mm × 15 cm column that contains 5 μm packing L60 (spherical, porous silica gel, 3 or 5 μm in diameter, the surface of which has been covalently modified with palmitamidopropyl groups and endcapped with acetamidopropyl groups to a ligand density of about 6 μmol/m^2). The flow rate is about 1 ml/min. The column temperature is maintained at 35°C. The relative retention times are about 0.7 for nevirapine related compound B, 1.0 for nevirapine, 1.5 for nevirapine related compound A, and 2.8 for nevirapine impurity C. The resolution, *R*, between nevirapine related compound B and nevirapine is not less than 5.0; and the resolution between nevirapine and nevirapine related compound A is not less than 7.4. The relative standard deviation for replicate injections is not more than 2.0%	[1]
 Amprenavir	Amprenavir concentrations in plasma and other solutions can be measured by HPLC with separation on a C_{18} column after liquid–liquid extraction from alkaline plasma and UV detection at 210 nm. First, amprenavir was extracted with diethylether from 0.2 ml of plasma after adding pH 9 buffer and 6,7-dimethyl-2,3-di-(2-pyridyl)-quinoxaline (internal standard from Sigma Aldrich Chemicals). Dry residues were dissolved in 100 μl of the mobile phase and 30 μl was injected onto the C_{18} column. The mobile phase consisted of water/acetonitrile/sodium hydroxide/orthophosphoric acid/triethylamine (650/350/0.9/0.7/0.5, v/v) and the flow rate was 1.2 ml/min. The HPLC system consisted of a Licrocart 125-4 mm column (licrospher phase 100 RP-18 encapped 5 μm, Merck)	[14]

(Continued)

Table 1 Conditions for the chromatographic analysis of anti-retroviral drugs. *(Continued)*

Drug	Analysis method	Refs.
 Fosamprenavir	Fosamprenavir is an oral prodrug of the protease inhibitor amprenavir, with a reduced daily dose. Since this is a prodrug, any analysis in biological fluids would be measuring amprenavir. Therefore, HPLC methods as described for amprenavir would apply	
 Atazanavir	Solid phase extraction: After viral inactivation by heat (60°C for 60 min), plasma (600 μl) with clozapine (internal standard) is diluted 1 + 1 with phosphate buffer pH 7 and subjected to an SPE on a C_{18} cartridge. Matrix components are eliminated with 2 × 500 μl of a solution of 0.1% H_3PO_4 neutralized with NaOH to pH 7. ATV is eluted with 3 × 500 μl MeOH. The resulting eluate is evaporated under nitrogen at room temperature and is reconstituted in 100 μl MeOH/H_2O 50/50. A 40 μl volume is injected onto a Nucleosil 100, 5 μm C_{18} AB column. Atazanavir is analyzed by UV detection at 201 nm using a gradient elution program with solvents constituted of MeCN and phosphate buffer adjusted to pH 5.14. The mobile phase also contains 0.02% sodium heptanesulfonate, enabling an excellent separation of ATV from the other HIV protease inhibitors (PIs) and the non-nucleoside reverse transcriptase inhibitors (NNRTIs). The calibration curves are linear up to 10 μg/ml, with a lower limit of quantification of 0.2 μg/ml	[15]
 Indinavir	Mobile phase: A filtered and degassed mixture of dibutylammonium phosphate buffer and acetonitrile (11:9). The dibutylammonium phosphate buffer is prepared by transferring 20 ml of dibutyl ammonium phosphate to 1,000 ml of water and adjusting the H 6.5 ± 0.05. Chromatographic system: A liquid chromatograph equipped with a 260 nm detector and a 4.6 mm × 25 cm C_8 column that contains 5 μm packing. The flow rate is about 1.0 ml/min. The column temperature is maintained at 40°C. The column efficiency is not less than 4,000 theoretical plates; the tailing factor is less than 2.0; and the relative standard deviation for replicate injections is not more than 1.0%	[1]
 Lopinavir	Sample preparation: After viral inactivation by heat (60°C for 60 min), plasma (600 μl), with clozapine added as internal standard, is diluted 1 + 1 with phosphate buffer pH 7 and subjected to a solid-phase extraction (SPE) on a C_{18} cartridge. Matrix components are eliminated with 2 × 500 μl of a solution of 0.1% H_3PO_4 neutralized with NaOH to pH 7. Lopinavir is eluted with 3 × 500 μl MeOH. The resulting eluate is evaporated under nitrogen at room temperature and is reconstituted in 100 ml MeOH 50%. A 40 μl volume is injected onto a Nucleosil 100, 5 μm C_{18} column. The drug is analyzed separately using a gradient elution program with solvents constituted of MeCN and phosphate buffer adjusted to pH 5.07 and containing 0.02% sodium heptanesulfonate. Lopinavir is detected by UV at 201 nm. The calibration curves are linear up to 10 μg/ml. This method can also be used to analyze nevirapine with detection at 282 nm. With slight adjustments, this HPLC method can be used for the simultaneous assay of amprenavir, ritonavir, indinavir, saquinavir, nelfinavir, and efavirenz.[17]	[16, 17]
 Ritonavir	Mobile phase: A mixture of acetonitrile, methanol, and 0.01 *M* tetramethylammonium perchlorate in 0.1% aqueous trifluoroacetic acid (40:5:55, v/v/v), at a constant flow rate of 1.0 ml/min at ambient temperature. Chromatographic system: Separation was accomplished on an ODS-AQ column 5 cm × 4.0 mm I.D., 3 μm particle size; similar separation could be achieved on a 5 cm × 4.6 mm, 3 μm ODS-2 column. The detector was operated at a wavelength of 205 nm. Standard curves were linear ($r > 0.9998$) over the concentration range 0.01–15 μg/ml with both inter- and intra-day coefficients of variation typically less than 5%	[18]
 Nelfinavir	Mobile phase: A mixture of acetonitrile (MeCN) and 25 m*M* monobasic ammonium phosphate (containing 25 m*M* triethylamine, pH 3.4 with phosphate acid) (40:60, v/v) was delivered at a flow rate of 1.0 ml/min with detection at 210 nm. Chromatographic system: A CN chromatographic column (250 × 4.6 mm, 5 μm) was used for the separation at 40°C. The injection volume was 10 μl	[19]

(Continued)

Table 1 Conditions for the chromatographic analysis of anti-retroviral drugs. *(Continued)*

Drug	Analysis method	Refs.
 Saquinavir	Mobile phase: A filtered and degassed mixture of triethylamine phosphate solution, tetrahydrofuran, and acetonitrile (14:5:1). Chromatographic system: A liquid chromatograph equipped with a 210 nm detector and a 4.6 mm × 25 cm C_{18} column. The column temperature is maintained at 20°C, and the flow rate is about 1 ml/min. The relative retention times are about 0.89 for saquinavir related compound A and 1.0 for saquinavir; and the resolution, *R*, between saquinavir related compound A and saquinavir is not less than 1.5. The column efficiency is not less than 500 theoretical plates; and the relative standard deviation for replicate injections is not more than 2.0%. This method is also used to assay saquinavir in capsules	[1]
 Tipranavir	An HPLC method previously described for the assay of amprenavir, ritonavir, indinavir, saquinavir, nelfinavir, lopinavir, atazanavir, nevirapine, and efavirenz can be also conveniently applied, with minor gradient program adjustment, for the determination of tipranavir in human plasma, by off-line SPE followed by HPLC coupled with UV–diode array detection (DAD).[15–17] Using this method, tipranavir is analyzed by UV detection at 201 nm using a gradient elution program constituted of MeCN and phosphate buffer adjusted to pH 5.12 and containing 0.02% sodium heptanesulfonate on a Nucleosil C_{18} AB column. Calibration curves are linear up to 75 μg/ml, with a lower limit of quantification of 0.125 μg/ml	[20]
Enfuvirtide: a 36 length protein sequence	Chromatographic system: The HPLC system used to assay used a Fluorimetric detector (excitation 280 nm, emission 350 nm). Chromatographic separation was performed by a Luna 5μ C18 column (150 × 4.6 mm I.D.) Phenomenex (CA) protected by a SecurityGuard with C_{18} (4.0 × 3.0 mm I.D.) precolumn Phenomenex (CA) at 35 °C. Analysis was performed with a gradient using a mobile phase composed of buffer A (water + 0.1% TFA + 0.5% arginine HCl) and buffer B (acetonitrile: water [70:30] + 0.1% TFA + 0.5% arginine HCl). The method showed lower limits of detection and quantification (LOD = 32 ng/ml, LOQ = 78 ng/ml), lower intra-day (RSD% 1.25–2.95) and inter-day (RSD% 1.75–4.69) coefficients of variation, greater recovery (>100%), lower duration (16 min)	[21]
Combination of nine ARVs: indinavir, saquinavir, ritonavir, amprenavir, lopinavir, delavirdine, efavirenz, elfinavir, and its M8 metabolite	Mobile phase: Separation was facilitated via gradient elution at 1.5 ml/min flow rate. The mobile phase consisted of (A) 25 m*M* potassium phosphate buffer, pH 3.1; (B) acetonitrile; and (C) methanol according to a specific program that allows linear adjustments in a 40 min run time. Chromatographic system: Analytes were isolated from plasma using tert-butyl methyl ether and separation was achieved via reversed-phase liquid chromatography on a C_8 column (5 μm, 25 cm × 4.6 mm I.D.) with a gradient mobile phase. A Discovery C (2 cm × 4 mm I.D., 5 μm) in-line guard column was used to extend the life of the analytical column. Detection at 210 nm provided adequate sensitivity. Limit of quantification is 50 ng/ml and all analytes demonstrated linearity across 50–10,000 ng/ml from a single 200 ml plasma sample	[22]
Combination of 16 ARVs: seven HIV protease inhibitors (amprenavir, atazanavir, indinavir, lopinavir, nelfinavir, ritonavir, and saquinavir), seven nucleoside reverse transcriptase inhibitors (abacavir, didanosine, emtricitabine, lamivudine, stavudine, zalcitabine, and zidovudine), and two non-nucleoside reverse transcriptase inhibitors (efavirenz and nevirapine)	Sample preparation: Automated solid-phase extraction with Oasis HLB Cartridge 1 cc (divinylbenzene and *N*-vinylpyrrolidone) and evaporation in a water bath under nitrogen stream. The extracted samples were reconstituted with 100 μl methanol. Mobile phase: The mobile phase is composed of solution A (0.01 *M* KH_2PO_4) and B (acetonitrile). Both solutions were degassed by purging with helium. The mobile phase was delivered by a linear gradient at 1.0 ml/min. The injection volume was 20 μl. Chromatographic system: Twenty microliters of extracted samples were injected into an HPLC–UV system. Separation was performed at 24.0°C on an analytical C_{18} Symmetry™ column (250 mm × 4.6 mm I.D.) with a particle size of 5.0 μm equipped with a guard column (20 × 3.9 mm I.D.) filled with the same packing material. The total run time for a single analysis was 35 min, the anti-HIV drugs were detected by UV at 240 and 260 nm. The calibration curves were linear up to 10 μg/ml. The absolute recovery ranged between 88% and 120%	[23]

Anti-Tuberculosis Drugs

Melgardt M. de Villiers
School of Pharmacy, University of Wisconsin, Madison, Wisconsin, U.S.A.

INTRODUCTION

The four drugs commonly used to treat tuberculosis are rifampin, isoniazid, pyrazinamide, and ethambutol hydrochloride (Fig. 1).[1] Although the drugs are used alone, the WHO recommends the four-drug fixed-dose combination (4FDC) tablet containing rifampicin 150 mg, isoniazid 75 mg, pyrazinamide 400 mg, and ethambutol (hydrochloride) 275 mg, as well as 3FDC (rifampin, isoniazid, and pyrazinamide) and 2FDC combination tablets for treating drug-resistant tuberculosis.[2,3] The combination of all four drugs in one tablet simplifies the treatment and management of drug supply, and may prevent the emergence of drug resistance.[3,4]

The official methods used to analyze these drugs alone or in drug products are published in several pharmacopoeias[5,8,9] and starting with the USP 25 onwards not only monographs for the individual drugs but also the fixed-dose combination products including the 4FDC tablets have been established, which require high-performance liquid chromatography (HPLC) for analysis of the drug substances to establish purity and also to measure the drugs in dissolution samples.[5] Similar HPLC methods are also used to measure the drugs in the fixed dose combination (FDC) products during stability testing and to monitor plasma concentrations of the drugs in biological fluids.[7,9–11]

In this report, the major chromatographic methods used for the analysis of anti-tuberculosis drugs, alone or in combination, in pharmaceutical products and biological fluids are summarized.

RIFAMPIN

The USP states that rifampin raw material contains not less than 95.0% and not more than 103.0% of $C_{43}H_{58}N_4O_{12}$, calculated on the dried basis.[5] When formulated into capsules and suspensions, it must contain not less than 90.0% and not more than 110.0% of the labeled amount, injections between 90.0% and 115%, FDC products containing isoniazid between 90% and 130%, and 3FDC and 4FDC products between 90.0% and 110.0%. The higher maximum concentration allowed when combined with isoniazid is because when present together rifampin and isoniazid (H) interact with each other, especially when moisture is present, to form isonicotinyl hydrazone.[12] This reduces the bioavailability of rifampin in an FDC combination product containing isoniazid. Therefore, accurate analysis of rifampin in the presence of isoniazid is very important.

According to the USP for the HPLC analysis of rifampin, the liquid chromatograph must be equipped with a 254 nm detector and a 4.6 mm × 10 cm column that contains 5 μm totally porous silica particles with chemically bonded octylsilane (C_8, L7).[5] The flow rate is about 1.5 ml/min. The mobile phase is a suitable mixture of water, acetonitrile, phosphate buffer (136.1 g of monobasic potassium phosphate in about 500 ml of water, to which 6.3 ml of phosphoric acid is added, before it is diluted with water to 1000 ml), 1.0 *M* citric acid, and 0.5 *M* sodium perchlorate (510 : 350 : 100 : 20 : 20), which is filtered through a suitable filter of 0.7 μm or finer porosity, and then degassed. Separately inject equal volumes (about 50 μl) of the rifampin standard solutions and assay preparations into the chromatograph, record the chromatograms, and measure the area responses for the major peaks. The relative retention times are about 0.6 for rifampin quinone (main degradation product) and 1.0 for rifampin. The quantity, in mg, of rifampin ($C_{43}H_{58}N_4O_{12}$) in the standard sample solutions are calculated on the dried basis, of rifampin in the standard preparation, using the area responses of the rifampin peaks obtained from the assay preparation and the standard preparation, respectively.[5] The resolution, *R*, between the rifampin quinone and rifampin peaks is not less than 4.0. The column efficiency determined from the rifampin peak is not less than 1000 theoretical plates, and the relative standard deviation for replicate injections is not more than 1.0%. Samples should be preserved in tight, light-resistant containers, protected from excessive heat. Stock solutions of reference standards should be used within 5 hr of preparation, while stock test solutions should be used within 2 hr. Final dilutions should be prepared immediately prior to injection into the chromatograph. The USP also requires a related substances test for rifampin where a test and diluted test preparation are injected into the chromatograph, the chromatograms recorded, and the responses for all of the peaks measured.[5] Then, the percentage of each related substance is calculated by the formula:

$$r_{Ti}/(r_D + 0.01\Sigma r_{Ti})$$

in which r_{Ti} is the area of the peak of the individual related substance in the chromatogram obtained from the test

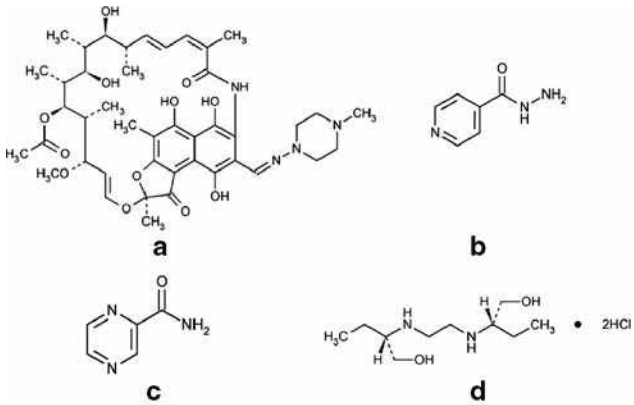

Fig. 1 (a) Rifampin (Rifamycin, 3-[[(4-methyl-1-piperazinyl)-imino]methyl]-, 5,6,9,17,19,21-Hexahydroxy-23-methoxy-2,4,12,16,18,20,22-heptamethyl-8-[*N*-(4-methyl-1-piperazinyl)formimidoyl]-2,7-(epoxypentadeca[1,11,13]trienimino)naphtho[2,1-*b*]furan-1,11-(2*H*)-dione 21-acetate, [*13292-46-1*]). $C_{43}H_{58}N_4O_{12}$, MW = 822.94. (b) Isoniazid (4-Pyridinecarboxylic acid, hydrazide, isonicotinic acid hydrazide, [54-85-3]). $C_6H_7N_3O$, MW = 137.14. (c) Pyrazinamide (Pyrazinecarboxamide, Pyrazinecarboxamide, [*98-96-4*]). $C_5H_5N_3O$, MW = 123.11. (d) Ethambutol hydrochloride (1-Butanol, 2,2′-(1,2-ethanediyldiimino)bis-, dihydrochloride, [*S*-(*R**,*R**)]-, (+)-2,2′-(Ethylenediimino)-di-1-butanol dihydrochloride, [*1070-11-7*]. $C_{10}H_{24}N_2O_2{\cdot}2HCl$, MW = 277.23.

preparation, r_D is the area of the rifampin peak in the chromatogram obtained from the dilute test preparation, and Σr_{Ti} is the sum of the areas of all of the peaks of the related substances obtained in the chromatogram of the test preparation. To comply, not more than 1.5% of rifampin quinone and not more than 1.0% of any other individual related substance can be present. In total, not more than 3.5% of all individual related substances, other than rifampin quinone, having retention times of up to 3 in relation to the retention time of rifampin can be present.

ISONIAZID

According to the USP, isoniazid contains not less than 98.0% and not more than 102.0% of $C_6H_7N_3O$, calculated on the dried basis.[5] Injections and tablets must contain between 90.0% and 110.0% of the drug while isoniazid syrups must contain in each 100 ml, not less than 0.93 g and not more than 1.10 g of isoniazid ($C_6H_7N_3O$). To determine this, a liquid chromatograph equipped with a 254 nm detector and a 4.6 mm × 25 cm column packed with porous silica or ceramic microparticles, 3–10 mm in diameter, chemically bonded to octadecyl silane (C_{18}, L1) is used. The mobile phase is made up by dissolving 4.4 g of docusate sodium in 600 ml of methanol, adding 400 ml of water, and adjusting the pH to 2.5 with 2 N sulfuric acid. The flow rate is about 1.5 ml/min. For the assay, separately inject equal volumes (about 10 μl) of the standard preparations and the assay preparations into the chromatograph, record the chromatograms, and measure the responses for the major peaks. The quantity, in mg, of $C_6H_7N_3O$ is then calculated from the peak responses of isoniazid obtained from the assay preparation and the standard preparation, respectively.[5] For this method to be accurate, the column efficiency determined from the isoniazid peak must not be less than 1800 theoretical plates; the tailing factor for the isoniazid peak not more than 2.0; and the relative standard deviation for replicate injections not more than 2.0%. For isoniazid tablets, most pharmacopoeias also require a content uniformity test.[5–7] Although this test requires the use of a spectrophotometer with absorbance at 263 nm, the accuracy of the test can be improved by using the HPLC method. Isoniazid powder and solutions of the drug must be preserved in tight, light-resistant containers and should be stored at 25°C, with excursions permitted between 15°C and 30°C.

PYRAZINAMIDE

According to the USP, pyrazinamide powder contains not less than 99.0% and not more than 101.0% of $C_5H_5N_3O$, calculated on the anhydrous basis.[5] This is determined using a titration method. This is a tedious and difficult method to perform accurately for the drug in products owing to the interference of excipients. Therefore, the assay method of pyrazinamide in tablets requires HPLC analysis to ensure that these tablets contain not less than 93.0% and not more than 107.0% of the labeled amount of pyrazinamide ($C_5H_5N_3O$).

This method requires using a liquid chromatograph equipped with a 270 nm detector and a 3.9 mm × 15 cm C_{18} column, a filtered and degassed mobile phase composed of 10 ml acetonitrile mixed with 1 L of a pH 8.0 phosphate buffer adjusted with phosphoric acid to a pH of 3.0, and a flow rate should be about 1 ml/min.[5] Separately inject equal volumes (about 20 μl) of standard and test solutions into the chromatograph, record the chromatograms, and measure the responses for the major peaks. Then calculate the quantity, in mg, of pyrazinamide ($C_5H_5N_3O$) in the tablets using the peak responses obtained from the test and the standard solutions, respectively. The column efficiency is not less than 2500 theoretical plates; and the tailing factor for the pyrazinamide peak is not more than 1.3. To determine the stability of pyrazinamide in a product, a system suitability test on a cooled solution prepared by transferring 1 ml of hydrochloric acid to a 5 ml volumetric flask, diluting with a standard solution, and then keeping it on a boiling water bath for 5 min, can be performed. The system suitability solution is chromatographed and the peak responses recorded. To comply, the relative retention times are about 0.45 for pyrazinoic acid

and 1.0 for pyrazinamide; and the resolution, *R*, between pyrazinamide and pyrazinoic acid is not less than 6.0.

ETHAMBUTOL HCL

Most pharmacopoeias specify that ethambutol hydrochloride contains not less than 98.0% and not more than 100.5% of $C_{10}H_{24}N_2O_2 \cdot 2HCl$, calculated on the dried basis. Pharmaceutical products such as tablets must contain not less than 95.0% and not more than 105.0% of the labeled amount.[5–7] As for pyrazinamide, the main pharmacopoeial assay method for ethambutol is a titration method.[5] However, an HPLC method is used for the assay of ethambutol HCl in tablets.[5] This method requires that a liquid chromatograph equipped with a 200-nm detector and a 4.6 mm × 15 cm base-deactivated column that contains 5 μm porous silica particles, 3–10 μm in diameter, with chemically bonded nitrile groups (CN, L10) is used. The mobile phase is a mixture of 1.0 ml of triethylamine and 1 L of water, adjusted with phosphoric acid to a pH of 7.0. The flow rate is about 1.0 ml/min. Separately inject equal volumes (about 50 μl) of standard preparations and the assay preparations into the chromatograph, record the chromatograms, and measure the responses for the major peaks and calculate the quantity, in mg, of ethambutol hydrochloride present in the tablets from the peak responses obtained from the assay preparation and the standard preparation, respectively. The tailing factor must not be more than 2.0, and the relative standard deviation for replicate injections not more than 2.0%.

The international pharmacopoeia recently also published an HPLC assay for ethambutol combined with isoniazid and pyrazinamide using a stainless steel C_{18} column (15 cm × 4.6 mm).[7] The mobile phase for this method is a solution prepared as follows: dissolve 50 g ammonium acetate and 0.2 g copper(II) acetate in 1000 ml of water and adjusted to pH 5.0 with glacial acetic acid. 940 ml of this solution is mixed with 60 ml methanol. The HPLC is operated at a flow rate of 2.0 ml/min. The detector is an ultraviolet spectrophotometer set at a wavelength of about 270 nm and 20 μl of the solutions are injected. The assay is not valid unless the resolution between the isoniazid peak (the peak with the shorter retention time) and the ethambutol hydrochloride peak is at least 10 (see Fig. 2) and the resolution between the isoniazid and pyrazinamide peaks is at least 2. The relative standard deviation for the peak areas of isoniazid, pyrazinamide, and ethambutol hydrochloride, eluting in this order, is less than 2.0%.

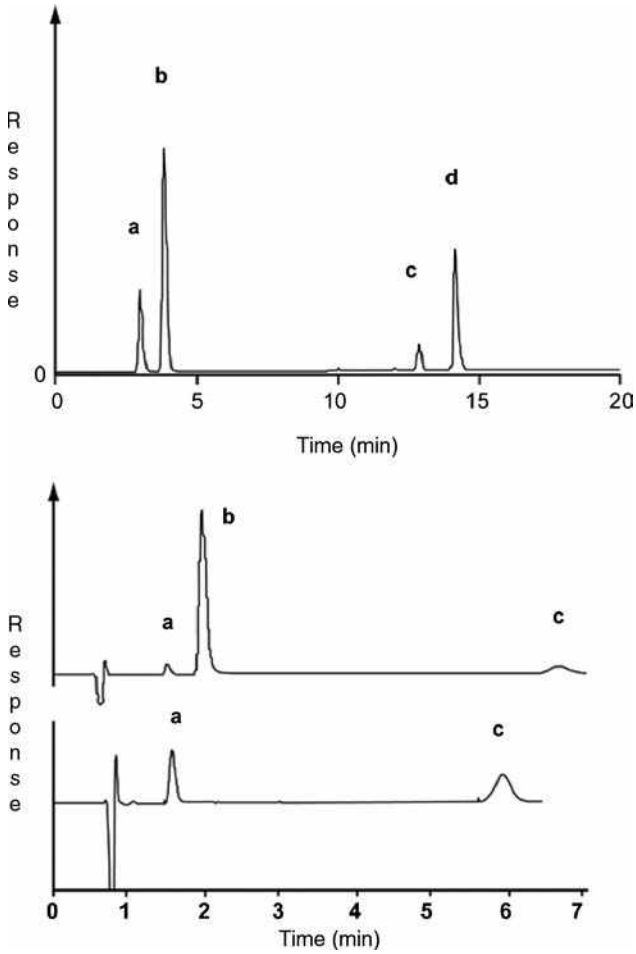

Fig. 2 Top: USP HPLC analysis of a 4FDC tablet showing the chromatograms of a, isoniazid; b, pyrazinamide; c, isonicotinyl hydrazone of 3-formylrifamycin; d, rifampin. Bottom: chromatogram of a, isoniazid, b, pyrazinamide, and c, ethambutol HCl. Adapted from United States Pharmacopeial Convention,[5] WHO,[7] and Lacroix et al.[13]

2FDC PRODUCTS—RIFAMPIN AND ISONIAZID

Most pharmacopoeias require that 2FDC products that contain at least 300 mg of rifampin and 150 mg of isoniazid shall not contain less than 90.0% and not more than 130.0% of the labeled amount of rifampin ($C_{43}H_{58}N_4O_{12}$) and not less than 90.0% and not more than 110.0% of the labeled amount of isoniazid ($C_6H_7N_3O$).[5,6] To ensure stability, these products must be preserved in tight, light-resistant containers, and avoid exposure to excessive heat.

A quick TLC identification test for the drugs in these products require that a portion of the content of a capsule tablet, equivalent to about 120 mg of rifampin, is transferred to a suitable flask, 20 ml of methanol added, and shaking for several minutes.[5] The suspension is passed through a filter having a 1 μm or finer porosity, discarding the first few ml of the filtrate. Then a volume of the filtrate is diluted with an equal volume of acetone, and mixed. A standard solution is prepared by dissolving a quantity of rifampin reference standard in methanol to obtain a

solution containing 6 mg/ml. Add an equal volume of acetone, and mix. Similarly, dissolve a quantity of isoniazid reference standard in methanol to obtain a solution containing 2.5 mg/ml. Add an equal volume of acetone, and mix. Apply 2 μl of the test solution and each of the relevant standard solutions to a suitable thin-layer chromatographic plate coated with a 0.25 mm layer of chromatographic silica gel. Place the plate in a presaturated chromatographic chamber containing the developing solvent solution (a mixture of acetone and glacial acetic acid, 100 : 1) and develop the chromatogram until the solvent front has moved about three-fourths of the length of the plate. Remove the plate from the developing chamber, mark the solvent front, and allow the solvent to evaporate. Locate the spots on the plate by examination under short-wavelength UV light. The R_f value of each principal spot in the chromatogram of the test solution corresponds to that of the principal spot in the chromatogram obtained from each relevant standard solution as appropriate for the labeled active ingredient.

The drugs in this combination product can also be assayed using an HPLC equipped with a 238 nm detector and a 4.6 mm × 25 cm base-deactivated C_{18} column with 5 μm packing. The flow rate is about 1.5 ml/min. The mobile phase consists of variable mixtures (see Table 1) of two solutions. Solution A: a filtered and degassed mixture of buffer solution and acetonitrile (96 : 4). The buffer solution is prepared by dissolving 1.4 g of dibasic sodium phosphate in 1 L of water, and adjusting with phosphoric acid to a pH of 6.8. Solution B: a filtered and degassed mixture of acetonitrile and the buffer solution (55 : 45). Standard solutions are prepared in a mixture of the buffer solution and methanol (96 : 4) so that the solutions contain rifampin and isoniazid reference standards in known concentrations of about 0.16 and 0.08 mg/ml, respectively. Assay preparations are prepared by taking the contents of not fewer than 10 capsules or tablets, mixing it, and transferring an accurately weighed portion of the powder, equivalent to about 16 mg rifampin and 8 mg of isoniazid, to a 100 ml volumetric flask, adding about 90 ml of the buffer solution, sonicating the solution for about 10 min, allowing it to equilibrate to room temperature, diluting it with buffer solution to volume and then analyzing it. These solutions must be used within 2 hr.[5]

Table 1 Conditions for the programmed change in mobile phase composition for the gradient elution of rifampin and isoniazid at a flow rate of about 1.5 ml/min.

Time (min)	Solution A	Solution B	Elution
0	100	0	Equilibration
0–5	100	0	Isocratic
5–6	100 → 0	0 → 100	Linear gradient
6–15	0	100	Isocratic

Source: From United States Pharmacopeial Convention, Rockville.[5]

For the actual HPLC assay, equal volumes (about 20 μl) of the standard preparations and the assay preparations are injected into the chromatograph, the chromatograms recorded, and the peak responses measured. From the peak responses of the standard versus the assay preparations, the quantity, in mg, of rifampin ($C_{43}H_{58}N_4O_{12}$) and isoniazid ($C_6H_7N_3O$) in the product is calculated. If the assay is performed correctly, the relative retention times are about 2.6 and 1.0 for rifampin and isoniazid, respectively; the column efficiency is not less than 50,000 and not less than 6000 theoretical plates for rifampin and isoniazid, respectively; the tailing factors are not more than 2.0; and the relative standard deviation for replicate injections is not more than 2.0%.

During dissolution testing, the amount of rifampin ($C_{43}H_{58}N_4O_{12}$) dissolved is determined from absorbances at the wavelength of maximum absorbance at about 475 nm of standard and test solutions. However, the amount of isoniazid ($C_6H_7N_3O$) dissolved is measured by HPLC. The liquid chromatograph is equipped with a 254 nm detector and a 4.0 mm × 30 cm C_{18} column (10 μm packing) and the flow rate is about 1.5 ml/min. The mobile phase is a filtered and degassed mixture of water, phosphate buffer solution, and methanol (850 : 100 : 50). Equal volumes (about 50 μl) of standard solutions and test solutions are injected into the chromatograph, the chromatograms recorded, and the responses for the isoniazid peaks measured. The capsules or tablets comply with the dissolution specification if not less than 75% (Q) of the labeled amount of rifampin and not less than 80% (Q) of the labeled amount of isoniazid are dissolved in 45 min.

3FDC PRODUCTS—RIFAMPIN, ISONIAZID, AND PYRAZINAMIDE

Rifampin, isoniazid, and pyrazinamide tablets combination products are available as tablets or capsules that must contain not less than 90.0% and not more than 110.0% of the labeled amounts of rifampin ($C_{43}H_{58}N_4O_{12}$), isoniazid ($C_6H_7N_3O$), and pyrazinamide ($C_5H_5N_3O$).[5–7] To maintain this stability, the products and raw materials must be preserved in tight, light-resistant containers at controlled room temperature. The TLC identification test for 3FDC products is similar as that for 2FDC combinations. For these products, the spots in the chromatograms of test solutions are compared with those of standard solutions of the three drugs.

The HPLC method used to assay the 2FDC products is also used for determining the drug content of 3FDC products.[5] Standard solutions are prepared by dissolving accurately weighed quantities of rifampin, isoniazid, and pyrazinamide reference standards in a mixture of buffer solution and methanol (96 : 4) to obtain a solution having known concentrations of about 0.16, 0.08, and 0.43 mg/ml, respectively. These solutions should be used within 10 min. The test solutions are prepared by weighing and

finely powdering not fewer than 20 tablets. Transfer an accurately weighed quantity of the powder, equivalent to about 8 mg of isoniazid, to a 100 ml volumetric flask, and add about 90 ml of buffer solution, sonicate for about 10 min, allow to equilibrate to room temperature, dilute with the buffer solution to volume, and mix. These solutions must be used within 2 hr.[5] Then separately inject equal volumes (about 20 μl) of the standard and test solutions into the chromatograph, record the chromatograms, and measure the peak responses. Calculate the quantities, in mg, of rifampin ($C_{43}H_{58}N_4O_{12}$), isoniazid ($C_6H_7N_3O$), and pyrazinamide ($C_5H_5N_3O$) in the product from the differences in the peak responses obtained from the standard and test solutions, respectively (see Fig. 2). The method complies to pharmacopoeial standards if the relative retention times are about 1.8, 0.7, and 1.0 for rifampin, isoniazid, and pyrazinamide, respectively; the resolution, *R*, between isoniazid and pyrazinamide is not less than 4; the column efficiency is not less than 50,000, not less than 6,000, and not less than 10,000 theoretical plates for rifampin, isoniazid, and pyrazinamide, respectively; the tailing factor is not more than 2.0; and the relative standard deviation for replicate injections is not more than 2.0%.[5–7]

In test solutions obtained during dissolution testing, the amount of rifampin present is determined spectrophotometrically at 475 nm. This method corresponds with that for rifampin in 2FDC products. The tablets comply with the dissolution specification if not less than 80% (*Q*) of the labeled amount of rifampin ($C_{43}H_{58}N_4O_{12}$) is dissolved in 30 min.[5] The amounts of isoniazid and pyrazinamide in dissolution test samples are determined by HPLC. This is done by preparing a filtered and degassed mobile phase composed of a mixture of water, 1 *M* monobasic potassium phosphate, and acetonitrile (860 : 100 : 40). This mobile phase is pumped at a flow rate of 1 ml/min on a liquid chromatograph that is equipped with a 254 nm detector and a 4.6 mm × 30 cm column that contains a multifunctional support, which consists of a high purity, 60 Å, spherical silica substrate that has been bonded with a cationic exchanger, sulfonic acid functionality in addition to a conventional reversed phase C_8 functionality (L44). Prior to the analysis of dissolution test samples, a system suitability test must be performed using a system suitability solution. This is a solution prepared by transferring 10 ml of a 0.125 mg/ml isonicotinic acid in the dissolution medium and 4 ml of the standard stock solution to a 100 ml volumetric flask containing 15 ml of 1 *M* dibasic potassium phosphate, which is then diluted with mobile phase to volume.[5]

Chromatograph this system suitability solution, the standard solutions, and dissolution test samples by separately injecting equal volumes (about 50 μl) of the solutions into the chromatograph, record the chromatograms, and measure the areas for the major peaks. For the system suitability solution, the relative retention times are about 0.7 for isonicotinic acid, 1.0 for pyrazinamide, and 1.8 for isoniazid; and the resolution, *R*, between isonicotinic acid and pyrazinamide is not less than 2.5 and between pyrazinamide and isoniazid not less than 4.0. In addition, the relative standard deviations determined from the pyrazinamide and isoniazid responses in all the solutions for replicate injections are not more than 1.5%. For 3FDC products to satisfy the dissolution criteria not less than 80% (*Q*) of the labeled amount of isoniazid ($C_6H_7N_3O$) and not less than 75% of the labeled amount of pyrazinamide ($C_5H_5N_3O$) are dissolved in 30 min.

4FDC PRODUCTS—RIFAMPIN, ISONIAZID, PYRAZINAMIDE, AND ETHAMBUTOL HCL

These products contain rifampin, isoniazid, pyrazinamide, and ethambutol hydrochloride in a single dosage form such as tablets or capsules. Such a product must contain not less than 90.0% and not more than 110.0% of the labeled amounts of rifampin ($C_{43}H_{58}N_4O_{12}$), isoniazid ($C_6H_7N_3O$), pyrazinamide ($C_5H_5N_3O$), and ethambutol hydrochloride ($C_{10}H_{24}N_2O_2 \cdot 2HCl$).[5] The products and raw materials must be preserved in tight, light-resistant containers, and stored at controlled room temperature. For the identification of rifampin, isoniazid, and pyrazinamide in these products, the same TLC method as for 3FDC products are used. While for ethambutol, the WHO prescribes the following semi-quantitative TLC method. TLC aluminum sheets precoated with silica gel 60 F254 are spotted with methanol solutions containing ethambutol, together with different mixtures of combinations of ethambutol hydrochloride, isoniazid, pyrazinamide, and rifampicin, 1.5 cm from the bottom of silica plates with a 3 μl capillary pipette. The plates are developed in a development chamber previously saturated with a freshly prepared mixture of methanol and concentrated ammonium hydroxide, the plates are then placed in the development chamber together with an iodine–potassium iodide solution, allowed to dry and the size and intensity of the spots measured and R_f values calculated. The R_f value of ethambutol hydrochloride is about 0.15.

The USP method to assay the ingredients in 4FDC products utilizes two HPLC methods.[5] The first is the method used for 3FDC products to determine the amounts of rifampin, isoniazid, and pyrazinamide described above and the second is a method to assay ethambutol HCl in tablets described earlier (Fig. 2). The analysis method for ethambutol complies with pharmacopoeial standards if the tailing factor is not more than 3; and the relative standard deviation for replicate injections is not more than 2.0%.[5] For ethambutol, in addition to the HPLC analysis, a flourometric test for aminobutanol is also required. This method determines the relative fluorescence intensities of test and standard solutions in 1 cm cells, with a suitable fluorometer, at about 485 nm, with the excitation wavelength at about 385 nm. The fluorescence intensity of the solution obtained from the test solution is not greater than the difference between the intensities of the two solutions (not

more than 1.0%). As mentioned under the subheading for ethambutol HCl in the International Pharmacopoeia, another HPLC method for isoniazid, pyrazinamide, and ethambutol HCl in 4FDC products is described (see Fig. 2).[7]

For dissolution samples, the amounts of rifampin ($C_{43}H_{58}N_4O_{12}$), isoniazid ($C_6H_7N_3O$), pyrazinamide ($C_5H_5N_3O$), and ethambutol hydrochloride ($C_{10}H_{24}N_2O_2{\cdot}2HCl$) dissolved in filtered portions of the solution under test are determined using the same procedures set forth in the HPLC assay for rifampin, isoniazid, and pyrazinamide and the assay for ethambutol hydrochloride described above.[5] The 4FDC tablet or capsule complies with the dissolution specification if not less than 75% (Q) of the labeled amounts of $C_{43}H_{58}N_4O_{12}$, $C_6H_7N_3O$, $C_5H_5N_3O$, and $C_{10}H_{24}N_2O_2{\cdot}2HCl$ is dissolved in 45 min.

CONCLUSION

The treatment of tuberculosis still largely relies on the use of rifampin, isoniazid, pyrazinamide, and ethambutol HCl. Although the chromatographic analysis of these drugs is well established, the recently notified USP gradient HPLC method for quantitative determination of rifampicin, isoniazid, and pyrazinamide in fixed-dose combination (FDC) formulations has enhanced our analytical capability to ensure the quality of these products.

However, this method is still being evaluated to determine its ability to resolve major degradation products of rifampicin, viz. 3-formylrifamycin, rifampicin *N*-oxide, 25-desacetyl rifampicin, rifampicin quinone, and the newly reported isonicotinyl hydrazone, an interaction product of 3-formylrifamycin and isoniazid, first observations show that although the requirements of theoretical plates listed in the given method are not always met and although the resolving power of the method was sometimes dependent on the make of the column used, this method gave reliable results when small modifications were made to the buffer: organic modifier ratio of solution B or the flow rate was decreased.[14]

Together with the HPLC method published by the WHO for isoniazid, pyrazinamide, and ethambutol HCl in 4FDC products, these methods provide the ability to assay these drugs in almost any pharmaceutical or biological matrix. This means that for the major drugs used for treating tuberculosis, well-established chromatographic methods, approved by the major regulatory agencies, exist. It also shows that chromatographic, especially HPLC, methods are favored for the analysis of anti-tuberculosis drugs in both pharmaceutical products and biological fluids because of their proven reliability and ease of use.[15]

Applied Voltage: Mobility, Selectivity, and Resolution in CE

Jetse C. Reijenga
Department of Chemical Engineering and Chemistry, Eindhoven University of Technology, Eindhoven, The Netherlands

INTRODUCTION

Generally, migration times t_m in capillary electrophoresis (CE) are inversely proportional to the applied voltage.

DISCUSSION

In terms of analysis time, the voltage should, therefore, be as large as possible:

$$t_m \cong \frac{1}{V}$$

Under conditions optimized for limited power dissipation, effective mobilities and selectivities (defined as effective mobility ratios) are independent of the applied voltage.

Efficiency is also determined by the applied voltage, but in a much more complicated manner (see *Band Broadening in CE*, p. 144). If efficiency is limited by diffusion, a higher voltage also leads to a higher efficiency. Limitations are due to insulation properties and heat dissipation. Voltages larger than 30 kV should always be avoided because of danger of sparking and leaking currents, even more so in cases of significant atmospheric humidity. Excessive heat dissipation leads to an average temperature increase inside the capillary, which can be reduced by forced cooling. What cannot be reduced is the contribution of heat dissipation to band broadening. This can only be reduced by a lower conductivity, a lower current density, or a smaller inner diameter (see *Band Broadening in CE*, p. 144). In the case of diffusion-limited efficiency, the efficiency (as given by the plate number) is directly proportional to the applied voltage:

$$N \cong V$$

The ultimate criterion for quality of separation is the resolution R, given by the following relationship:

$$R = \frac{\Delta t_m}{4\sigma}$$

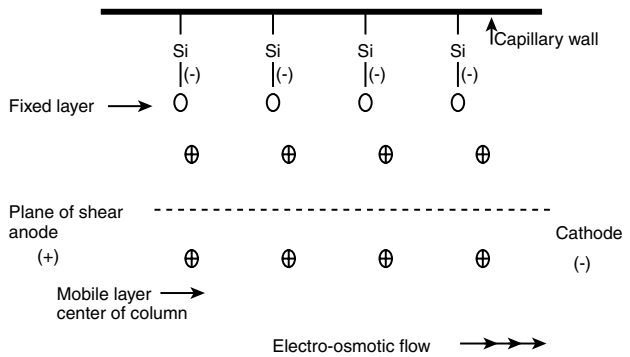

Fig. 1 Analysis of a mixture of weak anions at three different voltages. Suppressed EOF in a 400 mm capillary with negative inlet polarity. *Note*: The time axis is logarithmic.

With the definition of plate number, it follows that $R \cong \sqrt{V}$.

Fig. 1 shows a computer simulation of the resolution and analysis time of a mixture of anions at 5, 10 and 25 kV. In order to better visualize the effect on resolution, a logarithmic x axis was chosen.

Argon Detector

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

The argon detector was the first of a family of detectors developed by Lovelock[1] in the late 1950s; its function is quite unique. The outer octet of electrons in the noble gases is complete and, as a consequence, collisions between argon atoms and electrons are perfectly elastic. Thus, if a high potential is set up between two electrodes in argon and ionization is initiated by a suitable radioactive source, electrons will be accelerated toward the anode and will not be impeded by energy absorbed from collisions with argon atoms. However, if the potential of the anode is high enough, the electrons will eventually develop sufficient kinetic energy that, on collision with an argon atom, energy can be absorbed and a *metastable* atom can be produced. A metastable atom carries *no* charge but adsorbs its energy from collision with a high-energy electron by the displacement of an electron to an outer orbit. This gives the metastable atom an energy of about 11.6 electron volts. Now 11.6 V is sufficient to ionize most organic molecules. Hence, collision between a metastable argon atom and an organic molecule will result in the outer electron of the metastable atom collapsing back to its original orbit, followed by the expulsion of an electron from the organic molecule. The electrons produced by this process are collected at the anode, generating a large increase in anode current. However, when an ion is produced by collision between a metastable atom and an organic molecule, the electron, simultaneously produced, is immediately accelerated toward the anode. This results in a further increase in metastable atoms and a consequent increase in the ionization of the organic molecules. This cascade effect, unless controlled, results in an exponential increase in ion current with solute concentration.

The relationship between the ionization current and the concentration of vapor was deduced by Lovelock[2,3] to be

$$I = \frac{CA(x + y) + Bx}{CA\{1 - a\exp[b(V - 1)]\} + B}$$

where A, B, a, and b are constants, V is the applied potential, x is the primary electron concentration, and y is the initial concentration of metastable atoms. The rapid increase in current with increasing vapor concentration, as predicted by the equation, is controlled by the use of a high impedance in series with detector power supply. As the current increases, more volts are dropped across the resistance, and less are applied to the detector electrodes.

THE SIMPLE OR MACRO ARGON DETECTOR SENSOR

A diagram of the macro argon detector sensor is shown in Fig. 1. The cylindrical body is usually made of stainless steel and the insulator made of polytetrafluoroethylene (PTFE) or for high-temperature operation, a suitable ceramic. The very first argon detector sensors used a tractor sparking plug as the electrode, the ceramic seal being a very efficient insulator at high temperatures.

Inside the main cavity of the original sensor was a strontium-90 source contained in silver foil. The surface layer on the foil that contained the radioactive material had to be very thin or the β particles would not be able to leave the surface. This tenuous layer protecting the radioactive material is rather vulnerable to mechanical abrasion, which could result in radioactive contamination (strontium-90 has now been replaced by ^{63}Ni). The radioactive strength of the source was about 10 mCu which for strontium-90 can be considered a *hot* source. The source had to be inserted under properly protected conditions. The decay of strontium-90 occurs in two stages, each stage emitting a β particle producing the stable atom of zirconium-90:

$$\underset{\text{half-life 25 year}}{^{90}\text{Sr}} \xrightarrow[0.6\ \text{MeV}]{\varepsilon} \underset{\text{half-life 60 h}}{^{90}\text{Y}} \xrightarrow[2.5\ \text{MeV}]{\varepsilon} \underset{\text{stable}}{^{90}\text{Zr}}$$

The electrons produced by the radioactive source were accelerated under a potential that ranged from 800 to 2000 V, depending on the size of the sensor and the position of the electrodes. The signal is taken across a $1 \times 10^8\ \Omega$ resistor, and as the standing current from the ionization of the argon is about $2 \times 10^{-8}\ \Lambda$, there is a standing voltage of 2 V across it that requires "backing off."

In a typical detector, the primary current is about 10^{11} electrons/s. Taking the charge on the electron as 1.6×10^{-19} C, this gives a current of $1.6 \times 10^{-8}\ \Lambda$. According to Lovelock,[1] if each of these electrons can generate 10,000 metastables on the way to the electrode, the steady-state concentration of metastables will be about 10^{10} per milliliter (this assumes a life span for the

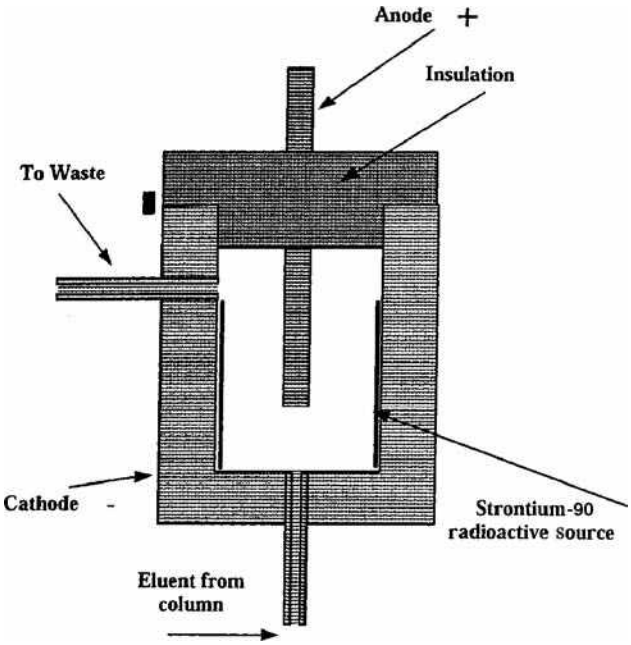

Fig. 1 The macro argon detector.

metastables of about 10^{-5} sec at NTP). From the kinetic theory of gases, it can be calculated that the probability of collision between a metastable atom and an organic molecule will be about 1.6 : 1. This would lead to a very high ionization efficiency and Lovelock claims that in the more advanced sensors ionization efficiencies of 10% have been achieved.

The minimum detectable concentration of a well-designed argon detector is about an order of magnitude higher than the flame ionization detection (FID) (i.e., 4×10^{-13} g/ml). Although the argon detector is a very sensitive detector and can achieve ionization efficiencies of greater than 0.5%, the detector was not popular, largely because it was not linear over more than two orders of magnitude of concentration ($0.98 < r > 1.02$) and its response was not predictable. In practice, nearly all organic vapors and most inorganic vapors have ionization potentials of less than 11.6 eV and thus are detected. The short list of substances that are not detected include and fluorocarbons. The compounds methane, ethane, acetonitrile, and propionitrile have ionization potentials well above 11.6 eV; nevertheless, they do provide a slight response between 1% and 10% of that for other compounds. The poor response to acetonitrile makes this substance a convenient solvent in which to dissolve the sample before injection on the column. It is also interesting to note that the inorganic gases H_2S, NO, NO_2, NH_3, PH_3, BF_3, and many others respond normally in the argon detector. As these are the type of substances that are important in environmental contamination, it is surprising that the argon detector, with its very high sensitivity for these substances, has not been reexamined for use in environmental analysis.

Aromatic Diamidines: Electrophoresis and HPLC Analysis

A. Negro
B. Rabanal
Analytical Chemistry Section, Faculty of Biological and Environmental Sciences, University of León, León, Spain

INTRODUCTION

High-performance liquid chromatography (HPLC) can be considered to have been established by Ettre and Horvath.[1] The popularity of HPLC may be explained by the versatility of this technique, which can be used to separate and quantify large or small; polar, non-polar, or inorganic; and chiral or achiral molecules. In addition, its methods are easily automated, increasing the number of analyses that can be performed in a given time, improving accuracy and precision, as well as reducing costs. It was around 1960 that HPLC achieved its peak growth. This can be attributed, in large part, to its widespread acceptance by the pharmaceutical industry.

Electrophoresis is an analytical technique that was first introduced by Tiselius[2] in 1937. Thirty-five years ago, Hjertén[3] showed that it was possible to carry out electrophoretic separations in a 300.0 μm glass tube and to detect the separation of compounds by ultraviolet absorption. Capillary electrophoresis (CE) did not become popular until 1981, when Jorgenson and Lukacs[4] published work in which they demonstrated the simplicity of the instrumental setup required and the high-resolving power of CE. The results shown were astonishing: sharp narrow peaks, 400,000 theoretical plates per meter (compared with 10,000 theoretical plates per meter of HPLC), and short analysis times. Galery introduced the first commercial instrument in 1988. There are excellent reviews of CE, among which should be mentioned are the ones done by Kuhr, Isaaq, or Camilleri. These look at the increasing number of applications and future prospects.

CAPILLARY ELECTROPHORESIS

CE has had considerable success over the last 20 years. Gas chromatography (GC) and HPLC[1] are still the dominant techniques. However, CE has several distinct advantages over other separation techniques.[5–7] One advantage CE has, relative to HPLC, is its simplicity and applicability for the separation of widely differing substances, such as organic molecules, inorganic ions, and so on, using the same instrument and, in most cases, the same capillary, while changing only the composition of the buffer used. This cannot be said with regard to any other separation techniques. In addition, CE offers the highest resolving power.

The aim of the work reported here was to study how changes in the principal parameters for each technique affect the separation processes when analyzing a series of aromatic diamidines, and, based on the results obtained, to establish comparisons between the two analytical techniques.

The aromatic diamidines are compounds of considerable pharmaceutical interest. This is, among others, for the following reasons: they have a strong antiprotozoan action and participate in the metabolism and transport of polyamines, inhibiting, for instance, *S*-adenosyl-L-methionine decarboxylase (SAMDC). Therefore, because this route is closely linked to cell proliferation processes, aromatic diamidines can slow down or prevent the growth of tumors.[8–10] The substances used in this work are as follows:[11,12]

1. Pentamidine: 4,4′-[1,5-pentanediyl *bis*(oxy)]*bis*-benzenecarboximidamide.
2. Stilbamidine: 4,4′-(1,2-ethenediyl)*bis*-benzenecarboximidamide.
3. DAPI: 4′,6-diamidino-2-(4-amidinophenyl)indole dilactate.
4. Propamidine: 4,4′-[1,3-propanediylbis(oxy)*bis*-benzenecarboximidamide.
5. Hydroxystilbamidine: 4-[2-[4-(aminoiminomethyl) phenyl]ethenyl]-3-hydroxybenzene-carboximidamide.
6. Phenamidine: 4,4′-diamidinodiphenylether.
7. Diampron: 3,3′-diamidinocarbanilide.
8. Berenil: 4,4′-diamidinodiazoamino benzene.
9. Dibromopropamidine: 2′,2″-dibromo-4′,4″-diamidino-1,3-diphenoxypropane.

EXPERIMENTAL TECHNIQUES

Chemicals and Reagents

Pentamidine isethionate salt, berenil diaceturate salt, and DAPI dihydrochloride salt were obtained from Sigma-Aldrich Química SA (Madrid, Spain). Diampron isethionate

salt, hydroxystilbamidine isethionate salt, propamidine isethionate salt, dibromopropamidine isethionate salt, phenamidine isethionate salt, and stilbamidine isethionate salt were generously donated by Rhône Poulenc Rorer (Dagenham, U.K.). The ion-pairing reagents, pentane sulphonate, hexane sulphonate, heptane sulphonate, octane sulphonate, and decane sulphonate sodium salts were supplied by Sigma-Aldrich Química SA. Methanol of HPLC grade and other chemicals of analytical grade were supplied by Merck (Darmstadt, Germany). The water used was purified with a Milli-Q system purchased from Millipore (Bedford, Massachusetts, U.S.A.).

Chromatographic System

The HPLC system comprised a Beckman 116 programable solvent pump with a Beckman 168 photodiode detector—this was checked and data were processed with the Gold Nouveau software system (Beckman Coulter, Palo Alto, California, U.S.A.) and a Beckman 507 automatic injector with a 100.0 μl loop and a heating chamber for the columns. Analyses were carried out with an Ultrasphere ODS column (5.00 μm particle size, 15.0 cm × 4.60 mm I.D.) purchased from Beckman Coulter. A guard column (2.00 cm × 2.00 mm I.D.), packed with Sperisorb RP-18 (30.0–40.0 μm pellicular), was supplied by Upchurch Scientific (Oak Harbor, Washington, U.S.A.).

Electrophoretic System

The CE system consisted of a P/ACE System 2100 high-performance CE apparatus (Beckman Coulter, Fullerton, California, U.S.A.). An untreated, fused silica capillary tube (Beckman Coulter) was used, with dimensions of 75.0 μm I.D., $L_t = 57.0$ cm, and $L_d = 50.0$ cm, enclosed in a liquid-cooled cassette. Detection was performed with a UV-Vis detector ($\lambda = 200.0$ nm). Equipment was checked and data were processed with the Beckman P/ACE Station V 1.2 software (Beckman Coulter).

RESULTS AND DISCUSSION

To carry out a comparison of HPLC and CE, the effects of varying the parameters common to the two techniques with the greatest impact on the separation processes were evaluated. These were: pH of the mobile phase and electrolytes, buffer concentration, and temperature, with the gathered data compared in each case.

As these are separation techniques based on radically differing physical principles, it is evident that there are certain parameters, specific to a given technique, that have a strong influence over the separation process in only one of the two and are not comparable. In HPLC, there is the influence of concentration and chain length of the ion-pairing reagent and the methanol percentage; in CE, there is influence of the choice of electrolyte, length of the capillary, and voltage applied. Variations in these parameters were also taken into account because they provide extremely useful information for making an overall comparison of the two techniques.

Parameters Common to HPLC and CE

Influence of pH in the mobile phase

The pH value is the parameter with the greatest impact on the separation of ionizable molecules. To keep aromatic diamidines ionized, it is necessary to work at very low pH levels, in the range 3.00–4.50, as the diamidine groups twice present in each molecule confer on them a strongly basic character ($pK_a = 13.86$).[13] To determine the influence of pH in HPLC, five diamidines were analyzed using a mobile phase consisting of 25.0 m*M* citrate buffer, 45.0% methanol, and 4.00 m*M* octane sulphonate sodium salt, at a temperature (T) of 30.0°C and at pH values of 3.00, 3.25, and 3.70. The chromatograms obtained are shown in Fig. 1. It can be observed that, as pH increases, retention times are noticeably shortened for all the substances, with no significant variations being noted in resolution. The influence of pH in CE[14] was studied by using 25.0 m*M* citrate buffer at $T = 30.0$°C, 14.0 kV voltage, and pH levels of 3.50, 3.70, and 4.25. Fig. 1 shows that a drop in pH does not bring with it any large change in migration times, but it does produce a significant variation in resolution. It may be observed that a good separation of all nine diamidines is possible only at pH = 3.70. For all the substances, it can be noted that the times required for analyses using CE are around half those in HPLC and that efficiency is much greater in all cases with CE than it is with HPLC, with good resolution. The most appropriate pH levels for the analyses of these substances in aqueous solutions and in the serum and urine are very similar with the two techniques because both require the molecules to be strongly ionized.

Influence of buffer concentration

For HPLC, it has been decided that the preferred buffer is citrate; it was necessary to establish the most suitable concentration. To study this influence, five diamidines were analyzed using a mobile phase consisting of 45.0% methanol, 4.00 m*M* octane sulphonate, and citrate buffer at various concentrations of 15.0, 25.0, and 35.0 m*M*, with $T = 30.0$°C and pH = 3.25 in all cases. In Fig. 2, we see the results obtained. A change from 25.0 to 35.0 m*M* barely affects retention times for any of the substances, but a drop from 25.0 to 15.0 m*M* decreases retention times by almost 30.0% in every case.

With CE, citrate buffer was also selected as the electrolyte for the study, and all nine diamidines were analyzed by using an electrolyte composed of citrate buffer at pH = 3.70,

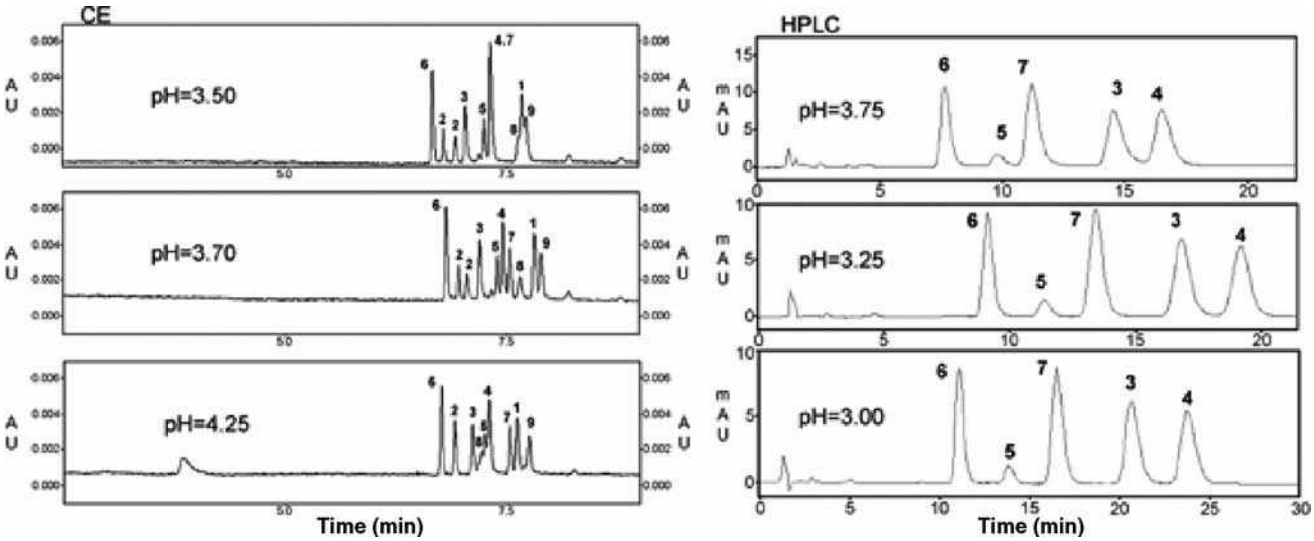

Fig. 1 Influence of pH in HPLC and CE. In HPLC, this effect was studied using a mobile phase consisting of 25.0 m*M* citrate buffer, 45.0% methanol, $T = 30.0°C$, 4.00 m*M* sodium octane sulphonate, and pH levels of 3.00, 3.25, and 3.75. In CE, a 25.0 m*M* citrate buffer electrolyte was used; pH values were 3.50, 3.70, and 4.25, and the voltage was 14.0 kV.

$T = 30.0°C$, and 14.0 kV voltage, at various concentrations (10.0, 25.0, and 40.0 m*M*), to determine which was the most appropriate. The results obtained are presented in Fig. 2. It can be seen that when concentrations go down to 10.0 m*M*, migration times are greatly reduced, but resolution also falls considerably; at 25.0 m*M*, resolution starts to be acceptable, and, at 40.0 m*M*, a good compromise between migration times and resolution is achieved. Comparison of the variations in buffer concentration in HPLC and CE allows one to conclude that, in both cases, a decrease in the concentration of the buffer reduces the time required for analyses. This reduction is much more striking in the case of CE and, in every instance, analysis times with CE are on the order of half of what they are with HPLC. Consequently, efficiency is much higher for all the compounds with CE than with HPLC, whereas resolution is good in both.

Influence of temperature

To study the effects of temperature in the analysis of these diamidines by means of HPLC, we used a mobile phase composed of 25.0 m*M* citrate buffer, with pH = 3.25,

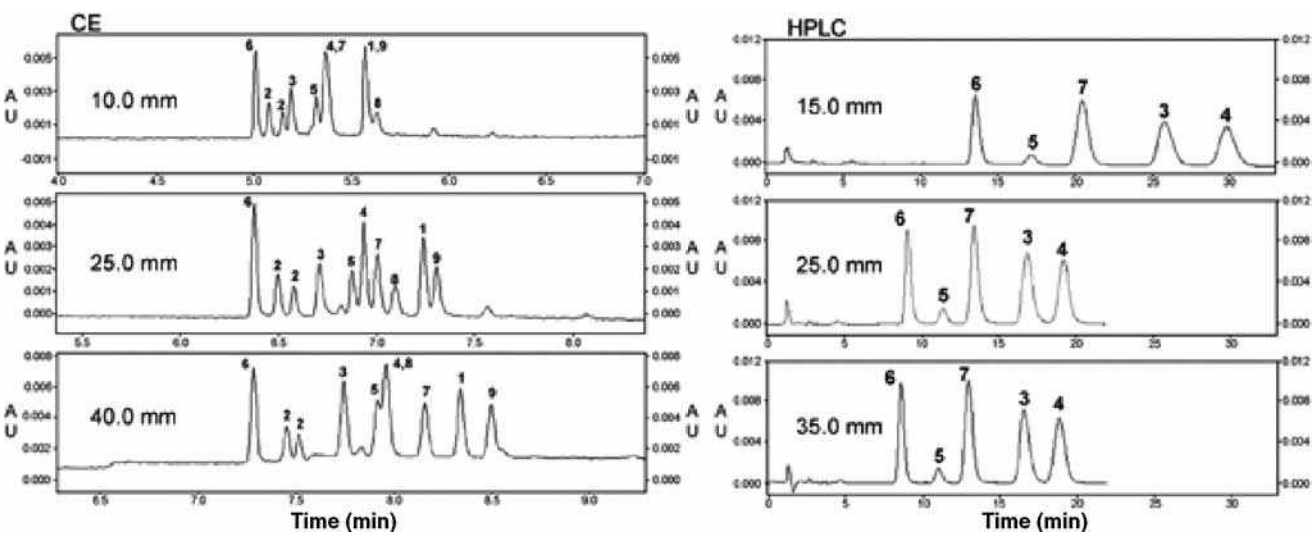

Fig. 2 Influence of buffer concentration in HPLC and CE. In HPLC, this effect was studied using a mobile phase consisting of citrate buffer at concentrations of 15.0, 25.0, and 35.0 m*M*, with 45.0% methanol, 4.00 m*M* sodium octane sulphonate, and pH = 3.25. In CE, a citrate buffer electrolyte was used at concentrations of 10.0, 25.0, and 40.0 m*M*, with pH = 3.70, voltage, 14.0 kV and $T = 30.0°C$.

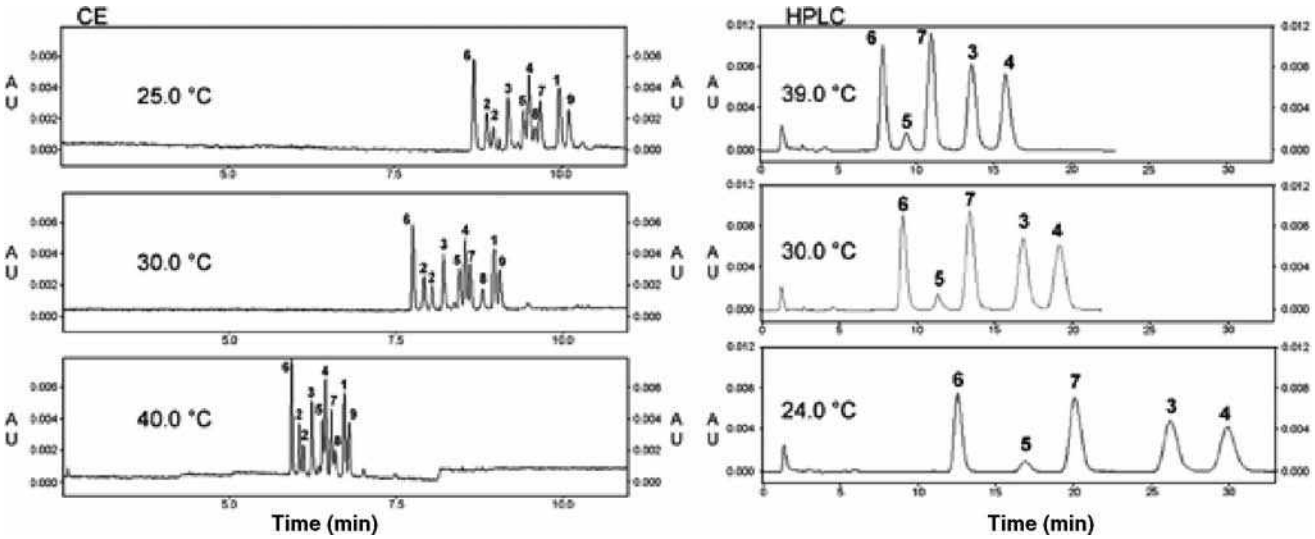

Fig. 3 Influence of temperature in HPLC and CE. In HPLC, this effect was studied using a mobile phase consisting of 25.0 m*M* citrate buffer, 45.0% methanol, 4.00 m*M* sodium octane sulphonate, pH = 3.25, and $T = 24.0°C$, 30.0°C, and 39.0°C. In CE, the electrolyte used was 25.0 m*M* citrate buffer, with pH = 3.70, 14.0 kV voltage, and $T = 25.0°C$, 30.0°C, and 40.0°C.

45.0% methanol, and 4.00 m*M* octane sulphonate, at three different temperatures: 24.0°C, 30.0°C, and 39.0°C. It may be noted in Fig. 3 that increasing the temperature causes a notable drop in retention times, whereas resolution remains at very good levels.

The temperature at which CE is carried out has to be selected carefully because this is one of the most influential parameters in the CE process.[15] Precise temperature control during the CE process is of great importance in achieving good separation selectivity and, above all, good reproducibility.[16,17] To study temperature variation in CE, an electrolyte composed of 25.0 m*M* citrate buffer, with pH = 3.70 and 14.0 kV voltage, was used at temperatures of 25.0°C, 30.0°C, and 40.0°C. Fig. 3 shows that an increase in temperature causes a drastic reduction in migration times, but also reduces resolution excessively, causing serious problems for separation from 30.0°C onward.

If CE and HPLC at 30.0°C are compared, it will be noted, as in all previous cases, that CE has much shorter analysis times than HPLC and that efficiency is much higher with CE than with HPLC, with good resolution being attained in both.

Parameters Exclusive to HPLC

Influence of concentration and chain length of the ion pair-forming agent

A technique often used in the analysis of ionic molecules is the formation of ion pairs[18] because this permits the separation of substances that are too ionized to separate by means of adsorption–partition methods, but are too insoluble in water to be analyzed through ion exchange techniques.[19] The pH of the mobile phase must be adjusted to ensure that the molecules are totally ionized and can combine with the ion pair-forming agent through the counterion. The substances most often used to form ion pairs are alkyl-sulphonate salts of varying chain length. In this work, several reagents of this type were evaluated, having chain lengths ranging from 5 to 10 carbons; the influence of the concentration of each was also investigated to determine which was the most suitable.

The effects of sulphonate salt concentration and chain length on the retention factor (k') were studied by measuring k', using only berenil as the diamidine, with a mobile phase consisting of 25.0 m*M* citrate buffer, pH = 3.25, 45.0% methanol, $T = 30.0°C$, with pentane sulphonate, hexane sulphonate, heptane sulphonate, octane sulphonate, and decane sulphonate sodium salts at concentrations of 0.00, 1.00, 2.00, 3.00, 4.00, 5.00, 6.00, 9.00, and 12.00 m*M*. The resultant data are shown in Fig. 4, where it may be observed that retention times and hence k' increase as the concentration of the ion pair-forming agent increases. This increase is much more pronounced when reagents with longer chain lengths are used.

Influence of methanol content

Two solvents were initially evaluated as organic modifiers for the mobile phase, these being acetonitrile and methanol. Methanol was finally selected, principally because of its greater solubility with respect to ion-forming reagents.

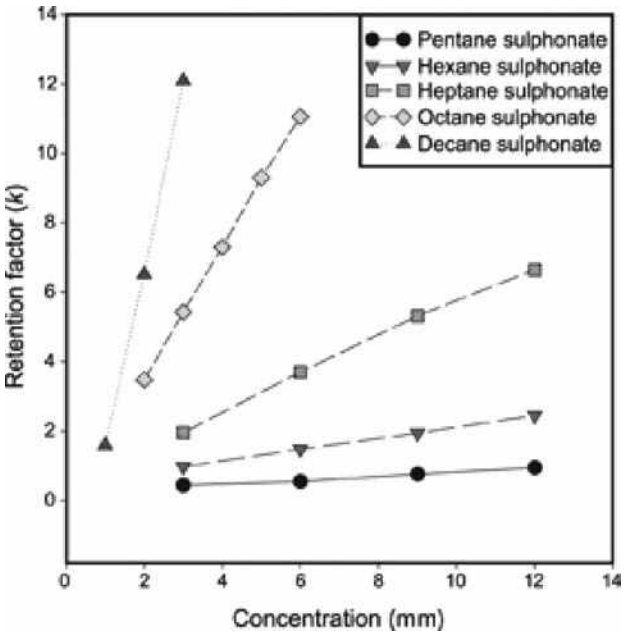

Fig. 4 Influence of concentration and chain length of the ion pair-forming agent in HPLC. This effect was studied using a mobile phase consisting of 25.0 m*M* citrate buffer, 45.0% methanol, and pH = 3.25, containing pentane sulphonate, hexane sulphonate, heptane sulphonate, octane sulphonate, and decane sulphonate sodium salts at concentrations of 0.00, 1.00, 2.00, 3.00, 4.00, 5.00, 6.00, 9.00, and 12.0 m*M*.

The effect of methanol percentage in the mobile phase on retention times was studied by using a mobile phase consisting of 25.0 m*M* citrate buffer, pH = 3.25, $T = 30.0°C$, and 4.00 m*M* octane sulphonate and methanol at 42.0%, 45.0%, and 50.0%. Fig. 5 shows that, with increasing percentages of methanol, retention times drop considerably and resolution decreases, but up to 50.0% methanol, this remains within acceptable limits.

Parameters Exclusive to CE

Selection of electrolyte

With a view to selecting the most suitable electrolyte for CE,[20,21] all the diamidines under study were analyzed by using various buffers (phosphate, acetate, and citrate), all at 25.0 m*M*, pH = 3.70, $T = 30.0°C$, and 14.0 kV voltage, as shown in Fig. 6. Only citrate gave useful values of resolution and efficiency for all the diamidines, together with migration times that were adequate for the kind of analysis they intended to optimize. Hence, citrate was also chosen for all the CE works.

Length of capillary

The length of the capillary is directly related to the electric field, efficiency, resolution,[22] and amount of sample loaded. An increase from 50.0 to 70.0 cm, up to the detector (from 57.0 to 77.0 cm overall dimension) in the length of the capillary, causes the quantity of sample loaded to be reduced by approximately 26.0% and the strength of the field to be generated when applying the same potential drops by approximately the same amount (Table 1). To study the influence of the length of the capillary on

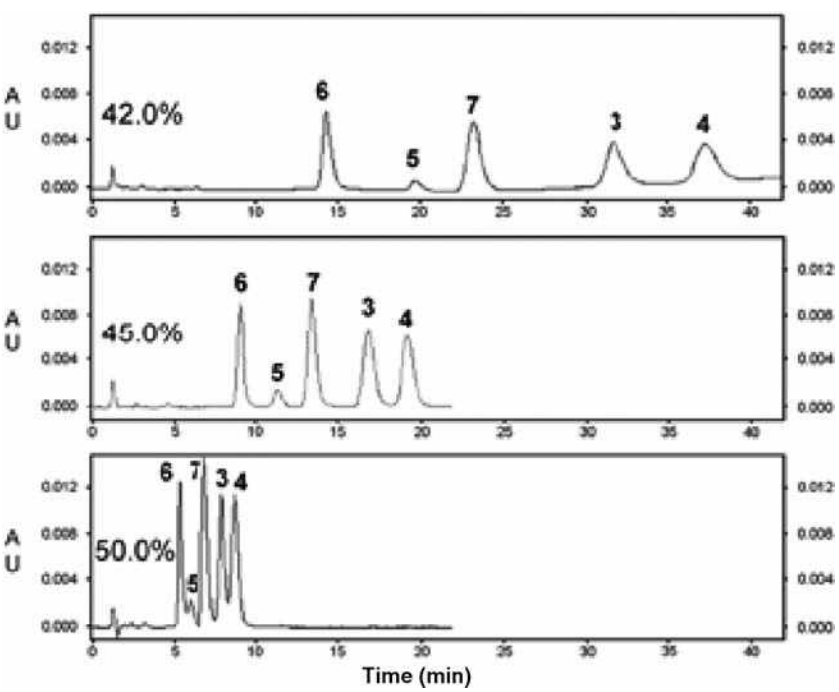

Fig. 5 Influence of methanol content in HPLC. This effect was studied using a mobile phase consisting of 25.0 m*M* citrate buffer, pH = 3.25, $T = 30.0°C$, 4.00 m*M* octane sulphonate, and 42.0%, 45.0%, and 50.0% methanol.

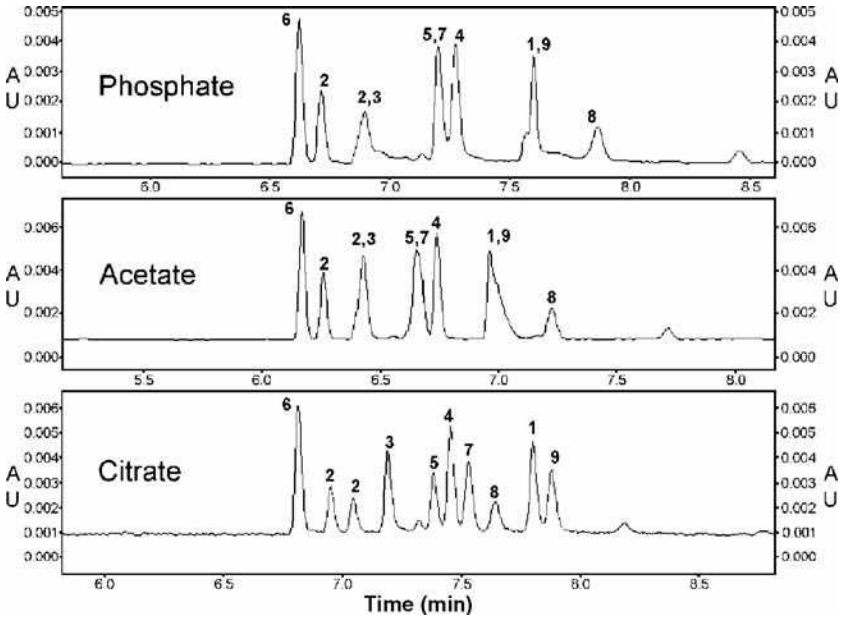

Fig. 6 Selection of electrolyte in CE. Electropherograms of nine diamidines using phosphate, acetate, and citrate electrolytes (25.0 m*M*), pH = 3.70, $T = 30.0°C$, and 14.0 kV voltage.

migration times, the following conditions were used: capillary, 75.0 μm I.D.; lengths, 50.0 and 70.0 cm to the detector (57.0 and 77.0 cm overall length); electrolyte, 25.0 m*M* citrate buffer; pH = 3.70; $T = 30.0°C$; and voltage, 14.0 kV. Fig. 7 shows that as the length is increased from 50.0 to 70.0 cm, migration times are virtually doubled and a striking improvement in efficiency is achieved (i.e., an increase of between 10.0% and 15.0% in the number of theoretical plates), with good resolution.

Voltage applied

The voltage applied is one of the factors of greatest influence in a CE experiment because almost all the parameters governing separation are related to this voltage. The analysis time is inversely proportional to the applied voltage because of, among other things, the higher electroosomotic flow (EOF). An increase in the voltage also brings with it a growth in Joule heating[15,16] and, if this is not effectively eliminated, it may cause variations in resistance, pH, viscosity of the electrolyte, and so on, thus rendering the analysis impossible to reproduce. With a view to optimizing the voltage, the Ohm's law plot of intensity against voltage must be kept in mind. The maximum efficiency in electrophoretic separation is attained at the point where this plot begins to deviate from linearity.[23] In the work reported here, this occurred from 24.0 kV upward, and, when this value was exceeded, a pronounced decrease in efficiency occurred.[24] In Fig. 8, the effects mentioned above can be readily seen; between the electropherogram at 8.00 kV and its counterpart at 14.0 kV, a clear increase in efficiency is observed, with resolution remaining at acceptable levels. On the other hand, in the electropherogram taken at 26.0 kV, outside the limits of linearity under Ohm's law, there is a complete loss of the improvements in both resolution and efficiency produced by higher voltage. This work was carried out using 25.0 m*M* citrate electrolyte, pH = 3.70, and $T = 30.0°C$, at voltages of 8.00, 14.0, and 26.0 kV.

CONCLUSIONS

A detailed study was undertaken of each of the parameters affecting the process of separation analysis in HPLC and CE for nine aromatic diamidines. The results obtained are noted and discussed; in the tables,

Table 1 Effect of capillary length on the volume of sample loaded and strength of the electric field.

Length of capillary (cm)	Volume injected (nl)	Capillary occupied by the injection (mm)	Percentage of capillary occupied	Analyte loaded (ng)	Strength of electric field (V/cm)
77.0	21.77	4.92	0.70	8.80	181.0
57.0	29.41	6.65	1.33	147.0	245.0

Capillary, 75.0 μm I.D.; overall lengths, 77.0 and 57.0 cm (70.0 and 50.0 cm to the detector); electrolyte, 25.0 m*M* citrate buffer; pH = 3.70; voltage, 14.0 kV; $T = 30.0°C$; injection under pressure for 5.00 sec.

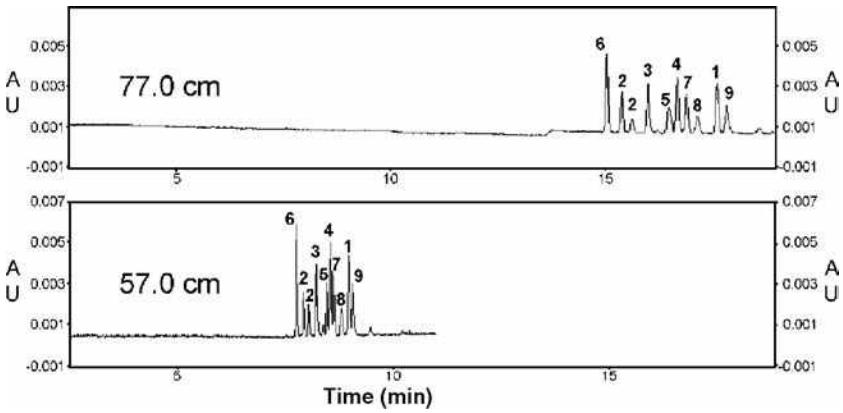

Fig. 7 Influence of capillary length in CE. Capillary, 75.0 μm I.D.; lengths, 50.0 and 70.0 cm to detector (57.0 and 77.0 cm overall); electrolyte, 25.0 m*M* citrate buffer; pH = 3.70; $T = 30.0°C$; and voltage, 14.0 kV.

comparative features of the two techniques that emerge from the data collected are recorded.

Performance of HPLC and CE in the Separation of Aromatic Diamidines

The data emerging from this work allow the selection of the optimum conditions for the analysis of each substance in aqueous solution, serum, and urine. For HPLC, they are: 25.0 m*M* citrate buffer, pH = 3.25, 45.0% methanol, column Ultrasphere ODS (5.00 μm particle size, 15.0 cm × 4.60 mm I.D.), 1.00 ml/min flow, and $T = 30.0°C$. The following features depend on the specific substance under analysis: pentamidine, 4.00 m*M* hexane sulphonate, λ = 265.0 nm; stilbamidine, 4.00 m*M* octane sulphonate, λ = 330.0 nm; DAPI, 8.00 m*M* heptane sulphonate, λ = 350.0 nm; propamidine, 6.00 m*M* heptane sulphonate, λ = 265.0 nm; hydroxystilbamidine, 4.00 m*M* octane sulphonate, λ = 350.0 nm; phenamidine, 4.00 m*M* octane sulphonate, λ = 265.0 nm; diampron, 4.00 m*M* octane sulphonate, λ = 254.0 nm; berenil, 4.00 m*M* octane sulphonate, λ = 370.0 nm; and dibromopropamidine, 3.00 m*M* hexane sulphonate, λ = 265.0 nm.

For CE, the optimum values were: overall length of capillary, 57.0 cm (50.0 cm to the detector); 75.0 μm I.D.; electrolyte, 25.0 m*M* citrate; pH = 3.70, injection under pressure for 5.00 sec; voltage, 14.0 kV; $T = 30.0°C$; and λ = 200.0 nm.

Analyses by means of HPLC and CE were carried out under these conditions for all the compounds, and comparative data for the two techniques are summarized in Table 2. The efficiency of CE is two orders of magnitude greater than HPLC for all the substances analyzed. The limits of detection (LOD) for HPLC are much lower than in

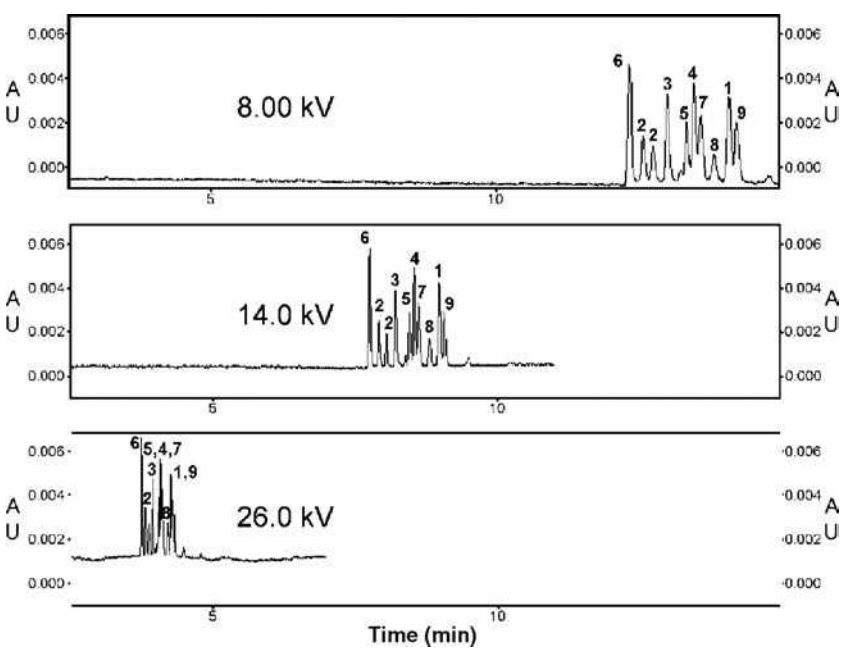

Fig. 8 Influence of variations in voltage in CE. Electrolyte, 25.0 m*M* citrate buffer; pH = 3.70; $T = 30.0°C$, and voltages, 8.00, 14.0, and 26.0 kV.

Table 2 Performance of HPLC and CE in separation of aromatic diamidines.

	HPLC	CE
Detection limit (ng/ml)		
Pentamidine	20.00	300.0
Stilbamidine	10.00	300.0
DAPI	5.00	300.0
Propamidine	30.00	200.0
Hydroxystilbamidine	15.00	400.0
Phenamidine	20.00	150.0
Diampron	10.00	300.0
Berenil	60.00	500.0
Dibromopropamidine	40.00	600.0
Precision (% CV)		
Pentamidine	1.09	3.04
Stilbamidine	1.03	1.68
DAPI	1.16	2.88
Propamidine	1.53	2.37
Hydroxystilbamidine	0.70	3.73
Phenamidine	0.70	3.52
Diampron	0.97	2.43
Berenil	0.85	1.55
Dibromopropamidine	1.36	5.30
Efficiency (theoretical plates)		
Pentamidine	2.22×10^3	2.92×10^5
Stilbamidine	3.91×10^3	3.04×10^5
DAPI	4.60×10^3	2.93×10^5
Propamidine	3.19×10^3	2.92×10^5
Hydroxystilbamidine	3.87×10^3	2.79×10^5
Phenamidine	3.65×10^3	3.06×10^5
Diampron	4.57×10^3	2.78×10^5
Berenil	3.17×10^3	2.43×10^5
Dibromopropamidine	2.63×10^3	2.46×10^5

Table 4 Schematic table of the advantages of HPLC and CE.

	HPLC	CE
Versatility	+++	++++
Speed of optimization of methods	++	++++
Stabilization time	++	++++
Analysis time	++	+++
Sensitivity	+++	++
Reproducibility of times	+++	++
Reproducibility of areas	+++	++
Precision	+++	++

CE, there being some cases, such as DAPI, where the detection limit is 60 times lower with HPLC than with CE. Values for precision are significantly better with HPLC than with CE.

Operational Differences Between HPLC and CE

Table 3 shows some of the differences in working practices between HPLC and CE.

Advantages of HPLC and CE

To summarize the work reported here, there is a schematic presentation of views on the advantages and drawbacks of each technique in Table 4.

Table 3 Operational differences between HPLC and CE.

	HPLC	CE
Quantity of sample introduced into the system	10.0–1000.0 μl	1.00–50.0 nl
Size of the detector cell	8.00–12.0 mm^3	0.015 mm^3
Detection wavelength	Generally from 230.0 nm upward	Possible to use wavelengths down to 185.0 nm
Interference	All components of the sample must pass through the detector	Possible to stop the analysis once the substance of interest has been detected
Flow	0.50–2.00 ml/min	Few microliters per minute
Equipment stabilization time	Requires balancing of the column with different timings before reliable results are obtained	Analysis can be carried out almost immediately after connection of equipment

Asymmetric FFF in Biotechnology

Christine Hürzeler
Thorsten Klein
Postnova Analytics, Munich, Germany

INTRODUCTION

The research and development in the fields of biochemistry, biotechnology, microbiology, and genetic engineering are fast-growing areas in science and industry. Chromatography, electrophoresis, and ultra-centrifugation are the most common separation methods used in these fields. However, even these efficient and widespread analytical methods cannot cover all applications. In this entry, asymmetric flow field-flow fractionation (AF4) is introduced as a powerful analytical separation technique for the characterization of biopolymers and bioparticles. Asymmetric flow field-flow fractionation (FFF) can close the gap between analyzing small and medium-sized molecules/particles [analytical methods: high-performance liquid chromatography (HPLC), gel filtration chromatography (GFC), etc.] on the one hand and large particles (analytical methods: sedimentation, centrifugation) on the other hand,[1,2] whereas HPLC and GFC are overlapping with asymmetric field-flow fractionation in the lower separation ranges.

The first publication about FFF by Giddings[3] appeared in 1966. From this point, FFF was developed in different directions and, in the following years, various subtechniques of FFF emerged. Well-known FFF subtechniques are sedimentation FFF, thermal FFF, electric FFF, and flow FFF. Each method has its own advantages and gives a different point of view of the examined sample systems. Using sedimentation FFF shows new insights about the size and density of the analytes, thermal FFF gives new information about the chemical composition and the size of the polymers/particles, and electric FFF separates on the basis of different charges. Flow FFF, and especially asymmetric flow FFF (the most powerful version of flow FFF) is the most universal FFF method, because it separates strictly on the basis of the diffusion coefficient (size or molecular weight) 2, and it has the broadest separation range of all the FFF methods. It is usable for a large number of applications in the fields of biotechnology, pharmacology, and genetic engineering.

SEPARATION PRINCIPLE OF ASYMMETRIC FLOW FIELD-FLOW FRACTIONATION

All FFF methods work on the same principle and use a special, very flat separation channel without a stationary phase. The separation channel is used instead of the column, which is needed in chromatography. Inside the channel, a parabolic flow is generated, and perpendicular to this parabolic flow, another force is created. In principle, the FFF methods only differ in the nature of this perpendicular force.

The separation channel in AF4 is approximately 30 cm long, 2 cm wide, and between 100 and 500 μm thick. A carrier flow which forms a laminar flow profile streams through the channel. In contrast to the other FFF methods, there is no external force, but the carrier flow is split into two partial flows inside the channel. One partial flow is led to the channel outlet and, afterward, to the detection systems. The other partial flow, called the cross-flow, is pumped out of the channel through the bottom of the channel. In the AF4, the bottom of the separation channel is limited through a special membrane and the top is made of an impermeable plate (glass, stainless steel, etc.). The separation force, therefore, is generated internally, directly inside the channel, and not by an externally applied force.

Under the impact of the cross-flow, the biopolymers/particles are forced in the direction of the membrane. To ensure that the analytes do not pass through the membrane, different pore sizes can be used. In this way, the analytes can be selectively rejected and it is possible to remove low-molecular compounds before the separation. The analytes' diffusion back from this membrane is counteracted by the cross-flow, where, after a time, a dynamic equilibrium is established. The medium equilibrium height for smaller sized analytes is located higher in the channel than for the larger analytes. The smaller sized analytes are traveling in the faster velocity lines of the laminar channel flow and will be eluted first. As a result, fractograms, which show size separation of the fractions, are obtained as an analog to the chromatograms from HPLC or GFC.

APPLICATIONS OF AF4 ASYMMETRIC FLOW FIELD-FLOW FRACTIONATION IN BIOTECHNOLOGY

In addition to widespread applications in the field of polymer and material science or environmental research, AF4 can be used in bioanalytics, especially for the characterization of proteins, protein aggregates, polymeric

proteins, cells, cell organelles, viruses, liposomes, and various other bioparticles and biopolymers.

Cells and Viruses

The advantage of AF4, in contrast to chromatography, is the capability to separate bioparticles and biopoylmers which usually stick onto chromatography columns. They are more or less filtered out (removed) by the stationary phase. Various applications using AF4 for the separation of shear-force sensitive bioparticles with high molecular weight and size have been reported in the literature. They deal with the efficient and fast separation of viruses[4,5], and bacteria.[5] Litzen and Wahlund[4] discuss the investigation of a virus (STNV) with AF4 and the separation of the viral aggregates. Litzen and Wahlund[5] report the separation of a virus (CPMV) together with different other proteins (BSA, Mab). They also present the characterization of bacillus *streptococcus faecalis* and its aggregates using AF4.

Proteins/Antibodies/DNA

The separation of proteins with AF4 has been demonstrated a number of times. For example, the fractionation of ferritin,[7] of HSA and BSA,[8] and of Mab,[8] including their various aggregates, were published. Asymmetric flow FFF is especially suitable for the separation and characterization of large and sensitive proteins and their aggregates because it is fast and gentle and aqueous solvents can be used that achieve maximum bioactivity of the isolated proteins and antibodies. Furthermore, even very large and sticky proteins can be analyzed because of the relatively low surface area and the separation in the absence a stationary phase. Nearly independent of the nature of the bioparticles, AF4 separates by size (diffusion coefficient). Therefore, DNA, RNA, and plasmids can be separated quickly and gently, together with proteins. Kirkland et al.[6] deal with this issue and present the AF4 separation of a mixture of cytochrome-*c*, BSA, ferritin, and plasmid DNA.

Artificial Polymeric Proteins

In addition to the characterization of well-known protein substances (serum proteins, aggregates, antibodies, etc.), AF4 is also a very promising separation/characterization technique for a new class of artificially made polymeric proteins from therapeutic/diagnostic applications, such as poly-streptavidin and polymeric hemoglobin (personal communication of the authors). These proteins usually have very high molecular weights and huge molecular sizes, and they are difficult to analyze by conventional GFC and related techniques. Very often, these proteins are also sticky and show adsorptive effects on the column material. Using AF4 without a stationary phase and without size-exclusion limit, these polymeric proteins can be readily separated and characterized. The application shown in Fig. 1 was done using an AF4 system (HRFFF 10,000 series, Postnova Analytics) and ultraviolet (UV) detection at 210 nm.

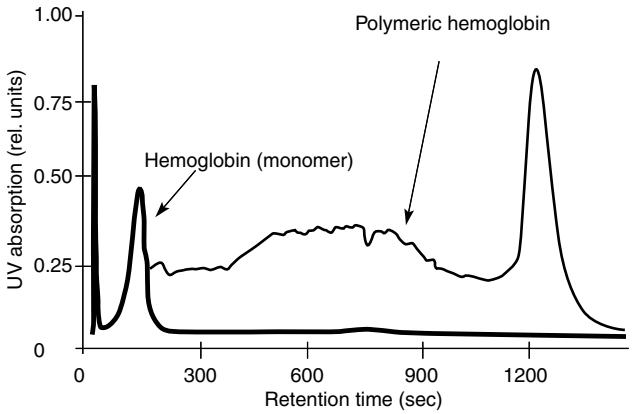

Fig. 1 Pig hemoglobin separated with AF4 and UV detection.

CONCLUSIONS

Asymmetric flow FFF is a new member in the FFF familiy of separation technologies; it is a powerful characterization technique, especially suited for the separation of large and complex biopolymers and bioparticles. Asymmetric flow FFF has many of the general benefits of FFF; it adds on several additional characteristics. In particular, these characteristics are as follows:

1. No sample preparation, or only limited sample preparation necessary.
2. Possibility of direct injection of unprepared samples.
3. Large accessible size molecular-weight range, no size-exclusion limit.
4. Very gentle separation conditions in the absence of a stationary phase.
5. Weak or no shear forces inside the flow channel.
6. Rapid analysis times, generally faster than GFC.
7. Fewer sample interactions during separation because of small surface area.
8. On-line sample concentration/large volume injection possible.
9. Gentle and flexible because it uses a wide range of eluents/buffers/detectors.
10. AF4 is a useful analytical tool, and when the limitations of the technology (e.g., sample interactions with membrane or the sample dilution during separation)

are carefully observed, samples can be characterized where other analytical technologies fail or only yield limited information.

Atomic Emission Detector for GC

Stanisław Popiel
Institute of Chemistry, Military University of Technology, Warsaw, Poland

Zygfryd Witkiewicz
Institute of Chemistry, Jan Kochanowski University, Kielce, Poland

INTRODUCTION

The gas chromatograph (GC) is one of the most popular analytical devices used in laboratories throughout the world. A reason for this is, among others, that devices being a combination of a GC and a mass spectrometer (MS), infra red and atomic emission spectrometers (AES) have been constructed to offer distinct advantages over other approaches to chemical analysis of complex mixtures. Owing to the combination of a chromatograph and a spectrometer, it is much easier to identify components of mixtures separated in a chromatographic column than was previously possible with commonly employed detectors.

GC–AES

A system comprising a GC and an AES (GC–AES) was first reported in 1965.[1] Because of the application of microwave-induced plasma (MIP) in AES, detection limits in the pg/sec range were achieved for several elements, but the selectivity against carbon was very poor. The first commercially available GC–MIP–AES device was introduced in 1978, but its production was soon abandoned.[2]

In 1989, Hewlett-Packard introduced a modernized and totally automated atomic emission detector (AED) connected with a GC equipped with a capillary column. At present, two names are used for the device: GC–AED and (less frequently) GC–AES.[3] The device utilizes a microwave-induced helium plasma for decomposition and excitation of analyzed compounds, and a photodiode array (PDA) for light emission measurement. The GC–AED may be used alone or in conjunction with GC–MS, and the situation allows for more effective use of both devices together than separately.[4]

Principle of Operation

The principle of operation of AED is based on measurement of wavelength and intensity of light emitted by the excited atoms formed by decomposition of molecules of chromatographed chemical compounds. Constituents of the mixture, separated in a capillary column, are passed into a microwave-powered, high-temperature helium plasma. This is why helium must be used as a carrier gas in GC–AED. Helium plasma-introduced compounds are decomposed into elements. Atoms or ions of these elements become excited to higher energy levels. Then, returning to their base states, they emit light with wavelengths characteristic for individual elements. To increase the detector's efficiency, after the column but before the plasma cavity, small quantities of reagent gases are added to helium. The kind of utilized reagent gas depends on the elements of analyzed chemical compounds to be detected (Table 1).

The light emitted by atoms of individual elements that formed a compound leaving a chromatographic column is focused by an optical lens onto a holographic grid. Here, it is separated into components of various wavelengths and detected by a PDA in the range from 171 nm (oxygen) through 837 nm (chlorine) with a precision of 0.004 nm. A rotating holographic grating is an important element of the optics. It varies the elemental light spectrum covered by the fixed-position PDA. Algorithms of applied computer software provide automatic wavelength calibration, automatic focus, and measurements of intensity, wavelength, and line width. Detection of an elemental emission line and its spectral background makes use of numerous simultaneous signals from the PDA. These signals are combined into pairs and the resulting portions of the chromatogram in the form of essential signals and the background is registered separately. As a result of this, the elements' selectivity can be improved after sample analysis has been completed. Detection selectivity for most elements is very high. As light emitted by carbon or hydrogen is registered as chromatograms of these elements, the detector is universal for organic compounds. When light emitted by another element is registered, the detector is specific for that element.

The signals generated by the PDA for particular elements are registered by a computer as chromatographic files. Following a single sample injection, it is possible to obtain one to six elemental chromatograms. Two of these can be displayed on a computer screen in real time, and the rest are stored in the computer memory. After separation of the mixture components is completed, chromatograms of all elements forming these components can be printed. Fig. 1 presents a schematic representation of the AED.

Table 1 Elemental properties and reagent gases that may be used for analysis.

Element	Emission wavelength (nm)	Limit of detection (pg/sec)	Reagent gases	Makeup flow (ml/min)	Dynamic range
Carbon	179	10	O_2, H_2	35	1,000
	193	0.5	O_2, H_2	35	10,000
	248	6.5	O_2, H_2	180	10,000
	264	200	O_2, H_2	180	1,000
	496	20	O_2	35	30,000
	834	50	O_2	35	1,000
Hydrogen	486	2	O_2	35	6,000
	656	0.5	O_2	180	5,000
Oxygen	171	50	H_2 and (10% CH_4 + 90% N_2)	35	5,000
Nitrogen	174	7	O_2, H_2	35	10,000
	388	20	O_2, H_2, CH_4	180	1,000
Sulfur	181	1	O_2, H_2	35	10,000
Iodine	183	10	O_2, H_2	35	5,000
	206	20	O_2, H_2	35	5,000
Arsenic	189	3	H_2	180	1,000
Selenium	196	4	H_2	180	1,000
Tellurium	208	10	H_2	180	1,000
Antimony	218	5	H_2	180	1,000
Boron	250	20	O_2	180	1,000
Silicon	252	1	O_2, H_2	180	—
Mercury	254	0.5	O_2, H_2	180	1,000
Manganese	259	2	O_2, H_2	180	1,000
Lead	261	2	O_2, H_2	180	1,000
	406	1	O_2, H_2	180	1,000
Germanium	265	10	O_2, H_2	180	1,000
Tin	271	2	O_2, H_2	180	1,000
	301	1	O_2, H_2	180	1,000
	303	1	O_2, H_2	180	1,000
	326	1	O_2, H_2	180	1,000
Vanadium	292	4	O_2, H_2	180	1,000
Nickel	301	0.8	O_2, H_2	180	1,000
Iron	302	0.05	O_2, H_2	180	1,000
Chlorine	479	15	O_2	35	20,000
	837	15	O_2	35	20,000
Bromine	478	20	O_2	35	4,000
	827	20	O_2	35	4,000
Fluorine	690	20	H_2	35	2,000
Carbon-13	177	10	O_2, H_2	35	1,000
Nitrogen-15	420	3.5	O_2, H_2, CH_4	35	1,000
Deuterium	656	1	O_2	180	4,000

A GC–AED system is characterized with resolution capacity characteristic of capillary chromatography and high selectivity characteristic of atomic emission spectrometry. Theoretically, the AED is useful for detection of all elements except helium. Practically, commercially available GC–AED devices allow detection of 26 elements, including many metals and three isotopes: deuterium, C-13 carbon, and N-15 nitrogen.

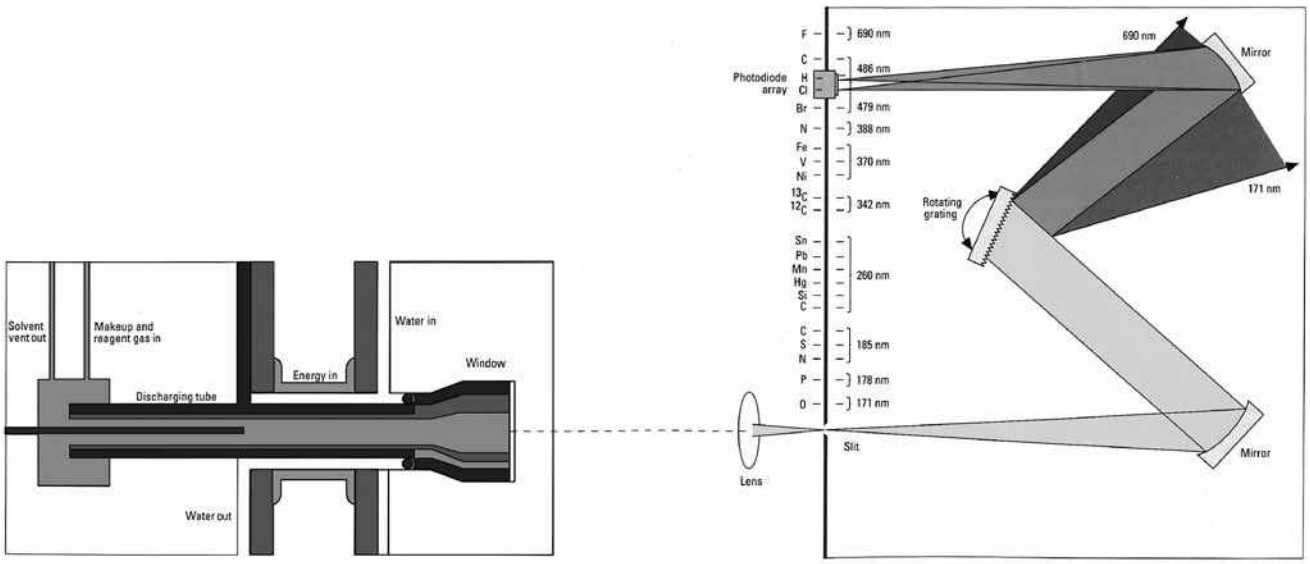

Fig. 1 Schematic diagram of AED.

Limits of detection for individual elements depend on the intensity of a particular emission line of each element—some elements can be detected with several light emission lines. In many cases, limits of detection achieved with GC–AED are at lower concentration levels than for other GC detectors. For a particular element, light emission intensity is proportional to the number of the element's atoms in a molecule of an analyzed compound; also, it is proportional to the concentration of the compound in an analyzed sample. Measuring emitted light intensity, it is possible to determine quantity of the element in a sample and to calculate the number of the element's atoms in molecules of particular compounds present in an analyzed sample.

Detector signal magnitude for an individual element is almost compound independent. The phenomenon of compound independence is used in quantitative analysis and also for identification of unknown compounds. In quantitative analysis, content of a given element in a particular compound is determined using a calibration graph for the same element, but present in various compounds in known amounts. It is then possible to perform quantitative analysis of compounds without standards of those compounds.

A direct result of a compound-independent elemental signal is the ability to measure elemental mole ratios (EMR) in analyzed compounds. For unknown compounds, the AED response in separate elemental channels for the compound is compared with the response to one or several standards. With computer software, first the EMR for known standards and then the empirical formula for an unknown compound are determined. Compound-independent calibration saves much time and cost for analysts, for it is possible to avoid using costly, and sometimes hazardous, standards.[5–9] Table 1 presents elements that can be detected and quantitatively assayed with AED, their limits of detection, wavelengths of their emissions, types of added reagent gases, and dynamic ranges of the detector signal.

Owing to a relatively low 193 carbon emission line limit of detection, it is possible for an AED to detect organic compounds at lower concentration levels compared to a flame ionization detector. Halides are detected at similar concentration levels as with an electron capture detector. AED is, however, less vulnerable to contaminations present in a sample; it also allows determination of fluorine, chlorine, bromine, and iodine. Most elements are detected in quantities ranging from several to dozens of pg/sec. The AED's sensitivity for oxygen is relatively low, however. This is manifested by the fact that the AED's oxygen detection limit in organic compounds reaches relatively high values (~50 pg/sec); one should remember, however, that it is the only detector capable of any oxygen detection in organic compounds. Owing to its high detectability and specificity toward many elements, GC–AED may be applied for analysis of environmental pollution, in the chemical industry, petroleum chemistry, pharmaceutical, cosmetic, and food industries, and in numerous other sectors where chromatographic analyses are used. GC–AED is particularly useful for analysis of organic compounds containing heteroatoms, including organometallic compounds. The method is also used for postsynthetic analysis of drugs and for monitoring them in a patient's organs, for analysis of polychlorinated biphenyls, halide derivatives of other hydrocarbons, pesticides, and other environmental pollutants such as mercury, tin, and lead compounds, and

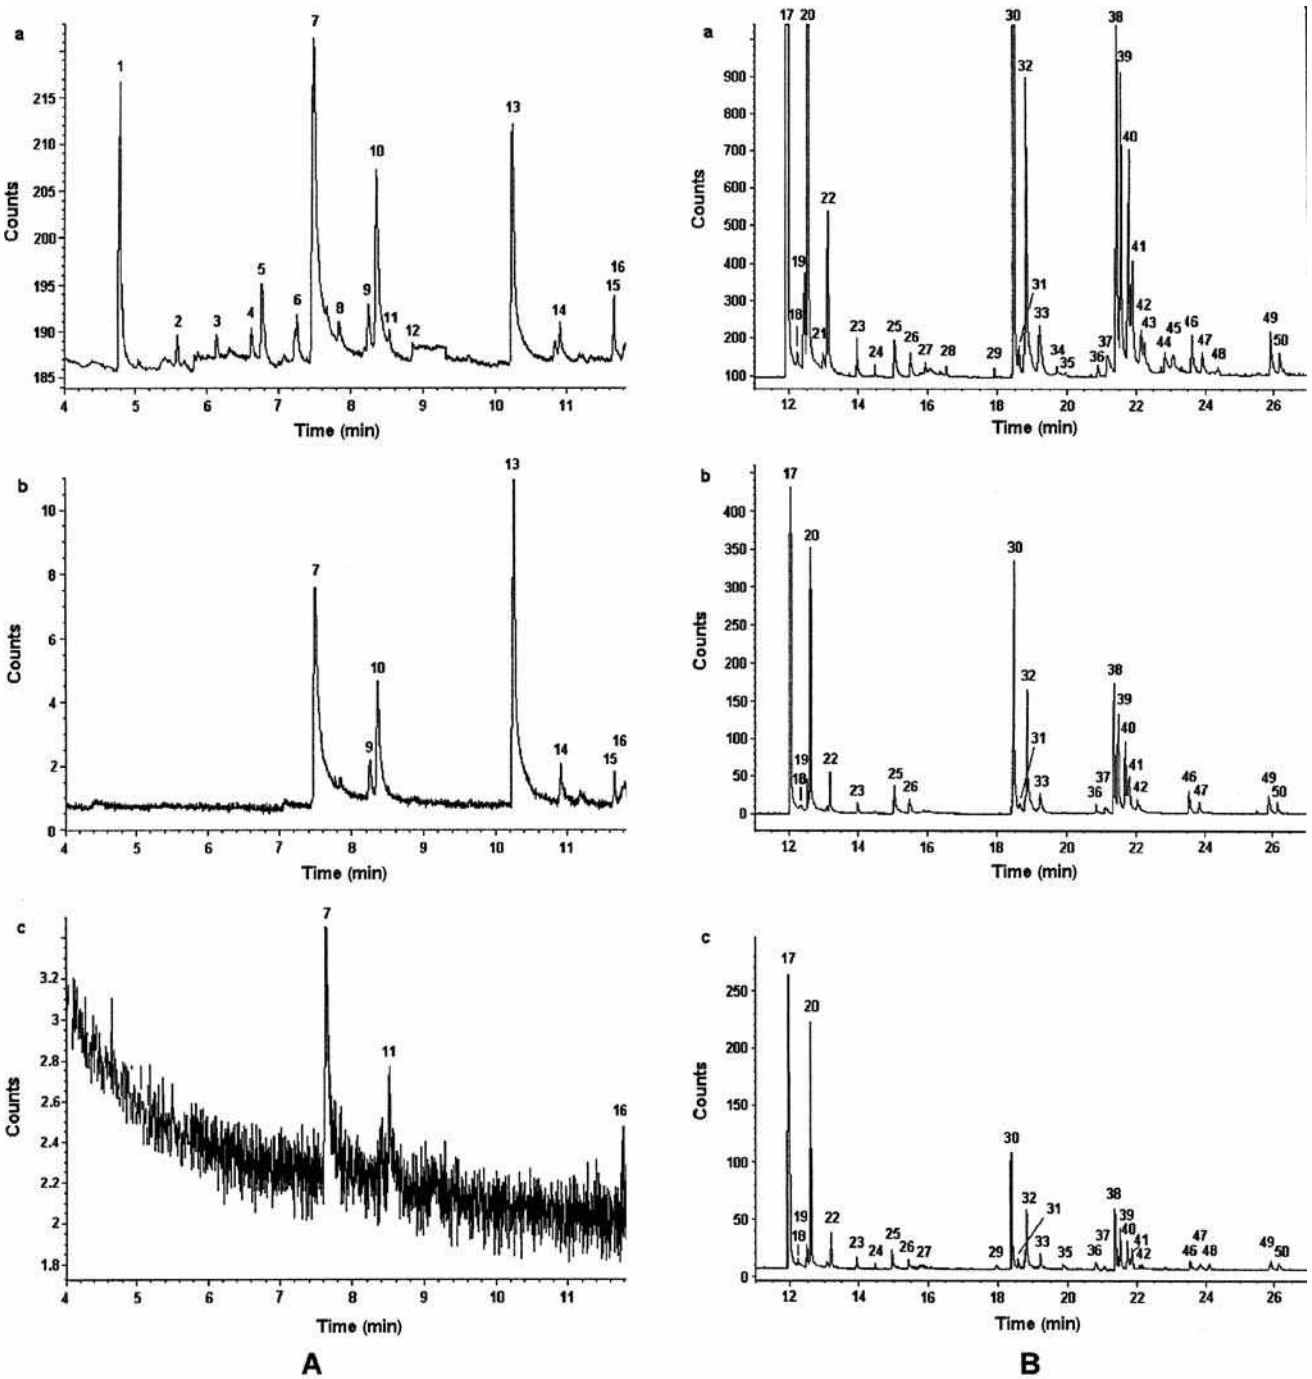

Fig. 2 A, The element chromatograms of a sample of the yperite block obtained by GC–AED on channel: (a) carbon, C-193 nm; (b) sulfur, S-181 nm; and (c) chlorine, Cl-479 nm, split ratio 20 : 1. B, The second part of the element chromatograms of a sample of the yperite block obtained by GC–AED on channel: (a) carbon, C-193 nm; (b) sulfur, S-181 nm; and (c) chlorine, Cl-479 nm, split ratio 60 : 1.

also of warfare agents. With GC–AED, it is possible to detect sulfur, nitrogen, oxygen, and lead compounds in petrochemical products.

Sample chromatograms obtained from GC–AED analysis of a sample collected from a block of yperite fished from the Baltic Sea are presented in Fig. 2.[10]

CONCLUSIONS

- GC connected with AES is a powerful technique for versatile, highly sensitive and selective analysis of heteroatoms (including metallic ones) containing compounds.

- Detector signal magnitude for individual element is almost compound-independent. The phenomenon is used in quantitative analysis and for determination of empirical formulas of unknown compounds. Contents of a given element in a particular compound can be determined using calibration graph for the same element but present in different compounds.
- Owing to a relatively low 193 carbon emission line limit of detection it is possible to detect organic compounds on five times lower concentration level comparing to flame ionization detector. Halides are detected on similar concentration levels as in electron capture detector. AED is ten times more sensitive for sulfur, with more linearity, than flame photometric detector.
- GC–MS and GC–AED can complement each other making the identification of analyzed compounds much easier and much sure than using them separately.

Band Broadening in CE

Jetse C. Reijenga
Department of Chemical Engineering and Chemistry, Eindhoven University of Technology, Eindhoven, The Netherlands

INTRODUCTION

As in chromatography, band broadening in capillary electrophoresis (CE) is determined by a number of instrumental and sample parameters and has a negative effect on detectability, due to dilution. Also, as in chromatographic techniques, the user can minimize some, but not all, of the parameters contributing to band broadening. In CE, injection and detection are generally on-column, so that band broadening is limited to on-column effects. As will be shown, several effects are similar in chromatography; others are specific for CE and, in particular, for the potential gradient as a driving force. General equations for CE in open systems are given where the relative contribution of electro-osmosis is given by the electromigration factor f_{em}, given by

$$f_{em} = \frac{\mu_{eff}}{\mu_{eff} + \mu_{EOF}}$$

in which is the effective mobility and μ_{EOF} is the electro-osmotic flow mobility. This electromigration factor is unity for systems with suppressed electro-osmatic flow (EOF).

The band-broadening contributions can be described in the form of a plate-height equation, where one usually assumes, as in chromatography, mutual independence of terms.

INJECTION

Band broadening due to injection is naturally proportional to the injection volume, relative to the capillary volume, but, in contrast to chromatography, sample stacking or destacking may decrease or respectively increase the injection band broadening thus defined. Without stacking or destacking, the following plateheight term can be used:

$$H_{inj} = \frac{\delta_{inj}^2}{12L_d}$$

in which δ_{inj} is the length in the capillary of the sample plug and L_d is the length of the capillary to the detector. Naturally, the above relationship can be rewritten in terms of sample and capillary volume, which are in the order of 10 nl and 1 μl, respectively.

DIFFUSION

As in chromatography, the effect of diffusion on band broadening is generally pronounced. It is directly proportional to the diffusion coefficient and the residence time between injection and detection. This effect can, consequently, be reduced by increasing the voltage, or by increasing the EOF, in cases where cations are analyzed at positive inlet polarity, where it further shortens the analysis times.The effect is less at lower temperatures (as the diffusion coefficient decreases approximately 2.5% per degree Celsius of temperature drop), but most significantly decreases with increasing molecular mass of the sample component.

$$H_{diff} = \frac{2Dt_m}{L_d}$$

in which L_d is the capillary length to the detector, D is the diffusion coefficient, and t_m is the migration time. Substituting the diffusion coefficient, using the Nernst-Einstein relation, yields

$$H_{diff} = \frac{2RTf_{em}}{z_{eff}EF}$$

in which R is the gas constant, T is the temperature, z_{eff} is the overall effective charge of the sample ion, E is the electric field strength, and F is the Faraday constant. In this relationship, z_{eff} and E, by definition, have opposite signs for negative values of f_{em} only.

DETECTION

The detector time constant and detector cell volume are both involved.The slit width along the length of the capillary is proportional to the latter. A value of 200 mm for the slit width in the case of 10^5 plates in a 370 mm capillary has negligible contribution to band broadening:

$$H_{slit} = \frac{\delta_{det}^2}{12L_d}$$

where δ_{det} is the detector slit width along the capillary axis. In cases of diode array detection, larger slit widths are

usually applied; this reduces the noise level but may affect the peak shape at high plate numbers ($>10^5$).

The contribution of the detector time constant τ is modeled by the following relation:

$$H_\tau = L_d \left(\frac{\tau}{t_m}\right)^2$$

A detector time constant τ of 0.2 sec is generally safe.

THERMAL EFFECTS

In cases of a relatively high current density, power dissipation in the capillary may result in significant radial temperature profiles. The plate-height contribution is given by

$$H_{\text{ther}} = \frac{f_T^2 \kappa^2 E^5 R_i^6 z_{\text{eff}} F f_{\text{em}}}{1536 R T \lambda_s^2}$$

where f_T is the temperature coefficient for conductivity, κ is the specific conductivity of the buffer, E is the electric field strength, R_i is the capillary inner diameter, and λ_s is the thermal conductivity of the solution.

As the effective mobility increases with the temperature at approximately 2.5% per degree, radial mobility differences may accumulate to significant bandbroadening effects. The effect increases with increasing current density and capillary inner diameter. In a 75 μm inner diameter capillary, a power dissipation of 1–2 W/m is generally safe. This value is calculated by multiplying the voltage and the current and dividing by the capillary length. Under these conditions, the radial temperature profile in the capillary is less than 0.5°C and the contribution to peak broadening negligible. In the case of higher conductivity buffers (e.g., a pH 3 phosphate buffer), the power dissipation and temperature profile can be 10 times higher and the effect on peak broadening significant. It should be emphasized that more effective cooling has no effect on thermal band broadening; the only effect is decreased averaged temperature inside the capillary.

ELECTRO-OSMOTIC EFFECTS

Electro-osmosis in open systems is generally considered not to contribute to peak broadening. In hydrodynamically closed systems with non-suppressed electro-osmosis, or in cases of axially different electro-osmotic regimes, however, a considerable contribution may result. The corresponding plate-height term is

$$H_{\text{EOF}} = \frac{R_i^2 \zeta^2 \varepsilon^2 z_{\text{eff}} E F}{24 R T \eta^2 \mu_{\text{eff}}^2}$$

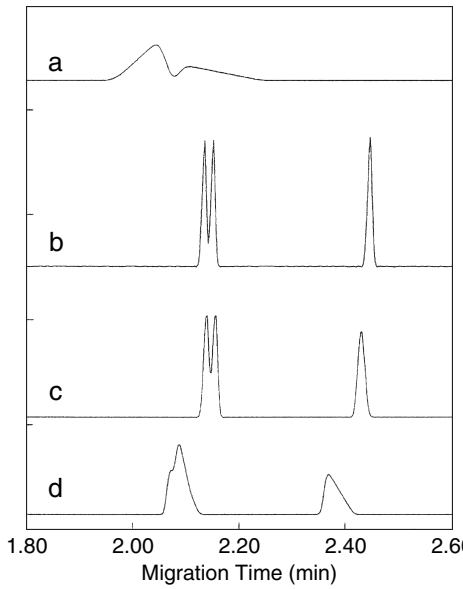

Fig. 1 Electrophoretic bandbroadening effects of benzoates as sample. Destacking trace (a) (1 m*M* sample in 1 m*M* buffer), stacking trace (b) (0.01 m*M* sample in 25 m*M* buffer), and trace (c) (1 m*M* sample in 25 m*M* buffer) and peak triangulation trace (d) (1 m*M* sample in 25 m*M* chloride buffer).

where ε is the dielectric constant and η is the local viscosity of the buffer at the plane of shear. This relationship shows that, in closed systems, the ζ-potential should be close to zero and that a viscosity increase near the capillary wall will be advantageous.

ELECTROPHORETIC EFFECTS

Peak broadening due to electrophoretic effects are generally proportional to the conductivity (and thus the ionic strength) of the sample solution, relative to that of the buffer. This effect is readily understood when considering that in the case of a high sample concentration, the electric field strength (and, consequently, the linear velocities) in the sample plug are much lower than in the adjacent buffer. Due to this, a dilution (destacking) of the sample occurs.This is illustrated in curve a in Fig. 1—the separation of a concentrated 1 m*M* solution benzenesulfonic, *p*-toluene sulfonic, and benzoic acid, dissolved in a buffer of 1 m*M* propionic acid/Tris to pH 8.

Alternatively, when injecting a low-conductivity (diluted, 0.01 m*M*) sample in a 25 m*M* buffer of same composition (curve b in Fig. 1–100 times amplified with respect to the others), the local field strength in the sample compartment is higher than in the adjacent buffer, resulting in a rapid focusing of ionic material at the sample-buffer interface (stacking), and resulting in very sharp sample injection plugs and high plate counts. This stacking takes

place during the first second after switching on the high voltage. It may thus be advantageous to inject a larger volume of a more diluted sample for better efficiency. Choosing a higher conductivity buffer also enhances the effect, where one has to consider that this may result in more pronounced band broadening due to other effects. Curve c in Fig. 1 shows that in such a high-conductivity buffer, even the 1 m*M* sample is separated to reasonable extent.

Peak symmetry is another important issue. Generally, capillary zone electrophoresis peaks are non-Gaussian and show non-symmetry.This peak triangulation increases with increasing concentration overload. It is also proportional to the difference in effective mobility of the sample ion and the coion in the buffer. For instance, analyzing the same 1 m*M* sample mixture in a buffer consisting of, for example, 25 m*M* chloride/Tris to pH 8 will give triangular peaks (curve d in Fig. 1) because the effective mobility of benzoic acid is much lower than that of the buffer anion chloride: The buffer co-ion is not properly tuned to the sample component mobilities.

Band Broadening in GPC/SEC

Gregorio R. Meira
Jorge R. Vega
National Scientific and Technical Research Council (CONICET), Santa Fe, Argentina

INTRODUCTION

In ideal size exclusion chromatography (SEC), fractionation is exclusively by hydrodynamic volume. Unfortunately, perfect SEC fractionation is impossible due to the presence of secondary fractionations and band broadening (BB). Secondary fractionations result from physicochemical interactions between the polymer, the solvent, and the column packing[1] and are not discussed further. Band broadening is mainly due to axial dispersion in the columns, while other broadening sources include column end-fitting effects, finite injection volumes, finite detection cell volumes, and laminar flow profiles in the capillaries.[2,3] Mathematical models have been developed that describe the detailed fractionation processes in SEC. Their aim is to estimate the chromatograms from a priori knowledge of the molar mass distribution (MMD), the polymer–solvent–matrix interactions, the column characteristics, and the flow conditions.[4–7] Unfortunately, these complex models have not been applied so far for BB correction, and therefore they are not discussed further.

If a broad and smooth chromatogram is obtained with modern high-resolution columns, the BB effect is generally negligible, and no specific corrections are required. In contrast, corrections for BB may be important when analyzing: 1) narrow chromatograms of half-widths close to those of monodisperse samples appearing at similar elution volumes; and 2) broad but multimodal chromatograms, with sharp elbows and/or narrow peaks.

First, consider the simpler case of a mass-sensitive detector (typically, a differential refractometer, DR) in combination with a molar mass calibration (in turn, obtained from narrow standards of the analyzed polymer). Due to BB (and even in the simpler case of analyzing a linear homopolymer), a whole distribution of hydrodynamic volumes (and therefore of molar masses) is instantaneously present in the DR cell. This establishes that the mass chromatogram $w(V)$ (i.e., the instantaneous mass w vs. the elution time or elution volume V) is a broadened version of a hypothetically true (or corrected) mass chromatogram $w^c(V)$, as follows:[8]

$$w(V) = \int_0^\infty g(V, \overline{V}) w^c(\overline{V}) \mathrm{d}\overline{V} \qquad (1)$$

where $g(V, \overline{V})$ is the (in general, non-uniform) BB (or spreading) function and $\overline{V}$ is a dummy integration variable that represents an average retention volume. At each $\overline{V}$, a different individual $g(V)$ function is defined. For any symmetrical $g(V)$ function, its $\overline{V}$ value is unambiguously assigned at its maximum (or mode). For skewed $g(V)$ functions, however, the average retention volume could be assigned at the mode, the mean, or any other measure of central tendency. This ambiguity in the origin of asymmetrical BB functions is still an unresolved question regarding the specification of $g(V, \overline{V})$. For uniform (or retention volume invariant) BB functions, Eq. 1 reduces to a simple convolution integral.

The molar mass calibration is normally expressed as $\log M(V)$. This calibration is obtained from narrow standards, by associating a set of average molar masses to a set of average retention volumes. If this association is carried out correctly, then the calibration is essentially unaffected by BB. When the MMD is estimated from a (broadened) mass chromatogram $w(V)$ and an unbiased (or "true") molar mass calibration $\log M(V)$, then the distribution is broader than real, the number-averaged molar mass ($\overline{M}_n$) is underestimated, and the weight-averaged molar mass ($\overline{M}_w$) is overestimated. The direct correction procedure for these biases is as follows: 1) From the knowledge of $w(V)$ and $g(V, \overline{V})$, calculate $w^c(V)$ by inversion of Eq. 1; and 2) from $w^c(V)$ and $\log M(V)$, obtain the unbiased MMD $w^c(\log M)$.

If the analyzed polymer is strictly monodisperse (both in hydrodynamic volume and in molar mass), then the corrected chromatogram $w^c(V)$ is an impulsive function, and the mass chromatogram is a direct measure of the BB function at the given $\overline{V}$. Thus, the global $g(V, \overline{V})$ could be obtained by interpolation, from a set of monodisperse (or uniform) standards. Unfortunately, uniform standards are only available for low molar masses (e.g., a pure solvent) and for some water-soluble biopolymers. "Almost" uniform standards have been produced by fractionating narrow (synthetic) standards through temperature-gradient interaction chromatography, and their chromatograms have been adequately fit with exponentially modified Gaussian (EMG) functions.[9] Inside the linear calibration range, these functions are quite uniform but skewed, with exponential decay (or tailing) toward the higher elution

volumes. However, when approaching the limit of total exclusion, the BB function becomes narrower and more skewed, and cannot be well approximated by an EMG.[9] Even for a "linear" calibration, resolution in SEC falls exponentially with increasing molar mass,[10] while the BB function remains essentially uniform.[9] For this reason, the effects of BB are particularly serious at the higher molar masses.

Apart from the use of uniform (or almost uniform) standards, other methods for determining the BB function have been developed. For example, by assuming a uniform and Gaussian BB function with a linear molar mass calibration, it is possible to use the mass and molar mass chromatograms for simultaneously estimating the standard deviation of the BB function and the calibration coefficients.[11,12] Alternatively, if the shape of the MMD is known (e.g., it is a Poisson distribution on a linear molar mass axis), then the BB function can be estimated from the difference between the (mass or molar mass) chromatogram and its theoretical prediction in the absence of BB.[13] Finally, the BB function can be theoretically predicted from a representative fractionation model.[4,7] Unfortunately, however, this approach is so far unfeasible due to the difficulty in determining the associated physicochemical parameters.

Consider the BB problem when molar mass sensitive detectors are employed. First, let us analyze the ideal case of a chromatograph fit with perfect detectors and not exhibiting BB, secondary fractionations, or interdetector volumes. In this case, the instantaneous MMD is strictly uniform, and any molar mass detector type would provide the same result:[14]

$$M(V) = K_{\mathrm{LS}} \frac{{s_{\mathrm{LS}}}^{\mathrm{c}}(V)}{w^{\mathrm{c}}(V)} = K_{\mathrm{IV}} \left[\frac{{s_{\mathrm{IV}}}^{\mathrm{c}}(V)}{w^{\mathrm{c}}(V)}\right]^{1/a} = K_{\mathrm{OS}} \frac{w^{\mathrm{c}}(V)}{{s_{\mathrm{OS}}}^{\mathrm{c}}(V)} \tag{2}$$

where ${s_{\mathrm{LS}}}^{\mathrm{c}}(V)$, ${s_{\mathrm{IV}}}^{\mathrm{c}}(V)$, and ${s_{\mathrm{OS}}}^{\mathrm{c}}(V)$ are respectively the "true," "corrected," or unbroadened chromatograms obtained from a light-scattering (LS) detector, a specific viscosity (IV) detector, and a (still under development) colligative-property osmometer (OS) detector; a is the Mark–Houwink–Sakurada exponent at the given measuring conditions; and K_{LS}, K_{IV}, and K_{OS} are calibration constants. Eq. 2 provides an unbiased (or MMD-independent) molar mass calibration log $M(V)$ that, in principle, is identical to that determined from uniform standards in a real chromatograph with BB.

The signal-to-noise ratios are generally poor at the chromatogram tails; for this reason, the signal ratios of Eq. 2 are only precise in the mid-chromatogram region. Also, the molar mass sensitive sensor is normally connected in series with the DR, and this shows that the molar mass signal slightly leads the mass signal. To correct for this bias (and independent of BB), the LS signal must be adequately shifted toward higher retention volumes prior to calculating any quality variable (e.g., the molar masses of Eq. 2).

The BB mainly occurs in the fractionation columns, and (to a first approximation) one can neglect the extra broadening introduced by the injector, the detector cells, and the interdetector capillaries. In this case, any generic chromatogram $s_k(V)$ is broadened by a common BB function $g(V, \overline{V})$ as follows:[15,16]

$$s_k(V) = K_k \int_{{V_1}^{\mathrm{c}}}^{{V_2}^{\mathrm{c}}} g(V, \overline{V}) {s_k}^{\mathrm{c}}(\overline{V}) \mathrm{d}\overline{V} \quad (k = \mathrm{DR}, \mathrm{LS}, \mathrm{IV}, \mathrm{OS}) \tag{3}$$

Note that Eq. 3 reduces to Eq. 1 for $K_{\mathrm{DR}} = 1$, $s_{\mathrm{DR}} \equiv w$, and ${s_{\mathrm{DR}}}^{\mathrm{c}} \equiv w^{\mathrm{c}}$. The instantaneous weight-, viscosity-, and number-averaged molar masses [$M_{\mathrm{w}}(V)$, $M_{\mathrm{v}}(V)$, and $M_{\mathrm{n}}(V)$, respectively] are obtained from the signal ratios:[14,17,18]

$$M_{\mathrm{w}}(V) = K_{\mathrm{LS}} \frac{s_{\mathrm{LS}}(V)}{w(V)}; \quad M_{\mathrm{v}}(V) = K_{\mathrm{IV}} \left[\frac{s_{\mathrm{IV}}(V)}{w(V)}\right]^{1/a}; \quad M_{\mathrm{n}}(V) = K_{\mathrm{OS}} \frac{w(V)}{s_{\mathrm{OS}}(V)} \quad [M_{\mathrm{w}}(V) \geq M_{\mathrm{v}}(V) \geq M_{\mathrm{n}}(V)] \tag{4}$$

Unlike $M(V)$ of Eq. 2, $M_{\mathrm{w}}(V)$, $M_{\mathrm{v}}(V)$, and $M_{\mathrm{n}}(V)$ now depend on the analyzed MMD; therefore, log $M_{\mathrm{w}}(V)$, log $M_{\mathrm{v}}(V)$, and log $M_{\mathrm{n}}(V)$ can be thought of as "biased" or ad hoc molar mass calibrations. Even if log $M_{\mathrm{w}}(V)$, log $M_{\mathrm{v}}(V)$, and log $M_{\mathrm{n}}(V)$ were perfectly accurate, the MMDs directly derived from the (broadened) mass chromatogram and any of such calibrations are distorted with respect to the true w^{c}(log M). In spite of BB, if an instantaneous variable is accurately estimated, then its corresponding global variable is also exact. Thus, the MMD represented by w(log M_{w}) produces an exact global $\overline{M}_w$ but an overestimated global $\overline{M}_n$, while the MMD represented by w(log M_{n}) produces an exact global $\overline{M}_n$ but an underestimated $\overline{M}_w$. In both cases, the global polydispersity is underestimated.[19,20] The previous observation is generalized to any other global average obtained from multidetection SEC. For example, if an instantaneous copolymer composition is accurately calculated from a signals ratio, then the global composition will also be accurate, in spite of BB.[21]

The correction for BB in SEC is still a matter of active research, and a "state of the art" review has recently been published.[14] At present, the authors are participating in an IUPAC project entitled "Data Treatment in the Size Exclusion Chromatography of Polymers"; one of the project objectives is the evaluation and standardization of existing BB correction techniques. Thus, the present article can be considered a first contribution toward that aim.

CORRECTION FOR MASS CHROMATOGRAMS WITH INDEPENDENT CALIBRATIONS

Consider the direct inversion of Eq. 1, i.e., the calculation of $w^c(V)$ from the knowledge of $w(V)$ and $g(V, \overline{V})$. First, let us transform Eq. 1 into the following equivalent discrete expression:

$$\mathbf{w} = \mathbf{G}\mathbf{w}^c \tag{5}$$

where $\mathbf{w}$ is an $(m \times 1)$-column vector containing the heights of $w(V)$ sampled at regular ΔV intervals in the elution volumes range $[V_1–V_m]$; $\mathbf{w}^c$ is a $(p \times 1)$-column vector containing the heights of $w^c(V)$ calculated at the same elution volumes but in the narrower range $[\overline{V}_1 - \overline{V}_p]$; and $\mathbf{G}$ is an $(m \times p)$ rectangular matrix representing $g(V, \overline{V})$ in the range $[\overline{V}_1 - \overline{V}_p]$. A typical sampling interval is $\Delta V = 0.1$ ml.

Specification of Matrix G[22]

For a successful inversion of Eq. 5, it is important to adequately define matrix $\mathbf{G}$. First, it is recommendable to adjust $g(V, \overline{V})$ with a continuous analytical expression, and then to calculate the heights of the individual $g(V)$ functions from that expression. Many analytical functions (e.g., a Gaussian distribution) never strictly drop to zero, and this would produce "full" $\mathbf{G}$ matrixes with positive and non-zero elements. Instead, it is preferable to set to 0 all of the "almost-null" elements of $\mathbf{G}$ (e.g., those smaller than 1% of the maximum). Also, choose $\mathbf{G}$ of minimal dimensions, in the sense that: 1) its p columns must strictly cover the range of the corrected chromatogram $[\overline{V}_1 - \overline{V}_p]$; and 2) its m rows must strictly cover the range of the measured chromatogram $[V_1–V_m]$.[22] Since, in general, the BB functions are skewed and non-uniform, it is convenient to specify each individual $g(V)$ to contain $(c + 1 + d)$ non-zero points, where c and d are the number of points before and after $\overline{V}$, respectively. Thus, the number of columns of $\mathbf{G}$ results: $p = m - c - d$, and the matrix is defined as follows:

$$\mathbf{G} = \begin{bmatrix} g(V_1,\overline{V}_1) & \cdots & 0 & \ddots & 0 \\ \vdots & \ddots & 0 & & \vdots \\ g(V_{c+1},\overline{V}_1) & & g(V_j,\overline{V}_j) & & \\ \vdots & \ddots & \vdots & \ddots & 0 \\ g(V_{c+1+d},\overline{V}_1) & & g(V_{c+j},\overline{V}_j) & & g(V_p,\overline{V}_p) \\ 0 & \ddots & \vdots & \ddots & \vdots \\ \vdots & & g(V_{c+j+d},\overline{V}_j) & & g(V_{c+p},\overline{V}_p) \\ & & 0 & \ddots & \vdots \\ 0 & \cdots & 0 & \cdots & g(V_m,\overline{V}_p) \end{bmatrix} \quad (m > p) \tag{6}$$

where each jth column of $\mathbf{G}$ contains $(c + 1 + d)$ non-zero heights of the discrete $g(V)$, with $\overline{V}_j = V_1 + (c + j - 1)\Delta V$. Note that by adopting $\overline{V}$ at the mode of $g(V)$, in each column, the largest element is c rows below the corresponding (j, j) "diagonal" element.

The direct inversion of Eq. 5 through, for example, the pseudoinverse $\hat{\mathbf{w}}^c = [\mathbf{G}^T\mathbf{G}]^{-1}\mathbf{G}^T\mathbf{w}$ (where "^" indicates estimated value) is not recommended because the square matrix $[\mathbf{G}^T\mathbf{G}]$ is generally ill-conditioned, and this produces highly oscillatory solutions with negative peaks. The propagation of errors is determined by: 1) the condition number of $\mathbf{G}^T\mathbf{G}$ (i.e., the ratio between the largest and the smallest eigenvalue of $\mathbf{G}^T\mathbf{G}$); and 2) the type and amplitude of the noise that contaminates $w(V)$.

In what follows, several BB correction techniques are presented and evaluated. To illustrate the effect of BB on the MMD, a molar mass calibration is adopted. The evaluated techniques are classified into two groups: 1) Methods I–III, which numerically invert Eq. 1 prior to calculating the MMD; and 2) Methods IV and V, which (avoiding the numerical inversion) calculate the corrected MMD in a single step. Methods I–III are more general, in the sense that they admit non-uniform and skewed BB functions. In contrast, Methods IV and V are strictly applicable to Gaussian chromatograms with Gaussian BB functions. Methods I–III have been developed to improve the (highly oscillatory) solution of the direct pseudoinverse, but at the cost of requiring an algorithm adjustment. The solutions of Methods I–III normally involve a trade-off between an excessively "rich" corrected chromatogram (with high-frequency oscillations and negative peaks) and an excessively smoothened solution (where some of the high-frequency components of the corrected chromatogram are lost).

Method I: Difference Function[23]

This iterative procedure was originally presented as Method 1 by Ishige, Lee, and Hamielec[23] and is based on the following recursive equation:

$$\Delta_i\mathbf{w} = \Delta_{i-1}\mathbf{w} - \mathbf{G}\,\Delta_{i-1}\mathbf{w}; \quad \text{with} \quad \Delta_0\mathbf{w} = \mathbf{w} \quad (i = 1, 2, \ldots) \tag{7a}$$

where i is the iteration step. After a few r iterations, $\Delta_i\mathbf{w}$ tends to almost zero, and at that point the corrected chromatogram is obtained from

$$\hat{\mathbf{w}}^c = \sum_{i=1}^{r} \Delta_i\mathbf{w} \tag{7b}$$

Method II: Singular Value Decomposition[24]

The final expression of this least-squares estimation procedure is

$$\hat{\mathbf{w}}^{c} = \sum_{k=1}^{r} \frac{\mathbf{u}_k{}^{T}\mathbf{w}}{\sigma_k}\mathbf{v}_k \quad (r \le p)$$
$$(\sigma_1 \ge \sigma_2 \ge \cdots \ge \sigma_r \ge \cdots \ge \sigma_p \ge 0) \tag{8}$$

where $\mathbf{u}_k$ and $\mathbf{v}_k$ are the eigenvectors of $\mathbf{G}\mathbf{G}^{T}$ and $\mathbf{G}^{T}\mathbf{G}$, respectively; σ_k are the singular values[24] of $\mathbf{G}$; and p is the (full) rank of $\mathbf{G}$. In Eq. 8, the number of "effective" summation terms is limited to r. The reason for discarding the lower σ_k's is to avoid amplifying the measurement noise. The lowest admissible σ_r is selected to slightly exceed the inverse of the lowest signal-to-noise ratio (normally encountered at the chromatogram tails).

Method III: Kalman Filter[25]

This fast and effective digital algorithm is based on a linear stochastic model that is equivalent to Eq. 1. The theoretical background is beyond the scope of the present article, and some knowledge on basic Kalman filtering theory is necessary for an adequate adjustment of the algorithm.[24–26] The adjustment involves estimating the variances of the measurement noise and of the expected solution.

Method IV: Rotation of the Linear Calibration[27]

Several (rather restrictive) conditions are here imposed: 1) The true mass chromatogram $w^{c}(V)$ is Gaussian (for example, because it corresponds to a Wesslau MMD and a linear calibration); 2) the BB function is uniform and Gaussian; and 3) the molar mass calibration is linear. Under these conditions, the ad hoc calibrations log $M_w(V)$, log $M_v(V)$, and log $M_n(V)$ are all linear and rotated counterclockwise with respect to the unbiased linear calibration log $M(V)$.[20,27,28] For a non-Gaussian chromatogram, the ad hoc calibrations are generally non-linear but less steep than log $M(V)$.[19,22,29] The method aims at recuperating unbiased estimates of the global averages $\overline{M}_n$ and $\overline{M}_w$ from an "effective" linear molar mass calibration defined by $M(V)|_{IV} = D_1'\exp(-D_2'V)$, with[27]

$$D_1' = D_1 \exp\left\{\frac{D_2\sigma_g{}^2[D_2(\sigma_w{}^2 - \sigma_g{}^2) - 2\overline{V}]}{2\sigma_w{}^2}\right\} \tag{9a}$$

$$D_2' = D_2 \exp\left(1 - \frac{\sigma_g{}^2}{\sigma_w{}^2}\right) \tag{9b}$$

where $\sigma_g{}^2$ and $\sigma_w{}^2$ are the variances of $g(V)$ and $w(V)$, respectively; and $\overline{V}$ is the retention volume of the chromatogram peak. Even though the method is strictly applicable to Gaussian chromatograms, it will be tested here on a non-Gaussian chromatogram (but still satisfying the other requirements of a linear calibration and a uniform and Gaussian BB).

Method V: Approximate "Analytical" Solution[30]

This approach is again based on the following (rather strict) assumptions: 1) The BB function is Gaussian (but generally non-uniform), of variance $\sigma_g{}^2(V)$; and 2) at each retention volume, the integrand of Eq. 1 can be approximated by the product of the measured chromatogram $w(V)$ and a Gaussian "correction" function of variance $\sigma_0{}^2(V)$ and averages $\overline{V}(V)$. The molar mass calibration may be non-linear, and is given by $M(V) = D_1(V)\exp[-D_2(V)V]$. The corrected chromatogram is obtained from

$$\hat{w}^{c}(V) = w(V)\left[\frac{\sigma_g(V)}{\sigma_0(V)}\right]\exp\left[-\frac{[V - \overline{V}(V)]^2}{2\sigma_0{}^2(V)}\right] \tag{10a}$$

with

$$\overline{V}(V) = V + \frac{1}{D_2(V)} \times \ln\left\{\frac{w[V + D_2(V)\sigma_g{}^2(V)]}{\sqrt{w[V - D_2(V)\sigma_g{}^2(V)]w[V + D_2(V)\sigma_g{}^2(V)]}}\right\} \tag{10b}$$

$$\sigma_0{}^2(V) = \sigma^2(V) + \frac{1}{D_2{}^2(V)} \times \ln\left\{\frac{w[V - D_2(V)\sigma_g{}^2(V)]w[V + D_2(V)\sigma_g{}^2(V)]}{w^2(V)}\right\} \tag{10c}$$

Evaluation Example

Correction methods are normally evaluated on numerical examples. This is because their real (or true) solutions are a priori known, and therefore the quality of their recuperations is properly quantified. In contrast, in real measurements, the true corrected chromatograms (and/or the true MMDs) are never exactly known. Consider, in what follows, a synthetic example that has been previously attempted on several occasions.[25,31–33]

The raw data are the corrected chromatogram $w^{c}(V)$ of Fig. 1A, the (uniform) broadening function $g(V)$ of Fig. 1A, and the linear calibration log $M(V)$ of Fig. 1B. By convolution of $w^{c}(V)$ and $g(V)$, a noise-free "measurement" was first obtained. Then, this noise-free function was rounded to the last integer;[33] this procedure is equivalent to adding a zero-mean random noise of uniform probability distribution in the range ±0.5. The resulting "chromatogram" is $w(V)$ of Fig. 1A. Note that the multimodality of $w^{c}(V)$ is lost in $w(V)$.

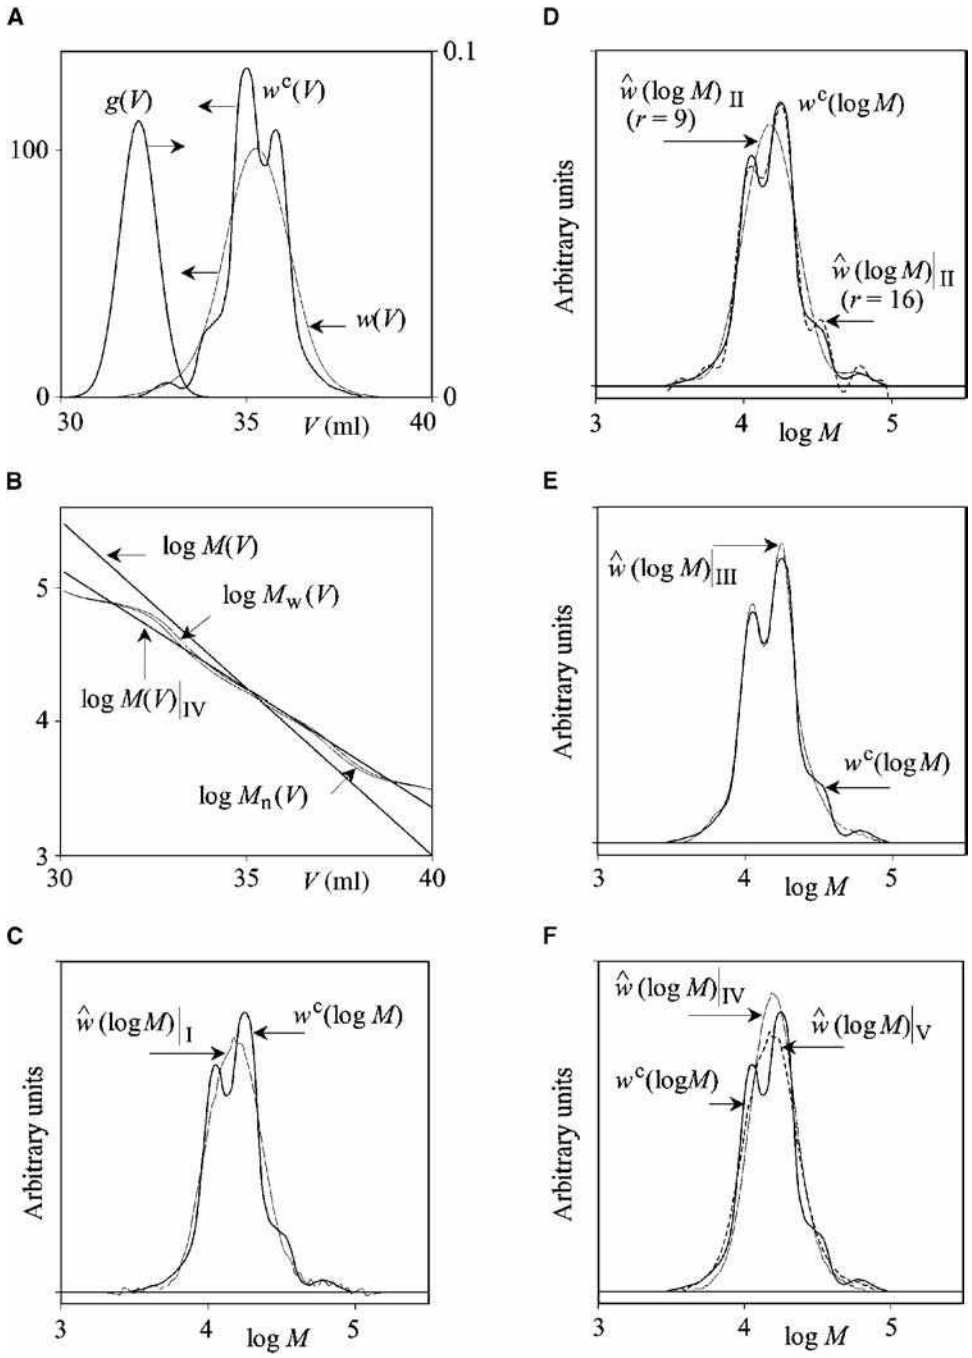

Fig. 1 Simulated example of DR detection and molar mass calibration. A) "True" mass chromatogram $w^c(V)$; uniform BB function $g(V)$; and resulting "measured" chromatogram $w(V)$. B) "True" molar mass calibration log $M(V)$; rotated "effective" calibration according to Method IV[27] log $M(V)|_{IV}$; and ad hoc calibrations assuming perfect molar mass sensors log $M_n(V)$ and log $M_w(V)$. C–F) Comparison between the true MMD $w^c(\log M)$ and its estimates according to Methods I,[23] II,[24] III,[25] IV,[27] and V,[30] respectively.

This example is particularly demanding because $w^c(V)$ is multipeaked, and the variance of $w^c(V)$ is similar to that of $g(V)$.

In previous publications,[25,31–33] only the ability of several inversion algorithms was evaluated, but not the effect of BB on the MMD. Here, the methods are compared on the basis of their performance in recuperating the true MMD. From log $M(V)$ and $w^c(V)$, the true MMD $w^c(\log M)$ of Figs. 1C–F is obtained. The aim is to estimate $w^c(\log M)$ from $w(V)$, $g(V)$, and log $M(V)$. Note that the selection of a uniform and Gaussian BB is not an impediment to adequately evaluating the (more comprehensive) Methods I–III.

In Fig. 1C–F, the MMDs recuperated through Methods I–V are compared with the real distribution; Table 1

presents the real and estimated average molar masses and polydispersities. In Method I, the best results were found after only 4 iterations (Fig. 1C). In Method II, the signal-to-noise ratio at the chromatogram tails suggested truncation of the summation of Eq. 8 at $r = 16$ (while the full rank of $\mathbf{G}$ is $p = 61$). The resulting solution exhibits a negative oscillation (Fig. 1D); and for comparison, the less "rich" solution with $r = 9$ is also presented. The Kalman filter of Method III was adjusted as follows: 1) The measurement noise variance was assumed time invariant, and estimated from the baseline noise; and 2) the solution variance was assumed time varying, and estimated by simply squaring the measured chromatogram heights (Fig. 1E). For Method IV, the "effective" linear calibration was calculated through Eq. 9, and is presented in Fig. 1B. In Method V, it was verified that (for a linear calibration) the solution becomes almost independent of $D_2(V)$.[30] The solutions of Methods IV and V are shown in Fig. 1F.

In relation to Methods IV and V, the instantaneous MMDs were simulated with the aim of calculating the (noise-free) calibrations $\log M_n(V)$ and $\log M_w(V)$ (Fig. 1B). These functions were obtained from the (noise-free or non-truncated) mass chromatogram in order to illustrate their "true" shapes in the complete range of the measured chromatogram. The resulting ad hoc calibrations are non-linear, generally less steep than $\log M(V)$, and close to the "effective" linear calibration $\log M(V)|_{IV}$ (Fig. 1B).

The following is observed. Only Method III (and to a lesser extent Method II with $r = 16$) was capable of recuperating the fine details of the true MMD, while all the other techniques yielded unimodal solutions. Methods III and II considerably improve the highly oscillatory direct pseudoinverse solution (not presented here for space reasons). The recuperated average molar masses of Table 1 are in all cases quite acceptable.

CORRECTION METHODS FOR MOLAR MASS SENSITIVE DETECTORS

Now, we wish to determine an unbiased MMD from measurements of mass and molar mass sensitive detectors. Rewrite Eq. 3 as follows:

$$\mathbf{s}_k = K_k \mathbf{G} \mathbf{s}_k^{\,c} \quad (k = \text{DR, LS, IV, OS}) \tag{11}$$

where $\mathbf{s}_k$ is an $(m \times 1)$-column vector containing the non-zero heights of $s_k(V)$, sampled at regular ΔV intervals; $\mathbf{s}_k^{\,c}$ is a $(p \times 1)$-column vector containing the non-zero heights of $s_k^{\,c}(V)$; and $\mathbf{G}$ is the $(m \times p)$ rectangular matrix of Eq. 6.

Inversion Methods

Two methods are described.[15,22] They both aim at correcting the raw chromatograms for BB prior to calculating the MMD, and are strictly applicable to linear homopolymers. Netopilík[15] proposed an iterative procedure for simultaneously estimating the MMD and the standard deviation of a uniform and Gaussian BB function (σ_g). The procedure is as follows: 1) Select a σ_g value; 2) estimate $w^c(V)$ and $s_k^{\,c}(V)$ by inversion of Eqs. 1 and 3, respectively; 3) use Eq. 2 for estimating a molar mass calibration $\log \widehat{M}(V)$; and 4) iterate until the slope of $\log \widehat{M}(V)$ coincides with that of an (independently determined) molar mass calibration. The method was theoretically tested on a narrow Schulz–Zimm MMD; while the original distribution was well recuperated, the standard deviation differed considerably from its original value.[15]

More recently, Vega and Meira[22] proposed a numerical method that does not impose any restriction on the shapes of the MMD or the BB function, and only implies a linear calibration in the range of the measured chromatograms. This last requirement is generally satisfied (especially if the MMD is narrow), and it is also easily verified from an independent calibration with narrow standards. The method is as follows: 1) Estimate $w^c(V)$ and $s_k^{\,c}(V)$ by inversion of Eqs. 1 and 3, respectively; 2) calculate an unbiased molar mass calibration $\log \widehat{M}(V)$ through Eq. 2, and use its mid-chromatogram region to adjust a linear calibration $\log \widehat{M}_{lin.}(V)$; and 3) from $\hat{w}^c(V)$ and $\log \widehat{M}_{lin.}(V)$ estimate the unbiased MMD $\hat{w}^c(\log \widehat{M}_{lin.})$.[22] Note the following: a) Any of the previously described Methods I–III can be used for solving step 1; b) by extrapolating a linear calibration toward the chromatogram tails, the technique also solves the problem of an oscillatory ad hoc calibration; and c) the resulting $\log \widehat{M}_{lin.}(V)$ can be verified with an independent calibration with narrow standards of the analyzed polymer.

Table 1 Simulated example that assumes a mass chromatogram, a linear calibration, and a Gaussian BB function: "true" and recuperated average molar masses.

	"True" values	Without BB correction	Correction method no.					
				II				
			I ($i = 4$)	($r = 9$)	($r = 16$)	III	IV	V
$\overline{M}_n$	13 975	13 464	14 029	13 993	14 033	14 084	14 871	14 038
$\overline{M}_w$	17 342	18 041	17 315	17 310	17 313	17 156	17 224	17 335
$\overline{M}_w/\overline{M}_n$	1.241	1.340	1.234	1.237	1.234	1.218	1.158	1.235

Reconsider the numerical example of Vega and Meira.[22] The basic raw data are: 1) the "true" or corrected mass chromatogram $w^c(V)$ of Fig. 2A; 2) the molar mass calibration $\log M(V)$ of Fig. 2C; and 3) the non-uniform and skewed broadening function $g(V, \overline{V})$ of Fig. 2A. All of these functions are discrete, with their heights sampled every $\Delta V = 0.1$ ml. The true mass chromatogram contains $p = 70$ non-zero points in the range

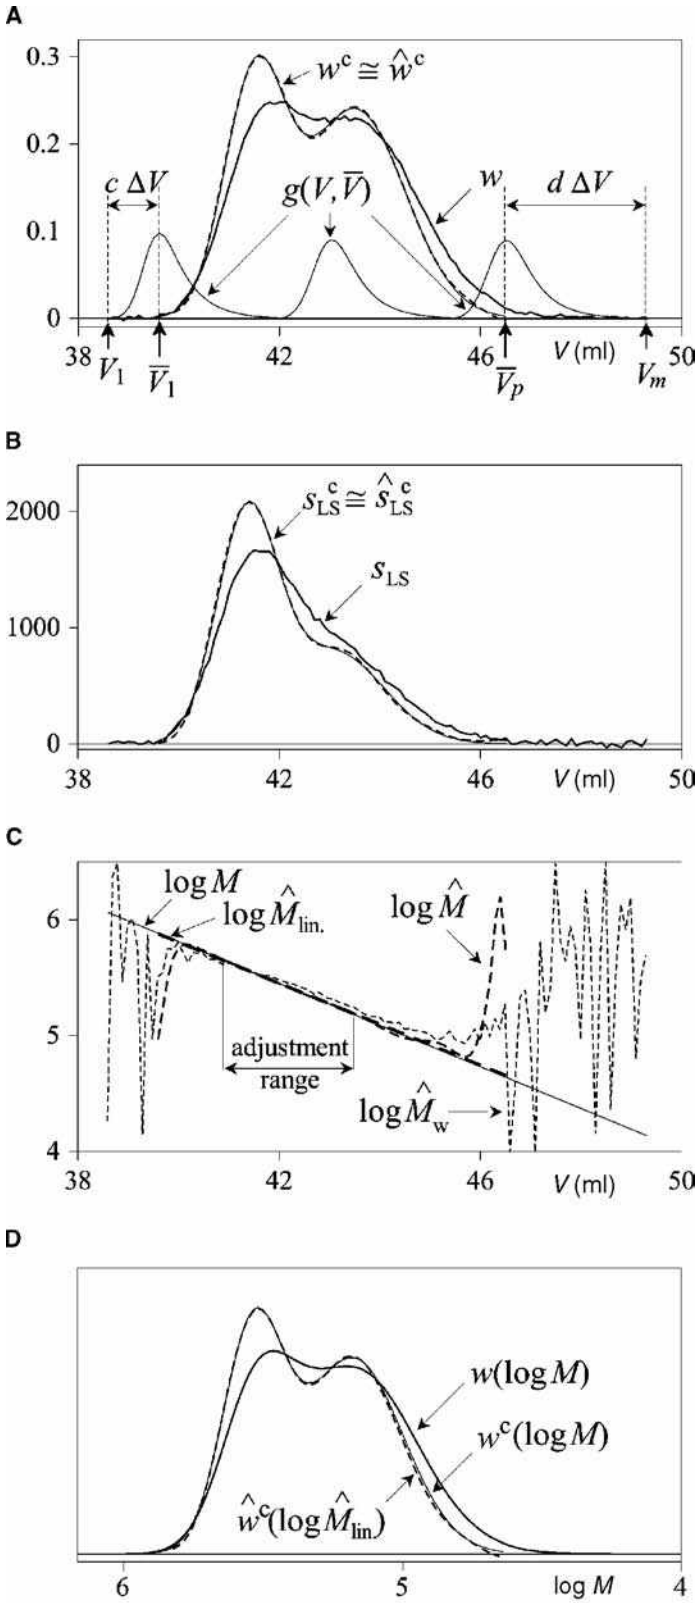

Fig. 2 Simulated example of DR/LS detection (after Ref. 22). A) "True" and "measured" mass chromatograms [$w^c(V)$, $w(V)$]; three samples of the BB function $g(V, \overline{V})$; and estimated corrected chromatogram [$\hat{w}^c(V)$]. B) "True" and "measured" molar mass chromatograms [$s_{LS}{}^c(V)$, $s_{LS}(V)$]; and estimated corrected molar mass chromatogram $\hat{s}_{LS}{}^c(V)$. C) Unbiased linear calibration [$\log M(V)$]; estimated ad hoc calibration [$\log \widehat{M}_w(V)$]; estimated unbiased calibration [$\log \widehat{M}(V)$], and estimated linear unbiased calibration [$\log \widehat{M}_{lin.}(V)$]. D) "True" MMD [$w^c(\log M)$]; MMD estimate obtained from $w(V)$ and $\log M(V)$ [$w(\log M)$]; and MMD estimate obtained from $\hat{w}^c(V)$ and $\log \widehat{M}_{lin.}(V)$ [$\hat{w}^c(\log \widehat{M}_{lin.})$].

Table 2 Simulated example for molar mass sensitive detectors: "true" and recuperated average molar masses from several MMDs.

MMD	$\overline{M}_n$	$\overline{M}_w$	$\overline{M}_w/\overline{M}_n$
$w^c(\log M)$[a]	182 000	242 000	1.33
$w(\log M)$[b]	160 000	224 000	1.40
$w(\log M_n)$[c]	182 000	233 000	1.28
$w(\log M_w)$[d]	191 000	242 000	1.27
$\hat{w}^c(\log \hat{M}_{lin.})$[e]	185 000	243 000	1.31

[a]"True" base distribution (Fig. 2D).
[b]Based on the linear calibration, without BB correction (Fig. 2D).
[c]Obtained from DR/OS detection, without BB correction.
[d]Obtained from DR/LS detection, without BB correction.
[e]Obtained from DR/LS detection, with BB correction (Fig. 2D).

$[\overline{V}_1 - \overline{V}_p]$, and it is presented in Fig. 2A. Then, the "true" molar mass chromatogram was calculated by assuming the relationship: $s_{LS}{}^c(V) = 0.02[M(V)w^c(V)]$ (Fig. 2B).

From $w^c(V)$ and $\log M(V)$, the "true" MMD $w^c(\log M)$ of Fig. 2D was obtained, and its average molar masses are shown in the second row of Table 2. The $\log M$ values of Fig. 2D vertically correspond (through the linear calibration) with the V values of Figs. 2A–C.

The non-uniform $g(V, \overline{V})$ is represented by an EMG of constant skewness, variable standard deviation, and $\overline{V}$ averages adopted at the peaks of the individual $g(V)$ functions. Each $g(V)$ exhibits 39 non-zero points (with $c = 10$ points before the maximum and $d = 28$ points after the maximum). In Fig. 2A, only the two limiting and one intermediate $g(V)$ functions are presented. The (noise-free) mass and molar mass chromatograms were calculated through Eqs. (1) and (3). Then, the "measured" chromatograms $w(V)$ and $s_{LS}(V)$ of Figs. 2A,B were obtained by adding a zero-mean Gaussian noise to the noise-free chromatograms. The broadened chromatograms contain $m = 70 + 39 - 1$ non-zero points. From $w(V)$ and $\log M(V)$, the (broadened) MMD $w(\log M)$ of Fig. 2A was obtained; its average molar masses are given in the third row of Table 2. Both averages are underestimated, while the global polydispersity is overestimated. The underestimation of the average molar masses is a result of having adopted the $\overline{V}$ averages at the maxima of skewed $g(V)$ functions.

At each retention volume of $w(V)$, the instantaneous MMDs in the detector cells were calculated by considering the contributions (toward that V) of all the hypothetical molecular species in the distribution, as determined by the discrete $w^c(V)$. From such instantaneous distributions, the ad hoc non-linear calibrations $\log M_n(V)$ and $\log M_w(V)$ were calculated.[22] From $w(V)$, $\log M_n(V)$, and $\log M_w(V)$, the MMD estimates $w(\log M_n)$ and $w(\log M_w)$ were obtained; their averages are presented in Table 2. As expected, $w(\log M_n)$ accurately estimates $\overline{M}_n$ but underestimates $\overline{M}_w$, while $w(\log M_w)$ accurately estimates $\overline{M}_w$ but overestimates $\overline{M}_n$. Thus, the global polydispersity is underestimated in both cases.

In a standard data treatment without BB correction, $M_w(V)$ would have been directly estimated from $\hat{M}_w(V) = s_{LS}(V)/[0.02w(V)]$. Due to the measurement noise, the resulting $\log \hat{M}_w(V)$ of Fig. 2C is oscillatory at the chromatogram tails, and these oscillations make it impossible to recuperate an MMD.

The proposed procedure was applied to the noisy chromatograms $w(V)$ and $s_{LS}(V)$. The dimension of $\mathbf{G}$ is $(m \times p) = (108 \times 70)$; the inversions were carried out through the singular value decomposition expression of Eq. 8. The algorithm was adjusted with the criterion of producing smooth solutions with minimal negative peaks, yielding $r = 14$ for the mass chromatogram and $r = 12$ for the molar mass chromatogram. The final estimates were $\hat{w}^c(V)$ and $\hat{s}_{LS}{}^c(V)$ of Fig. 2A,B. These functions are smooth and almost coincident with the true $w^c(V)$ and $s_{LS}{}^c(V)$.

The resulting (unbiased) calibration of Fig. 2C, $\log \hat{M}(V)$, almost overlaps the "true" $\log M(V)$ in the mid-chromatogram region, while it diverges at the tails. The linear calibration $\log \hat{M}_{lin.}(V)$ was obtained from the points of $\log \hat{M}(V)$ contained in the "adjustment range" of Fig. 2C. Finally, the unbiased distribution $\hat{w}^c(\log \hat{M}_{lin.})$ of Fig. 2D was obtained from $\hat{w}^c(V)$ and $\log \hat{M}_{lin.}(V)$. This distribution is smooth and close to the "true" $w_c(\log M)$. Accordingly, the estimated average molar masses are very close to the real values (Table 2).

Direct Calculation of the Corrected MMD

The interdetector volume compensation generally involves shifting the (leading) molar mass signal toward higher elution volumes. Independent of this compensation, a BB correction procedure has been proposed, which calculates the MMD in a single step by appropriately reducing the normal interdetector volume shift.[34] The procedure is equivalent to rotating the linear molar mass calibration counterclockwise.[28,35,36] Therefore, it is based on the following (rather strict) assumptions: 1) Both the (uniform) BB function and the measured mass chromatogram are Gaussian functions of (known) standard deviations σ_g and σ_w, respectively; 2) the calibration is linear and given by $M(V) = D_1 \exp(-D_2 V)$; and 3) the interdetector volume introduces a pure signal shift, but no additional BB. In the case of an LS/DR combination, the LS signal must suffer a (secondary) shift that involves a small reduction in the normal lag. This secondary lag reduction is given by

$$\Delta V_{LS} = \sigma_{w^c}(\sigma_w - \sigma_{w^c})D_2 \tag{12a}$$

with

$$\sigma_{w^c} = (\sigma_w{}^2 - \sigma_g{}^2)^{1/2} \tag{12b}$$

where σ_{w^c} is the standard deviation of the corrected chromatogram.

The commercially available molar mass sensitive detectors do include a correction for BB in their software. Unfortunately, the applied correction procedures are not fully disclosed, but they seem to involve an interdetector volume readjustment. For example, the Viscotek™ Model 200 detector combines a DR in parallel with a specific viscometer. First, the (mass and molar mass) chromatograms of several narrow standards must be measured to determine the interdetector volume and a (uniform EMG) BB function. Then, the MMD is corrected for BB in an unspecified manner. Similarly, Wyatt Corp. has recently introduced a patented BB correction procedure for their triple-detector system (multiangle LS, DR, and specific viscosity sensors).

CONCLUSIONS

Band broadening correction in SEC is still not a totally resolved issue, even when the MMD of a linear homopolymer is determined with a mass detector and a molar mass calibration. Fortunately, modern SEC columns are highly efficient, and the correction for BB is mainly limited to the case of narrowly distributed polymers. Even in the presence of BB, if an instantaneous quality variable is accurately measured, its corresponding global average will also be accurate.

Numerical inversion techniques aim at correcting the raw chromatograms prior to determining the MMD or any other polymer quality characteristics. Their main advantage is that they admit arbitrary shapes for the chromatograms or the BB function. Their disadvantage, however, is the ill-posedness of numerical inversions, which amplify the measurement noise. With molar mass sensitive detectors, two independent inversions are required prior to calculation of the molar masses. From the comparison of Methods I–III, Method II (a singular value decomposition technique) has shown a good compromise between a reasonably good solution and a relatively simple adjustment procedure. To improve the ill-conditioned nature of the numerical inversions, it is important to set to zero all the ultra-low elements of the BB matrix (normally placed at its upper-right and lower-left corners).

The techniques that avoid numerical inversions, correct the MMDs in a single step, and are based on either: 1) rotating the linear calibration (when only a mass chromatogram and a linear calibration are available); or 2) modifying the interdetector volume shift (when molar mass sensitive detectors are employed). Their main advantage is that they produce smooth and unique solutions. Their limitation, however, is that they produce only approximate solutions.

In general, the BB function seems to be moderately uniform in the linear calibration range, but definitely skewed toward the higher retention volumes. Its determination is only simple for low molar masses. In general, the BB function would be simpler to specify if the manufacturers of narrow standards provided the true MMDs of their samples.

A proper correction for BB and other sources of error seems essential for quantitative determinations in SEC. The following developments are expected in the future: 1) simpler techniques for determining the BB function; 2) a validation of several BB algorithms on real experimental data; and 3) a standardization of the "best" BB correction procedures (possibly, a trade-off between accuracy and simplicity).

Band Broadening in SEC

Jean-Pierre Busnel
Physical Chemistry of Material Polymers, University of Main, Le Mans, France

INTRODUCTION

In classical chromatography, band broadening (BB), which defines the shape of the chromatogram of a pure solute, is one of the factors limiting the resolution, but individual peaks are generally observable and the discussion of BB extent is direct. In size-exclusion chromatography (SEC), the situation is more complex, as we observe, generally, only the envelope of a large number of individual peaks (Fig. 1). Imperfect resolution and its consequences on results cannot be directly observed. A few years after the pioneer publication on SEC by Moore,[1] Tung[2] presented the general mathematical problem of band-broadening correction (BBC). Until 1975, a number of simplified procedures have been proposed in order to compensate for the limited resolution of columns. After 1975, a spectacular increase in column resolution rendered the problem less important, but, recently, there is a growing interest in BBC as SEC users intend to obtain more and more detailed information on molecular-weight distributions (MWDs) and not only average MW values. For this reason, this discussion is separated into three parts:

- Experimental determination of extent of BB.
- Interpretation of BB processes.
- Correction methods for BB.

Experimental Determination of the Extent of Broad-Banding

It is useful to choose a solute which is really eluted by a size-exclusion process, without adsorption or any additional interaction phenomena which might modify the shape of the peak. The most trivial method is to analyze the shape of a low-MW pure substance. This is usually used to determine the number of theoretical plates, $N = (V_r/\sigma)^2$ where V_r is the retention volume (volume at peak top) and σ is the standard deviation. σ can be computed from the weighing of each data point of the peak or can be estimated from the width at 10% maximum height ($\sigma = W_{0.1}/4.3$).

For this reason, when using tetrahydrofuran (THF) as eluent and styrene/DVB gels, methanol or toluene are not good candidates; octadecane is preferred. For aqueous SEC, saccharose is the classical standard.

For polymers, a number of authors have claimed that the peak width increases as the MW increases, but to discuss BB for polymers, several precautions are required. First, it is necessary to be sure that the injected solution is sufficiently dilute to prevent any viscous effect. (Practically no viscous effect is observable, even for narrow standards when $[\eta]C < 0.1$; for flexible polymers, this corresponds roughly to a concentration <1 mg/ml for MWs up to 500,000; for a higher MW, it is necessary to reduce the concentration.) Then, the real difficulty is to analyze very narrow standards for which polymolecularity is sufficiently low, so as not to participate in the peak width, or at least which polymolecularity is very precisely known.

Commercial indications on standards are in progress, but suppliers rarely guarantee the exact value for $I_p = M_w/M_n$. A tendency is to guarantee that I_p is lower than a given value, but that is not sufficient for precise BB study. Usual values for medium MW standards are $I_p < 1.03$ and $I_p < 1.05$ for high MW standards; the situation is worse for aqueous SEC with values around 1.1.

Recently, possibilities appeared with the results from thermal gradient interaction chromatography (TGIC).[3] That method has a much better resolution than SEC and allows a very precise determination of I_p. It is even possible to use it for a preparative scale to obtain extremely narrow standards, but, until now, it is only available for organic-soluble standards.

With all these precautions and when using modern columns, it clearly appears that peaks are not Gaussian, but systematically skewed. New computing facilities allow one to analyze more precisely such peaks by various functions. The best results seems to be obtained by exponentially modified gaussian (EMG) functions,[4] which are the convolution of a Gaussian dispersion and an exponential decay. In that case, two parameters define the shape of the peak s and t, which allow quantitative mapping of BB characteristics for further correction. Generally, σ and τ are constant or admit a limited increase with MW for samples eluted well after the void volume. However, a dramatic increase of σ and τ occurs near the total exclusion volume.[5]

BAND-BROADENING INTERPRETATION

As previously indicated, this discussion is organized for chromatograms from very narrow polymer standards for which we can consider that the effect of molecular weight

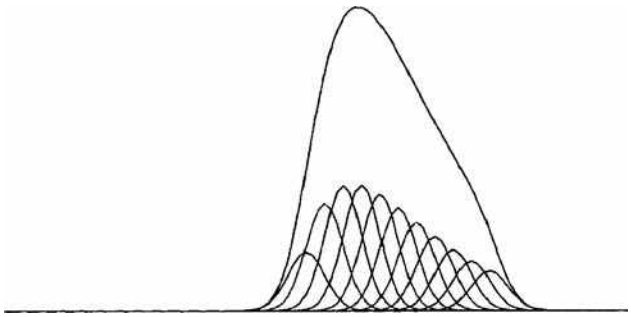

Fig. 1 Example of imperfect resolution: 10 peaks, $R = 0.25$ between neighbors.

distribution is negligible and for which the unique separation process is size exclusion. With these limitations, the contribution to band broadening is conveniently separated into extra column effects, eddy dispersion, static dispersion, and mass transfer. In the most classical chromatographic interpretation, extra-column effects are not discussed and the three other contributions are considered as Gaussian, so there is simply the addition of their variances. The number of theoretical plates is defined as $N = (V_e/\sigma)^2$ and the influence of υ, the linear velocity of the eluent, is summarized by the so-called Van Deemter equation:

$$H = \frac{L}{N} = a + \frac{b}{\upsilon} + c\upsilon$$

This classical interpretation is not sufficient, as experimental results clearly indicate that there is peak skewing; for this reason, it is useful to study each contribution separately.

Static Dispersion

This classical contribution corresponds to the diffusion of the sample along the axis of the column by Brownian motion during the time t_0 spent in the interstitial volume. That spreading effect is Gaussian and its standard deviation σ is related to D, the diffusion coefficient of the solute: $\sigma = (2Dt_0)^{1/2}$. In classical operating conditions in modern LC, that contribution is generally a minor one, due to the use of relatively high flow rate. In SEC, the diffusion coefficients of polymers are very low and that contribution becomes negligible.

Extra-Column Effects

Generally, these effects are not discussed in detail, considering it is only necessary to select a chromatographic apparatus with a proper design to render these effects negligible. Recent results indicate that this situation tends to be different for macromolecular solutes. Using a chromatographic apparatus for which the column is replaced by tubings of various lengths, the end of elution is characterized by an exponential decay, the time of which is dependent not only on geometry but also strongly increases for high-MW solutes. The explanation is related to the more or less rapid averaging of radial positions of the solute in a cylindrical tube. In the case of high-molecular-weight solutes, the diffusion coefficient is small. Solute molecules which enter near the center of the tube stay in the high-velocity zone and those which enter near the walls stay in low velocity zones; this introduces skewing which is much more important than for low-molecular-weight solutes.

Eddy Dispersion

This contribution is related to the variety of channels available for any solute molecule throughout the elution process. These channels are defined by the interstitial volume between the beads of the column package, so they correspond to a variety of shapes and flow velocities. This produces a distribution in elution time which is classically considered as Gaussian and weakly depends on flow rate. As a rule of thumb, the theoretical plate height corresponding to this effect can be considered as being equal to the bead diameter of the packing for well-packed columns.

More detailed results take into account a "wall effect" to explain why elution profiles are skewed, even for non-retained solutes in modern columns. Detailed experimental results were recently presented by Farkas and Guiochon[6] on the radial distribution of flow velocity using local multichannel detection devices. On average, the flow velocity is very homogeneous in the center of the column, but, inevitably, it becomes lower near the walls. Similarly, the peak shape from a local microdetector situated near the wall is clearly distorted and skewed compared with that of a similar detector situated near the center of the column.

Mass Transfer

The simple model of a theoretical plate, which is simply the affirmation of the existence of N successive equilibrium steps, is not satisfactory, as it assumes a Gaussian spreading.

To obtain more realistic information, it is necessary to discuss the rate of exchange between the interstitial volume and pores.[7] Potschka[8] proposed taking into account the competition between diffusion and convection in the special situation of "perfusion chromatography," where very large pores exist inside the beads, which allow some distribution of the solute by convection.

Recently, a model has been proposed for which pores are simply long cylinders and time of residence corresponds to a one-dimension Brownian motion.[5] Exact mathematical expressions are available for describing that process[9] and the distribution of such time of residence is highly skewed. Additionally, for each solute

molecule, the number of visited pores obeys a Poisson distribution, and when the average number of visits becomes small, the distribution of elution time becomes wider and more skewed. That explains, precisely, why strong peak distortion is observed for samples eluted near the total exclusion limit.

Band-Broadening Correction

As first stated by Tung, the general starting point is that the experimental chromatogram $H(V)$ (from a concentration detector) is the convolution of $g(V, V_r)$, the spreading function defining the elution of a single species with a peak apex position of V_r, and $w(V_r)\,dV_r$, the weight fraction of species which peak apex, is between V_r and $V_r + dV_r$:

$$H(V) = \int_{V_1}^{V_2} g(V, V_r) w(V_r) dV_r$$

In any case, a second step consists of converting $w(V_r)$ into $w(M)$ by defining a calibration curve which correlates M and V_r.

As there is only a finite number of data points and, with some instrumental noise, generally such an inversion problem is ill-defined, the stability of the values of $w(V_r)$ depends on the algorithm which is used. Among the huge number of articles treating such problems, a review by Meira and coworkers[10] gives useful information on the mathematical aspects and a detailed review by Hamielec[11] presents a variety of instrumental situations, from the simplest one (constant Gaussian spreading function and simple concentration detector) to the most complex (general spreading function, multidetection).

To take into account experimental evidence which clearly indicates systematic skewing, this discussion will no longer concern methods limited to Gaussian spreading functions.

SIMPLEST SITUATION: CONSTANT SPREADING FUNCTION, LINEAR CALIBRATION CURVE, SINGLE CONCENTRATION DETECTOR

This situation corresponds to a useful approximation in many cases, and it is almost strictly exact when the sample has a narrow MWD. From the chromatogram of an ideal isomolecular sample, considering that it is defined by a set of h_i values equidistant on the elution volume axis, classical summations give the uncorrected molecular-weight values:

$$M_{n_{\text{uncorrected}}} = \frac{\Sigma h_i}{\Sigma (h_i / M_i)} \quad \text{and} \quad M_{w_{\text{uncorrected}}} = \frac{\Sigma (h_i M_i)}{\Sigma h_i}$$

and the peak apex position gives the real molecular weight: M_{peak}.

Therefore, two correction factors exist for M_n and M_w:

$$K_n = \frac{M_{\text{peak}}}{M_{n_{\text{uncorrected}}}} \quad \text{and} \quad K_w = \frac{M_{peak}}{M_{w_{\text{uncorrected}}}}$$

For any other isomolecular sample analyzed on the same system, the change is simply a shift along the elution volume axis and each value M_i is multiplied by the same factor. Thus, the correction factors are unchanged. Finally, any broad MW sample analyzed on the same system is the addition of a set of isomolecular species; therefore, when summing, there is factorization of the correction factors and

$$M_{n_{\text{corrected}}} = K_n M_{n_{\text{uncorrected}}}$$
$$M_{w_{\text{corrected}}} = K_w M_{w_{\text{uncorrected}}}$$

This very simple BBC can always be used, at least to give a preliminary indication of the extent of BB. When using extremely narrow standards, as obtained by preparative TGIC, the result is accurate; more easily, it is possible to set the correction factors between two limits: lower one using data from a low-MW pure chemical and a higher limit using data from an imperfect narrow standard.

GENERAL SITUATION: SPREADING FUNCTION DEPENDS ON ELUTION VOLUME AND CALIBRATION CURVE IS NOT LINEAR, SINGLE CONCENTRATION DETECTOR

In such cases, as stated by Meira and coworkers,[10] the quality of results depends on computational refinements. It is necessary to add specific constraints related to the chromatographic problem: rejection of negative values or unrealistic fluctuations in the weight distribution. The normal way is to invert the large matrix defining the spreading function for any position on the elution volume scale. With modern computational facilities, that becomes easy, but it is still not trivial to obtain stable results, and proper filtering processes are useful.

Good results can be obtained by using a more direct iterative method which can be briefly presented: n equidistant values are chosen on the elution volume scale; let us note these values as V_i (typically, n can be 200). Any sample is arbitrarily defined as the sum of n isomolecular species, whose positions at the peak apex are V_j. For each peak j, n values of heights h_{ij} for each V_i value are computed, normalizing the surface (the peak shape is defined by interpolation from experimental BB data).

The chromatogram corresponding to the sample is defined by a set of n H_i values at positions V_i.

To define the weight distribution of the sample, it is simply necessary to adjust a set of w_i values until the summation converges toward the experimental H_i values.

For the first attempt, $w_i = H_i$. This gives, by addition, a chromatogram ($H1_i$). Then, $w_i = w_i{*}H_i/H1_i$; that gives $H2_i$ and so on until convergence.

The method is reasonably efficient. Stable convergence is observed except for very large samples for which the problem is too severely ill-conditioned. Applying it to narrow PS standards allows one to find, again, the true polymolecularity index.

MULTIDETECTION PROBLEM

The aim of multidetection, especially LS/DRI coupling, is to find a useful calibration curve directly from the sample data and without external information from standards. A crude calibration curve is obtained by plotting, on a semilogarithmic scale, the instantaneous weight average M_{wi} values for each data point at elution volume V_i. At this point, correction for BB is rarely used, as the accuracy of the calibration curve is generally poor and does not justify sophisticated corrections. Additionally, for complex polymers (blends, copolymers, branched polymers, etc.), a variety of molecular weights are eluted at the same position, even in the absence of band broadening,[12] so it is still very difficult to propose a general solution for the problem and results are available only for simplified situations. Normally, it would be necessary to find the exact weight distribution w_i as in the preceding paragraph, simply using the DRI signal; then, it becomes possible to adjust the calibration curve until the calculated M_{wi} values converge toward the experimental set of M_{wi} values.

CONCLUSIONS

Band broadening in SEC has several specific aspects, compared with other chromatographic processes. Solutes may have very low diffusion coefficients and that introduces additional tailing due the imperfect averaging of radial positions all along the tubing. Mass transfer can be described from Brownian motion properties, and for samples eluted near total exclusion volume, as the number of visited pores become small, this introduces a significant increase of skewing and a very important loss of resolution.

For correcting band broadening, the main difficulty is in obtaining precise mapping of the spreading function of the system. Normally, this needs very high quality standards and TGIC offers new possibilities in that area. Computational techniques are now sufficiently efficient to solve the general inversion problem associated with band-broadening correction, but it still needs some precautions to obtain stable results without artificial oscillations. Finally, as corrections become very important and unstable near total exclusion volume, it remains very imprudent to interpret data when part of the sample is totally excluded. It is better to first find a well-adapted column set, able to efficiently fractionate the whole sample.

Barbiturates: CE Analysis

Chenchen Li
College of Chemistry and Molecular Engineering, Peking University, Beijing, China

Huwei Liu
Institute of Analytical Chemistry, Peking University, Beijing, China

INTRODUCTION

Capillary electrophoresis (CE) is becoming a popular analytical tool for determining drugs because of its simplicity, high speed, and high efficiency. The present review studies different modes of CE used in the determination and chiral separation of barbiturates, as well as current developments in sample preparation for barbiturates in biological fluids. The comparison of different modes of CE with other separation approaches is also discussed.

BARBITURATES

Barbiturates, derivatives of barbituric acid, are found in a variety of pharmaceuticals, such as sedatives, hypnotics, and antiepileptics. However, their levels in body fluids have to be regulated within a narrow therapeutic window to avoid toxicity. Therefore determination of barbiturates in serum, plasma, and urine is important for investigation of intoxication, therapeutic drug monitoring, and pharmacokinetic and metabolic studies. Hence, many instrumental approaches for the analysis of barbiturates in body fluids, including immunoassays[1] and chromatographic methods, such as gas chromatography (GC),[2] gas chromatography/mass spectrometry (GC/MS),[3] and high-performence liquid chromatography (HPLC),[4–6] have been developed. Immunological techniques offer high performance, speed of analysis, and sensitivity. However, they are not specific enough to distinguish a single compound because barbiturates interfere with each other. Chromatographic methods have been applied for the determination of all common barbiturates, even while they require time-consuming sample pretreatment and are characterized by a low sample throughput.[7]

In recent years, CE has been successfully applied in the field of biochemical and analytical chemistry. It has been found to be attractive for pharmaceutical analysis because of its advantages related to excellent separation efficiency, high mass sensitivity, minimal use of samples and solvents, and the possibility of using different direct and indirect detection systems. This review focuses on analytical assays for barbiturates by CE.

SAMPLE PREPARATION FOR BARBITURATES IN BODY FLUIDS

Sample preparation is important here because matrices of biological fluids are so complicated that interfering signals are likely to appear in typical separation-based determinations. Among various sample preparation techniques, there are two major approaches combined with CE: liquid–liquid extraction (LLE) and solid-phase extraction (SPE) [or solid-phase microextraction (SPME)].

Liquid–Liquid Extraction

LLE with chloroform from acidified serum is widely executed[7–11] after the method of Shiu and Nemoto.[12] However, chloroform is of great toxicity and is not suitable for routine use. LLE with pentane at pH 6.4[7] was investigated for feasibility with seven barbiturates and was found to be specific for thiopental—an important barbiturate being used for anaesthetic medication and treatment of head trauma with severe brain injury. Comparing acetonitrile deproteinization with chloroform deproteinization, Shihabi demonstrated the feasibility of acetonitrile for extraction of pentobarbital. However, electropherograms obtained by extraction with chloroform are more sensitive and cleaner.[9] Wu et al.[10] used LLE with ether for extraction from serum, and chloroform for extraction from urine. They obtained recoveries of six barbiturates from 86.6% to 118%.

Solid-Phase Extraction and Solid-Phase Microextraction

Although LLE is useful, it is being replaced by SPE or SPME because LLE is a time-consuming and laborious process that involves consumption of large volumes of organic solvents. The use of SPE for subsequent analysis is achieved in one step, and the results have shown that this is a reproducible, safe, convenient, and time-saving alternative to LLE. Most SPE applications use disposable cartridges or columns packed with C_{18}-bonded silica, which is the most classic packing for this technique.[7,10,11,13,15] Moreover, SPME is based on partition equilibrium of target compounds between the sample matrices and a polymeric

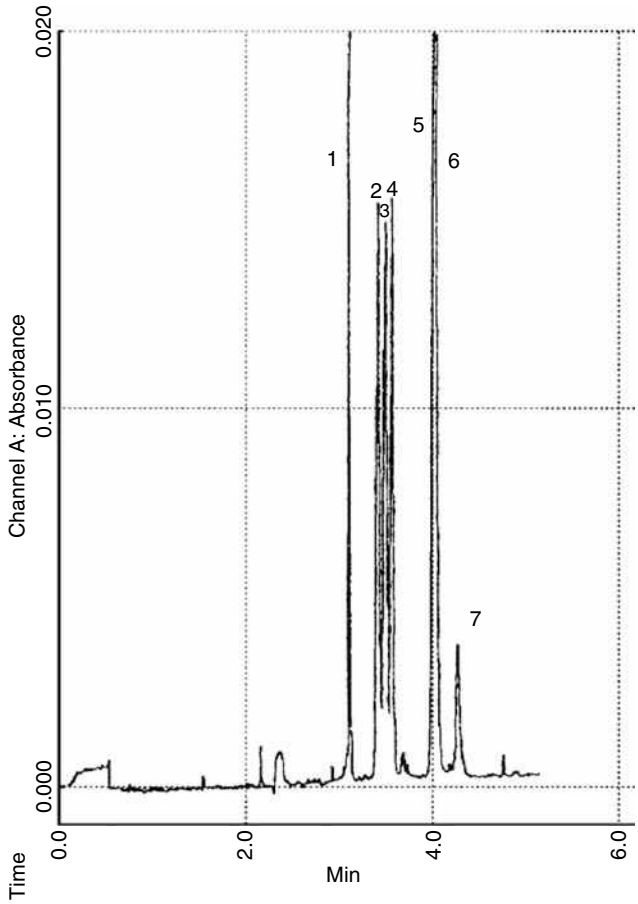

Fig. 1 Separation of different barbiturates using a 500 mmol/L borate buffer, pH 8.5. 1, Internal standard; 2, pentobarbital; 3, secobarbital; 4, amobarbital; 5, phenobarbital; 6, butabarbital; and 7, contamination.

stationary phase, such as plasticized poly vinyl chloride (PVC),[14] which is coated onto a fused silica fiber.

Among these techniques, the SPME device is reported to be the easiest to construct and it performs very reliably. Thus alkaline or neutral compounds are expected not to be extracted or backextracted, and will not interfere with analysis of barbiturates. Barbiturate concentrations of 0.1–0.3 ppm in urine and about 1 ppm in serum can be determined.[14,16]

CAPILLARY ELECTROPHORETIC MODES OF OPERATION

Capillary zone electrophoresis (CZE) and micellar electrokinectic chromatography (MEKC) are the most common CE modes used in determining barbiturates. We will discuss them separately.

Analysis by Capillary Zone Electrophoresis

In CZE, the separation mechanism is based on differences in the charge/mass ratios of ionic analytes. An electric field is applied to the capillary filled with a running buffer, and cations go to the cathode, whereas anions migrate to the anode. But because of the electro-osmotic flow (EOF) of the buffer, which is the driving force of CE, all analytes will move in the direction of EOF (usually toward the negative electrode as the inner surface of fused silica capillary is negatively charged). Although barbiturates are negatively charged at high pH, their migration velocities are close to each other and their separations by CZE are more or less insufficient. A separation of some common barbiturates using a 500 mmol/L borate buffer (pH 8.5) and an applied voltage of 11 kV is illustrated in Fig. 1.[9] The phenobarbital peak was not resolved from butabarbital. Boone et al.[17] improved separation performance by using a 90 mmol/L borate buffer (pH 8.5) and an applied voltage of 30 kV. It was found that an applied voltage of 30 kV resulted in faster separations and a better resolution compared to lower voltages. In addition, the Tapso–Tris buffer has a higher buffering capacity but lower conductivity. Baseline separation of 10 barbiturates and eight benzoates was achieved in a 50 m*M* Tapso–Tris buffer system.[14] Recently, Delinsky et al.[15] completely resolved barbiturates from meconium

Table 1 Running conditions of MEKC for determination of barbiturates.

Analytes	Running buffer	Refs.
Barbital, allobarbital, phenobarbital, butalbital, thiopental, amobarbital, and pentobarbital	50 m*M* SDS, 9 m*M* $Na_2B_4O_7$, 15 m*M* $Na_2H_2PO_4$ (pH 7.8)	[7]
Barbital, phenobarbital, methyl phenobarbital, amobarbital, thiopental, pentobarbital, and secobarbital	100 mmol/L SDS:100 mmol/L $Na_2H_2PO_4$: MeOH : H_2O (70 : 15 : 5 : 10)	[10]
Seven barbiturates and 14 benzodiazepines	100 m*M* borate, 10 m*M* SDS, and 5 *M* urea (pH 8.5)	[11]
Heptabarbital, hexobarbital, pentobarbital, butalbital, and phenobarbital	30 mmol/L SDS, 30 mmol/L borate (pH 9.3), with 200 ml/L acetonitrile	[13]
Twenty-five barbiturates	50 m*M* SDS, 20 m*M* phosphate (pH 8.4)	[17]

Table 2 Comparison of CZE and MEKC for determining barbiturates.

	CZE	MEKC
Total analysis time	No more than 10 min	About 15 min
Separation efficiencies	High	High
Analytical window	Relatively small window because of the resemblance of the chemical structures and the p*K* values of the barbiturates[17]	Provides a significantly increased analytical window
Resolution	Some barbiturates interfere with each other	Improved
Pretreatment process	Complex and time-consuming (unsatisfied resolution with LLE)	Both LLE and SPE produce good results

in a 150 m*M* Tris running buffer after sample preparation by SPE.

Analysis by MEKC

MEKC is another CE method based on the differences between interactions of analytes with micelles present in the separation buffer, which can easily separate both charged solutes and neutral solutes with either hydrophobic or hydrophilic properties. Micelles are formed by adding a surfactant [at a concentration above its critical micelle concentration (CMC)] to the separation buffer, and act as the so-called pseudo-stationary phase. The most striking observation is the resolution of MEKC,

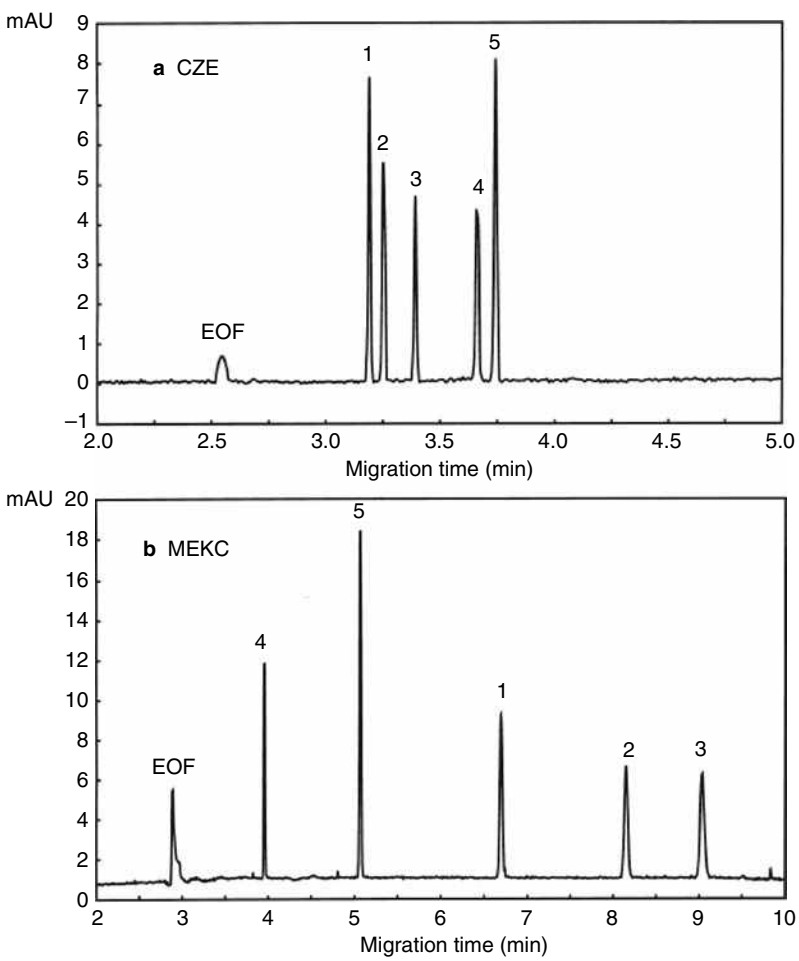

Fig. 2 Electropherograms of the separation of five barbiturate standards using a, CZE and b, MEKC. Peaks: 1, hexobarbital; 2, methohexital; 3, secobarbital; 4, barbital; and 5, phenobarbital.

which is more likely to separate complex mixtures than CZE. Because of their similar migration velocities, barbiturates are most commonly investigated in the MEKC mode.[7,8,10–13,16–19] There are various buffers and modifiers that can be selected and combined in MEKC to optimize separation; some typical examples are summarized in Table 1.

COMPARISON OF CZE AND MEKC

A comparison of the CZE and MEKC modes for determining barbiturates is summarized in Table 2.

Fig. 2[17] shows electropherograms of a mixture of five barbiturate standards; it can be observed that the addition of micelles in MEKC clearly resulted in a different separation mechanism, reflected in various changes in elution order, compared to CZE. The migration behavior in MEKC depends largely on the hydrophobic interaction of the analytes with the micelles. Hydrophobic components are more solubilized in the micelles, resulting in a slower migration compared to less hydrophobic compounds.

OPTIMIZATION OF SEPARATION

Various types of coated capillaries have been applied to the CE separation of barbiturates for improvement of separation selectivity and efficiency.[11,20,21] Jinno et al. reported a series of investigations on polyacrylamide (PAA) and AA-co-IPAAM-coated columns in both CZE and MEKC modes. By the use of PAA coating for the capillary, EOF was sufficiently eliminated, leading to a shorter analysis time and better resolution.[11,20] In addition, the elution order of barbiturates partly changed because of the hydrophobic nature of PAA. It must be noted that a non-cross-linked copolymer containing IPAAM had thermosensitive properties, and elution order was different at elevated temperatures when compared with that at ambient temperature,[21] as illustrated in Fig. 3.

In CE, the use of a reproducible identification parameter is very important because it influences identification power (IP). Boone et al.[17] used μ_{eff} and μ_{eff}^{c} instead of migration times to enhance reproducibility, to reduce the upward trend of RSD with increasing migration time, and to correct for outliers.

CHIRAL SEPARATION OF BARBITURATES

Chiral separation is one of the major outstanding advantages for CE compared to other separation techniques. As enantiomers have identical electrophoretic mobilities, some chiral complexing reagents, called chiral selectors, must be added to the separation buffer to form diastereomeric complexes in dynamic equilibrium. One of the most

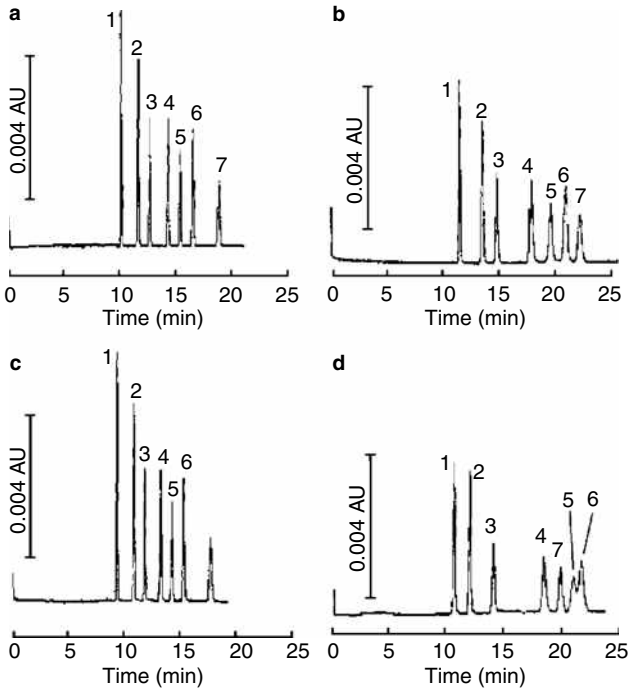

Fig. 3 Separation of barbital by the use of a capillary coated with (a and c) 10% T PAA and (b and d) 10% T poly (AA-co-IPAAM) containing 85% IPAAM. Experiments were carried out at (a and b) ambient temperature or (c and d) elevated temperature. Conditions: capillary column, 50 cm × 0.075 mm I.D. (25 cm effective length); buffer, 100 m*M* Tris–150 m*M* boric acid (pH 8.3); field strength, 300 V/cm; injection, electromigration for 5 sec at the side of cathode. Peak identification: 1, phenobarbital; 2, barbital; 3, mephobarbital; 4, amobarbital; 5, secobarbital; 6, pentobarbital; 7, metharbital.

versatile techniques for achieving chiral recognition is the addition of cyclodextrins (CDs). It is reported that determination of (*R*)-secobarbital and (*S*)-secobarbital from serum was achieved by addition of hydroxypropyl-γ-cyclodextrin (HP-γ-CD)[16] or hydroxypropyl-β-cyclodextrin (HP-β-CD)[18] in the running buffer. Fig. 4 illustrates a typical electropherogram of pentobarbital and secobarbital enantiomers, separated by HP-β-CD. Conradl and Vogt et al.[22] investigated the separation of (*R*)-thiopental and (*S*)-thiopental, and (*R*)-phenobarbital and (*S*)-phenobarbital by using α-CD and β-CD as chiral selectors, separately. They found out that the enantiomers of thiopental were not separated by β-CD, whereas cyclobarbital enantiomers were separated by both α-CD and β-CD. It is assumed that the size of the cavity of β-CD allows the side chain of thiopental, with the asymmetric carbon atom, to penetrate completely. Therefore the formation of stereoselective complexes is unlikely. In the case of α-CD, the C_5 substituents of thiopental are optimal in size and structure to fit into the cavity whereas; for cyclobarbital, a partial inclusion of the cyclohexene ring or the methyl

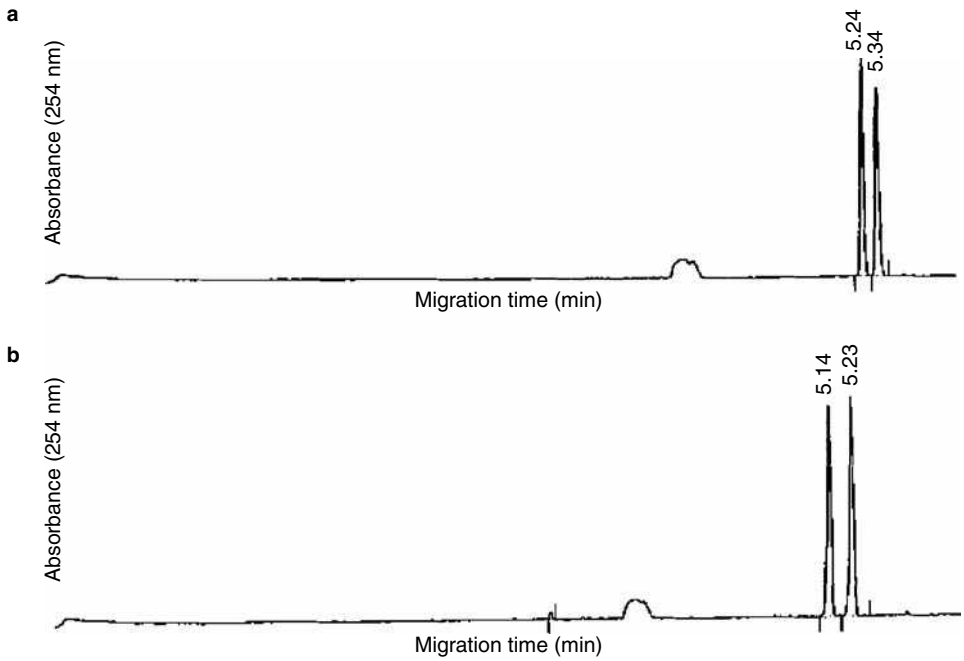

Fig. 4 Typical electropherograms of enantiomers of A, pentobarbital and B, secobarbital on a 57 cm × 75 μm I.D. fused silica capillary. The run buffer contained 40 m*M* HP-β-CD in 20 m*M* ammonium acetate buffer (pH 9.0) with detection at 254 nm. The capillary was thermostated at 25°C and the run voltage was set to 15 kV.

group at the C_5 of the heterocycle into the cavity is probable. However, the separation of cyclobarbital with low α-CD concentration was less efficient.

COMPARISON OF CE, GC, AND LC

LC, GC, and CE are three typical analytical separation approaches used to determine barbiturates. The advantages and disadvantages of the three techniques are summarized in Table 3.

CONCLUSIONS

CE offers fast analysis, low consumable expenses, ease of operation, high separation efficiency, and selectivity. Now, CE has undoubtedly become an attractive technique for the determination and therapeutic monitoring of barbiturates and other drugs, and it is becoming more and more important in biological and toxicological analyses. It was also indicated that CE has a good potential for systematic toxicological analysis (STA).[17]

At present, the coupling of CE to MS is attractive because it facilitates the identification of analytes and

Table 3 Comparative study of three techniques to determine barbiturates.

Techniques	Advantages	Disadvantages
GC	High sensitivity and selectivity	Inadequate for polar, thermolabile, and low-volatility analytes
	Coupled with MS for the identification of unknowns	High consumption of expensive, high-purity gases
LC	Application to all organic solutes in spite of volatility or thermal stability	Insufficient separation selectivity and efficiency
	Both mobile and stationary phase compositions are variables	Related long analysis time
		Large amounts of expensive and toxic organic solvents used as mobile phase, such as acetonitrile[5] and methanol.[6]
CE	High separation efficiency	Inadequate detection limit
	Small consumption of expensive reagents and toxic solvents	Lack of highly selective detectors

improves detection sensitivity. Combining CE with fluorescence detection greatly improves the sensitivity and selectivity for determining proteins and other biological molecules. Future trends of CE will be used to develop more coupling methods to combine CE with highly selective detectors and to achieve miniaturization and automation for extremely fast, easy, and real-time determination in pharmaceutical and biological analyses.

β-Lactam Antibiotics: Effect of Temperature and Mobile Phase Composition on RP/HPLC Separation

J. Martin-Villacorta

N. Montes
J.C. Garcia-Glez
Physical Chemistry Department, University of León, León, Spain

INTRODUCTION

In previous papers,[1,2] we reported the effect of column temperature on resolution in reversed-phase high-performance liquid chromatography (RP-HPLC) to separate various β-lactams (penicillins and cephalosporins) from a single sample. In this work we describe the effect of column temperature and volume fraction of an organic solvent on resolution in the isocratic elution conditions of some β-lactam antibiotics.

Mobile phase composition and column temperature are two important experimental parameters that can be altered when a mixture of several compounds is to be separated.[3–5]

The relationships between capacity factor, k', and organic modifier concentration in the mobile phase, and the effect of the column temperature on k' for the antibiotics studied have been used to define k' as a function of T and V (volume fraction) on the basis of a small number of experimental measurements for a given combination of column, organic solvent, and type of antibiotic. From calculated values of k', resolution values, R_S, may be estimated for adjacent band-pairs under all conditions. The method developed enables the optimization of RP-HPLC separations of the β-lactam antibiotics in the absence of difficult theoretical calculations, using a small number of experimental data, including the influence of the organic solvent in the mobile phase (isopropanol) and the column temperature.

INSTRUMENTS

The HPLC system consisted of a Model 600E multisolvent delivery system equipped with a heated column compartment, a Model 484 variable-wavelength detector, and a Model 745B computing integrator, all from Waters Assoc., Inc., Milford, Massachusstts, U.S.A. The chromatograph was equipped with a Spherisorb ODS column (10 μm particle size, 25 cm × 4.6 mm I.D.).

CHROMATOGRAPHIC PROCEDURE

The mobile phases used to separate the compounds were acetate buffer (pH 5.00, 0.1 *M*)/isopropanol, 96.5/3.5, 95/5, 93/7, and 90/10 (v/v). A precolumn (3 cm × 4.6 mm I.D.), packed with the same packing materials, was used to guard the main column. The detector was set at 254 nm. The flow rate of the mobile phase was 1.0 ml/min. The column dead time, t_0, was measured by injecting methanol.

RESULTS AND DISCUSSION

The mixture of β-lactams was chromatographed at each of five column temperatures from 20°C to 60°C, and at four different volume fractions of isopropanol in mobile phase, from 0.035 to 0.1. Fig. 1A shows chromatograms with the volume fraction of isopropanol ranging from 0.035 to 0.1 at a constant column temperature (30°C). Fig. 1B shows the chromatograms obtained for each column temperature at 0.05 volume fraction of isopropanol. As one can see, a marked effect is produced for both parameters on the chromatographic behavior of each antibiotic.

Capacity Factor as a Function of Volume Fraction of Isopropanol in the Mobile Phase

The volume fraction (V) of organic solvent in the mobile phase is one of the most important parameters controlling capacity factor in RP-HPLC. Many reported studies[6–10] show that, for a given solute and separation temperature, T, the relationship between capacity factor (k') and the volume fraction (V), or the eluent concentration, can be expressed as follows:

$$k' = aV^{-b} \tag{1}$$

where a and b are constants.

For all antibiotics, the plots of log k' vs. log V gave straight lines for all temperatures, with a correlation of 0.9992 or greater (Fig. 2a). As one can see, there are different slopes, which may probably be ascribed to different separation mechanisms.

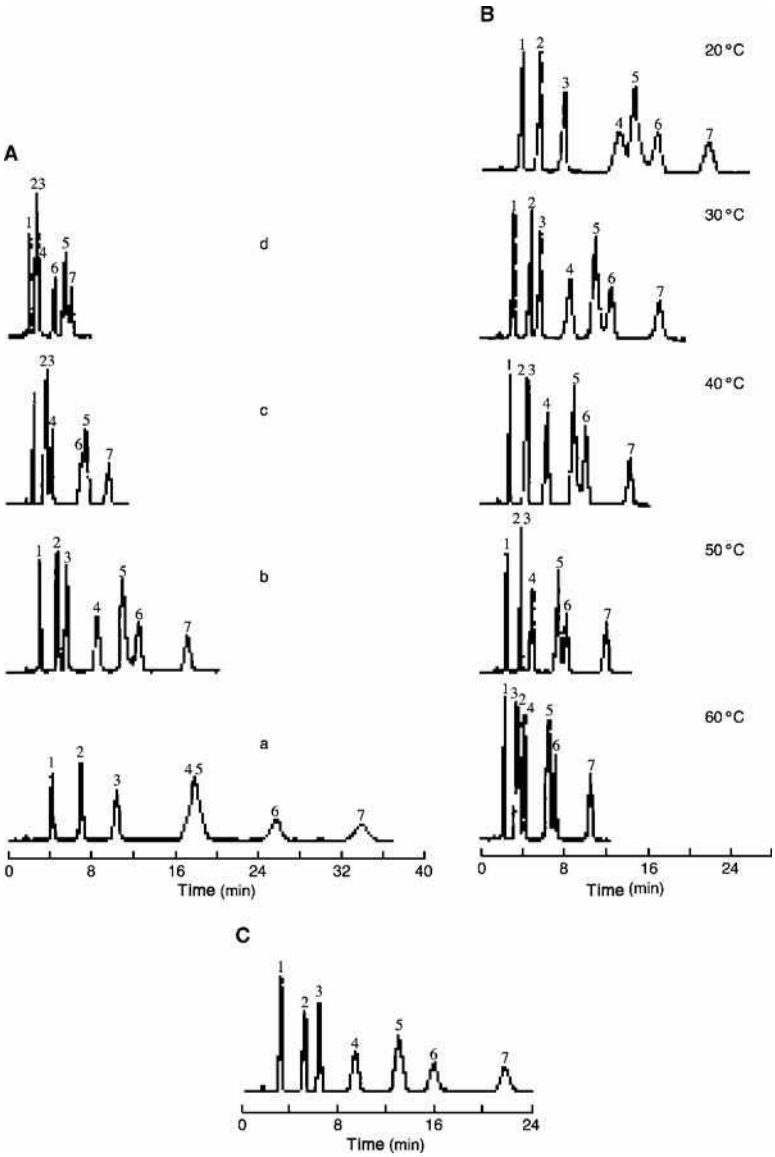

Fig. 1 A, Effect of changing isopropanol volume fraction in the mobile phase on the elution profiles of cefonicid (1), cefaclor (2), cephazolin (3), cefodizime (4), cephaloridine (5), cephamandole (6), and cephalotin (7), using a mobile phase of 0.1 *M* acetate buffer (pH 5.00)/isopropanol (v/v) $a = (96.5/3.5)$, $b = (95/5)$, $c = (93/7)$, and $d = (90/10)$ at a column temperature of 30°C. B, Effect of column temperature on the elution profiles of cephalosporins studied [numbering as in (A)], using a mobile phase of 0.1 *M* acetate buffer (pH 5.00)/isopropanol (95/5) (v/v). C, Isocratic elution profile under optimal conditions. Mobile phase 0.1 *M* acetate buffer (pH 5.00)/isopropanol (95.4/4.6) (v/v), column temperature, 32°C, numbering as in (A).

Table 1 lists constants a and b, calculated from the intercepts and the slopes, respectively, by means of a least-squares method. The slopes for 1, 2, and 7 were found to be slightly affected by the column temperature, especially the slope for 1 (Cefonicid).

Capacity Factor as a Function of Column Temperature

Fig. 1B shows five chromatograms for the mixture of β-lactams, obtained at different temperatures. As one can see, the retention time of each antibiotic increased strongly as the column temperature was increased from 20°C to 60°C.

The dependence of the capacity factor on temperature is given by the Van't Hoff equation:

$$\ln k' = -H^\circ/RT + S^\circ/R + \phi \qquad (2)$$

where R is the gas constant, ΔH° and ΔS° are the enthalpy and entropy changes, respectively, associated with the solute retention process. The parameter ϕ is the phase ratio and T is the absolute temperature.

Fig. 2b shows a van't Hoff plot for each antibiotic. It can be seen that the lines generated from the $\ln k'$ of each compound at different temperatures are linear with a correlation coefficient of 0.995 or greater. The linearity of the plots supports the assumption that single sorption mechanisms are operative for each antibiotic. As for β-lactams and other compounds,[2,11,12] the slopes of these lines were not all the same, as one might expect if the effect of temperature was generalized.

For all antibiotics, the values of enthalpy change are negative, which indicates that the transfer of antibiotic from the mobile phase to sorption sites is favored.

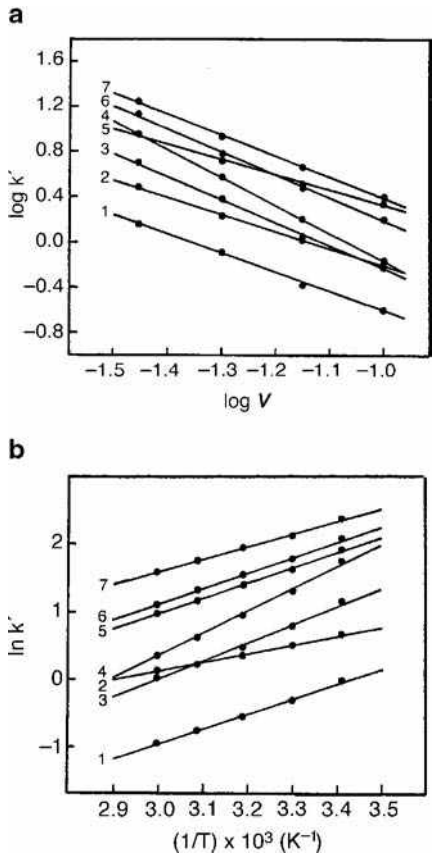

Fig. 2 a, Effect of isopropanol volume fraction (V) in mobile phase on the capacity factor (k') at 30°C. Mobile phases as in Fig. 1B and numbering as in Fig. 1A. B, Effect of column temperature on the capacity factor (k'). Mobile phase as in Fig. 1B and numbering as in Fig. 1A.

Determination of Capacity Factor for Any Value of Volume Fraction of Isopropanol and Column Temperature

Following the methodology developed by Gant et al.,[3] it is possible to obtain the values for the capacity factor ($k_{T,V}'$) for any value of volume fraction of isopropanol and any column temperature. In this methodology, a standard state is defined by a temperature (T_S) and mobile phase composition (V_S). In the present study, $T_S = 20°C$ (293.3 K) and $V_S = 0.035$. The standard state value of k' for the solute in question is k_{T_s},V_s'.

From Eq. 1, we can write:

$$\log k_{T_S,V}' = \log k_{T_S,V_S}' - b(\log V - \log V_S) \quad (3)$$

where $k_{T,V}'$ is the capacity factor for a value of V and the temperature T_S.

From Eq. 2, we can write at any value of T and V:

$$\log k_{T,V}' = \log k_{T_S,V}' - c(1/T_S - 1/T) \quad (4)$$

where $k_{T,V}'$ is the capacity factor for any value of T and V, and the parameter c varies with the β-lactam and with mobile phase composition.

According to Eqs. 3 and 4, the temperature coefficient c must be of the form:

$$c = d - e \log V \quad (5)$$

where d and e are constant for a given β-lactam and system.

Using Eqs. 3, 4, and 5, it is possible to calculate the capacity factor $k_{T,V}'$ for any value of T and V, after determining the values of b and c from these equations and the experimental data. The parameter c used for each volume fraction of isopropanol is determined from Eq. 5, using the constants d and e previously determined by plotting experimental c values vs. log V. Table 2 compares the experimental and calculated values of the capacity factor, k', for the antibiotic studied, experimental k' values being predicted generally with good agreement.

EFFECT OF ELUTION CONDITIONS ON RESOLUTION

The conventional equation to evaluate the effect of elution conditions on resolution (R_S) is:

$$R_S = 1/4\sqrt{N}(k'/1 + k')(\alpha - 1/\alpha) \quad (6)$$

Table 1 Values of constants a and b in Eq. 1 at different column temperatures.

Volume fraction of isopropanol $V = 0.05$.
Numbering as in Table 1.

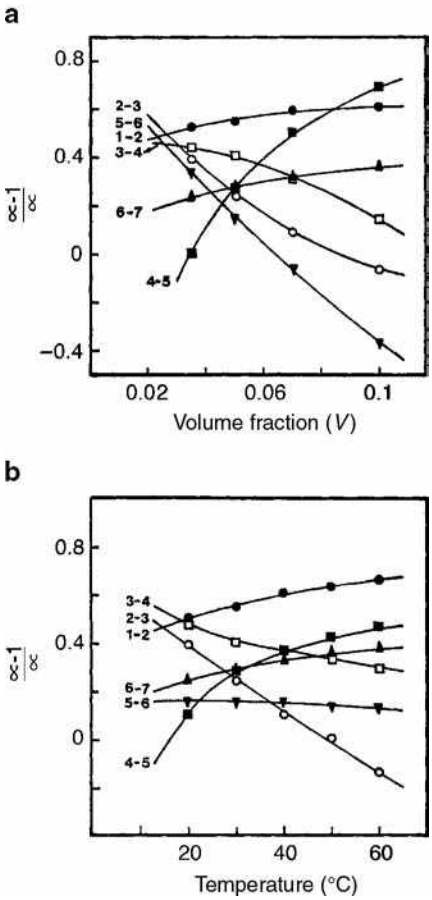

Fig. 3 a, Effect of column temperature on the selectivity factor ($\alpha - 1/\alpha$) of the six pairs of sequentially resolved peaks. Mobile phase as in Fig. 1B and numbering as in Fig. 1A. b, Effect of isopropanol volume fraction (V) in mobile phase on the selectivity factor ($\alpha - 1/\alpha$) of the six pairs of sequentially resolved peaks at 30°C. Mobile phases and numbering as in Fig. 1B and numbering as in Fig. 1A.

Here, N is the plate number, α is the selectivity factor (defined as k_2'/k_1'), where k_1' and k_2' are the capacity factors for bands 1 and 2, and k' is the average capacity factor of k_1' and k_2'. The three factors, α, N, and k', control the resolution. It is assumed that the three terms of Eq. 6 are approximately independent, which allows their separate optimization. The resolution equation Eq. 6 must be applied to each of the adjacent band-pairs considered.

As one can see in Fig. 1B, the band broadening of any peak appearing at a fixed retention time decreases as the temperature increases; accordingly, the N value increases with increasing temperature. A linear relationship was obtained for the plot of N vs. T: $N = 24.7\ T - 6560$ (T has the dimension of absolute temperature) with a correlation coefficient of 0.991. The N value is practically independent of the volume fraction of isopropanol for the β-lactam studied.

In general, the contribution of $k'/1 + k'$ terms to R_S is approximately constant as long as k' is not small. As the selectivity factor (α) is of greater concern in Eq. 6, the separate optimization of the influence of the temperature and mobile phase composition in values is in many cases a good criterion for establishing the elution conditions of the separation.

Fig. 3 shows the influence of temperature and isopropanol volume fraction in the term: ($\alpha - 1/\alpha$). There are examples of different situations: for pairs 5–6 and 4–5, the ($\alpha - 1/\alpha$) term is markedly influenced by the isopropanol volume fraction; the column temperature also exerts an important influence on this term for pairs 2–3 and 4–5. It is interesting to note that both parameters (T and V) have important and similar effects on pairs 4–5 and 2–3 in this resolution term. For these cases, both parameters can be used to obtain a better resolution. Fig. 1C shows an elution profile under optimal elution conditions.

CONCLUSIONS

The present work demonstrates that there is linear relationship between the log k′ and both the log V (volume fraction of organic solvent in the mobile phase) and the reciprocal of the absolute temperature. Therefore, it is possible with a small number of initial experimental data of the capacity factor (k') to predict k' for each cephalosporin as a function of T and V, which reveals the optimal elution conditions for the isocratic separation of a mixture of cephalosporins.

Bile Acids: TLC Analysis

Alina Pyka
Department of Analytical Chemistry, Medical University of Silesia, Sosnowiec, Poland

Abstract
The separations and the detections of selected bile acids such as: cholic acid (C), glycocholic acid (GC), glycolithocholic acid (GLC), deoxycholic acid (DC), chenodeoxycholic acid (CDC), glycodeoxycholic acid (GDC), and lithocholic acid (LC) by using normal-phase thin-layer chromatography (NP-TLC), reversed-phase thin-layer chromatography (RP-TLC), and densitometry have been discussed. The chromatographic lipophilicity parameters (R_{MW} and φ_0) were compared both with measured ($\log P_{exp}$) and calculated partition coefficients ($A\log P_S$, $IA\log P$, $\log P_{Kowwin}$, $x\log P$, $C\log P$, $\log P_{Rekker}$) for selected bile acids. The significance of structural descriptors in quantitative structure-property relationships (QSPR), quantitative structure-retention relationships (QSRR), and quantitative structure-activity relationships (QSAR) of selected bile acids has been also discussed.

INTRODUCTION

Bile acids fulfill many important functions; e.g., they facilitate digestion and absorption of fat, vitamins soluble in fat (A, E, D, and K), and cholesterol. Glycocholic (GC) and taurocholic acids emulsify hydrophobic substances which are present in the aqueous environment of the alimentary tract by reducing surface tension. Bile acids, as distinct from GC and taurocholic acids, activate the liver to produce bile; thus, they are used as cholagogues. Beef bile, which is used as a cholagogic agent, can be a source of cholic acid (C), deoxycholic acid (DC), chenodeoxycholic acid (CDC), ursodeoxycholic acid, and lithocholic acid (LC). Of all above-mentioned acids, CDC and ursodeoxycholic acid—which quite well dissolve gallstones at longer application—play a special role. CDC is generally used in the case of lithiasis caused by radiolucent cholesterol stones, whereas ursodeoxycholic acid is usually used to dissolve uncalcified gallstones, both in preserved secretory function of the gallbladder and for reflux gastritis. Numerous pharmaceutical preparations contain CDC and ursodeoxycholic acid, whereas C is generally used in the form of its sodium, magnesium, or calcium salt or in a methamine mixture.[1]

Respective ketocholanic acids, which are absent from bile, can be obtained from C, DC, and LC by oxidation of secondary alcoholic groups (dehydrogenation). Dehydrocholic acid, used both in a free and conjugated form (of sodium salt), is about 10 times less toxic than C. Dehydrocholic acid activates production of bile, speeds up its flow, and facilitates resorption of fat because it intensifies the activity of pancreatic lipase. Bile acids are well absorbed from the alimentary tract; next, they enter the blood stream and then activate liver cells to produce bile. However, bile acids are strongly toxic compounds, and their overdose leads to degeneration of cardiac muscle or lesions of the liver and kidneys. Additionally, bile acids became quite important initial material for the half synthesis of steroidal hormones.

Bile acids are the object of wide investigations because of their biological properties. High-performance liquid chromatography (HPLC), thin-layer chromatography (TLC), and gas chromatography are the principal techniques used for qualitative and quantitative investigations of bile acids. Analysis of bile acid by chromatographic techniques is the subject of many scientific publications.[1–24] Scalia[2] presented a review of the methods available for the separation of bile acids. TLC, gas chromatography, and HPLC techniques and combined detection systems for the determination of bile acids were critically evaluated, and their advantages and disadvantages were discussed.[2] Gaica et al.[3] separated C and 14 of its synthetic derivatives by using their TLC behavior in six reversed-phase systems and three normal-phase systems. Four different adsorbents were used, namely RP-18 silica, CN-silica, polyacrylonitrile adsorbent, and unmodified silica gel. Reversed-phase chromatography was performed with water–organic modifiers (methanol, dioxane, or acetone) as mobile phases in various volume compositions. However, normal-phase chromatography was performed with petroleum–acetone, chloroform–methanol, and ethyl acetate–toluene as mobile phases. Results obtained by Gaica et al. indicate that the different normal- and reversed-phase systems employed can be successfully used for separation of the substances examined. The selectivity of the RP systems is significantly better, because RP-18 silica gel, combined with mobile phases containing 65–70% methanol or 50–60% dioxane in water, can be recommended as the most suitable chromatographic system for these compounds.[3] Zarzycki, Wierzbowska, and Lamparczyk[4] studied the influence of temperature on retention and separation of cholesterol and bile acids

(taurodeoxycholic acid–sodium salt, GC, GC–sodium salt, glycodeoxycholic acid (GDC), GDC–sodium salt, C, C–sodium salt, CDC, CDC–sodium salt, and LC), using reversed-phase thin-layer chromatography (RP-TLC). As mobile phases, methanol–water mixtures of various volume compositions were used. Chromatographic experiments were performed using vapor-saturated chambers at temperatures ranging from 5°C to 60°C. In the higher temperature region, excellent separations (excepting DC and CDC) were obtained. The separation studies of multicomponent mixtures have shown that the degree of separation in the high-temperature region can be increased due to an improvement of the efficiency of the chromatographic system.[4] Earlier, Rivass-Nass and Müllner[5] evaluated the influence of temperature, ionic strength, and apparent pH of the eluent (rather than its composition) on the thin-layer chromatographic separation of sodium salts of selected bile acids. This study indicates that the overall effect of temperature on bile acid separation is dependent upon the eluent used. Reducing the running temperature is, however, strongly recommended, as this leads to an improvement not only of band shape and intensity, but also of resolution. Variation of the apparent pH and of the overall ionic strength should be carefully considered, especially if reversed-phase supports are used.[5]

Pyka and Dołowy published manuscripts which concern investigations of chromatographic separations by use of TLC, lipophilicity and application of structural descriptors in quantitative structure-activity relationships (QSAR), quantitative structure-property relationships (QSPR), and quantitative structure-retention relationships (QSRR) analysis of selected bile acids [C, GC, GDC, CDC, DC, LC, and glycolithocholic acid (GLC)].[1,6–9,11–22] In this entry, the most important results of these investigations will be presented and discussed.

SEPARATION OF SELECTED BILE ACIDS[6–16]

Separation of Bile Acids by Normal-Phase Thin Layer Chromatography (NP-TLC) on Unmodified Silica Gel and Mixtures of Silica Gel and Kieselguhr at Room Temperature[6–11]

The optimum conditions of the separations of the selected bile acids were determined: C, GC, GLC, DC, CDC, GDC, and LC by using TLC on aluminum plates which have been precoated with silica gel 60 (E. Merck, #1.05553), silica gel $60F_{254}$ (E. Merck, #1.05554), or mixtures of silica gel 60 and Kieselguhr F_{254} (E. Merck, #1.05567), as well as on glass plates precoated with silica gel $60F_{254}$ without a concentration zone (E. Merck, #1.05715) and with a concentration zone (E. Merck, #1.11798) using *n*-hexane–ethyl acetate–acetic acid in various volume compositions as mobile phases[7–9] and on aluminum plates precoated with silica gel $60F_{254}$ (E. Merck, #1.05554) using *n*-heptane–ethyl acetate–acetic acid in various volume compositions as mobile phases.[6] Chromatographic separations of studied bile acids were characterized using R_F, as well as separation factors ΔR_F and R_S. Separation factors R_S were determined by use the visual method. Table 1 presents the data, which allows an estimation of the usefulness of the examined stationary phases and mobile phases (*n*-hexane–ethyl acetate–acetic acid) in different volume compositions for the separation of all the investigated bile acids. Separation of each investigated pair of bile acids is satisfactory when $\Delta R_F \geq 0.05$ and $R_S > 1$. An optimum separation for other chromatographic adsorbents was obtained by use of one-dimensional (1-D) development at 18°C and *n*-hexane–ethyl acetate–acetic acid mobile phases in the following volume compositions: 20:20:5 and 22:22:5 on glass plates precoated with silica gel $60F_{254}$ (E. Merck, #1.05715); 22:21:5 and 25:20:8 on aluminum plates precoated with silica gel $60F_{254}$ (#1.05554); 20:20:5, 22:21:5, 22:22:5, and 25:20:8 on aluminum plates precoated with silica gel 60 (#1.05553); and 20:20:5 on glass plates precoated with silica gel $60F_{254}$ with concentration zone (#1.11798).[7,8] Fig. 1 presents a densitogram of bile acids separated on an aluminum plate precoated with silica gel $60F_{254}$ (#1.05554) by using the mobile phase *n*-hexane–ethyl acetate–acetic acid in volume composition 22:21:5.[10]

When aluminum plates precoated with the mixture of silica gel 60 and Kieselguhr F_{254} (#1.05567) were used, the selection of mobile phases depended on the kind of bile acids which are being separated. The mobile phase 25:20:8 (v/v/v) allows separation of all pairs of bile acids, with the exception of the pair of LC and DC. Using mobile phases in other volume compositions can separate the pair of LC and DC. In this case—the separation on the silica gel 60 and Kieselguhr F_{254} mixture—the biggest problem was to

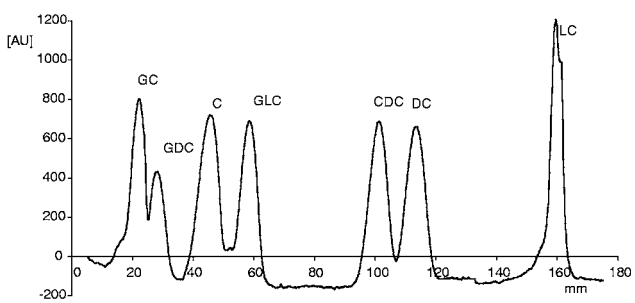

Fig. 1 Densitometric profiles obtained for the investigated bile acids on aluminum plate precoated with silica gel $60F_{254}$ (E. Merck, #1.05554) using *n*-hexane–ethyl acetate–acetic acid (22:21:5, v/v). Glycocholic acid (GC), glycodeoxycholic acid (GDC), cholic acid (C), glycolithocholic acid (GLC), chenodeoxycholic acid (CDC), deoxycholic acid (DC), lithocholic acid (LC). separate GLC and C. Separation of these acids was possible only by using a mobile phase in volume composition 25:20:8.[8]

The mobile phase *n*-hexane–ethyl acetate–acetic acid in a volume composition of 25:20:5 (v/v/v) is not optimal for separating all seven bile acids on aluminum plates precoated with silica gel 60 (#1.05553). However, when this mobile phase is used, the difference between R_F values of C and GLC is 0.05, but the R_S of this pair of bile acids is smaller than 1 ($R_{S(C/GLC)} = 0.96$; see Table 1). To obtain complete separation of the seven examined bile acids on aluminum plates precoated with silica gel 60 (#1.05553), a two-dimensional (2-D) technique was used. The first development used the mobile phase *n*-hexane–ethyl acetate–acetic acid in a volume composition of 25:20:5. Chloroform–*n*-butanol–acetic acid–water (2:32:2:2, v/v/v/v) as mobile phase was used for the second development. The scheme of the chromatogram of separated bile acids with the use of a 2-D technique is presented in Fig. 2. The chromatogram indicates that, under these conditions, all the bile acids studied were completely separated. Better separation for C and GLC was obtained.[7]

Similar analyses were also used to compare the separations of studied bile acids. Both analyses showed that on the plates precoated with silica gel, the biggest problem was to separate GC from GDC. In the case of the separation on the silica gel 60 and Kieselguhr F_{254} mixture, the biggest problem was to separate C from GLC. The obtained results indicate that similar analysis can be an alternative method of the estimation of chromatographic separations of studied acids.[9]

The separations of these bile acids on silica gel 60 with concentrating zone (E. Merck, #1.11845) and by use of *n*-hexane–ethyl acetate–acetic acid and *n*-hexane–ethyl acetate–methanol–acetic acid in different volume compositions were also investigated.[11] It was affirmed that *n*-hexane–ethyl acetate–methanol–acetic acid mobile phase in the volume composition 20:20:5:2 is optimum for the separation of the investigated bile acids. Densitometric analysis of the examined bile acids after the detection by use of methanolic solution of sulfuric acid was performed. Densitometric scanning was then performed at multi wavelength in the range of 380–460 nm, with wavelength change at every step 20 nm. A three-dimensional (3-D) densitogram of investigated substances at different wavelengths (380, 400, 420, 440, and 460 nm) is presented in Fig. 3. The resolution of peaks for the studied pairs of compounds were calculated by the use visual method $R_{S(c)}$ and by densitometric methods ($R_{S(b)}$, $R_{S(h)}$, and $R_{S(a)}$). It was affirmed that $R_{S(b)}$, $R_{S(h)}$, and $R_{S(a)}$ values calculated on the basis of the densitograms are considerably lower than the $R_{S(c)}$ values calculated using the visual method on the basis of the chromatograms. This shows that R_S values can be correctly marked exclusively on the basis of the densitograms. The scientific literature data indicate that at R_S values higher than 1.5 we can expect the complete separation of the neighboring compounds on the

densitograms. It was shown that resolutions $R_{S(b)}$, $R_{S(h)}$, and $R_{S(a)}$ value larger than 1.5 were obtained at all analyzed wavelengths for the studied pairs of substances GC/GDC, GDC/GLC, C/CDC, and DC/LC. These conditions did not provide for the complete separation of the pair of substances GLC/C and CDC/DC. The characteristics of the obtained densitometric bands were also presented. Characteristic of the chromatographic band was realized using the densitometric method by determination of peak height, peak area, and the angle (β) between the tangents at the inflection points to the curves of the densitometric peak. From the obtained data, it is apparent that the band of GC has the lowest numerical value of angle β. It shows that band of GC is compact in spite of its large area. However, the heights and areas of chromatographic band obtained at different wavelengths have differentiated values. The densitometric bands with the largest area were obtained at wavelengths in the neighborhood of absorption maximum (λ_{max}) for particular substances investigated. It was affirmed that analysis of chromatographic bands was not by visual but by their densitometric characteristic, which is a supplementary element of the separation effect evaluation. Each visual evaluation is subjective and a little precise in relation to the densitometric method. Only the densitometric method can be used for the objective evaluation of the separation effect and characteristic of particular chromatographic bands.[11]

SEPARATION OF BILE ACIDS BY NORMAL PHASE HIGH-PERFORMANCE THIN-LAYER CHROMATOGRAPHY (NP-HPTLC) ON CYANO- AND DIOL-MODIFIED SILICA GEL AT ROOM TEMPERATURE[12]

The optimum conditions were determined for the separations of selected bile acids such as C, GC, GLC, DC, CDC, GDC, and LC by high-performance TLC on glass plates precoated with modified silica layers, using *n*-hexane–ethyl acetate–acetic acid in the following volume compositions: (a) 49:49:2, 47.5:47.5:5, and 37.5:37.5:25 in the case of CNF_{254} plates (E. Merck, #1.12571); (b) 48.7:48.7:2.6, 47.5:47.5:5, 45:45:10, 42:42:16, 40:40:20, and 37.5:37.5:25 in the case of $DiolF_{254}$ plates (E. Merck, #1.05636). Generally, in applied chromatographic conditions, the adsorption of the studied bile acids increases in the following order: LC, DC, CDC, GLC, C, GDC, and GC. On CNF_{254} plates, when the above-mentioned mobile phase in volume composition 37.5:37.5:25 was used, GC separated very well from GLC ($\Delta R_{F(GC/GLC)} = 0.09$, $R_{S(GC/GLC)} = 2.12$). However, weak separation was observed for other pairs of bile acids. The mobile phase in the volume composition 47.5:47.5:5 allowed separation of the following pairs of neighboring bile acids: GC/GDC, GDC/C, and DC/LC, while the mobile phase in the volume composition 49:49:2 separates almost all pairs of bile acids except for CDC/DC. Thus, it can be concluded that the application of the mobile phase *n*-hexane–ethyl acetate–acetic acid on cyano-modified silica gel plates hinders the separation of CDC from DC.[12] However, these conditions facilitate the separation of GC from GDC when compared to their separations on non-modified silica gel and a mixture of silica gel 60 and Kieselguhr F_{254}.[8,9] However, it was concluded that on $DiolF_{254}$-modified silica gel plates at 18°C and by using the above-mentioned mobile phase in the volume composition 42:42:16, the optimal separation of all examined bile acids was obtained ($\Delta R_F \geq 0.05$ and $R_S > 1$ for all pairs of neighboring bile acids). When the mobile phase in the volume composition 45:45:10 was applied, very good separations were obtained for almost all examined bile acids except for GLC and CDC ($\Delta R_{F(GLC/CDC} = 0.08$, $R_{S(GLC/CDC)} = 1.00$).[12]

Table 2 presents the R_F values and separation factors, ΔR_F and R_S, of bile acids examined at 18°C on cyano-modified silica gel CNF_{254} (#1.12571) and diol-modified silica gel $DiolF_{254}$ (#1.05636), and developed by using the mobile phase *n*-hexane–ethyl acetate–acetic acid in volume compositions 49:49:2 and 42:42:16, respectively.[12]

SEPARATION OF BILE ACIDS BY NP-TLC ON UNMODIFIED SILICA GEL AND MIXTURE OF SILICA GEL AND KIESELGUHR AT 40°C[13]

An attempt was made to determine the influence of temperature on bile separation using adsorption TLC on aluminum plates precoated with silica gel 60 (E. Merck, #1.05553), silica gel $60F_{254}$ (E. Merck, #1.05554), or the mixture of silica gel 60 and Kieselguhr F_{254} (E. Merck, #1.05567); as well as on glass plates precoated with silica gel $60F_{254}$ without concentrating zone (E. Merck, #1.05715) and with concentrating zone (E. Merck, #1.11798). The mobile phase *n*-hexane–ethyl acetate–acetic acid was used as a mobile phase in the volume compositions for which the complete separation of examined bile acids was not obtained at 18°C.[6–9] The chromatographic plates were developed with the use of the above-mentioned mobile phases at 40°C. It was observed that temperatures at 18°C and 40°C influence the effect of separation of selected bile acids. The right choice of temperature can improve the separation of some bile acids; it also causes a change of their relative positions on aluminum plates precoated with the mixture of silica gel 60 and Kieselguhr F_{254} (#1.05567). Generally, it can be stated that the temperature of 40°C improves the separation of GC from GDC on silica plates (#1.05715, #1.11798, #1.05554, and #1.05553). However, under the above-mentioned conditions, a problem concerning the separation of CDC from DC arises. For example, the development of investigated bile acids at 18°C on glass plates precoated with silica gel $60F_{254}$ without concentration zone (#1.05715), using *n*-hexane–ethyl acetate–acetic acid in a volume composition 22:20:5, leads to complete

separation of almost all neighboring pairs of the studied bile acids, except for the pair GC and GDC ($\Delta R_{F(GC/GDC)} = 0.03$, $R_{S(GC/GDC)} = 1.00$). The separation of the pair GC and GDC improves at 40°C ($\Delta R_{F(GC/GDC)} = 0.07$, $R_{S(GC/GDC)} = 1.82$), but the separation of CDC and DC deteriorates at 40°C ($\Delta R_{F(CDC/DC)} = 0.05$, $R_{S(CDC/DC)} = 0.90$) compared to separation at 18°C ($\Delta R_{F(CDC/DC)} = 0.10$, $R_{S(CDC/DC)} = 1.46$).[13]

In the case of the separation on silica gel 60 and Kieselguhr F_{254} mixture at 18°C, the biggest problem was to separate C from GLC. Unfortunately, increasing the temperature to 40°C does not improve the separation of the above-mentioned pair of acids.[13]

SEPARATION OF BILE ACIDS BY NP-TLC ON SILICA GEL IMPREGNATED WITH SELECTED CATIONS[14,15]

To separate bile acids (LC, DC, CDC, GLC, C, GDC, and GC) using adsorption TLC at 18°C, the glass plates precoated with silica gel $60F_{254}$ (#1.05715) were impregnated with 1%, 2.5%, and 5% aqueous solutions of the following salts: $CuSO_4$, $MnSO_4$, $NiSO_4$, and $FeSO_4$. The mixtures of *n*-hexane–ethyl acetate–acetic acid in the volume compositions 22:20:5, 25:20:2, 25:20:5, and 25:20:8 were used as mobile phases.[14,15] These mobile phases were not effective for the separation of bile acids on non-impregnated silica gel $60F_{254}$ plates at 18°C.[8,9] The total number of experimental combinations regarding the impregnation of applied stationary and mobile phases used to separate bile acids was 48. The plates impregnated with the cations whose application resulted in $\Delta R_F \geq 0.05$ and $R_S > 1$ for all pairs of neighboring bile acids were considered the most effective for bile acid separation. All pairs of studied bile acids were separated on plates impregnated with the following aqueous solutions of inorganic salts:

- 1% $CuSO_4$, 2.5% $CuSO_4$, 5% $CuSO_4$, 2.5% $MnSO_4$, 1% $NiSO_4$, 2.5% $FeSO_4$, and 5% $FeSO_4$ with a mobile phase in volume composition 25:20:5 (v/v/v).
- 1% $CuSO_4$, 5% $CuSO_4$, 1% $NiSO_4$, 5% $NiSO_4$, 1% $FeSO_4$, 5% $FeSO_4$ with a mobile phase in volume composition 25:20:8 (v/v/v).
- 1% $CuSO_4$, 2.5% $CuSO_4$, 2.5% $MnSO_4$, and 5% $FeSO_4$ with a mobile phase in volume composition 22:20:5 (v/v/v).

The comparison of the selected values of separation factors ΔR_F and R_S of bile acids examined on glass plates with non-impregnated silica gel $60F_{254}$ (#1.05715) and silica gel $60F_{254}$ (#1.05715) impregnated with selected salts of inorganic acids developed by using mobile phase *n*-hexane–ethyl acetate–acetic acid is presented in Table 3.[7–9,14] It was observed that impregnation of silica gel $60F_{254}$ on glass plates with aqueous solutions of $CuSO_4$, $MnSO_4$, $NiSO_4$, and $FeSO_4$ facilitated the separation of GC from GDC and also C from GLC, which separated more poorly using NP-TLC on non-impregnated silica gel at 18°C.

Dołowy also separated selected bile acids on silica gel 60 (E. Merck, #1.05553) and on silica gel $60F_{254}$ (E. Merck, #1.05554) aluminum plates impregnated with Cu(II), Ni(II), Fe(II), and Mn(II) cations.[15]

RP18W (Merck, #1.14296), RP2 (Merck, #1.13726), and CNF_{254} (Merck, #1.12571), using methanol–water, dioxane–water, acetone–water, and organic mixture (methanol–acetonitrile, 50:50, v/v)–water as mobile phases; as well as on RP18W (Merck, #1.14296) and RP18 (Merck, #1.05914), using acetonitrile–phosphate buffer (V) in different compositions as mobile phases. None of the applied chromatographic conditions enabled complete separation of all bile acids. Complete separation ($\Delta R_F \geq 0.05$ and $R_S > 1$) was obtained for four or five pairs among six pairs of the investigated bile acids. Five neighboring pairs of bile acids—LC/DC ($\Delta R_{F(LC/DC)} = 0.10$, $R_{S(LC/DC)} = 1.38$), CDC/GLC ($\Delta R_{F(CDC/GLC)} = 0.08$, $R_{S(CDC/GLC)} = 1.56$), GLC/C ($\Delta R_{F(GLC/C)} = 0.08$, $R_{S(GLC/C)} = 1.04$), C/GDC ($\Delta R_{F(C/GDC)} = 0.12$, $R_{S(C/GDC)} = 1.38$), and GDC/GC ($\Delta R_{F(GDC/GC} = 0.09$, $R_{S(GDC/GC)} = 1.23$)—were separated only when CNF_{254} plates and the mobile phase acetone–water, 50:50 (v/v) were used. The biggest problem was how to separate DC from CDC. These bile acids were separated only on RP2 plates by using methanol–water, 65:35 (v/v) as the mobile phase ($\Delta R_{F(DC/CDC)} = 0.07$, $R_{S(DC/CDC)} = 1.26$).[16]

Selected bile acids (LC, DC, CDC, GLC, C, GDC, and GC) were separated by NP-TLC and RP-HPTLC. Two hundred forty-one combinations, which included changes of mobile and stationary phases (non-modified and modified adsorbents) as well as the influence of temperature on separation were examined using NP-TLC. One hundred sixty-one combinations, which included the changes of mobile and stationary phases, were examined using RP-HPTLC. It was stated that only some conditions of NP-TLC made possible separation of all neighboring pairs of bile acids.[6–16]

LIPOPHILICITIES OF SELECTED BILE ACIDS[17–20]

Lipophilicity of bile acids was investigated by RP-HPTLC on RP2, RP18, RP18W, and CNF_{254} plates using a water–organic modifier (methanol, acetonitrile, dioxane, acetone) in different volume proportions, which were varied in steps of 5% (v/v) from 35% to 80% (v/v), as mobile phases. Regular retention behavior was observed for each solute on investigated layers. The R_M values of the investigated acids were decreased with increasing fraction volume of organic modifier in the mobile phase. Because the R_M values were extrapolated to zero concentration of organic modifier in the mobile phase (R_{MW}), in accordance with the Soczewinski–Wachtmeister equation, $R_M = R_{MW} - S\varphi$ (where R_M is the value of the examined substance by content φ of volume fraction of organic modifier in mobile

phase, R_{MW} is the theoretical value of R_M of analyte extrapolated to zero concentration of organic modifier in mobile phase, S is the slope of the regression curve, and φ is the volume fraction of organic modifier in the mobile phase). It was found that the values of lipophilicity parameters of R_{MW} obtained by using RP-HPTLC depend linearly on the slope of the regression curve S. Therefore, the parameters of lipophilicity φ_0 were also calculated for studied bile acids. The lipophilic parameters R_{MW} and φ_0 values indicate that the investigated bile acids may be listed in order of decreasing lipophilicity as follows: LC > DC ≈ CDC ≈ GLC > C ≈ GDC > GC. Lipophilic parameters (R_{MW} and φ_0) were compared both with measured (logP_{exp}) and with calculated partition coefficients (*A*logP_S, *IA*log*P*, logP_{Kowwin}, *x*log*P*, C log*P*, logP_{Rekker}). The best agreement was affirmed between R_{MW} values and experimental partition coefficients (logP_{exp}). It was observed that partition coefficients obtained by using different methods (*A*logP_S, *IA*og*P*, *C*log*P*, logP_{Kowwin}, *x*log*P*, and logP_{Rekker}) for respective bile acids differ from each other in several cases. The most compatibility of absolute experimental values log*P* was found with the following:

- *A*logP_S and *IA*log*P* for DC, CDC, and GDC.
- *A*logP_S, *IA*log*P*, and *C*log*P* for C.
- *A*logP_S and *C*log*P* for GC.

The R_{MW} values for LC and GLC are most similar to the *A*logP_S.

Generally, it was stated that the most significant correlation was found between the values of R_{MW} and φ_0 lipophilic parameters and logP_{Kowwin} calculated from atom/fragmental contribution values. *IA*log*P* correlates with the above-mentioned lipophilic parameters slightly worse than logP_{Kowwin} does ($r > 0.90$). It was found that chromatographic parameter of lipophilicity R_{MW} may be an alternative method of lipophilicity determination for examined bile acids. Selected R_{MW} and φ_0 lipophilicity parameters and the values of experimental *n*-octanol–water partition coefficients and partition coefficients calculated by using different theoretical methods are presented in Table 4.[17–20]

APPLICATION OF STRUCTURAL DESCRIPTORS IN QSPR, QSRR, AND QSAR OF SELECTED BILE ACIDS[1,21,22]

Selected topological indices based on adjacency matrix (Gutman (M^{ν}), Randic [$^0\chi^{\nu}$, $^1\chi^{\nu}$ and $^2\chi^{\nu}$], and Pyka χ_{012}), distance matrix (Wiener (W) and Pyka [A, ^{0}B, ^{1}B, and C]), the electrotopological states ($SdO_{(acid)}$, $SsOH_{(acid)}$, $SsOH_{(aliph)}$ $SdO_{(amid)}$ and SsNH) were calculated. Correlation between selected physicochemical properties; i.e., molar mass (M_W), molar refraction (R_m), molar volume (V_m), parachor (P), refraction index (I_r), density (d), lipophilicity parameter (R_{MW} and φ_0), and obtained structural descriptions, was found.[1] Different possibilities of application of the structural descriptors to calculate certain physicochemical data of examined bile acids (QSPR)—depending on examined physicochemical properties—were found. The structural descriptions are not useful for calculating the density (d) of the examined bile acids. Substance density, especially the densities of liquids, not only changes with mass and structure; but, to a large extent, also depends on molecular interaction. Regression equations for respective physicochemical properties with the greatest correlation coefficients were found with the following structural descriptors:[1]

- For molar mass (M_W) with Wiener index (W) and with indices based on adjacency matrix M^{ν} and ${}^{0}\chi^{\nu}$ ($r > 0.98$).
- For molar refraction (R_m) with indices based on distance matrix W and A and adjacency matrix: ${}^{0}\chi^{\nu}$, ${}^{1}\chi^{\nu}$, and χ_{012} ($r > 0.99$).
- For molar volume (V_m) with index based on distance matrix ${}^{1}B$ and electrotopological states: $SdO_{(acid)}$ and $SsOH_{(acid)}$ ($r > 0.99$).
- For parachor (P) with indices based on distance matrix W and A and distance matrix: ${}^{0}\chi^{\nu}$, ${}^{1}\chi^{\nu}$, and χ_{012} ($r > 0.99$).
- For refraction index (I_r) with electrotopological states $SsOH_{(aliph)}$ and SsOH ($r > 0.98$).

Calculated structural descriptors were also used to determine linear relationships between lipophilicity R_{MW} or φ_0, determined for the 12 chromatographic systems studied,[17–20] or theoretical values of partition coefficients ($A\log P_S$, $I\log P$, $C\log P$, $\log P_{Kowwin}$, $x\log P$, and $\log P_{Rekker}$) or experimental values determined by the classical method ($\log P_{exp}$), and the respective structural descriptors.[21] It was stated that only two structural descriptors; i.e., the Gutman index (M^{ν}) and the Pyka index (C), are best for QSAR analysis of selected bile acids.

Structural descriptors can be used for the estimation of chromatographic separation of studied bile acids (QSRR), but only for optimal conditions of their separations. It was found that among all descriptors, only the values of topological index C change inversely proportionally to the R_F values and directly proportionally to the R_M values of examined bile acids. Thus, only the topological index C was used for determining the regression equations, which allowed calculation of R_F and R_M values of studied bile acids. The topological index C made it possible to obtain linear or quadratic equations. Generally, it was found that the regression equations which describe the relationships $R_F = f(C)$ have higher values of correlation coefficients than the relationship $R_M = f(C)$. Greater compatibility between calculated and real R_F values than between calculated and real (experimental) R_M values was stated. Therefore, the topological index C is more suitable for R_F calculation of examined bile acids than for R_M calculation.[1,22]

DETECTION OF BILE ACIDS

Spots of bile acids can be visualized by spraying the chromatographic plate with an anisaldehyde–sulfuric acid reagent (solution of 8 ml sulfuric acid, 0.5 ml anisaldehyde, 10 ml acetic acid, and 85 ml methanol),[23] a solution of antimony (III) chloride (Carr Price reagent) in chloroform (1:5, w/v),[23] a manganese (II) chloride–sulfuric acid reagent [solution of 0.2 g manganese (II) chloride, 30 ml water, 30 ml methanol, and 2 ml sulfuric acid],[23] or a 10% or 50% water solution of sulfuric acid and then heating until the spots became visible.[3,18] Bile acids can be also detected by dipping plates into 10% of phosphomolybdic acid in ethanol and then heating for 20 min at 120°C[18,23] or by spraying the plates with a 1% solution of phosphomolybdic acid in 2-propanol and then heating at 120°C for 5–10 min.[4] Wardas and Jedrzejczak[24] separated selected free and conjugated

bile acids by NP-TLC. Eleven visualizing agents were used for detection of these investigated bile acids. The best results of detection of bile acids were obtained with bromocresol blue.[24]

The solutions of sulfuric acid in methanol in different volume compositions were also used to detect investigated bile acids.[11] Chromatographic plates with separated bile acids were dipped in particular sulfuric acid solutions and then heated at temperature from 60°C to 120°C for times ranging from 2 to 45 min. The best detection conditions for high signal intensity [AU] of the separated bile acid spots were determined. Particularly robust and sensitive detection of investigated bile acids separated was observed using the solution of sulfuric acid in methanol in the volume composition 1:19 and for temperature equal to 90°C and heating for 20 min. However, phosphomolybdic acid was used as the comparative visualizing reagent for the detection of studied bile acids in these investigations. The absorption maximum of separated bile acids on silica gel 60 (E. Merck, #1.11845) with concentrating zone after application of methanolic solution of sulfuric acid in volume composition 1:19 and heating at 90°C for 20 min and of phosphomolybdic acid as visualizing reagents are presented in Table 5. Colors of chromatographic spots of separated bile acids are also presented in Table 5. It was affirmed, that the resolution $R_{S(c)}$ values obtained by the visual method are better for separated bile acids after their optimal detection using sulfuric acid in relation to the detection by the use of phosphomolybdic acid. Moreover, it was affirmed that the background of a chromatogram after detection with phosphomolybdic acid is heterogeneous, which is the cause of appearance of large noises on densitograms. Therefore phosphomolybdic acid as visualizing reagent in under conditions can be used only for qualitative or semi-quantitative investigations of investigated bile acids. Particularly robust and sensitive detection of investigated bile acids separated was observed using the solution of sulfuric acid in methanol in the volume composition 1:19 and for temperature equal to 90°C and heating for 20 min.[11] Chromatographic bands of bile acids on the densitogram after the use of spray solution of phosphomolybdic acid in methanol were irregular.[25] Therefore, this way of the detection of bile acids cannot be recommended. Regular chromatographic bands of bile acids on the densitogram were obtained after the use of dipping water solution of sulfuric acid.[11]

Binding Constants: Affinity Chromatography Determination

David S. Hage
John E. Schiel
Department of Chemistry, University of Nebraska-Lincoln, Lincoln, Nebraska, U.S.A.

Abstract
The use of affinity chromatography for the determination of binding constants is described in this entry. Approaches such as zonal elution, frontal analysis, and free fraction measurements can be utilized in affinity chromatography to obtain information on the extent and nature of solute–ligand binding. Information on the kinetics of solute–ligand binding can also be obtained through a variety of methods, such as band-broadening measurements, peak profiling, peak fitting, split-peak studies, and peak decay analysis. Advantages of using affinity chromatography for this type of work include the simplicity of this approach, its good precision and accuracy, and its ability to reuse the same ligand preparation for multiple studies.

INTRODUCTION

Numerous interactions within cells and the body are characterized by the specific binding that occurs between two or more molecules. Examples include the binding of hormones with hormone receptors, drugs with enzymes or receptors, antibodies with antigens, and small solutes with transport proteins. The study of these interactions is important in determining the role they play in biological systems. Because of this, there have been many methods developed to characterize such reactions. One of these approaches is affinity chromatography.

Affinity chromatography is a liquid chromatographic technique that makes use of an immobilized ligand, usually of biological origin, for the separation or analysis of chemicals within a sample. However, it is also possible to use affinity chromatography as a tool for studying the interactions between the ligand and injected solutes. This application is known as *quantitative affinity chromatography*, *analytical affinity chromatography*, or *biointeraction chromatography*.

Some advantages in using affinity chromatography to study biological interactions include the relative simplicity of this approach as well as its good precision, accuracy, and ability to use the same ligand preparation for multiple studies. The last feature creates a situation in which only a relatively small amount of ligand is needed for a large number of studies, which in turn helps provide good precision by minimizing run-to-run variations. Other advantages include the ease with which affinity methods can be automated, especially when used in high-performance liquid chromatography (HPLC) (giving a method known as *high-performance affinity chromatography*, or *HPAC*), and the relatively short periods of time that are required with such systems for binding studies (i.e., often 5–15 min per analysis). The continuous washing of the immobilized ligand by the application of the solvent is another advantage as this process minimizes the effects produced by soluble contaminants in the initial ligand preparation.

ZONAL ELUTION

The method of zonal elution is one of the most common techniques used in affinity chromatography to examine biological interactions.[1–5] An example of this method is shown in Fig. 1.[6] In its usual form, zonal elution involves the application of a small amount of analyte (in the absence or presence of a competing agent) to a column that contains an immobilized ligand. The retention of the analyte in this case will depend on how strongly the analyte and competing agent bind to the ligand and on the amount of ligand that is in the column. This makes it possible to measure the equilibrium constants for these binding processes by examining the change in analyte retention as the competing agent's concentration is varied.

Zonal elution was first used in affinity chromatography in 1974 for the quantitative analysis of biological interactions. This work was performed by Dunn and Chaiken, who examined the retention of staphylococcal nuclease on a low-performance column containing immobilized thymidine-5′-phosphate-3′-aminophenylphosphate.[1] By the late 1980s and early 1990s, reports that used this approach with HPLC also began to appear. Zonal elution and affinity chromatography have since been used to examine numerous systems, including the binding of drugs with transport proteins or receptors, lectins with sugars, enzymes with inhibitors, and hormones with hormone-binding proteins.[2–5]

Zonal elution has been used in various ways to obtain information on the binding of solutes to a ligand. These methods include not only measurements of the degree and affinity of solute–ligand binding but also studies examining changes in binding with variations in the mobile phase composition or temperature and experiments that consider

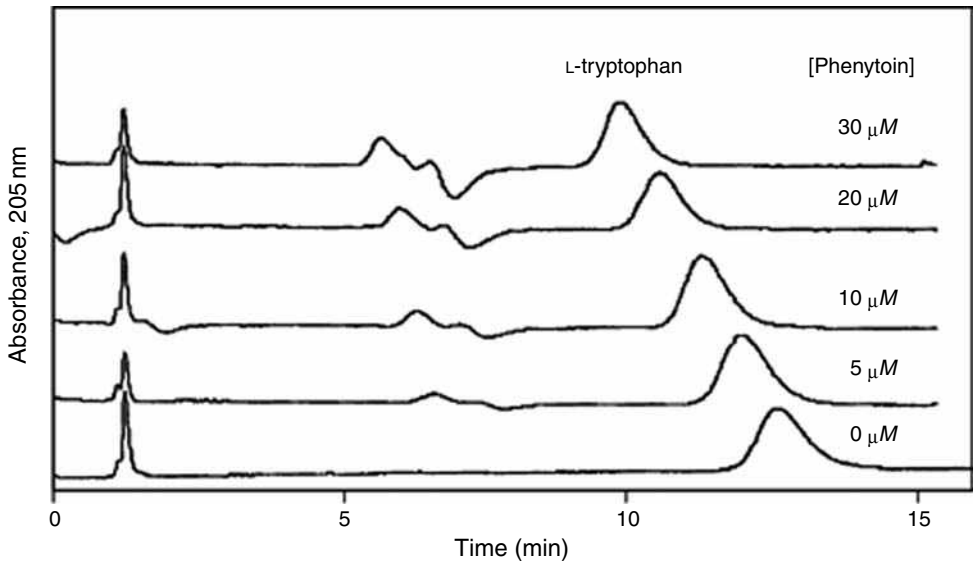

Fig. 1 Zonal elution studies for the injection of L-tryptophan onto an immobilized human serum albumin column in the presence of various concentrations of phenytoin as a mobile phase additive.
Source: From Studies of phenytoin binding to human serum albumin by high-performance affinity chromatography, in J. Chromatogr. B.[6]

how alterations in solute or ligand structure affect these interactions. Each of these applications relies on the fact that the retention observed for an injected analyte is a direct measure of the strength of binding of the analyte to the ligand within the column. This idea is described by Eq. 1, which shows how the overall retention factor (k) for an analyte is related to the moles of binding sites in the column (m_L) and to the association equilibrium constants for the analyte at each of these sites.[3]

$$k = \frac{(K_{a1}\ n_1 + \ldots\ K_{an}\ n_n)m_L}{V_M} \quad (1)$$

In Eq. 1, V_M is the column void volume; the association equilibrium constants for the analyte at the individual sites are given by the terms K_{a1} through K_{an}, while the fraction of each type of site in the column is given by the terms n_1 through n_n. From this equation, it can be seen that a change in the strength of binding, the number of binding sites, or the relative distribution of these sites can result in a shift in analyte retention.

One way zonal elution has been employed in quantitative studies of solute–ligand interactions is as a means to measure the average extent of binding that occurs between a solute and immobilized ligand.[3] This approach is based on the fact that the retention factor, when measured at true equilibrium, is equal to the fraction of an injected solute that is bound to the ligand (b) divided by the fraction of solute that remains free in the mobile phase (f), or $k = b/f$. The relative binding of two solutes can also be compared by using zonal elution and by taking the ratio of their retention factors on the same affinity column. According to Eq. 1, if both solutes have a single common binding site on the ligand, the ratio of their retention factors should equal the ratio of their association constants at this site. However, caution must be exercised when using this approach with solutes that have multisite binding or slightly different binding regions on a ligand, because these regions and sites may have different susceptibilities to a loss of activity during ligand immobilization.[7]

The second and most common use for zonal elution and affinity chromatography in the examination of biological interactions has been in competition and displacement studies. This work is performed by injecting the analyte while a fixed concentration of a potential competing agent is passed through the column in the mobile phase. It is relatively easy in such an experiment to determine whether two compounds interact as they bind to the same immobilized ligand. However, to obtain further information on this interaction (e.g., the nature of this competition and the number of sites that are involved), it is necessary to compare the zonal elution data to the response expected for various models, as given in Eq. 2 for a system with 1:1 competition between an injected analyte (A) and a competing agent (I).

$$k = \frac{K_{a,A}\ m_L}{V_M\left(1 + K_{a,I}\ [I]\right)}$$

or

$$\frac{1}{k} = \frac{K_{a,I}\ [I]\ V_M}{K_{a,A} m_L} + \frac{V_M}{K_{a,A} m_L} \quad (2)$$

Similar equations can be derived for other systems, such as those involving multiple binding sites or both the soluble

and immobilized forms of a ligand.[2–5] In Eq. 2, $K_{a,A}$ and $K_{a,I}$ are the association equilibrium constants for the binding of the ligand to the analyte and competing agent at their site of competition. The term [I] is the concentration of I that is being applied to the column in the mobile phase, m_L is the moles of common binding sites on the immobilized ligand for A and I, and k is the retention factor measured for A. In this case, the values of the association constants $K_{a,A}$ and/or $K_{a,I}$ can be obtained by examining how the retention factor for A changes as [I] is varied.

A third way zonal elution and affinity chromatography can be used is to consider how changes in the reaction conditions affect solute–ligand binding. For instance, these factors can be examined by varying the pH, ionic strength, or general content of the mobile phase.[4] This information can be valuable in determining the relative contributions of various forces to the formation and stabilization of a solute–ligand complex. As an example, changing the pH can affect the interactions between a ligand and solute by altering their conformations, net charges, or coulombic interactions. An increase in ionic strength tends to decrease coulombic interactions through a shielding effect, but may also cause an increase in non-polar solute adsorption. Adjusting the solvent polarity by adding a small amount of organic modifier can alter solute–ligand binding by disrupting non-polar interactions or by causing a change in solute and ligand structure.[4,8]

Temperature is another factor that can be varied during zonal elution studies. For instance, Eq. 3 can be used for a system with 1:1 binding

$$\ln k = -\left(\frac{\Delta H}{RT}\right) + \frac{\Delta S}{R} + \ln\left(\frac{m_L}{V_M}\right) \quad (3)$$

where T is the absolute temperature at which the retention factor is measured, R is the gas law constant, ΔH is the change in enthalpy for the reaction, ΔS is the change in entropy, and other terms are as defined previously. If it is known that there is no temperature dependence in the number of binding sites (m_L) for a ligand, the slope of a linear plot of ln k versus $1/T$ can be used to determine the value of ΔH for a solute–ligand system.[9]

Another application of zonal elution in affinity chromatography is its use in determining the location and structures of binding regions on a ligand. If it is known that one agent interacts with a specific site on a ligand, competition studies with this agent can be used to determine if other compounds bind at the same site. Another approach for learning about binding sites is to study how a change in the structure of a solute or ligand will affect their interactions. This is the principle behind the use of zonal elution to develop a *quantitative structure–retention relationship* (*QSRR*). This method involves measuring the retention factors on an affinity column for a large set of structurally related compounds under constant temperature and mobile phase conditions. The resulting data are then compared to factors that describe various structural features of the solutes.[10,11] A complementary approach is to use zonal elution to investigate how solute retention changes as alterations are made to binding sites on a ligand, as has been performed in work with modified proteins and protein fragments.[4,12,13]

FRONTAL ANALYSIS

An alternative approach for equilibrium constant measurements in affinity chromatography is to use frontal analysis. This method is sometimes known as *frontal affinity chromatography* (*FAC*). In this technique, a solution containing a known concentration of the analyte is continuously applied to an affinity column at a fixed flow rate (Fig. 2). As the analyte binds to the immobilized ligand, the ligand

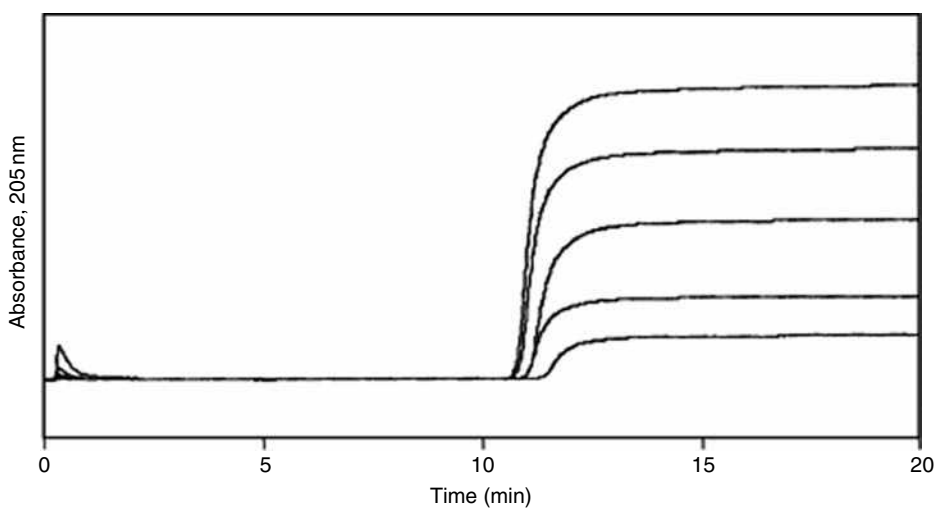

Fig. 2 Frontal analysis studies for the binding of phenytoin to immobilized human serum albumin at applied analyte concentrations (bottom-to-top) of 5, 10, 20, 30, and 40 μM.
Source: From Studies of phenytoin binding to human serum albumin by high-performance affinity chromatography, in J. Chromatogr. B.[6]

becomes saturated and the amount of analyte eluting from the column gradually increases. This forms a characteristic breakthrough curve. The volume of analyte solution or moles of applied analyte that is required to reach the mean position of this breakthrough curve is then measured. If the association and the dissociation kinetics are fast, the mean position of this curve can be related to the concentration of the applied solute, the amount of ligand in the column, and the association equilibrium constants for solute–ligand binding. Frontal analysis experiments have been used to examine such systems as drug–protein binding, antibody–antigen interactions, and enzyme–inhibitor interactions.[3–5]

A simple example of a frontal analysis system is one where an applied analyte binds to a single type of immobilized ligand site. In this situation, Eq. 4 can be used to relate the total moles of active binding sites in the column (m_L) to the apparent moles of analyte ($m_{L,app}$) that are required to reach the mean position of the breakthrough curve at a given concentration of applied analyte [A].

$$m_{L,app} = \frac{K_{a,A} m_L [A]}{1 + K_{a,A}[A]}$$

or

$$\frac{1}{m_{L,app}} = \frac{1}{K_{a,A}\ m_L\ [A]} + \frac{1}{m_L} \quad (4)$$

As defined earlier, $K_{a,A}$ is the association equilibrium constant for the binding of the analyte to the ligand. In this case, the value of $K_{a,A}$ can be determined by calculating the ratio of the intercept to the slope in the second form of Eq. 4, and $1/m_L$ can be obtained from the inverse of the intercept. Similar relationships can be derived for cases in which there is more than one type of binding site or in which both a competing agent and solute are applied simultaneously to the column.

A second application of frontal analysis has been as a tool to examine the competition between solutes for an immobilized ligand.[14–16] This is carried out in a manner similar to that described for zonal elution, in which the change in analyte retention is measured as a function of the competing agent's concentration in the mobile phase. In frontal analysis, direct competition between the analyte and competing agent leads to a smaller breakthrough time for the analyte as the competing agent's level is increased. Positive and negative allosteric effects can also be observed, which lead to a shift to higher and lower breakthrough times, respectively, with an increase in the competing agent's concentration. The same technique can be used to examine how temperature, pH, ionic strength, or solvent polarity might affect solute–ligand binding.[3] Like zonal elution, frontal analysis can be used to examine the binding of solutes to modified proteins to provide information on the nature of solute–ligand binding sites.[12,17]

Another application of frontal analysis is its use in affinity chromatography for screening mixtures of compounds for any targets that might bind to a given immobilized ligand.[18,19] The use of these tools with mass spectrometry (MS), leading to an approach known as *frontal affinity chromatography–mass spectrometry* (*FAC–MS*), is of particular interest.[19] In this approach, a mixture of analytes is passed through the affinity column and the individual analytes bind to the ligand based on their affinity for this agent. Selective detection at the characteristic mass-to-charge (m/z) value for each analyte makes it possible to generate separate breakthrough curves for each of these compounds. This information is then used to evaluate and rank the relative affinity of each compound in the mixture for the ligand in the affinity column.[18]

One disadvantage of frontal analysis is that it often requires a relatively large amount of analyte for study. However, this requirement can be minimized through the use of small-scale columns.[19] Frontal analysis is advantageous in that it provides information on both the association constant for a solute and its total number of binding sites in a column. This feature makes frontal analysis the method of choice for high accuracy in equilibrium measurements, because the resulting association constants are essentially independent of the number of binding sites in the column.

FREE FRACTION ANALYSIS

Another recent method employed for solute–ligand studies is chromatographic *free fraction analysis*. This uses small columns with antibodies that bind the solute of interest and are capable of extracting this solute in very short periods of time (i.e., 80–200 msec). With such a column it is possible to isolate the non-bound fraction of a solute from a solution in which most of this compound is bound to a soluble ligand, even when dissociation of the solute from this ligand occurs on the timescale of a few seconds. This approach can be used to examine the binding of *R*- and *S*-warfarin with human serum albumin (HSA) in solution, in which antiwarfarin antibodies were used to extract free warfarin fractions in less than 180 msec.[20] The same general approach was used to measure the free fractions of L-thyroxine and phenytoin in serum samples and in the presence of HSA.[21,22] The advantages of this approach are its speed and the ability to study the binding of solutes with ligands directly in solution.[20–22]

BAND-BROADENING MEASUREMENTS AND PEAK PROFILING

Another group of methods in quantitative affinity chromatography are those that examine the kinetics of biological interactions. Band-broadening measurements (also known as the *isocratic method* or *plate height method*) represent

one such approach. This is a modification of the zonal elution method in which the widths of the eluting peaks are measured along with their retention times. Systems that have been studied with this method include the binding of lectins with sugars, the interactions of drugs and amino acids with serum albumin, and the kinetics of protein-based chiral stationary phases.[2,23,24]

This type of experiment involves injecting a small amount of analyte onto an affinity column while carefully monitoring the retention time and width of the eluting peak. These injections are performed at several flow rates on both the affinity column and on a column of the same size that contains an identical support but with no immobilized ligand present. This control column is needed to correct for any band broadening that occurs due to processes other than the binding and dissociation of analyte from the immobilized ligand. By using plots of the peak widths (or plate heights) for the affinity and control columns, it is possible to determine the value of the dissociation rate constant for the analyte–ligand interaction. An example of such a study is given in Fig. 3.

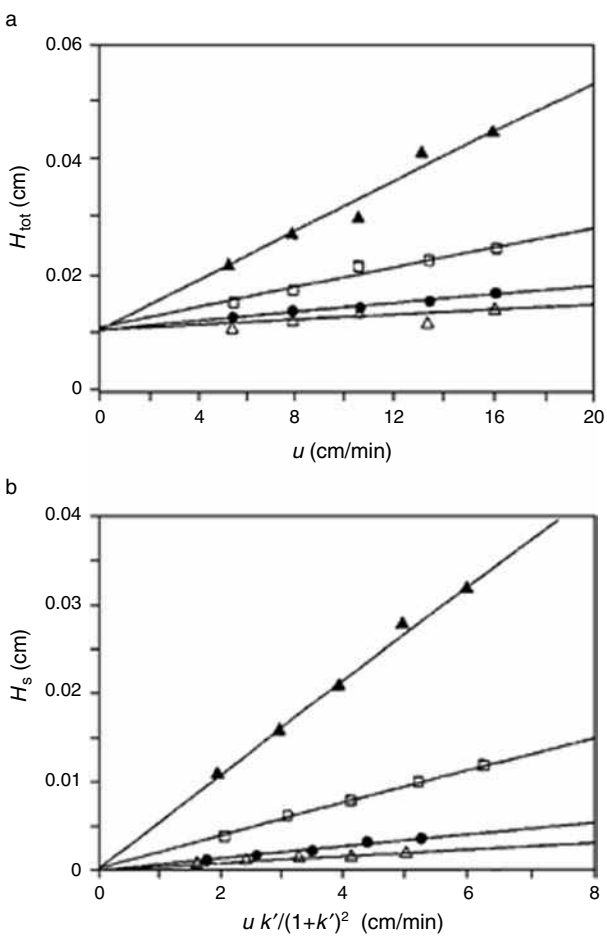

Fig. 3 Typical plots of (a) total plate height (H_{tot}) and (b) the plate height contribution due to stationary phase mass transfer (H_s) for injections of D-tryptophan at various flow rates onto an immobilized human serum albumin column. Symbols: u, linear velocity; k', retention factor.

Source: From Effect of mobile phase composition on the binding kinetics of chiral solutes on a protein-based high-performance liquid chromatography column: Interactions of D- and L-tryptophan with immobilized human serum albumin, in J. Chromatogr. A.[24]

An approach that is closely related to the plate height method is the technique of *peak profiling*. This approach was first suggested in 1975 by Denizot and Delaage.[25] In this method, measurements of the retention time for an analyte (t_R) and the elution time of a non-retained solute (t_M) are made on the same column. These elution times are then used with variances observed for the peaks of the analyte (σ_R^2) and non-retained species (σ_M^2) to calculate the apparent dissociation rate constant ($k_{d,app}$), as is demonstrated in Eq. 5.[25]

$$k_{d,app} = \frac{2\,t_M^2\,(t_R - t_M)}{\sigma_R^2\,t_M^2 - \sigma_M^2\,t_R^2} \tag{5}$$

Although this method is relatively simple and fast to perform, the use of Eq. 5 does assume that other band-broadening processes are the same for the non-retained and retained species. This assumption can create errors if significant peak broadening due to stagnant mobile phase mass transfer is present. In this situation, conditions that minimize the contribution of these other effects must be used,[26] or an alternative form of the peak profiling method can be utilized in which corrections are made for these other contributions to band broadening.[27]

PEAK FITTING METHODS

Some methods for obtaining kinetic information by affinity chromatography fit experimental elution data to empirical equations that can be used to describe profiles for a given set of application conditions. For instance, this approach has been used with zonal elution data obtained under non-linear elution conditions by using the following function.[28,29]

$$y = \frac{a_0}{a_3}\left[1 - \exp\left(\frac{-a_3}{a_2}\right)\right]\ \frac{\sqrt{\frac{a_1}{x}}\,I_1\left(\frac{2\sqrt{a_1 x}}{a_2}\right)\exp\left(\frac{-x-a_1}{a_2}\right)}{1 - T\left(\frac{a_1}{a_2},\frac{x}{a_2}\right)\left[1 - \exp\left(\frac{-a_3}{a_2}\right)\right]} \tag{6}$$

In this equation, y is the intensity of the measured signal, x is the reduced retention time, T is a switching function, and I_1 is a modified Bessel function. The terms a_0 through a_3 are the best-fit parameters used to estimate the value of the rate constants and equilibrium constant for the analyte–ligand interaction. This method has been employed in studying pNp–mannoside binding to immobilized concanavalin A[28] and the binding of various inhibitors to

immobilized nicotinic acetylcholine receptor membrane affinity columns.[30,31]

The kinetics of biological interactions have also been examined by fitting profiles generated when using frontal analysis and affinity chromatography. Many of the models and expressions that are used for this purpose are based on the initial work of Thomas.[29] This model gives an apparent rate constant for analyte binding to the column, in which it is assumed that mass transfer is infinitely fast and analyte adsorption is described by second-order Langmuir kinetics based on interaction at a single type of homogeneous ligand-binding site.[29,32,33]

SPLIT-PEAK EFFECT

Another way in which kinetic information can be obtained by affinity chromatography is the *split-peak method*.[2,34] This is based on an effect that occurs when the injection of a single solute gives rise to two peaks: the first representing a non-retained fraction and the second representing the retained solute. This effect can be observed even when only a small amount of analyte is injected and is the result of slow adsorption kinetics and/or slow mass transfer of analyte within the column (Fig. 4). Such an effect can occur in any type of chromatography but is most common in affinity columns because of their smaller size, their lower amount of binding sites, and the slower association rates of affinity ligands compared to other types of stationary phases.

Split-peak measurements can be performed by injecting a small amount of analyte onto an affinity column at various flow rates. A plot of the inverse negative log of the measured free fraction is then made versus flow rate. The slope of this graph is related to the adsorption kinetics and mass transfer rates within the column. If the system is known to have adsorption-limited retention, or if the mass transfer rates are known, then the association rate constant for analyte binding can be determined. This approach has the advantages of being fast to perform and potentially has greater accuracy and precision than band-broadening measurements. Its disadvantages are that it requires fairly specialized operating conditions that may not be suitable for all analytes. Examples of biological systems that have been examined by the split-peak method include the binding of protein A and protein G to immunoglobulins, and the binding of antibodies with antigens.[2,34–36]

PEAK DECAY METHOD

The *peak decay method* can also be used in affinity chromatography to examine the kinetics of an analyte–ligand interaction.[2,37] This technique is performed by first equilibrating and saturating a small affinity column with a solution that contains the analyte of interest or an easily detected analogue of this analyte. The column is then quickly switched to a mobile phase in which the analyte is not present. The release of the bound analyte is monitored over time, resulting in a decay curve. This decay is related to the dissociation rate of the analyte and the mass transfer kinetics within the column. If the mass transfer rate is known or is fast compared to analyte dissociation, the decay curve can be used to provide the dissociation rate constant for the analyte from the immobilized ligand. Systems studied with this approach include the dissociation of drugs from transport proteins and the dissociation of sugars from immobilized lectins.

CONCLUSION

It has been shown that there are a variety of ways in which information on solute–ligand binding can be obtained by affinity chromatography. Zonal elution, frontal analysis, and free fraction analysis are the approaches that have been developed for such studies. With these methods, information can be obtained on the extent of solute–ligand binding, binding affinity and stoichiometry, and the structure of binding sites. Kinetics information can also be obtained through a variety of methods, including band-broadening measurements, peak profiling, peak fitting methods, split-peak studies, and peak decay analysis.

Binding Molecules via –SH Groups

Terry M. Phillips
Ultramicro Analytical Immunochemistry Resource (UAIR), DBEPS, ORS, OD, National Institutes of Health, Bethesda, Maryland, U.S.A.

INTRODUCTION

A prerequisite for producing a good affinity support is a firm, stable attachment of the ligand to the surface of the support. There are numerous linkage chemistries available for performing this task, and although the most popular approach is a reaction between the reactive side groups on the support and a primary amine on the ligand, there are a number of supports that can perform similar attachments through free thiol or sulfhydryl groups.

METHODOLOGY

Supports containing maleimide reactive side groups are specific for free sulfhydryl groups present in the ligand when the reaction is performed at pH 6.5–7.0. At pH 7.0, the interaction of maleimides with sulfhydryl groups is approximately a 1000-fold faster than with amine groups. The stable thioether linkage formed between the maleimide support and the sulfhydryl group on the ligand cannot be easily cleaved under physiological conditions, therefore ensuring a stable affinity matrix. Immobilization of sulfhydryl-containing molecules can also be achieved using either α-haloacetyl or pyridyl sulfide cross-linking agents. The α-haloacetyl cross-linkers [i.e., *N*-succinimidyl(4-iodoacetyl)aminobenzoate] contain an iodacetyl group that is able to react with sulfhydryl groups present in the ligand at physiological pH. During this reaction, the nucleophilic substitution of iodine with a thiol takes place, producing a stable thioether linkage. However, a shortcoming of this approach is that the α-haloacetyls interact with other amino acids, especially when a shortage or absence of free sulfhydryl groups exists. Linkage of pyridyl disulfides with aliphatic thiols at pH 4.0–5.0 produces a disulfide bond with the release of pyridine-2-thione as a by-product of the reaction. A disadvantage of this approach is the acidic pH of the reaction, which is essential for optimal linkage. The reaction can be performed at physiological pH, but under these conditions, the reaction is extremely slow.

Ligand immobilization through sulfhydryl groups can be advantageous due to its ability to be site-directed. Additionally, depending upon the linkage, the ligand–support can be cleavable, allowing the same support to be reused. However, many useful affinity ligands do not possess free sulfhydryl groups and in such cases, free sulfhydryl groups can be engineered into the ligand via a series of commercially available reagents. Traut's reagent (2-iminothiolane) is the most common, although *N*-succinimidyl *S*-acetylthioacetate (SATA), dithio-*bis*-maleimidoethane (DTME), and *N*-succinimidyl-3-(2-pyridyldithio)-propionate (SPDP)[1] can also be used (Fig. 1). Traut's reagent reacts with primary amines present in the ligand introducing exposed sulfhydryl groups for further coupling reactions.

Chrisey, Lee, and O'Ferrall[2] describe an interesting use of sulfhydryl-mediated immobilization for binding thiol-modified DNA. A hetero-bifunctional cross-linker bearing both thiol and amino reactive groups was used to immobilize thiol-modified DNA oligomers to self-assembled monolayer silane films on fused silica and oxidized silicon substrates. The advantage of this approach

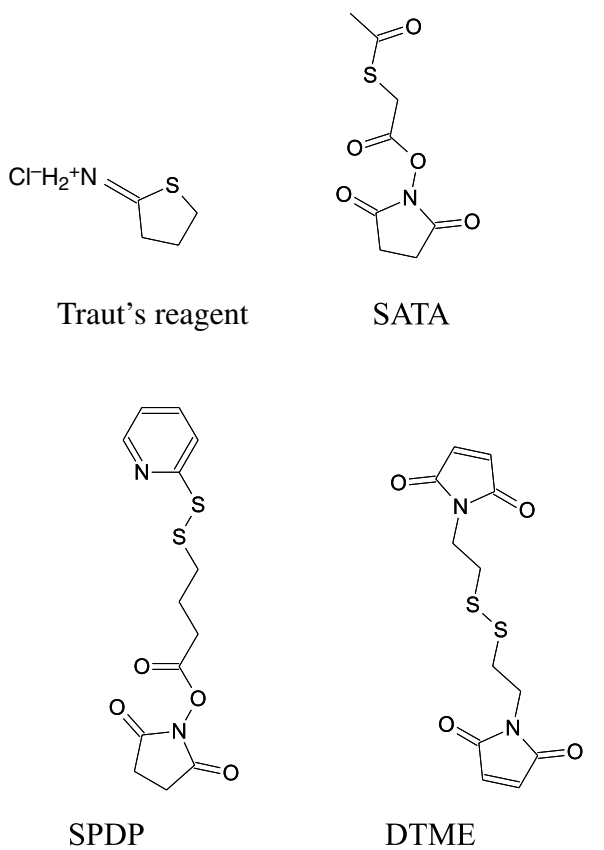

Fig. 1 Chemical structures of commercially available reagents for introducing sulfhydryl groups into molecules.

was the use of site-directed immobilization to ensure the correct orientation of the DNA molecule.

ANTIBODY IMMOBILIZATION

Cleaving disulfide bonds already present in the ligand can also generate free sulfhydryl groups. The classic example of this approach is the digestion of the IgG antibody molecule to produce two monovalent, reactive Fab fragments each containing a free sulfhydryl group. In this case, reduction of the disulfide bridge (holding the two Fab arms together) is achieved using Cleland's reagent (dithiothreitol—DTT). Each Fab is then attached to free thiol groups present on the support by reforming a disulfide bond.[3–5] Free thiol groups can be condensed into silane-activated surfaces via sulfosuccinimidyl-4-(*N*-maleimidomethyl)-cyclohexane-1-carboxylate (sulfo-SMCC) or *N*-(β-maleimidopropyloxy) succinimide ester (BMPS). The advantage of this approach is that not only is a covalent linkage formed but also the linkage helps to orient the antigen receptor of the Fab away from the support matrix.

Abstract
There has been significantly more interest over the past decade in what is now termed *monolithic*. This is not because the current column technology is unsatisfactory, but monolithic material has opened up a new avenue for separation and has a significant impact on just about all analytical procedures. The use of this material for high-performance liquid chromatography (HPLC), ion chromatography (IC), and capillary electrochromatography (CEC) is finally taking hold, being provided commercially by manufacturers. Similarly, the increase in applications has proved that this material is finally becoming mainstream. The goal of this entry is to provide an overview of silica- and polymer-based monolithic material, with a special focus on how the material is being used in the manufacture of analytical columns. A comparison of silica- and polymer-based monolithic columns is made with an emphasis on their differences and similarity. Key applications are presented as a reference to highlight how the monolithic columns are being used for high-throughput drugs and metabolites, ion chromatographic separation, and proteomics.

INTRODUCTION

The introduction of a monolithic column might be a new approach or paradigm shift in how chromatography is done, but high-performance liquid chromatography (HPLC) has been very successful for decades. HPLC analysis has addressed issues encountered daily in the field of biochemistry and analytical chemistry by separation of mixtures, identification and quantitation of the individual component in the mixtures. HPLC utilizes a column that holds a packing material, a pump that moves the mobile phase(s) through the packed column, and a detector to determine the component in the mixture.[1] At the "center" of the entire HPLC procedure is the column (packed, porous material), through which the mobile phase passes. The choice of the packing material and mobile phase is made in such a way that the sample components equilibrate rapidly between the liquid and the solid phase (Fig. 1). For this process to work, the analytes should be exchanged rapidly and frequently between the mobile phase and the column material.[2] This approach leads to high column efficiency. The prerequisite for this fast equilibrium and high efficiency is fast mass transfer and the surface area of the column material must be large.

The search for the perfect chromatography began over a century ago with the work of the Russian botanist Michael Tswett,[1] who used column liquid chromatography in which the stationary phase was a solid adsorbent and the mobile phase was a liquid. The major breakthrough that would eventually lead to many of the developments of modern-day chromatography came from the work of Martin and Synge.[3] Packing material with a smaller particle size is necessary to achieve the necessary efficiency in today's chromatography. However, since particle size has an inverse squared dependence on column pressure, all particle-based chromatographic columns are limited by pressure. To overcome this hurdle, a new approach to column technology was necessary, and it was found with the development of monolithic columns.[4] The first appearance of the word monolith appeared in a publication in 1993, which describes the material as a single mass of material.[5] This term has taken hold and has provided the field of chromatography with a new and promising approach to analysis.

Several different monolithic supports are described in the literature, going back several decades. They have been synthesized from different chemicals to form silica,[6–9] acrylamide,[10–13] styrene and methacrylate,[14–16] and methacrylate[17–19] monoliths. Generally, the different types of monolithic material synthesized over the years can be subdivided into two classes: 1) silica-based and 2) polymer-based monoliths. The monolithic column that is manufactured can be viewed as a single piece of porous material. The bed of the polymer-based monolithic column resembles that of a loose packing of spherical particles with a wide size distribution. However, the silica monolith is more of a fractal morphology showing a bimodal pore size (mesopores and macropores) distribution (Fig. 2). The pores of the columns are highly interconnected to form an integrated network of channels. The mesopores, about

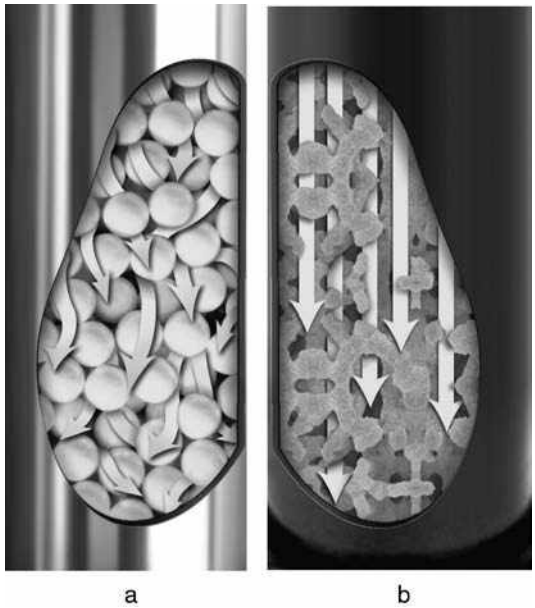

Fig. 1 Mobile phase flow through particle-based column (a) and a monolithic column (b).

13–25 nm in size, form the intraparticle network that gives access to the large surface area of the stationary phase primarily responsible for retention and column efficiency. The macropores with a size of 1 μm are the channels that the mobile phase percolates. As a result of the pores, monolithic columns operate at a significantly reduced back pressure. As reported by Cabrera,[9] the reduced pressure permits flow rates as high as 1–9 ml/min, which is not possible with typical particle columns (Fig. 3).

In the 1990s there was great interest in using monoliths for liquid chromatography (LC) or capillary electrochromatography (CEC), with extensive research devoted to developing a robust and reliable commercially available product. Siouffi[20] listed four approaches taken by researchers in creating the perfect monolith:

1. Formation of a silica-based network.
2. A polymer-based monolith from an organic monomer with additives.
3. Fusing the porous particulate in a capillary by the sintering process.
4. Organic hybrid materials.

If we can use the number of applications and published papers as a measure of success, silica- and polymer-based monoliths are certainly the winner. In part, this has come about as a result of industry getting involved and making the product available on a mass scale. The introduction of the first commercially available product, the Chromolith™ from Merck KGaA (Darmstadt, Germany), saw the beginning of a new routine chromatographic media.

The aim of this entry is to provide an overview of the monolithic phases that are most commonly or widely used (silica- and polymer-bases) in chromatography. In describing these materials, the focus will be on highlighting the differences between the phases and finally providing key applications to demonstrate the use of material.

SILICA-BASED MONOLITHS

This type of monolithic column was first reported by Tanaka et al.[6–8] It uses a new sol-gel process developed by Nakanishi and Soga that was based on the hydrolysis and polycondensation of alkoxy silicon derivatives [e.g., tetramethoxysilane (TMOS) or tetraethyloxysilane (TEOS) in the presence of polyethylene oxide (PO)].[21–26] They described the procedure enabling control of the bimodal pore size that is critical in the manufacture of successful analytical columns. Generally, the silica-based monoliths are prepared through a two-step process, the first step being a sol-gel mechanism overlapping the spinodal phase transition. This process determines the mesopore size and diameter. The second step is a solvent exchange with the material to carve out the silica skeleton of the mesopores. The uniform structure of the monolithic material with regular spacing and size of pores provides a surface area that is much larger than polymer-based monoliths.

In the preparation of this material, the silicon derivative is dissolved in a solvent with an aqueous solution (acid or base), which reacts to produce a gel material.[2,20] The pore size, distribution, and mechanical properties of the gel can be controlled with an additive. In the case of Nakanishi and Soga, they used polyacrylic acid and later changed to PO. By adjusting the concentration of TMOS or PO, they were able to control the pore size distribution or to produce a matrix of different degrees of strength. After preparation, the silica monolithic material has to undergo an aging and drying process. This is a critical stage in making a successful silica monolithic column and special care has to taken. Aging in a solution tends to increase the stiffness and strength of the gel. As reported by Nakanishi et al.,[27] aging the gel in the presence of a basic solution with heat treatment has an influence on the size and distribution of the mesopores. The temperature also influences the rate of formation of the pores and its network distribution. Drying of the monolith is as important as the aging process, as poor drying could lead to cracking or shrinkage of the material. The shrinkage and possible cracking of the monolithic material is a much more serious problem in the preparation of normal size HPLC columns. Nevertheless, cracking of the monolithic material could make the material unusable for chromatography. Shrinking upon drying causes the material to be separated from the column wall, thereby creating a void space. The void space would create a nonuniform flow across the column, the mobile phase tending to bypass the monolithic pores for the void space. Minakuchi et al. have demonstrated a fall of almost 2 mm after drying.[8] The drying process is very slow and takes place under an inert gas. For large HPLC columns, this process can take as long as 1 month.

Cladding the monolithic material is the last process to make a successful chromatographic column. The preparation process for monolithic silica rods was first patented in Japan and later in the United States.[24–26] Although other academic research groups have been working on monolithics, the difficulty (drying and cladding) described above has created an opportunity for industry to bring this material to market. Moreover, most of these groups have focused their interest in developing in situ preparation of capillary monolithic columns based on the work of Nakanishi et al. because of the difficulty of encasing the monolithic rods.

Although capillary columns are used in analytical chemistry, a large percentage of the columns in use today are still the conventional HPLC columns (2–4.6 mm). This has created a great opportunity for Merck KGaA, which has independently developed a process for the manufacture of monolithic columns (Chromolith) with the work of Cabrera et al. and has patented it.[16] Certainly with the gradual developments in analysis by LC/MS, Merck KGaA (http://www.Merck.de) has made available the Chromolith CapRod® (150 × 0.1 mm). Likewise, Phenomenex (http://www.phenomenex.com) has developed its line of monolithic columns (Onyx™) based on the same technology as Merck KGaA. The Onyx monolithic columns are available both in the conventional (100 × 4.6 mm) and in the capillary (150 × 0.1 mm) form.

POLYMER-BASED MONOLITHS

Hjerten and coworkers first introduced this type of monolithic column, based on polyacrylamide, in the early 1990s.[10–13] This process was further enhanced by the work of Svec and Frechet, which demonstrated the in situ copolymerization of glycidyl methacrylate and ethylene dimethacrylate.[14,17–19] As a result of these developments, a unique branch of monolithic column technology was developed. Creating this form of monolithic material requires a mold or tube that is sealed at one end, filled with the polymerization mixture, and then sealed at the other end. The polymerization is initiated by either heat or ultraviolet light. A wide variety of material have been used as the mold such as poly(ether-ether-ketone) (PEEK), fused silica capillary, or stainless steel. This process is an exothermic reaction and the heat must be controlled in order to produce a homogeneous porous structure. The polymerization comprises monomers, initiator, and porogenic solvent. Guiochon[2] has highlighted the fact that polymer-based monolithic columns can be classified based on the monomers used in the preparation. As stated by Svec,[28] the versatility of these preparation techniques was demonstrated by the use of hydrophilic (2-hydroxyethyl methacrylate, methacrylamide, methylenebisacrylamide), hydrophobic (styrene, divinylbenzene, butyl methacrylate, ethylene dimethacrylate), ionizable (vinylsulfonic acid, 2-acrylamido-2-methyl-propanesulfonic acid), and tailor-made (norbone-2-ene, 1,4,4a,5,8,8a-hexahydro-1,4,5,8-exo, endo-dimethanonapthalene) monomers.

As detailed by Guiochon,[2] the preparation of a successful polymer base column can be broken down into three steps:

1. Treating the wall of the column.
2. Polymerization of the suitable mixture of reagents.
3. Modifying the surface chemistry of the polymeric bed.

Treating the wall of the column is critical because it helps the synthesized polymer to adhere to it. This is done by treating the wall with a monomer that binds with the mixture of monomers used in making the monolith. This step is important because it enables the monolith to adhere to the wall of the mold and void any space that may be created. Since this polymerization is an in situ process, it avoids the problem of cladding that is encountered in silica-based monoliths.

The second step is the polymerization, which, in the case of hydrophilic gels, includes a monomer, a catalyst (*N*,*N*,*N*,*N*-tetramethylethylenediamine). The precipitation takes place under: 1) a high ion strength solution or 2) porogen (dextran or polyethylene glycol). For the hydrophobic gels, the reagents are the selected monomers, a catalyst [azobisisobutyronitrile or 2,2-azobis(iosbutyronitrile)], and a porogen (propanol, butanediol, cyclohexanol, dodecanol), or a mixture of porogens. After the precipitation of the polymer, the last step is modification of the surface chemistry to suit one's needs for separation. These modifications allow the column of cation or anion, reverse phase, hydrophobic, or chiral to be made.

COMPARSION OF SILCA- AND POLYMER-BASED MONOLITHICS

Overall, both silica- and polymer-based monolithic materials have their place in chromatography. However, there are differences between these monolithic materials. An awareness of these differences could provide the end user with the knowledge to make an educated decision. In describing the difference, reference will be made to the conventional particulate HPLC columns. The mesoporous structure of the silica monolithic columns is more homogeneously spaced and sized and, as a result, provides a much larger surface area than the polymeric columns. The columns sold by manufacturers have macropores and mesopores of 2 μm and 13 nm, respectively, which give them a total porosity greater than 80% and a surface area of 300 m^2/g.[2] The monolithic columns sold are equivalent to a 3 μm particulate silica column in terms of efficiency and equivalent to a 7–15 μm particle with respect to permeability. Capillary silica monolithic columns are manufactured to have 1.3 μm mesopores and, when compared to silica columns, are equivalent to a 2–2.5 μm particulate column and permeability of 5 μm HPLC columns.[9]

However, the silica-based monolithic produces a more uniform and reproducible skeleton than the polymer-based monolithic. It has several shortcomings such as:

1. pH stability;
2. improper aging;
3. proneness to cracking and shrinkage during the drying process;

4. a potential problem when cladding the monolithic material.

At pH > 8, the silica dissolves, resulting in poor reproducibility, poor efficiency, and high back pressure. Improper aging of the silica gel under an uncontrolled temperature can result in poor size and distribution of the mesopores. Drying of the monolith is just as important as the aging process, because poor drying could lead to cracking or shrinkage of the material. The shrinkage and possible cracking of the monolithic material is a much more serious problem in the preparation of normal size HPLC columns. Moreover, cladding of a silica-based monolithic column is a difficult process and it is not easily done in an academic environment. In spite of the difficulties, silica produces a more uniform and reproducible structure than most polymers.

Not all of the above problems are encountered in the manufacture of a polymer-based column as it is an in situ process that can be done in a single step. Furthermore, the polymer-based columns can be tailored by modifying the surface chemistry to perform a wide variety of analytical separation. In addition, this type of material is stable over a wide pH range. Separation that cannot be performed over pH > 8 can be accomplished with this material.

If the number of publications is a sign of the success of both these materials, the future is bright and these materials have sealed their place in chromatography. Overall, monoliths show better mass transfer at higher flow rates than particulate columns, while maintaining high efficiency.[29] At high flow rates monoliths do not produce the large back pressure seen with particle-based columns. As a result, monolithic columns can be use in fast HPLC systems for high-throughput analysis.

KEY APPLICATIONS

Since the invention of silica- and polymer-based monolithic columns, users have been finding new applications for this material (Table 1). These applications are not driven because monoliths are a new material; they are driven by a direct need or void that was present for a long time in chromatography. Sample preparation and analysis have been the limiting factor in overall sample analysis time. The main driving force in using monolithic columns in chromatography is the speed of analysis. Chromatography can now be done with flow rates from 1 to 9 ml/min, while still maintaining the necessary resolution. Many applications have compared the conventional particulate columns with the new monolithic columns. They range from direct plasma analysis, drugs of abuse, food additives, proteins and peptides, inorganic ions, and high-throughput bioanalytical separations. Overall, based on what they report in their publications, the authors are satisfied with the durability and reproducibility of the columns.

DIRECT PLASMA AND HIGH-THROUGHPUT BIOANALYSIS OF DRUGS AND METABOLITES

The demand for high sensitivity and high-throughput bioanalytical methods is substantial in the discovery process for pharmaceutical drugs. High-resolution chromatography coupled to a mass spectrometer is well suited for this type of analysis because it is viewed as an orthogonal technique that is selective and provides structural information. Hsieh et al.[30] reported rapid analysis of clozapine and 12 test compounds with an analysis time of 1.3 min. The chromatography was done on a Chromolith SpeedROD, RP-18e, with over 200 plasma injections done on the column, and was reported to have excellent reproducibility and recovery of greater than 90%.

Likewise, toxicokinetic or pharmacokinetic studies revealed the drug-like characteristics of new chemical entities by measuring the plasma time concentration profiles of preclinical species. For these methods, it is important to have rapid, selective, and sensitive bioanalytical methods capable of quantitatively determining the new chemical entities and major metabolites in biological fluids. Here Zang et al.[31] developed a rapid SPE/LC/MS/MS method for Indiplon, Verapamil, and six test compounds using a Chromolith SpeedROD, RP-18e, with a gradient mobile phase for a total analysis time of 2.80 min. A total of 300 direct plasma injections were made without any noticeable change in system performance. Similarly, three other high-throughput analyses were published showing an analysis time of <3 min. One of them demonstrated a total of 600 plasma analyses with flow rates as high as 6 ml/min within an overnight run.[32–39] CEC coupled to a mass spectrometer as a microanalysis technique has higher separation efficiency, shorter analytical times, and lower sample and solvent consumption when compared to LC/MS. Here Lu et al.[40] described an analysis of narcotics from urine using a capillary silica-based monolithic column. Likewise, Wei et al.[41] and Fan et al.[42] described an in-tube solid-phase microextraction of four amphetamines and methylxanthine from biological fluids. This extraction procedure is preferable since it uses a convective mass transfer in a monolithic column as against the diffusion mass transfer mechanism used in conventional liquid-phase-coated capillaries. Using this mechanism, the extraction is completed within a shorter time.

ION CHROMATOGRAPHY SEPARATIONS

Ion chromatography (IC) has cemented its position as an integral part of analytical chemistry for the analysis of inorganic and biological ion analysis. IC operates on a principle similar to that of HPLC (a pump, injector, column, and detector), but the main difference is that the entire flow path is constructed with a metal-free material. The principle

Table 1 Applications of monolithic columns in bioanalysis.

Sample	Column	Detector	Mobile phase	Comments	Refs.
13 Drugs in plasma high-throughput analysis	Chromolith SpeedROD, RP-18e (4.6 50 mm)	API 3000	Acetonitrile/4 m*M* ammonium acetate	Recovery > 90% efficiencies > 36,000 1.2–8 ml/min	[30]
8 Drugs in plasma high-throughput analysis	Chromolith SpeedROD, RP-18e (4.6 × 50 mm)	API 4000	Acetonitrile and water with 0.1% formic acid	3–4 ml/min	[31]
4 Drugs in plasma high-throughput analysis	Chromolith SpeedROD, RP-18e (4.6 × 50 mm)	Quattro Ultima	Acetonitrile and water with ammonium acetate	6 ml/min 600 analysis with 12 hr	[32]
3 Drugs in plasma high-throughput analysis	Chromolith SpeedROD, RP-18e (4.6 × 50 mm)	API 3000	Methanol and water with 0.1% formic acid	1–5 ml/min	[33]
Vitamin C	Onyx C18 (4.6 × 100 mm)	UV detector	30 n*M* potassium phosphate buffer/acetonitrile	2.5 ml/min Runtime 3 min.	[34]
Cytochrome markers 5 marker substrates	Chromolith SpeedROD, RP-18e (4.6 × 50 mm)	API 3000	Acetonitrile and water with 1% formic acid.	2.5 ml/min Runtime 1.4 min	[35]
Antidepressant (5 drugs) high-throughput analysis	Chromolith SpeedROD, RP-18e (4.6 × 50 mm)	API 4000	8 m*M* ammonium acetate and acetonitrile	5 ml/min Runtime 1 min	[36]
Famotidine histamine antagonist	Chromolith SpeedROD, RP-18e (4.6 × 100 mm)	UV detector	0.03 *M* phosphate buffer and acetonitrile	1.5 ml/min Runtime 8 min	[37]
Rifampicin (5 drugs) Antibiotic	Chromolith SpeedROD, RP-18e (4.6 × 100 mm)	UV detector	Phosphate buffer, methanol, and acetonitrile	2 ml/min Runtime 11 min	[38]
Drugs and metabolites 16 Illicit drugs	Chromolith SpeedROD, RP-18e (4.6 × 100 mm)	Bruker ion trap	Methanol and water	Runtime 30 min	[39]
Narcotics (5 analytes)	Home-made (56 cm × 100 μm)	Agilent MS	65% Acetonitrile/20 mmol/L ammonium acetate, pH 6.0	Runtime 10 min	[40]
Amphetamines (4 analytes)	Home-made (15 cm × 50 μm)	UV detector	0.1 *M* disodium hydrogen phosphate (pH 4.5) and 20% methanol (v/v)	Runtime 10 min	[41]
Methylxanthine (4 analytes)	Home-made (20 cm × 0.25 mm)	UV detector	70% 0.05 mol/L ammonium acetate, pH 4.5% and 30% methanol	Runtime 12 min	[42]
Inorganic ions (7 analytes)	RP-18e (4.6 × 25 mm)	ELCD detector	6 and 9 m*M* 4-cyanophenol at pH 7.3–7.4	Runtime 2 min	[46]
Inorganic ions (7 analytes)	Home-made (30 cm × 250 μm)	Conductivity or UV	Acetate or hydroxide	Runtime <2 min	[47]
Inorganic ions (7 analytes)	Home-made (10 cm × 75 μm)	UV detector	Tris/perchlorate	Runtime 90 sec	[48]
Inorganic ions (5 analytes)	Home-made (15 cm × 250 μm)	UV detection	10 m*M* copper sulfate	Runtime depends on the flow rate	[49]
Protein	10 cm × 20 μm 10 cm × 50 μm	LTQ-FTMS	Acetonitrile and water with 0.1% formic acid	Na	[50]
Protein	15 × 100 μm	QSTAR XL/ MS	Acetonitrile and water with 0.1% formic acid	Na	[51]
Protein	4.6 × 0.6 cm	UV detector	0.1% TFA in water/0.1% TFA in acetonitrile	Na	[52]

of IC includes ion interaction, ion exchange chromatography, and ion exclusion chromatography. The application of monoliths to IC has evolved over the years to affect every facet of our lives. Svec[43] has provided an in-depth review of polymer monoliths in liquid capillary chromatography and their application. Likewise, Josic, Buchacher, and Jungbauer[44] have provided an excellent review of the use of ion exchange chromatography for the separation of proteins and polynucleotides. The main reason ion exchange columns were made is for biological analysis. However, because of the speed of analysis, monolithic columns have been used for small ion analysis.

The area of focus for the use of monolithics in IC has been in post column modification. Here an ion interaction reagent or a surfactant coating can be applied to a reversed-phase column and as a result make it a column applicable to ion chromatography. Chambers, Glenn, and Lucy[45] give an excellent summary of all the surfactants used on monolithic columns, the column, eluent, detector used, and the analyte analyzed. Furthermore, this entry addresses surfactants used for anion and cation exchange chromatography. Pelletier and Lucy[46] described a fast ion exchange separation of seven analytes (iodate, chloride, nitrate, bromide, nitrate, phosphate, and sulfate) in 2 min at 2 ml/min using a silica-based column coated with the surfactant didodecyldimethylammonium bromide. Although surfactant coatings are very popular and widely used, the instability of the coating has driven the development of new technology. An electrostatically bound latex coating (or covalently bonding a reagent material) directly to the monolithic material is becoming popular. Zakaria et al.[47] described a procedure for the analysis of seven inorganic anions using latex-coated monolithic polymeric phases in less than 2 min. Likewise, Hutchinson et al.[48] described a procedure for the analysis of seven inorganic anions in 90 sec using a sulfonated methacrylate monolithic with quaternary ammonium latex particles. Ueki et al.[49] described a procedure for cation exchange analysis using a sulfonated glycidyl methacrylate and ethylene dimethacrylate monolithic column.

PROTEIN AND PEPTIDE ANALYSIS

The analysis of proteins falls under the umbrella of proteomics. For years, the field of proteomics relied on two-dimensional polyacrylamide gel electrophoresis for the separation of complex protein mixtures. With the drive to produce methods with more selective and structural methods, HPLC with new column technology combined with the mass spectrometer has revolutionized the analysis of proteins. The quality and quantity of information generated by this approach has given rise to a new field called bioinformatics. The use of monolithic material has made a significant contribution to this field and appears to be promising. Zhang et al.[50] described an LC/MS procedure for the analysis of peptides as large as 10 kDa using a narrow-bore poly(styrene-divinylbenzene) monolithic column. The authors show approximately 30% higher separation than for packed columns and a high recovery of large peptides. Callanan et al.[51] described a convective interaction media disk (short columns) with a phase that has a high-binding capacity for large molecules. The authors describe procedures using anion and cation exchanges or affinity ligands for the separation of complex biological mixtures. The LC/MS/MS procedure was used for the identification of proteins. Hjerten et al.[52] described the synthesis of monolithic column using piperazine diacrylamide, methylacrylamide, and allyl glycidyl ether. The column bed was covalently bonded with non-polar ligands and polar substance. These columns were used to separate proteins.

CONCLUSION

Within last decade, monolithic materials (silica and polymeric) have evolved into products that have a significant impact on a large number of fields in analytical chemistry. If one had to identify one feature that this material has provided for chromatography, it would be the ability to perform analysis at a high flow rate and still maintain the required resolution. The high flow rate has a significant influence in high-throughput analysis. With the wide variety of options available in making a monolithic column, one can "tailor" a specific column for a class of compounds. Looking ahead, as more analysis is carried out using mass spectrometry, the future holds great promise for the field of proteomics. In addition, more progress in the polymeric monolithic columns will be required. In the future, new monolithic columns with different range of selectivity, high loadability, improved pH stability, and improved longevity are required.

Biological Fluids: Glucuronides from LC/MS

Adnan A. Kadi
Mohamed M. Hefnawy
Department of Pharmaceutical Chemistry, King Saud University, Riyadh, Saudi Arabia

Abstract
The use of liquid chromatography–mass spectrometry (LC–MS) in the direct analysis and detection of glucuronide conjugates from biological fluids is described. The analysis of labile drug metabolism-conjugated molecules such as glucuronides has traditionally been carried out indirectly by enzymatic hydrolysis and subsequent analysis of the released parent compound. This approach suffered a number of disadvantages, which makes direct analysis desirable. With the advent of softer LC–MS ionization techniques, e.g., electrospray ionization (ESI), direct analysis of conjugated glucuronides has increasingly become possible. A review of recent literature shows various examples of this approach.

INTRODUCTION

Glucuronidation is a major detoxification pathway for many endogenous and exogenous materials, converting them into generally inactive water-soluble molecules, which can be easily excreted through urine. For some compounds, however, glucuronidation may be a bioactivation process that can lead to compounds that are more active than the parent drug, e.g., morphine-6-glucuronide,[1–3] or to compounds that are more toxic, e.g., compounds capable of forming acyl glucuronides[4] such as all *trans*-retinoic acid or valproic acid glucuronides.[5] Glucuronidation is considered the most important phase II metabolism pathway in mammals owing in large part to the abundance of glucuronic acid in the liver and the wide diversity of structurally unrelated compounds that can be the substrates for the reaction. Glucuronidation involves the conjugation of (D)-glucuronic acid, transferred from the endogenous material uridine-5′-diphosphoglucuronic acid (UDPGA), to a xenobiotic molecule with nucleophilic functional groups such as alcohols, phenols, carboxylic acids, amines, imides, activated methylenes, and sulfhydryl groups.[6] The conjugation process is catalyzed by UDP-glucuronosyltransferase (UGT).[7] Compounds with these functional groups give rise to conjugated β-(D)-glucuronides. Although alpha (α) anomers of the glucuronide conjugates can be chemically synthesized, biosynthesized glucuronides are invariably of the beta (β) configuration.

Traditionally, analysis of phase II metabolism conjugates, e.g., glucuronides, was carried out indirectly by first subjecting the glucuronide conjugate to appropriate enzymatic hydrolysis (β-glucuronidase) or acid hydrolysis prior to analyzing the released metabolite. While this method has been in use for a long time, it suffers certain drawbacks. First, the method is time-consuming owing to the needed sample pretreatment and subsequent sample extraction and preparation for analysis. Second, accurate quantitative analysis cannot be achieved because hydrolysis is often incomplete and some conjugated materials may still remain, even after enzymatic or acid hydrolysis. Moreover, contaminants that may be present in the enzymatic hydrolysis mixture might interfere with the identification of the aglycone.[8] Third, in the case of phase II metabolites that are actually clinically active, e.g., morphine glucuronide, it is desirable to have the intact molecule analyzed rather than the hydrolyzed drug. This can aid in the accurate quantification of the active metabolite and therefore gives a better idea about the extent to which it contributes to the parent drug's biological activity. Fourth, it is known that phase II conjugation of some drug molecules gives rise to isomers as a result of the creation of an asymmetric center. Such isomers cannot be distinguished if the traditional enzymatic or acid hydrolysis methods are used to liberate the parent drug prior to analysis. Thus, direct analysis of phase II conjugated molecules presents a clear advantage in its ability to overcome the shortcomings of the traditional methods of analysis. It is important to understand the different methods used in the liquid chromatography–mass spectrometry (LC–MS) analysis of phase II conjugated metabolites along with their respective strengths and/or weaknesses.

LC–MS

LC–MS and, in particular, tandem mass spectrometry (LC–MS/MS) techniques, offer a number of experiments for the determination of conjugated materials such as glucuronides from biological fluids.[9,10] In LC–MS instruments, the typical analyzer used (e.g., quadrupole) analyzes ions that are sampled to the MS vacuum and generates molecular weight information that is, in most cases, limited to the parent ion. In drug metabolism research, where often

the structures of metabolites are unknown, the molecular weight information alone is not sufficient for structural elucidation, and more information about the structure is needed. In tandem mass spectrometry, two analyzers are used instead of a single one. The first analyzer would analyze the ions coming from the MS source; the ions are then passed into a collision chamber where energy is applied to cause fragmentation, and the fragments are passed to the second analyzer where they can be analyzed. This yields more detailed structural information as not only the molecular weight will be known, but the fragmentation pattern of the molecule, which can aid in the overall identification and characterization process of an unknown metabolite, can be determined as well. While the triple quadrupole (QQQ) tandem MS is the most common type, newer instruments are available that combine a quadrupole analyzer with a time-of-flight analyzer for more powerful structural elucidation capabilities. QQQ mass analyzers are the instruments used most often in LC–MS/MS studies of drug metabolism.

With a QQQ instrument it is possible to scan for ions of interest using one of three modes, namely, precursor ion scan, constant neutral loss scan, and product ion scan.[11] These powerful methods can provide a great deal of information about the structure of an unknown metabolite. In the precursor ion scan mode, the metabolite is identified by determining whether it contains a portion of the unaltered parent compound. Thus, one does not need to know the exact structure of the metabolite of interest and only needs some knowledge of the fragmentation pattern of the parent compound. With glucuronide conjugates, this mode can be used by predicting precursor ion fragments of the aglycone. For example, a precursor ion scan for *m*/*z* 166, which is a fragment of the protonated parent molecule epothilone B, enabled the identification of a new metabolite for the drug.[12] In constant neutral loss scans, one looks for an expected loss of a particular molecular weight from a molecule. In the case of conjugated metabolites, such as glucuronides, neutral loss targeted is usually 176 Da, which represents the loss of a glucuronic acid moiety from the parent compound. An example would be a 176 Da loss from the drug entacapone molecule,[13] which indicated the formation of a glucuronide conjugate of the drug. This mode does not require any knowledge of the structure or fragmentation patterns of the parent compound. Unlike the first two methods, which are used for the detection of metabolites, product ion scan is intended for structure characterization. A product ion scan experiment is performed by first selecting a candidate ion to undergo further fragmentation. This information is obtained from previous knowledge of the metabolism pattern of the parent compound, as well as from the above-mentioned precursor ion and neutral loss scans. The candidate ion is subjected to an extra round of fragmentation, where it enters a trap containing an inert gas such as argon. Collision with the gas molecules will induce dissociation of the product ion and, thus, will give rise to fragments that can be detected and analyzed. This results in a series of fragment masses each of which corresponds to a part of the unknown molecule. The analysis of the combined fragmentations can lead to structure elucidation. For example, the methylated metabolite of dobutamine (*m*/*z* 316), containing a characteristic product ion at *m*/*z* 151, was identified using this technique.[14]

Selected reaction monitoring (SRM), sometimes referred to as multiple reaction monitoring (MRM), is a technique that can be utilized in the quantitative determination of drugs and metabolites, e.g., glucuronides, by tandem mass spectrometry from biological matrices. In this technique, a single ion is selected, often representing the parent compound, and the fragmentation of this ion to another known ion is monitored. This transition from parent to daughter ion is unique to every compound under the experimental conditions used and can be used for quantitatively determining any compound in the analyzed matrix. The tandem MS approach is a valuable technique for the analysis and identification of drug metabolites, e.g., glucuronides.

Scientific publications documenting the use of LC–MS for the direct analysis of glucuronide conjugates have become abundant in recent years. In the last decade or so, over 100 papers have been published on the subject. In most of the studies it has been emphasized that glucuronide conjugates are being detected directly using LC–MS techniques without the need for extensive sample preparation or hydrolysis of the conjugated compound prior to determining the unconjugated precursor. Selected xenobiotic compounds for which LC–MS studies were conducted for the analysis of glucuronide conjugates are shown in Table 1. This includes therapeutic agents, investigative drugs, and a host of other xenobiotics. The *O*-glucuronide conjugates were the most commonly analyzed, which is consistent with *O*-glucuronides being the most commonly formed glucuronide conjugates. Among the *O*-glucuronides analyzed, the majority were phenolic glucuronides, followed by acyl and hydroxy glucuronides. The *N*-glucuronides studied were formed from aromatic and aliphatic amines. Based on the diversity of the glucuronide conjugates analyzed in the reviewed literature, it is possible to conclude that LC–MS analysis can be effectively conducted for a wide spectrum of glucuronidated xenobiotics with good sensitivity and reproducibility.

CITED EXAMPLES

The LC–MS analyses documented in the reviewed literature include both in vivo and in vitro studies. In in vivo studies, conditions represented various biological matrices including plasma, urine, bile, and feces. In vitro studies, LC–MS analyses were conducted for glucuronides obtained using recombinant UGT,[21,46] liver microsomes,[28] brain microsomes,[47] hepatocytes,[24] and liver slices.[48] In most of the experiments, electrospray ionization–MS (ESI–MS) was the ionization

interface of choice for the analysis of conjugated glucuronides. Although the choice of the LC–MS interface is governed by the nature of the analyte, various studies have documented the preference for ESI over atmospheric pressure chemical ionization (APCI) for the analysis of polar, non-volatile, and thermolabile molecules such as glucuronide conjugates. This is mainly because of the milder ionization conditions employed by ESI in comparison with APCI. APCI experiments are carried out at temperatures that can be high enough to cause the decomposition of molecules having easily cleavable bonds such as sugar and sulfate conjugates. This results in a decrease in the concentrations of the intact analyte available for detection and, consequently, decreased sensitivity of the method. Nevertheless, APCI modes can be successfully used for the analysis of glucuronide conjugates. Some studies have reported that negative-ion modes are better suited for the analysis of polar anionic species such as glucuronide and sulfate conjugates. It has been observed that negative-ion mode is the most commonly used one for ionization in both ESI and APCI.

Mobile-phase additives are known to play an important role in the efficient separation of chromatographic peaks in LC–MS. Mobile-phase additives used for LC–MS studies are most often volatile molecules that can be easily evaporated in the LC–MS interface to prevent ionization suppression and/or detection contamination. The most commonly used mobile-phase additives in LC–MS analysis are the small organic acids, acetic and formic acids, together with their ammonium salts. Trifluoroacetic acid (TFA) is also widely used in LC–MS analysis despite reports of ionization suppression in the ESI mode. Some studies suggest that the drawback of TFA use can be overcome for some neutral analytes by using minute concentrations of the acid in the mobile phase.[49] A number of studies presented here used TFA as the mobile-phase additive, and in all those instances, ESI was the ionization interface. However, formic acid was the additive most commonly used, followed closely by TFA and then by the ammonium salts of both formic and acetic acid. The type of glucuronide conjugate (*O* vs. *N*) did not appear to influence the type of mobile-phase additive used.

Novel applications of LC–MS methodologies in the analysis of glucuronide conjugates of some drugs have been documented. The 4-vinylphenol glucuronide conjugate of styrene has been recognized as a metabolite of styrene; however, it had never been determined as the intact glucuronide until Manini et al.[34] reported the direct determination of this glucuronide conjugate as the intact glucuronide by LC–MS. Ohta et al.[38] reported the use of an LC–APCI–MS method for the determination of acetaminophen glucuronide; however, the authors encountered difficulty in the direct ionization of the glucuronide. Therefore, derivatization of the carboxyl group to the methyl ester was necessary to obtain satisfactory ionization. Skopp and Potsch[40] looked at the stability over time and at various temperatures of 11-nor-Δ9-carboxy-tetrahydrocannabinol glucuronide in plasma and urine by direct LC–MS/MS analysis of the conjugate. Liu et al.[50] used a novel approach for the elucidation of the structure of a carbamoyl-linked glucuronide conjugate of an investigational compound with the help of online hydrogen/deuterium exchange in LC–MS/MS. This was possible by the use of deuterium oxide (D_2O), instead of water, as a mobile-phase component to facilitate structure elucidation carried out with LC–MS techniques. The actual structure of the investigational compound was not revealed by the author, but was given the general representation outlined in Fig. 1. The amine group in the compound carries two exchangeable hydrogen atoms and the glucuronic acid moiety contains four exchangeable hydrogen atoms. Upon formation of a carbamoyl of the amine group followed by phase II conjugation with glucuronic acid, the total number of exchangeable hydrogen atoms was 4, and the conjugate showed a protonated molecular ion peak of *m/z* 429 as opposed to the ion peak at *m/z* 423 that results when water is used instead of deuterium oxide. The authors concluded that this experiment coupled with tandem mass spectrometry could be a very useful tool to facilitate identification of glucuronides and other metabolic products.

Dalgaard and Larsen[20] investigated the formation of glucuronide conjugates of citalopram, a potent selective serotonin uptake inhibitor. The acyl and quaternary ammonium glucuronides of citalopram, which had been previously unreported, were successfully detected in positive-ion ESI. The authors allude to the fact that acyl glucuronides are difficult to analyze under conventional enzymatic hydrolysis methods owing to their instability, and that using LC–MS techniques, these types of glucuronides can be detected. Although determining the site of glucuronidation is not possible based on LC–MS studies alone, Cui and Harvison[17] reported that LC–MS, when coupled with chemical derivatization, could be used for determining the site of glucuronidation within a xenobiotic compound. The authors described a novel glucuronide conjugate of a metabolite of the nephrotoxicant *N*-(3,5-dichlorophenyl)succinimide. The metabolite, *N*-(3,5-dichlorophenyl)-2-hydroxysuccinamic acid (NDPSA),

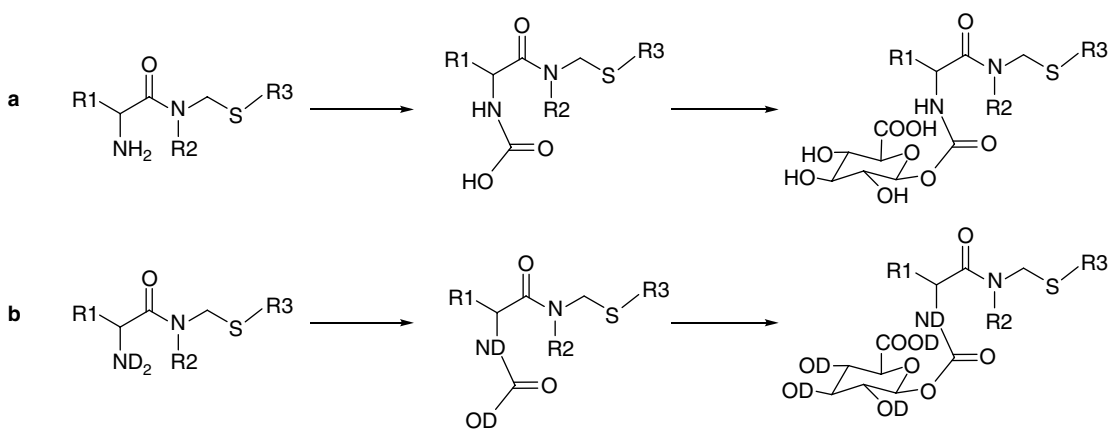

Fig. 1 Structures of the carbamoyl metabolites and their glucuronides (a) using water as a mobile-phase component and (b) using deuterium oxide as a mobile-phase component.

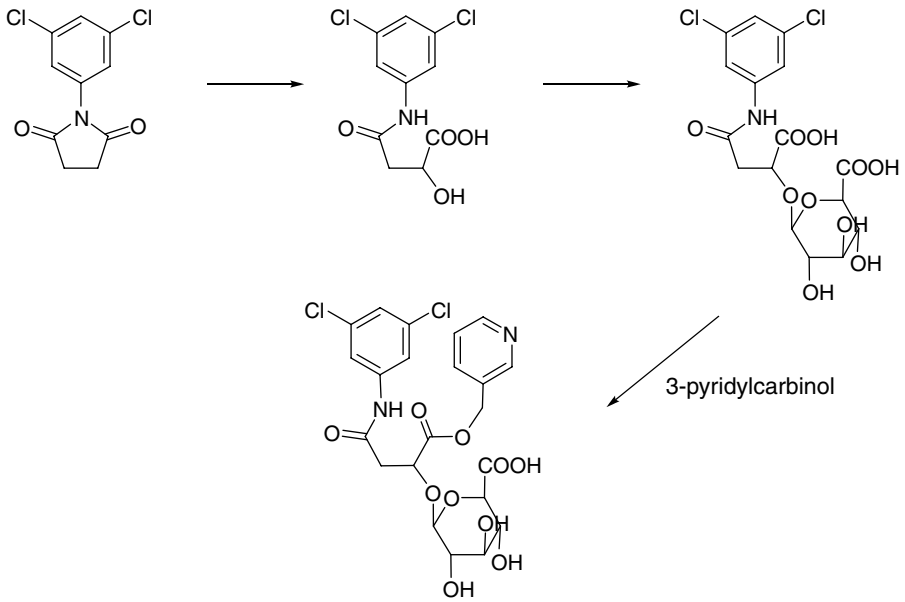

Fig. 2 Derivatization of *N*(3,5-dichlorophenyl)-2-hydroxysuccinamic acid metabolite.

contained two possible sites for glucuronidation, namely, an aliphatic hydroxy group and a carboxylic acid moiety. To determine which site was glucuronidated, the authors derivatized the glucuronide conjugate with 3-pyridylcarbinol. Based on molecular ion peaks obtained from positive-ion ESI studies of the derivatized compound, the authors were able to determine that glucuronidation indeed took place at the alcoholic hydroxyl group, rather than at the carboxylic acid group (Fig. 2).

More recently, LC–MS has been used to analyze glucuronic acid conjugates of the industrial chemical 1-bromopropane from plasma and urine of rats and mice after inhalation and intravenous injection.[41] The method demonstrates the sensitivity of LC–MS when applied to the analysis of glucuronic acid conjugates. Lin, Lee, and Chuang[51] reported on a method using positive-ion LC–ESI–MS for the analysis of the Chinese medicinal preparation Gan-Lu-Yin. Two of the components analyzed were glucuronic acid conjugates, namely oroxylin A-7-*O*-glucuronide and wogonin-7-*O*-glucuronide. The method was sensitive and accurate enough to detect the glucuronic acid conjugates, with no need for hydrolysis. Glucuronic acid-conjugated metabolites of a new Na^+/H^+ reversible-exchange inhibitor, [5-(2-methoxy-5-chlorophenyl)furan-2-ylcarbonyl]guanidine, for the treatment of ischemia have been recently analyzed by Kim et al.[42] The metabolites were formed from human liver microsomes on incubation with UDPGA and nicotinamide adenine dinucleotide phosphate (NADPH).

CONCLUSION

LC–MS techniques have been shown to be very useful for the direct analysis of glucuronide conjugates of xenobiotic molecules in biological fluids, as well as in in vitro metabolism studies. As new techniques are developed and tested, especially in the fields of sample introduction, chromatography front end, and the amount of liquid introduced into the MS analyzer, and as the volume of literature available describing the use of LC–MS grows rapidly, it will not be surprising if LC–MS procedures assume a leading place, or be the method of choice, in the analysis of glucuronic acid and other phase II conjugated metabolites of xenobiotics.

Chong-Kook Kim
Research Institute of Pharmaceutical Sciences, Seoul National University, Seoul, and Department of Pharmaceutical Engineering, Inje University, Gyeongnam, Korea

Abstract
As pharmaceutical and clinical industries are developing, various sensitive and simple analytical methods have been developed for the analysis of drugs and metabolites including endogenous compounds in biological fluids. Among these developing methods, column switching system has been mainly used to obtain a more simple pretreatment step and a more sensitive result. Column switching system can be used for determent analytes in complex biological matrix by direct injection of biological fluids or by only simple sample treatment such as a filtration step. Specially, large volume injection of sample is possible without any interference and results in significant increase of sensitivity when column switching system is connected to a microbore column. Therefore, column switching system with microbore column is applied to various analytical systems such as HPLC and mass spectrometry for the analysis of trace compounds in biological fluids. In this entry, the application of column switching system with microbore column for sample cleanup and sample enrichment for the analysis of trace compounds in various biological fluids is presented.

INTRODUCTION

High-performance liquid chromatography (HPLC) has advanced to become one of the most widely used analytical techniques since its commercial introduction in 1968. The significance of HPLC arises from its rapid resolving power and applicability to a wide range of sample types. In pharmaceutical and clinical study, HPLC is one of the most important techniques for the separation and determination of drugs and their metabolites in body fluids. Specially, the use of HPLC with mass spectrometry (MS) instead of UV and fluorescence as a detector is significantly increasing for the analysis of substances in biological matrices (plasma, blood, urine, and tissue). However, the analysis of drugs and their metabolites or endogenous compounds in biological fluids by HPLC regardless of the kind of detector is usually laborious, because of the large number of substances present; moreover, the compounds of interest are often present at low concentrations in the samples. Therefore, to improve the sensitivity and specificity, both sample pretreatment and enrichment of the investigated compounds are carried out using sample preparation step and microbore column. Between these things, sample pretreatment is the most common method to obtain high specificity and sensitivity in bioanalytical area. In general, the selective separation and concentration of compounds for biological matrix can be achieved using procedures such as liquid–liquid extraction, liquid–solid extraction, centrifugation, precipitation, and derivatization. These sample pretreatment steps are time-consuming and often result in poor recovery and reproducibility, despite the speed and accuracy of HPLC analytical techniques. Another approach to obtain more high sensitivity and resolution is the use of microbore analytical column with smaller inner diameter instead of the conventional column. Microbore column has inner diameters ranging from 1.0 to 2.1 mm and they offer some significant advantages over conventional columns. First, the use of microbore column has potential for considerable saving in mobile-phase consumption. Second, the sensitivity has 5–21 times higher value than that obtained by conventional column. Fig. 1 shows that the detection response of the microbore increases approximately twentyfold that of an analytical column with the same mass load on both a conventional analytical column (4.6 mm i.d.) and a microbore column (1.0 mm i.d.). In addition to these advantages, microbore columns are attractive for trace analysis where sample quantities may be limited, and where conventional detector system that can accommodate only small volumes of column eluent would be useful. In HPLC–MS system, flow rates of 5–10 and 50–200 μl min^{-1} were generally applied with electrospray ionization (ESI)

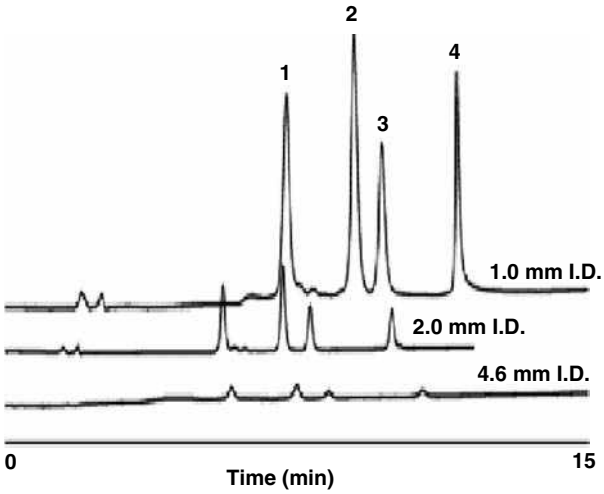

Fig. 1 Separation of peptides on RP-C_{18} column of various inner diameters.

and pneumatically assisted ESI techniques, respectively.[1] As a result, the use of narrow or microbore column is common in HPLC–MS. However, microbore column has a disadvantage that the concentration sensitivity is no higher than that of conventional column because of the limited injection volume. Therefore, a solution for the problems of these microbore column and pretreatment steps is needed and column-switching devices are well suited to such problems.

COLUMN-SWITCHING HPLC WITH MICROBORE COLUMN

The term column switching in liquid chromatography is used if two or more columns are connected to form a network. Column switching is a technique that changes the direction of flow of the mobile phase by valves, so the effluent from a primary column passes to a secondary column for a defined period of time as illustrated in Fig. 2. The objectives of column switching are to increase the chromatographic resolution and selectivity, to enrich trace amounts of sample, to protect sensitive detectors such as electrochemical detectors from contamination by coextractives, to prevent destabilization of the chromatographic equilibrium of the column by coextractives, and to achieve further objectives or a combination of

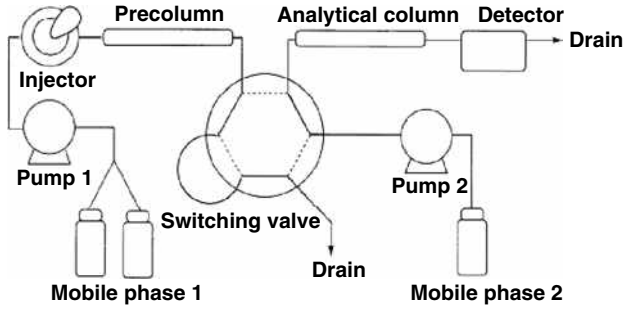

Fig. 2 A schematic diagram of a column-switching system.

several objectives within one chromatographic network. Integration of HPLC with column switching has led to the quantification of a number of compounds. This system has some advantages for the determination of drugs in biological fluids. First, this system can minimize the use of sample and the loss of sample by sample pretreatment. Second, for detection specificity, little or no baseline interference is observed because the cleanup is excellent. Third, analytical column can be used for thousands of injections. Fourth, drug recoveries in excess of 95% are often observed with high reproducibility without using an internal standard. These results indicate that it is possible to have a high-throughput analysis in clinical and pharmaceutical areas. This technology has been successfully applied to the analysis of various drugs in biological fluids using various detectors such as MS, UV, and fluorescence. Especially, in recent years, the use of column switching has been reported to be very useful in conjunction with MS detectors. In the column-switching system, switching valves are used to remove aqueous eluents used in the cleanup and separation steps. After that, the trapped analytes are eluted in a suitable solvent for HPLC–MS,[2, 3] HPLC–UV, or fluorescence. In addition, the fully automated HPLC system with precolumn sample enrichment is always not needed for additional standard compounds. Yeon et al.[4] achieved accurate and precise analysis of cilostazol in plasma without any pretreatment and internal standard.

An example of the separation steps by a column-switching system is explained:[5] in order to determine the switching time, first, a biological sample containing methamphetamine (MA) was injected on a precolumn and detected using the primary mobile phase, as illustrated in Fig. 3A, and then the time program for the column-switching system was set up as given in Table 1. Two columns containing packings with

Table 1 Time schedule of column switching for the analysis of methamphetamine (MA) enantiomers in urine.

Time after injection (min)	Switching valve position	Precolumn	Analytical column
0.0–4.0	1	Sample loading and cleanup	(Re)conditioning
4.0–6.0	2	Analytes transfer	Analytes transfer, separation
6.0–24	1	Reconditioning, next injection	Separation

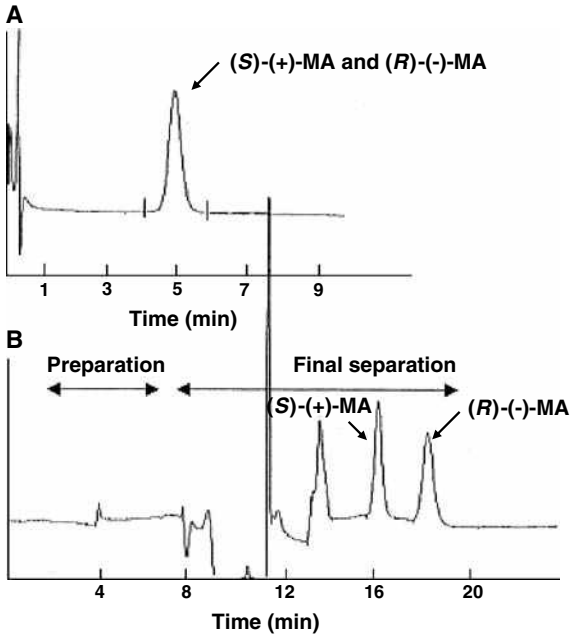

Fig. 3 Profile of separation methamphetamine enantiomer (A) in precolumn and (B) analytical column.

different column selectivities are connected in series through a six-port valve and these columns were controlled according to the time program. At position 1 of the switching valve, the primary mobile phase flushes impurities and analytes with weak retention from the precolumn. After rotating the switching valve into position 2, the secondary mobile phase with a higher elution power than the primary mobile phase elutes the analytes from the precolumn onto the analytical column. After the transfer of analytes is completed, the valve is rotated back. The analytes are separated at the secondary mobile phase and analytical column. At the same time, the primary column is reconditioned with the primary mobile phase. Fig. 3B shows typical chromatograms of plasma sample processed using column-switching system. Fig. 4 shows the reaction of the sample and mobile phase according to the time program.

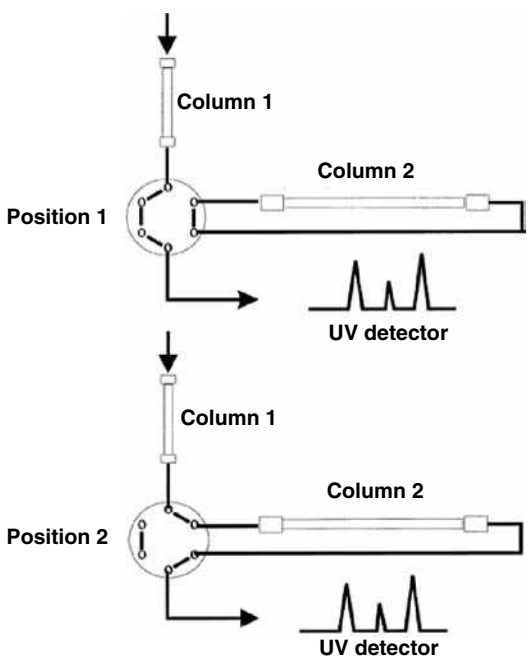

Fig. 4 A change of mobile phase and sample flow according to the valve position in the column-switching system.

COLUMN-SWITCHING HPLC SYSTEM CONFIGURATION

In order to determine optimal analysis condition for the analysis of drugs in biological fluids using column-switching HPLC system, the choice of separation media is critical to effective analysis of analytes in biological fluids. Precolumn and mobile phases are an important separation media to achieve cleanup and preconcentration in column-switching HPLC system. In most cases, short precolumns are preferable because the duration of the flushing needed to remove undesirable matrix components is minimized. And particle sizes in the 10–40 μm range provide suitable stability and loading capacity, for the majority of the applications. Peak compression can be best obtained if the analytes are introduced into a precolumn in a solvent with low elution strength.

APPLICATIONS OF COLUMN-SWITCHING HPLC WITH MICROBORE COLUMN

There have been thousands of articles published on the application of column-switching HPLC method. Today, column-switching HPLC method is being used around the world in all areas of chemistry, environmental problem solving, medical research, and so forth. In clinical and pharmaceutical analysis, column switching has been mainly applied to online sample cleanup and trace enrichment using microbore analytical column. Examples of column-switching HPLC method not discussed in any detail are presented in Table 2.

Sample Cleanup

Probably the most important application of column switching is sample cleanup, which is based on the use of multicolumn chromatography and can induce an increase in selectivity. The principle of column switching for sample cleanup is to trap, in a primary column or precolumn, the fraction of the sample that contains the analytes. The compounds of the biological matrix are eluted to waste, whereas the cut of effluent containing the analytes is diverted to the secondary column or analytical column, where they are separated for the identification and/or quantification. The

Sibutramine	Plasma	Metabolism	[20]

fraction of effluents to be transferred may be eluted at the front (front-cut technique), in the middle (heart-cut technique), or at the end (end-cut technique) of the chromatogram of the primary precolumn. Zone cutting is probably one of the most useful and versatile among the entire column-switching techniques.[21] Fig. 5 shows chromatograms obtained for human plasma spiked with 100 ng/ml of paraquat in a separation column by zone cutting after the paraquat was separated from the plasma in the precolumn.[22] Also, column-switching configuration is a powerful technique for the stereoselective analysis of drugs in biological fluids. In this case, a various chiral stationary phases (CSP) with different chiral selectors, such as cyclodextrins,[23] cellulose derivatives,[24] proteins,[25] and antibiotics,[26] have been successfully coupled to extraction precolumns. A typical application is a CSP packed with human serum albumin as selector coupled to a LiChrospher RP-18 ADS for the determination of ketoprofen enantiomers in human plasma.[25] Biological samples are injected onto the extraction support with a phosphate buffer and, after the extraction step, analytes are flushed to the chiral column, with a loading mobile phase constituted of a mixture of phosphate buffer, propanol, and octanoic acid. Walhagen and Edholm[27] reported the isolation of terbutalin, metoprolol, oxazepam, bipivacaine, and metroprolol enantiomers in plasma. Other applications using column-switching HPLC method for the analysis of drugs including endogenous material in biological fluids have been reported in the literature. They deal with the efficient and simple analysis of a drug in biological fluid without any pretreatment step. However, centrifugation, dilution, filtration, prior off-line extraction, and protein precipitation are used as a sample

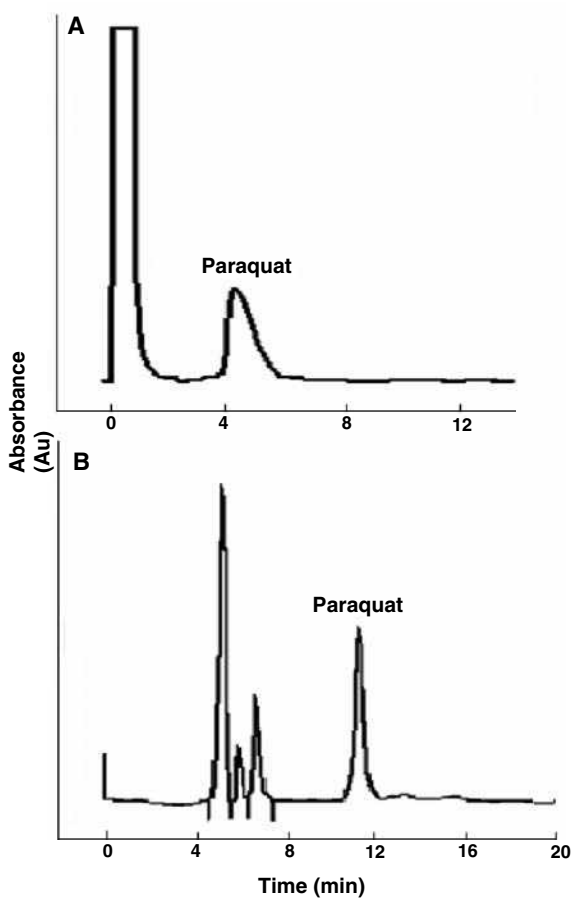

Fig. 5 Typical chromatogram of (A) precolumn matrix elution profile and (B) sample in analytical column after injection of human blood plasma spiked with 100 ng/ml of paraquat.

treatment technique before injection into the switching system to increase precolumn lifetime. The system based on the sample treatment technique was applied to the determination of baclofen in plasma.[28] Zinc sulfate solution and acetonitrile were used to precipitate protein. After centrifugation, the analyte was analyzed using column-switching HPLC system with microbore column. Precolumn and analytical column were C_8 and C_{18} stationary phase with 5 μm particle, respectively.

Sample cleanup in HPLC–MS system

As mentioned in the previous section, the application and investigation of the column-switching technique connected to an HPLC–MS system have witnessed tremendous growth due to the increase in HPLC–MS system applications in the pharmaceutical and clinical area. Recently, in the case of an HPLC–MS system with column switching, a lot of researches were mainly focused on online sample pretreatment such as online solid-phase extraction technique[29–31] and direct injection after filtration[32–34] in order to accompany high-throughput analysis by reduced sample pretreatment and analysis time. HPLC combined with MS detection played a key role in accelerating the sample throughput and providing outstanding sensitivity. In addition, the use of a column with a microbore is common for a low flow rate and for allowing sensitivity improvement. However, the absence of selectivity, which speeds up the analytical process, can become an important limitation. Indeed, the coelution of analytes and interfering substances in biological matrices can modify the MS response of the target molecules. Therefore, during method development, special attention has to be paid to remove interfering substances in biological sample using sample pretreatment. Biotransformation products can also disturb the quantitative determination of analytes in biological materials by HPLC–MS. Analysis of isomeric compounds has to be performed considering interference between each isomeric compound because of their similar physicochemical properties. Therefore, despite high MS selectivity, chromatographic separation remains essential. The coupling of an analytical column and another column for the extraction of sample using column-switching configuration appears as a suitable alternative in HPLC–MS system.

Sample Enrichment

Column switching suggests an alternative method to increase sensitivity as well as simple sample pretreatment. In a column-switching system, increase of sensitivity is based on the fact that the components will be retained in a narrow zone on the top of the column when a large volume of sample is pumped through the column. Koenigabauer et al. analyzed diazepam in serum using column-switching HPLC method with microbore column.[35] This research showed that the concentration sensitivity increased 1500 times with a 1 ml injection volume of highly dilute aqueous paraben solutions. The optimization of the chromatographic conditions should include careful choice of the type of precolumn (dimensions and packing), eluent conditions, and system design, to obtain good recovery and minimum peak broadening of the compounds of interest. The best enrichment factors can be achieved by back-flush configuration. The back-flush techniques reverse the flow of the primary column, so the analytes retained at the head of the precolumn are directly transferred to the analytical column. The precolumn can also be back-flushed to remove the components of the matrix that are strongly retained, after the fraction of interest has been eluted.[36] The back-flush configuration also minimizes peak broadening. Nielson permits samples up to 50 ml to be directly injected without significant loss of resolution although microbore separation column is used.[37] A lot of papers have demonstrated the separation of trace materials in biological fluids by large volume injection using a column-switching system. Furthermore, column-switching systems are often used, after conventional off-line cleanup or preconcentration of the samples, to improve sensitivity and the analytical separation. Kim et al.[38] have reported the determination of cetirizine in plasma using liquid–liquid extraction and column switching. After samples were extracted with dichloromethane, the extracted samples were injected on a short C_8 precolumn and cetirizine and the internal standard were transferred to the analytical microbore column. Then, the analytes were analyzed with the mobile phase containing acetonitrile and phosphate buffer (pH 2.8). The recovery was found to be higher than 80%. The analyte could be detected with detection limit 10 ng/ml (using 210 μl injection). Therefore, trace material in biological fluids can be analyzed with high sensitivity and specificity.

CONCLUSION

Here we presented column-switching HPLC system with microbore column. This system has many desirable features for performing the separation and identification by combining the valve configurations described for the specified transfer techniques. The use of column-switching system offers highly specific and sensitive results with both high speed and precision. Especially it is well suited to the analysis of samples requiring significant sample cleanup and concentration to improve selectivity and sensitivity in HPLC–UV and fluorescence as well as HPLC–MS system. Thus, column-switching HPLC with microbore column analysis has become a powerful technique in pharmaceutical and clinical areas.

Biological Samples: LC/MS Detection and Quantification of Naturally Occurring Steroids

Tatsuya Higashi
Tadashi Nishio
Kazutake Shimada
Division of Pharmaceutical Sciences, Graduate School of Natural Science and Technology, Kanazawa University, Kanazawa, Japan

INTRODUCTION

The basic steroid molecular skeleton consists of four rings of carbon atoms, perhydro-1,2-cyclopentenophenanthrene. Almost all natural steroids possess either one or more, usually two, methyl groups at "angular" positions where two rings meet. The steroids with which we are mainly concerned consist of five skeletal types, according to the number of C-atoms, i.e., estrane (C_{18}), androstane (C_{19}), pregnane (C_{21}), cholane (C_{24}), and cholestane (C_{27}). Almost all of these compounds are natural hormones or precursors. Steroid hormones, which mostly act as ligands to intracellular/nuclear receptors, can be divided into estrogens, androgens, progestogens, and corticoids, based on their functions. It is well known that an active metabolite of vitamin D_3 (9,10-secosteroid), 1α,25-dihydroxyvitamin D_3 [1,25-$(OH)_2$-D_3], also has hormonal properties via binding to its specific nuclear receptor. Bile acids (cholane) have been also recently reported to be ligands for orphan nuclear receptors (liver X receptor), and play an important part in lipid metabolism.[1] On the other hand, some oxosteroids (androstane and pregnane) have been found to be modulators of several membrane receptors in the nervous system, and such steroids are now universally referred to as neuroactive steroids.[2]

These steroids exert strong biological activities at very low concentrations (nanomolar and even picomolar) in the target tissues. A specific and sensitive method for the characterization and determination of the steroids in body fluids or tissues is necessary to elucidate the nature of the many endocrine disease processes and, thus, be useful for diagnosis and treatment. Because of their close structural similarity, metabolic versatility, and their occurrence at low concentrations in body fluids and tissues, the development of reliable analytical methods for the steroids is a challenging subject for analytical chemists. Numerous methods have been described to characterize and determine the steroids, such as immunoassay, receptor binding assay, high-performance liquid chromatography (HPLC), and gas chromatography (GC)–mass spectrometry (MS),[3,4] but each of these approaches has both advantages and disadvantages.

Among the alternative methods, liquid chromatography (LC), coupled with atmospheric pressure ionization (API), such as electrospray ionization (ESI) and atmospheric pressure chemical ionization (APCI)-MS has been used for steroid analyses owing to its specificity and versatility.[4,5] However, apart from the glucuronidated (G) and sulfated (S) metabolites and bile acids, the ionization efficiencies of most of the steroids are relatively low for ESI and APCI. Therefore, conventional LC–MS sometimes does not demonstrate the required sensitivity for the trace analysis of steroids in biological samples. Although a newly developed API technique, atmospheric pressure photoionization (APPI), has also been examined for steroids that are poorly ionizable in ESI or APCI,[6,7] this technique is, in the present state, far from the stage of practical application. To enhance the detection sensitivity, chemical derivatization,[8–10] enzymic conversion,[11] and mobile-phase additives[12,13] have been positively used for the LC–MS analysis of steroids. The electron capture APCI (ECAPCI) technique, combined with derivatization, which Blair and coworkers first put to practical use,[14] also has a significant advantage for the LC–MS of steroids.[15] A capillary LC has been examined for increasing the sensitivity.[16–18]

In this entry, the authors present an overview of the LC–MS of naturally occurring steroids in biological samples, which was published from January 2001 to June 2006. Steroids are divided into six categories, based on their structures and functions, and no attention has been paid to steroid hormones used as growth promoters of animals and used in sports doping. This entry also does not take up references on the in vitro assays for the measurement of enzyme activity using a steroid as the substrate.

GENERAL PROCEDURE

For the precise measurement of the trace levels of steroids in complex biological matrices, some pretreatment

(purification and concentration) procedures are usually applied prior to the LC–MS analysis. Most analytical methods employ deproteinization with an organic solvent and solid-phase extraction (SPE) using a disposable cartridge as the pretreatment. Liquid–liquid extraction (LLE) is also often used in place of/with a combination of SPE. To reduce the labor and the analysis time, an online extraction using a mini SPE cartridge or a short column (ex., restricted-access column), along with a column-switching technique, has been recently and widely introduced.

Reversed-phase (RP) chromatography with an octadecylsilyl column is usually employed for the separation of steroids from biological components. A conventional column (inside diameter, 4.0–4.6 mm) is used for LC–APCI-MS, whereas, because a low flow rate (0.05–0.2 ml/min) is required for ESI-MS detection, a semi-micro column (inside diameter, 1.0–2.1 mm) is usually employed in this mode. Methanol and acetonitrile are the most generally used organic modifiers for the mobile phase. In ESI-MS, acids (positive-ion mode) such as formic acid and acetic acid, bases (negative-ion mode) such as triethylamine or volatile salts (positive- and negative-ion modes) such as ammonium formate and ammonium acetate, are used as the mobile-phase additives to promote protonation or deprotonation of the analyte.

In LC–MS assays, it goes without saying that it is important to select the ionization methods (ESI, APCI or, in some cases, APPI) and ionization polarity (positive-ion or negative-ion mode) suitable for the analyte. Instrumental parameters, such as the flow rate of the nebulizer gas and desolvent gas, desolvation temperature, and electrospray capillary voltage can significantly affect the generation of ions during LC–API-MS detection and, therefore, the optimization of these parameters is a necessary part of the development of analytical methods. The use of the selected ion monitoring (SIM) and selected reaction monitoring (SRM) modes may allow for the improvement of the assay sensitivity, because it can significantly reduce background noise derived from the matrices. However, the chemical and physical properties of the analyte are the most critical parameters for superior sensitivity in the various modes of ionization. Therefore, if the required sensitivity cannot be obtained, chemical derivatization is now the most widely used procedure for increasing the sensitivity of the target analyte. That is, derivatization changes the chemical and physical properties of the analyte, resulting in its ionization efficiency (conversion of a poorly ionizable compound into a derivative that is easily detectable by API-MS). The chromatographic behavior of the analyte will also be changed after derivatization, therefore decreasing the ionization suppression related to the co-elution of the biomatrix components. That is, derivatization increases not only the sensitivity, but also the specificity.

ESTROGENS

Representative estrogens, estrone (E_1) and estradiol (E_2), are synthesized from androgenic precursors by demethylation and aromatization; these are transformed to each other by the action of 17β-hydroxysteroid dehydrogenase. Estriol (E_3) is formed via the 16α-hydroxylation of E_1, especially during the period of pregnancy. Among them, E_2 is functionally the most potent estrogen. Estrogens are metabolized by hydroxylation, at the steroid A-ring, into catechol estrogens [ex. 2- or 4-hydroxyE_1 (2- or 4-OH-E_1)] and, further, by methylation into guaiacol estrogens [ex. 2- or 4-methoxyE_1 (2- or 4-MeO-E_1) or E_1-3-methyl ether]. Estrogens are responsible for the development and maintenance of the female reproductive organs and female secondary gender characteristics. Furthermore, estrogens play an important role in bone maintenance, in the cardiovascular system, and in the central nervous system. Estrogens also have an injurious action; breast cancer and endometrium cancer are promoted by prolonged exposure to endogenous and/or synthetic estrogens or their metabolites.

The LC–MS assays of estrogens are summarized in Table 1. With a few exceptions, estrogens are analyzed using LC–MS after derivatization, due to their low ionization efficiencies in ESI or APCI and occurrence at low concentrations in biological fluids and tissues. Dansylation, which was first proposed as the derivatization of phenolic compounds for ESI by Quirke, Adams, and Van Berkel,[19] is now the reference and most practical derivatization procedure for the LC–MS analysis of estrogens.[20–22] Derivatization with *p*-toluenesulfonhydrazide is also useful to enhance the sensitivities of E_1 and its metabolites; the resulting derivatives are analyzed by ESI-MS.[23,24] When urinary glucuronidated metabolites of E_3 [E_3-3G and -16G], whose abundance is in the μg/ml range, are analyzed, derivatization is unnecessary.[25]

ANDROGENS

Androgens are an important group of C_{19} steroids, principally comprised of testosterone (T) and its active metabolite, 5α-dihydrotestosterone (DHT). In addition, androstenedione (AD) and dehydroepiandrosterone (DHEA) are usually classified as androgens, although their androgenic activity is low or negligible.

To review the androgen assays using LC–MS published during the last five years, many papers were concerned with prostate cancer (PCa) and benign prostate hyperplasia (BPH).[26–31] PCa is the most common malignancy in aged males in the United States. Because prostatic diseases usually depend on androgens, the measurement of androgens in the prostatic tissue, which is collected by a biopsy needle, is very important in the clinical field for the differential diagnosis of prostatic

Table 1 Estrogens.

Analyte	Sample treatment	LC conditions (analytical column, mobile phase, and flow rate)	MS (instrument, ionization mode, and detection)	Sensitivity	Refs.
E_2 IS: d_3-E_2	Human serum (3–5 ml) → RP-SPE → derivatization with dansyl chloride	Zorbax Eclipse XDB-C_{18} (150 × 2.1 mm I.D., Agilent Technologies), gradient (acetonitrile–water containing 0.1% acetic acid) and 0.25 ml/min	API 4000 (Applied Biosystems), positive ESI and SRM ($[M + H]^+$ → product ion)	LOD (S/N = 3): 0.6 pg	[20]

E_3-3G and E_3-16G IS: d_3-T-G	Human urine (50 μl) → filtration → column-switching technique	Capcell Pak C_{18} UG 120 (250 × 1.5 mm I.D., Shiseido Fine Chemical), acetonitrile–water containing 0.1% triethylamine and 0.1 ml/min	LCQ (ThermoFinnigan), negative ESI and SRM ($[M–H]^-$ → product ion)	LOD (S/N = 3): 10 ng/ml (E_3-3G) and 5 ng/ml (E_3-16G) Measurable range: 0.1–20 μg/ml	[25]

diseases and to evaluate the effects of therapy. However, the sample volume collected by a biopsy needle is about 10 mg, and, therefore, the prostatic androgen assay requires a very high sensitivity. Recently, the introduction of derivatization with a permanently charged reagent enabled the quantification of prostatic DHT with a 10-mg tissue sample using LC–ESI-MS–MS.[26–28] The abundance of the precursors [DHEA and 5-androstenediol (Δ^5-Adiol)] and the downstream conversion products [androsterone (A) and epiandrosterone (EpiA)] of T in biological fluids reflects the individual androgen status (balance of production and excretion), which may also be a maker of prostatic diseases. Based on this, the LC–MS assays of sulfates of the above steroids have been reported.[29–31] Glucuronides of T and DHT excreted into urine were also analyzed by LC–ESI-MS–MS.[32]

The anesthetic and anxiolytic effects of androgens, mainly T and 5α-androstane-3α,17β-diol (3α,5α-Adiol), is another hot topic; these steroids are classified now as, not only androgens, but also neuroactive steroids. The determination of the brain and circulating levels of these steroids in animal models is useful for the elucidation of their physiological roles and pharmacological effects. Based on this information, papers that deal with the determination of these steroids in the rat brain and serum/plasma are recently increasing.[35–37]

The LC–MS assays of androgens, including the above-mentioned methods, are summarized in Table 2.

PROGESTOGENS

17α-Hydroxyprogesterone (17-OH-PROG), a metabolic precursor of corticoids and androgens, is the most important parameter for diagnosing and monitoring congenital adrenal hyperplasia (CAH) caused by the 21-hydroxylase deficiency. 17-OH-PROG has been conventionally determined by immunoassay, but this method has a serious drawback, i.e., a false positive due to poor antibody specificity and interference from endogenous components, such as lipids. As an alternative method, LC–MS has recently been proposed as the analytical technique of choice for the determination of 17-OH-PROG in a dried blood spot[38–40] or serum[41] (Table 3). Methods that can simultaneously determine 17-OH-PROG, some androgens, and cortisol (F) in blood spots have been reported.[42,43]

Neuroactive steroids affect neurotransmission through their action at the membrane ion-gated and other neurotransmitter receptors.[2] Recent studies have demonstrated that pregnane-type neuroactive steroids, such as pregnenolone (PREG) and its downstream conversion products, play an important role in the homeostatic mechanisms that counteract the inhibitory effect of stress on the γ-aminobutyric acid type A receptor function and are involved in the stress-elicited disorders, such as depression. Therefore, a method for the determination of neuroactive steroids in the brains of animal models can contribute to the elucidation of their physiological roles and the development of new antipsychotic agents targeting neurosteroidogenesis. Based on this background information, the LC–MS analysis of pregnane-type neuroactive steroids has been reported, in which derivatization is employed because of the low ionization efficiencies and low concentrations of the neuroactive steroids (Table 3).[44,45]

CORTICOIDS

Corticoids are also called corticosteroids; they are physiologically divided into mineralocorticoids acting during the metabolism of electrolytes (sodium and potassium) and glucocorticoids acting during saccharometabolism, the antiinflammatory response, and the sodium pool.

Aldosterone (ALDO) is a major mineralocorticoid, and hyperaldosteronism is a recognized cause of hypertension, whereas, a low level of ALDO is observed in patients with Addison's disease. Because of its low blood concentration (picomolar–nanomolar range), ALDO has been conventionally measured by immunoassay, and no LC–MS method has been proposed during the last five years.

F (Cortisol) is a major glucocorticoid and its serum/plasma and urinary levels are good biochemical markers of several diseases, such as Cushing's syndrome. A large number of LC–MS methods have been described for the quantitative measurement of F in the serum/plasma[46–49] and urine[50–54] (Table 4). In some of these methods, the simultaneous determination of F and its inactive metabolite, cortisone (E), was done.[49,53] F and E are usually ionized by ESI[46–49,52,53,55,56] and APCI[51] operating in the positive-ion mode, but seldom in the negative-ion mode.[50,54] The level of F circulation is also considered to be a marker of stress and the salivary F assay using LC–ESI-MS–MS has been proposed.[56]

F and E are metabolized into tetrahydrocortisol (THF), allotetrahydrocortisol (ATHF), and tetrahydrocortisone (THE), respectively, and are excreted into the urine. Measurement of their urinary ratio [(THF + ATHF)/THE] is clinically important for the diagnosis of hypertension caused by the congenital absence of 11β-hydroxysteroid dehydrogenase type 2 (apparent mineralocorticoid excess). The measurement of the blood 21-deoxycortisol (21-DOF) level is useful for the diagnosis of CAH. The endogenous ratio of 6β-hydroxycortisol (6β-OH-F) and F in the urine is an index for the activity of cytochrome P450 3A4. Based on their clinical importance, the LC–MS methods for THF,

Analyte	Sample treatment	LC conditions (analytical column, mobile phase, and flow rate)	MS (instrument, ionization mode, and detection)	Sensitivity	Refs.
F IS: d_3-F	Human serum (2 ml) → RP-SPE → LLE (ethyl acetate and water)	Zorbax Eclipse XDB-C_{18} (150 × 2.1 mm I.D., Agilent Technologies), methanol–water containing 0.1% acetic acid and 0.25 ml/min	Quattro Ultima (Micromass), positive ESI, SRM ($[M + H]^+$ → product ion)	LOD (S/N = 3–5): 10 pg	[46]
F IS: d_3-F	Human serum (1 ml) → LLE (dichloromethane)	Hypersil ODS (C18) (10 × 2.1 mm I.D., Agilent Technologies), gradient (methanol–20 m*M* ammonium acetate) and 0.4 ml/min	Quattro Ultima (Micromass), positive ESI, SIM ($[M + H]^+$)	LOD (S/N = 3): 10 ng/ml	[47]
F IS: d_3-F	Human serum (0.15 ml) → deproteinization (methanol and zinc sulfate) → online RP-SPE and column-switching technique	Reprosil pur C18-AQ (125 × 2.0 mm I.D., Maisch), methanol–2 m*M* ammonium acetate and 0.4 ml/min	Quattro (Micromass), positive ESI, SRM ($[M + H]^+$ → product ion)	LOD (S/N = 4): 1 ng/ml Measurable range: 7.8–500 ng/ml	[48]
F IS: 6α-Methyl-prednisolone	Human urine (1 ml) → LLE (dichloromethane)	Purospher Star RP-18 (55 × 2.0 mm I.D., Merck), gradient (methanol–water) and 0.3 ml/min	API 2000 (Applied Biosystems), negative ESI, SRM ($[M–H]^-$ → product ion)	LOD (S/N = 3): 1 pmol/ml Measurable range: 10–400 pmol/ml	[50]
F IS: d_4-F	Human urine (0.5 ml) → RP-SPE	Eclipse XDB-C18 (75 × 4.6 mm I.D., Mac-Mod Analytical), methanol–water containing 0.03% TFA and 1.0 ml/min	TSQ 7000 (Finnigan), positive APCI, SRM ($[M + H]^+$ → product ion)	Measurable range: 5–500 ng/ml	[51]
F IS: d_2-F	Human urine (0.3 ml) → RP-SPE	Chromolith RP-18 SpeedRod (50 × 4.6 mm I.D., Merck), methanol–2 m*M* ammonium acetate containing 0.1% formic acid and 0.6 ml/min	Quattro (Micromass) positive ESI, SRM ($[M + H]^+$ → product ion)	LOD (S/N = 3): 3 pmol/ml Measurable range: 20–1000 pmol/ml	[52]
F IS: d_4-F	Human saliva (0.25 ml) → deproteinization (acetonitrile)	Genesis C_8 (20 × 2.1 mm I.D., Jones), gradient (methanol–water containing 0.5% acetic acid) and 0.2 ml/min	API 3000 (Applied Biosystems/ MDX-SCIEX), positive ESI, SRM ($[M + H]^+$ → product ion)	LOD (S/N = 3): 0.2 ng/ml Measurable range: 0.8–80 ng/ml	[56]
F and E IS: d_4-F	Human serum or plasma (0.1 ml) → LLE (methyl *t*-butyl ether)	Luna Phenyl-Hexyl (50 × 2.1 mm I.D., Phenomenex), methanol–water and 0.45 ml/min	API 3000 (Applied Biosystems/ MDX-SCIEX), positive APPI, SRM ($[M + H]^+$ → product ion)	LOD (S/N = 5): 1 ng/ml (F) and 5 ng/ml (E) Measurable range: 10–200 ng/ml	[49]
F and E IS: d_4-F	Human urine (0.5 ml) → LLE (dichloromethane)	LC-18l (33 × 4.6 mm I.D., Supelco), methanol–water and 0.2 ml/min	API 2000 (Applied Biosystems), positive ESI, SRM ($[M + H]^+$ → product ion)	Measurable range: 7–828 pmol/ml	[53]
F and E IS: d_4-F	Human adipose homogenate (0.2 g) → extraction (ethyl acetate) → LLE (heptane, and methanol–water)	Luna C18 (2) (150 × 2.0 mm I.D., Phenomenex), gradient (methanol containing 0.02% TFA–water containing 0.02% TFA) and 0.3 ml/min	Micromass Ultima Pt (Micromass), positive ESI, SRM ($[M + H]^+$ → product ion)	Measurable range: 0.6–1200 pmol/mg	[55]

THF, ATHF and THE	Human urine (1 ml) → RP-SPE	Discovery HS F5 (50 × 2.1 mm I.D., Supelco), gradient (methanol–water) and 0.25 ml/min	API 2000 (Applied Biosystems), negative ESI, SRM ($[M-H]^-$ → product ion)	LOD (S/N = 3): 0.4–0.8 pmol/ml Measurable range: 7.5–120 pmol/ml	[57]
THF, ATHF and THE	Human urine (1 ml) → RP-SPE	Luna C8 (50 × 2.0 mm I.D., Phenomenex), gradient (methanol–water containing 0.1% formic acid)	API 4000 (Applied Biosystems/MDX-SCIEX), positive ESI, SRM ($[M + H]^+$ → product ion)	Measurable range: 2.5–600 ng/ml (THF and ATHE) and 5–500 ng/ml (THE)	[58]
F and 6β-OH-F IS: 6α-Methyl-prednisolone	Human urine (0.1 ml) → online RP-SPE → column-switching technique	Symmetry Shield RP_{18} (100 × 2.1 mm I.D., Waters), gradient (methanol containing 0.1% formic acid–water containing 0.1% formic acid) and 0.3 ml/min	API 3000 (Applied Biosystems/MDX-SCIEX), negative ESI, SRM ($[M + HCOO]^-$ → product ion)	Measurable range: 2–56 ng/ml (F) and 17–300 ng/ml (6β-OH-F)	[54]
21-DOF	Human plasma (2 ml) → LLE (isooctane–ethyl acetate)	Alltima C_{18} (250 × 2.1 mm I.D., Alltima), gradient (methanol containing 0.025% TFA-water containing 0.025% TFA) and 0.2 ml/min	LCQ^{xp} (ThermoFinnigan), positive ESI, SRM ($[M + H]^+$ → product ion)	LOD: 4 pg Measurable range: 0.25–600 ng/ml	[59]
B IS: 5-Pregnen-3β-ol-20-one-16α-carbonitrile	Rat plasma (0.1 ml) → LLE (diethylether)	Zorbax-Eclipse C_8 (50 × 4.6 mm I.D., Agilent Technologies), gradient (methanol–water) and 0.8 ml/min	1100 series (Agilent Technologies), positive ESI, SIM ($[M + Na]^+$)	LOD: 9 fmol Measurable range: 2–400 pg/ml	[60]
B and 11-dehydro-corticosterone IS: E	Mouse liver homogenate (0.1 g) or adipose (0.2 g) → extraction (ethyl acetate) → LLE (heptane and methanol–water)	Symmetry C8 (150 × 2.1 mm I.D., Waters), gradient (methanol containing 0.02% TFA-water containing 0.02% TFA) and 0.3 ml/min	Micromass Ultima Pt (Micromass), positive ESI, SRM ($[M + H]^+$ → product ion)	Measurable range: 60–1200 pmol/mg (liver) and 6–600 pmol/mg (adipose)	[55]
B and 11-dehydro-corticosterone IS: E	Mouse adipose homogenate (0.2 g) → extraction (ethyl acetate) → LLE (heptane, methanol and water)	Symmetry C8 (150 × 2.1 mm I.D., Waters), gradient (methanol containing 0.02% TFA–water containing 0.02% TFA) and 0.3 ml/min	Micromass Ultima Pt (Micromass), positive ESI, SRM ($[M + H]^+$ → product ion)	Measurable range: 6–600 pmol/mg	[55]

ATHF and THE,[57,58] 21-DOF,[59] and 6β-OH-F[54] have also been reported. Corticosterone (B) is the most typical glucocorticoid in rodents, and its plasma level in the rat[60] and tissue level of the mouse[55] have been measured using LC–MS.

BILE ACIDS

Bile acids play a pivotal role in the metabolism of cholesterol and lipids. Their blood concentrations are important prognostic and diagnostic indicators of the hepatobiliary and intestinal dysfunction. The naturally occurring common bile acids are saturated C_{24} steroid carboxylic acids, including cholic acid (CA), chenodeoxycholic acid (CDCA), deoxycholic acid (DCA), lithocholic acid (LCA), and ursodeoxycholic acid (UDCA). Bile acids are conjugated in the human liver with taurine or glycine before they are secreted via the biliary canaliculi into the bile. Thus, bile acids usually have an ionic functional group and, therefore, their LC–MS assays are performed using negative ESI[61–65] (Table 5).

Bile acid CoA esters are the intermediates in the oxidative shortening of the side chain of the C_{27}-bile acids (β-oxidation) in the biosynthesis of bile acids. Therefore, the blood levels of the bile acid CoA esters and C_{27}-bile acids are good markers for the diagnosis of peroxisomal disorders, such as Zellweger syndrome. The development and clinical applications of the LC–ESI-MS methods for bile acid CoA esters[66] and C_{27}-bile acids[67] have been reported.

Recently, it was found that unconjugated bile acids (CA, CDCA, and DCA) are present at high (nmol/g tissue) levels in the rat brain cytoplasmic fraction,[64] but their functions in the central nervous system are unclear. To clarify this point, a profile analysis of the rat serum bile acids (eight common bile acids and their glycine and taurine conjugates) has been demonstrated.[65]

VITAMIN D METABOLITES

The measurements of the serum/plasma concentration of the vitamin D [vitamin D_2 (D_2) and vitamin D_3 (D_3)] metabolites are widely used for the diagnostic assessment and the follow-up of several diseases (osteoporosis, renal osteodystrophy, parathyroid gland disorders, and sarcoidosis). Although the ionization efficiencies of the vitamin D metabolites are very low in ESI or APCI, the serum/plasma 25-hydroxyvitamin D_3 [25-OH-D_3] can be measured using LC–ESI- or APCI-MS without derivatization when a relatively large volume of sample (0.1–0.2 ml) is used,[68–71] because of its relatively high serum/plasma level (10–40 ng/ml) (Table 6). Some of these methods can simultaneously determine the 25-hydroxyvitamin D_2 [25-OH-D_2] levels.[69–71] If the available sample volume is limited, a derivatization is required to measure the serum/plasma 25-OH-D_3 and 25-OH-D_2 (sample volume, 20 μl).[72,73] Cookson-type reagents rapidly and quantitatively react with vitamin D compounds to form Diels–Alder adducts, which increase their detection responses (more than 10 times) in APCI-MS. 4-[2-(6,7-Dimethoxy-4-methyl-3-oxo-3,4-dihydroquinoxalyl) ethyl]-1,2,4-triazoline-3,5-dione (DMEQTAD) and 4-(4-nitrophenyl)-1,2,4-triazoline-3,5-dione (NPTAD) were used as the derivatization reagents for the positive APCI-[72] and ECAPCI-MS detection,[73] respectively. Another Cookson-type reagent, 4-[4-(6-methoxy-2-benzoxazolyl)phenyl]-1,2,4-triazoline-3,5-dione (MBOTAD), was also used for the plasma 24,25-dihydroxyvitamin D_3 [24,25-$(OH)_2$-D_3] measurement.[74]

Because the serum/plasma concentration of the active form of vitamin D_3, 1,25-$(OH)_2$-D_3, is extremely low (30–70 pg/ml), it has been conventionally measured by a radioreceptor assay technique using the vitamin D receptor in the clinical field. Although a method has been reported for the LC–MS assay of 1,25-$(OH)_2$-D_3,[75] its applicability was proved only for the rat serum assay; this method is of less practical use in the clinical field. Even if an up-to-date mass spectrometer model is employed, it may be difficult to measure the serum/plasma 1,25-$(OH)_2$-D_3 levels with a clinically available sample volume (<1 ml).

OTHERS AND STEROID PROFILES

Oxysterols are oxidized derivatives of cholesterol (Ch) and of potential diagnostic interest because their circulating levels may reflect the cholesterol metabolism in the brain. For example, it has been reported that the plasma 24*S*-hydroxycholesterol (24-OH-Ch, cerebrosterol) is increased in Alzheimer and vascular demented patients.[76] Recently, application of LC–MS for the measurement of these sterols,[18,77] which are conventionally measured by GC–MS, has been attempted (Table 7).

Steroid profile analysis (simultaneous measurement of various types of steroids) plays an important role in the clinical evaluation of a number of common endocrine disorders in humans and animal models. LC–MS profiles of steroids in bovine adrenal cells,[78] the rat brain,[17] and human serum[7] have been reported during the past five years (Table 7).

Table 5 Bile acids.

Analyte	Sample treatment	LC conditions (analytical column, mobile phase, and flow rate)	MS (instrument, ionization mode, and detection)	Sensitivity	Refs.
UDCA, its glycine and taurine conjugates IS: 23-Nordeoxycholic acid	Human plasma (0.3 ml) → RP-SPE	Prism RP (100 × 4.6 mm I.D., ThermoHypersil), methanol-25 m*M* ammonium acetate containing 0.05% acetic acid and 1 ml/min (split rate of 1 : 5)	API 2000 (Sciex), negative ESI, SRM ($[M–H]^-$ → product ion)	Measurable range: 10–3000 ng/ml	[61]
CA, CDCA, DCA, LCA, their glycine and taurine conjugates, UDCA and its taurine conjugate	Human plasma (0.25 ml) → deproteinization (acetonitrile)	Pinnacle ODS (100 × 4.6 mm I.D., Restek), gradient (methanol-5 m*M* ammonium acetate containing 0.012% formic acid) and 1 ml/min (split rate of 1 : 20)	API 365 (Applied Biosystems-SCIEX), negative ESI, SRM ($[M–H]^-$ → product ion)	Measurable range: 0.1–100 nmol/ml	[62]
CA, CDCA, DCA, LCA, UDCA, their glycine and taurine conjugates IS: d_4-CA, d_4-CDCA, d_4-DCA, d_4-LCA, d_4-UDCA, and glycine conjugates of d_4-CA, d_4-CDCA	Human serum (0.75 ml) → RP-SPE	Uptisphere C_{18} ODB (125 × 2.0 mm I.D., Interchim), gradient (methanol containing 0.012% formic acid–10 m*M* ammonium acetate) and 0.2 ml/min	TSQ 7000 (Finnigan), negative ESI, SIM ($[M–H]^-$, unconjugates), SRM ($[M–H]^-$ → product ion, conjugates)	Measurable range: 0.12–60 nmol/ml	[63]
Dihydroxycholestanoic acid CoA ester and trihydroxycholestanoic acid CoA ester IS: d_4-CA CoA ester	Rat liver homogenate (0.1 g) → extraction (ethyl acetate) → RP-SPE	Synergi HydroRP 80A (150 × 2.0 mm I.D., Phenomenex), isopropanol–acetonitrile–water adjusted to pH 2.7 with formic acid and 0.4 ml/min	API 365 (Sciex), positive ESI, SRM ($[M + H]^+$ → product ion)	LOD: 0.1 nmol	[65]
CA, CDCA, DCA, LCA, UDCA, hydroxycholic acid, α-muricholic acid, β-muricholic acid, their glycine and taurine conjugates IS: d_2-$^{18}O_2$-CDCA and d-^{18}O-LCA	Rat serum (0.1 ml) → RP-SPE	Luna C18 (2) (150 × 2.0 mm I.D., Phenomenex), gradient (acetonitrile–methanol–20 m*M* ammonium acetate) and 0.2 ml/min	Quattro II (Micromass), negative ESI, SRM ($[M–H]^-$ → product ion)	Measurable range: 5–2000 ng/ml (CA, CDCA, DCA, UDCA, hydroxycholic acid, α-muricholic acid, β-muricholic acid, and their conjugates) and 5–500 ng/ml (LCA and its conjugate)	[66]
Dihydroxycholestanoic acid, trihydroxycholestanoic acid and their taurine conjugates IS: d_4-CA and taurine conjugate of d_4-CA	Human plasma (50 μl) → deproteinization (acetonitrile)	Alltima C_{18} (250 × 2.1 mm I.D., Alltima), gradient (ethanol–5 m*M* ammonium formate) and 0.3 ml/min	Quattro II (Micromass), negative ESI, SRM ($[M–H]^-$ → product ion, unconjugates), SIM ($[M–H]^-$, taurine conjugates)	LOD: 0.05 nmol/ml	[67]
CA, CDCA, DCA IS: d_2-$^{18}O_2$-CDCA	Rat brain (30 mg) → denaturation of protein (1.65 *M* Tris–HCl buffer containing 0.03 *M* EDTA and 7.3 *M* guanidine hydrochloride) → deproteinization (ethanol)	Inertsil ODS-2 (150 × 2.1 mm I.D., GL Science), acetonitrile-20 m*M* ammonium acetate and 0.22 ml/min	JMS-LC mate (JEOL), negative ESI, SIM ($[M–H]^-$)	LOD (S/N = 5): 5 pg	[64]

Table 6 Vitamin D metabolites.

Analyte	Sample treatment	LC conditions (analytical column, mobile phase, and flow rate)	MS (instrument, ionization mode, and detection)	Sensitivity	Refs.
25-OH-D_3 IS: d_4-25-OH-D_3	Human serum (0.2 ml) → deproteinization (acetonitrile) → online RP-SPE → column-switching technique	LiCrospher 100RP-18 (125 × 4.0 mm I.D., Merck), methanol-0.5 m*M* ammonium acetate and 0.85 ml/min	Quattro (Micromass), positive ESI and SRM ($[M + H]^+$ → product ion)	Measurable range: 7.3–182 pmol/ml	[68]
25-OH-D_2 and 25-OH-D_3 IS: d_3-Δ^9-Tetrahydro-cannabinol	Human serum (0.2 ml) → LLE (heptane)	XTerra (50 × 2.1 mm I.D., Waters), methanol–2 m*M* ammonium acetate containing 0.1% formic acid and 0.1 ml/min	Quattro (Micromass), positive ESI, SRM ($[M + H]^+$ → product ion)	LOD: 0.06 ng/ml (25-OH-D_3) and 0.09 ng/ml (25-OH-D_2)	[69]
25-OH-D_2 and 25-OH-D_3 IS: d_6-25-OH-D_3	Human plasma (0.1 ml) → deproteinization (methanol) → RP-SPE	Capcell Pak C18 UG120 (250 × 4.6 mm I.D., Shiseido Fine Chemical), methanol–water and 0.5 ml/min	API 3000 (Applied Biosystems), positive APCI and SRM ($[M + H]^+$ → product ion)	LOD (S/N = 3): 2.5 ng/ml Measurable range: 5–100 ng/ml	[70]
25-OH-D_2 and 25-OH-D_3 IS: d_6-25-OH-D_3	Human serum (0.1 ml) → deproteinization (methanol–propanol)	BDS C_8 (51 × 2.1 mm I.D., ThermoHypersil), gradient (methanol–water containing 0.05% formic acid) and 0.3 ml/min	API 3000 (Applied Biosystems), positive ESI, SRM ($[M + H]^+$ → product ion)	Measurable range: 4.0–256 pmol/ml (25-OH-D_3) and 4.95–316 pmol/ml (25-OH-D_2)	[71]
25-OH-D_2 and 25-OH-D_3 IS: 25-OH-D_4	Human plasma (20 μl) → deproteinization (acetonitrile) → LLE (ethyl acetate and water) → derivatization with DMEQTAD	J'sphere ODS H-80 (150 × 4.6 mm I.D., YMC), acetonitrile–water and 1 ml/min	LCQ (ThermoQuest), positive APCI and SRM ($[M + H]^+$ → residual $[M + H]^+$)	LOD (S/N = 3): 12.5 fmol (25-OH-D_3) and 20 fmol (25-OH-D_2) Measurable range: 0.05–1 ng/tube	[72]
25-OH-D_3 IS: 25-OH-D_4	Human plasma (20 μl) → deproteinization (acetonitrile) → LLE (ethyl acetate and water) → derivatization with NPTAD	J'sphere ODS H-80 (150 × 4.6 mm I.D., YMC), methanol–water and 1 ml/min	LCQ (ThermoQuest), ECAPCI and SRM ($[M]^-$ → residual $[M]^-$)	LOD (S/N = 3): 10 fmol, Measurable range: 0.05–1 ng/tube	[73]
24,25-$(OH)_2$-D_3 IS: d_6-24,25-$(OH)_2$-D_3	Human plasma (0.3 ml) → deproteinization (acetonitrile) → RP-SPE → silica gel column → derivatization with MBOTAD	J'sphere ODS H-80 (150 × 4.6 mm I.D., YMC), acetonitrile–water and 1 ml/min	LCQ (ThermoQuest), positive APCI and SRM ($[M + H]^+$ → residual $[M + H]^+$)	LOD (S/N = 3): 18 fmol, Measurable range: 0.05–1.2 ng/tube	[74]
1,25-$(OH)_2$-D_3 IS: d_6-1,25-$(OH)_2$-D_3	Human, rat, and pig serum (1 ml) → deproteinization (acetonitrile) → RP-SPE	Symmetry C_8 (50 × 2.1 mm I.D., Waters), gradient (methanol–2 m*M* ammonium acetate) and 0.3 ml/min	API 3000 (PE/Sciex), positive ESI and SRM ($[M + NH_4]^+$ → product ion)	Measurable range: 20–100 pg/ml	[75]

Table 7 Others and steroid profile.

Analyte	Sample treatment	LC conditions (analytical column, mobile phase, and flow rate)	MS (instrument, ionization mode, and detection)	Sensitivity	Refs.
24-OH-Ch and 27-OH-Ch IS: d_7-24-OH-Ch	Human plasma (0.5 ml) → saponification (NaOH) → RP-SPE	Nucleosil C_{18} HD (125 × 2.0 mm I.D., Machery-Nagel), methanol–acetonitrile–10 m*M* ammonium acetate buffer and 0.25 ml/min	TSQ 7000 (ThermoQuest), positive APCI and SIM ($[M + H–H_2O]^+$ or $[M + H–2H_2O]^+$)	LOQ: 40 ng/ml (24-OH-Ch) and 25 ng/ml (27-OH-Ch)	[77]
Various hydoxy-cholesterol	Rat brain (100 mg) → ethanol extraction → anion-exchange column (Lipidex DEAP) → NP-mini-column → oxidation with cholesterol oxidase → derivatization with Girard reagent P	PepMap C18 (150 × 0.18 mm I.D., Dionex), gradient (methanol–water containing 0.1% fomic acid) and 1 μl/min	Q-TOF Global (Micromass), positive ESI and MS or MS–MS (not quantitative analysis)	LOD: sub-pg	[18]
ALDO, F, E, DOC, PREG and PROG IS: d_2-F and d_2-E	Bovine adrenal cell culture medium → LLE (ethyl acetate)	Kromasil (250 × 2.0 mm I.D., Eka Chemical), gradient (methanol–water) and 0.25 ml/min	1100 series (Agilent), positive ESI, SIM ($[M + Na]^+$)	LOD (S/N = 3): 2 pg on column [except for PREG (10 pg on column)] Measurable range: 5–1000 pg [except for PREG (25–5000 pg)]	[78]
DHEA, PREG, PROG, T, pregnanolone, allopregnanolone, epipregnanolone and epiallopregnanolone, IS: d_4-DHEA and $^{13}C_2$-PROG	Rat brain (50–300 mg) → extraction (ethanol) → RP-SPE → cation exchange column (SP-LH-20) → anion exchange column (Lipidex-DEAP) → derivatization with hydroxylammonium chloride → RP-SPE → cation exchange column (SP-LH-20)	Genesis C18 (350 × 0.1 mm I.D., Jones Chromatography), gradient (methanol–water containing 10 m*M* ammonium acetate) and 0.2–0.3 μl/min	AutoSpec-OATOFFPD, Quattro Ultima or Quattro Micro (Micromass), positive ESI and SRM ($[M + H]^+$ → product ion) or precursor ion scan	LOD (S/N = 10); 1.5 pg (DHEA, PREG, allopregnanolone), 3 pg (PROG) and 1 pg (T)	[17]
E_2, E_3, DHEA, DHEA-S, AD, T, PROG, 17-OH-PROG, F and 11-DOF IS: d_4-E_2, d_2-E_3, d_2-DHEA, d_7-AD, d_2-T, d_8-PROG, d_8-17-OH-PROG, d_4-F and d_2-11-DOF	Human serum (760 μl) → deproteinization (acetonitrile) → column-switching technique	LC-18-DB (33 × 3.0 mm I.D., Supelco), gradient (methanol–water) and 0.5 ml/min	API 3000 (Applied Biosystems), positive APPI and SRM ($[M + H]^+$ → product ion)	LOD: 100 pg/ml	[7]

Bioluminescence: Detection in TLC

Joseph Sherma
Department of Chemistry, Lafayette College, Easton, Pennsylvania, U.S.A.

Abstract
Toxicity screening of complex mixtures using the bioluminescent bacteria *Vibrio fischeri* following separation on a thin-layer chromatography (TLC) or high-performance thin-layer chromatography (HPTLC) plate is described. A commercial kit, Bioluminex™, is available for the method.

BIOLUMINESCENCE DETECTION

Physical, chemical, and biological, or bioactivity-based methods are used to detect zones in thin-layer chromatography (TLC) after the development of the plate with the mobile phase.[1] Advantages of combining TLC with a bioassay are high specificity and reduced interference of the matrix leading to less need for sample cleanup;[2] high sensitivity, with detection limits typically in the subnanogram to picogram range; and the identification of separated toxic compounds, degradation products, and metabolites based on chromatographic retention (R_f values), physical detection, and specific biological activity related to the test system.

Biological detection methods for microbiologically active compounds have been classified as diffusion methods, dilution methods, and bioautography.[3] The principle of direct bioautography is that a suspension of a microorganism growing in a suitable medium is applied to a developed TLC plate after drying; incubation of the plate with the microbes at optimum humidity and temperature allows growth of the bacteria; and, by use of a specific dye, live cells can be visualized because, for example, dehydrogenases from living microorganisms convert a tetrazolium salt into intensely colored formazan.[4] This entry will be limited to a description of TLC in combination with bioluminescence detection, in which antibacterial compounds are detected as dark zones against a luminescent layer background instead of as colorless zones against a colored layer background in bioautography. Bioluminescence–TLC is increasingly being used because of the commercial availability of a reagent kit, detection device, and supporting accessory instruments to standardize the method and provide the optimum results.

PRINCIPLES OF TLC–BIOLUMINESCENCE COUPLING

The technology for bioactivity screening by TLC–bioluminescence direct coupling was developed by Bayer AG (Leverkusen, Germany) and published in 1996.[5] The method is based on the change in emission by luminescent microorganisms in the presence of bioactive substances, which provides an effective way to detect toxic compounds on a TLC plate. The combination of TLC separation technology with the biospecific sensing ability of living cells represents a novel screening tool for targeting bioactive compounds in complex samples. In the published study,[5] the TLC–bioluminescence technique proved to be superior to a high-performance liquid chromatography (HPLC)–bioluminescence method.

After TLC separation and evaporation of the mobile phase, the plate is coated with a bioluminescent solution of the non-pathogenic marine organism *Vibrio fischeri* by dipping. *V. fischeri* emits light as a product of cellular respiration. As *V. fischeri* cells reach a critical cellular density, the bioluminescence catalyst, luciferase, is expressed. Luciferase, in the presence of oxygen, catalyzes an oxidation reaction that releases excess energy in the form of light. Toxic substances on the layer are selectively identified as dark zones (inhibited bacteria) on a luminescent background (viable bacteria). The degree of toxicity is proportional to the luminescence inhibition. The results occur within seconds and last until the plate dries. Results can be documented by video imaging with a charge coupled device (CCD) camera inside a dark box or by X-ray filming. The detection approach of bioluminescence is similar to classical fluorescence quenching detection in which compounds that contain aromatic rings or multiple bonds absorb 254 nm light from a UV source and appear as dark zones against a bright background when layers impregnated with a fluorescent phosphor (F_{254} layers) are used. Because a TLC plate is used only once, less purified samples can be tolerated, as compared with column chromatography, in which strongly retained impurities from a previous sample can be eluted and can interfere with later samples injected onto the column.

HPTLC–BIOLUMINESCENCE WITH THE BIOLUMINIZER®

In modern TLC–bioluminescence analysis, an HPTLC plate is used instead of a TLC plate in order to achieve greater resolution and speed. The sample is separated by HPTLC, and the plate is subsequently immersed in the luminescent bacterial suspension (*V. fischeri*; Bioluminex™ assay kit from ChromaDex, Irvine, California, U.S.A.). After an incubation time for completion of the reaction, all zones with inhibitory or toxic effects appear as black zones and those with stimulatory effect as lighter zones in the chromatograms on the plate, which is photographed by the Camag (Muttenz, Switzerland) BioLuminizer® (Fig. 1), a dark box imaging system employing a high-resolution cooled CCD camera with 16-bit data acquisition carried out for a specified time period. The BioLuminizer was developed specifically to accumulate the light signal from HPTLC plates for bioluminescence-based effect-directed analysis (EDA). The BioLuminizer has a holder that enables exact plate positioning (to 0.1 mm) and an optimized compartment that resists plate dryout and keeps the bacteria moist and luminescent for hours, leading to predictable bioluminescence activity for consistent results. EDA, combining HPTLC with direct bioluminescence, is a practical alternative to complex target analysis and provides a fast, low-cost means of demonstrating biological activity in cases where many unknown substances are present, such as environmental samples. The time and effort required to examine structures or isolate substances can be restricted to a few relevant substances. By using HPTLC to separate the test sample into individual substances, the possibility of antagonistic or synergistic effects leading to false results that can occur with classic cuvette tests are eliminated. Detection levels are typically in the picomole range. Inhibition values can be determined by special software for quantification of luminescence inhibition. In addition to bioluminescent bacteria, HPTLC–EDA has proven effective for other types of bioassays, such as acetylcholinesterase inhibition, penicillin, and *Bacillus subtilis*, as well as for genotoxicity tests such as umu (*Salmonella thyphimurium*) and yeast estrogen screen (YES).

Fig. 1 BioLuminizer® detection system for bioactive compounds.

Typically, the plate is dipped for 2 sec into the luminescent bacteria in the Bioluminex assay. Instead of manual dipping, this step can be carried out more reproducibly using the Camag Chromatogram Immersion device or Desaga TLC Dip-Fix (Desaga products are supplied by Sarstedt, Inc., Newton, North Carolina, U.S.A.),[6] which offer uniform vertical speed of immersion and withdrawal for selectable time periods. The dipping devices are also useful for prewashing the HPTLC plates to remove layer impurities before sample application. For highest resolution, samples can be applied bandwise with an automated instrument such as the Camag Linomat 5 or Desaga HPTLC-Applicator As 30.[7] Ascending chromatogram development is usually carried out in a traditional rectangular glass chamber such as the ridged-bottom twin-trough chamber,[8] but improved reproducibility can be achieved by using the Camag Automatic Developing Chamber or Desaga TLC-MAT automatic chamber,[6] which control chromatographic conditions such as saturation, layer activity, and drying; the highest-resolution separations can be performed by automated multiple development (AMD).[9] Chromatograms can be photographed under white light (colored zones detected), 254 nm (fluorescence-quenched zones), or 366 nm UV light (fluorescent zones) using a Desaga Digital Documentation System DD 50, ChromaDoc-IT Imaging System (Analtech, Newark, Delaware, U.S.A.), or Camag Digistore-2 Documentation System.[6] The light-quenching zones can be quantified based on their scan areas compared to standard zones measured with a slit-scanning densitometer such as the TLC Scanner 3 or Desaga CD 60,[6,10] or using image analysis software available with the three documentation systems mentioned above. These accessory instruments improve the methodology and complement the analytical information generated by the Bioluminex.

APPLICATIONS OF TLC–BIOLUMINESCENCE ANALYSIS

Application areas suggested by ChromaDex[11] are natural biological and chemical toxins, chemical contaminants and pollutants, identification of potential biological activity (antimicrobiological screening), raw material identity testing, simultaneous chemical and biological profiling, parallel processing of up to 22 samples, and qualitative and quantitative analysis. Specific applications offered by ChromaDex are mycotoxin in corn; strychnine in infant formula; carbaryl insecticide in wine; fingerprint of *Capsicum annuum* in cayenne; and steroid As (III) and the herbicide metolachlor in tap water. For these applications, images of chromatograms are presented by ChromaDex. Other applications of TLC–bioluminescence described by Bayer[12] are toxicity profiling of wastewater over a 15 day period, analysis of natural product extracts, detection of tea seed oil residual, quantification of toxicity by toxicity equivalents based on calibration with 4-nitrophenol, United States Pharmacopeia (USP) method for *Matricaria chamomilla* detection using bioluminescence and anisaldehyde/366 nm, analysis of kava kava, and toxicity in process water.

Specific applications for the HPTLC-BioLuminizer method offered by Camag[13] are the following: analysis of wastewater containing X-ray contrast media for oxidation products produced by irradiation with UV light; toxicity screening for environmental applications; risk assessment and monitoring of drinking water, wastewater, and natural attenuation processes; detection of toxins and chemical adulterants in foodstuffs, beverages, and cosmetics; identification of biological activity in natural product extracts; determination of the biological activity of berberine-containing drugs (Figs. 2 and 3); determination of pesticides, heavy metals, organic pollutants, pharmaceuticals, and mycotoxins in a variety of complex matrices; and bioactivity-based analysis of irradiated sunscreens.

CONCLUSION

TLC or HPTLC combined with bioluminescence detection is an important method for the EDA of bioactive zones on the layer. Bioluminescent bacteria can be used or other types of bioassays can be carried out. A system incorporating *V. fischeri*, HPTLC, and detection with a CCD camera

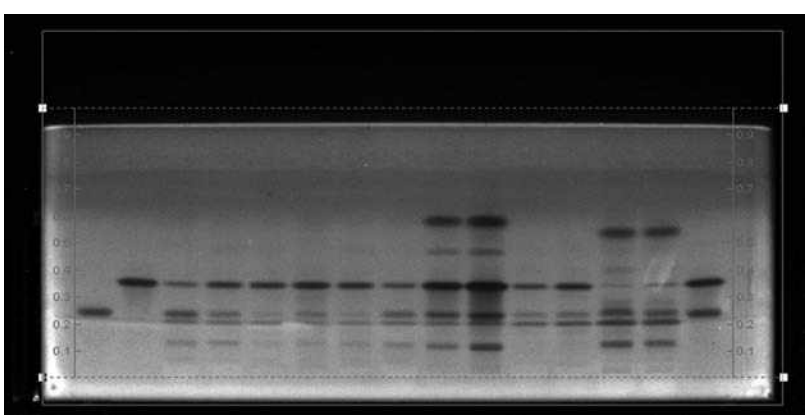

Fig. 3 HPTLC bioluminescence image of the same plate as in Fig. 2. Note that the different numbers of zones in the chromatograms detected in some of the lanes by the two methods provide complementary information on the samples.

in a dark box (BioLuminizer) is available from Camag. Various accessory HPTLC instruments can be incorporated to obtain improved results and additional analytical information. Key advantages are the avoidance of tedious single-compound screening, rapid response time and fast results, absence of false results due to antagonistic effects/interferences, detection in the picomole range, high sample throughput due to parallel analysis of multiple samples on one plate, low cost, and possibility of further investigation of toxic zones.

Biomarkers and Metabolites: HPLC/MS Analysis

Clayton B'Hymer
Kenneth L. Cheever
National Institute for Occupational Safety and Health, Centers for Disease Control and Prevention, U.S. Department of Health and Human Services, Cincinnati, Ohio, U.S.A.

Abstract
High-performance liquid chromatography–mass spectrometry (HPLC–MS) is a powerful analytical technique widely used in recent years for the analysis of biomarkers and metabolites. Biomarker determination and quantification, whether metabolic or adducted biomolecules, are commonly used to evaluate exposure and support biomonitoring research, especially in the area of occupational exposure and health. Some of the common problems and strategies of HPLC–MS biomarker analysis involve matrix effects, the use of isotope-labeled internal standard compounds, and sample cleanup; usually all of these factors must be evaluated within the development phase of an analysis procedure. Specific examples of biomarker analysis using HPLC–MS include acrylamide, aromatic compounds, and 1-bromopropane, and these examples are discussed in detail.

INTRODUCTION

A biomarker can be described as a substance from an organism that can be measured from a biological sample and can reflect *either* exposure, the effect of exposure or susceptibility to exposure. Biomarkers can be specific molecular, cellular, genetic, or protein changes resulting from environmental conditions including exposure to toxicants. Molecular biomarkers of chemical exposure, such as from an environmental toxicant, are commonly metabolites, protein adducts, or DNA adducts derived from the parent chemical. Developments in analytical chemistry have considerably improved the capability to detect biomarkers; thus, individual human exposure to occupational or environmental contaminants can be characterized by the measurement of the sampled biological media collected. Metabolites, adducted molecules, or residues from adducted proteins can be detected and quantified by means of modern analytical techniques using high-performance liquid chromatography (HPLC) and utilizing the detection capability of mass spectrometry (MS). Although other separation techniques have been employed for metabolite detection or the monitoring of biomarkers, HPLC offers the advantage of requiring only the solubility of the analyte and its inherent separation reliability. MS offers an ideal detection system for analyte specificity, excellent sensitivity, and reasonably low detection limits. The application of HPLC–MS in biomonitoring analysis for specific metabolites or adducted molecules is extensive, and HPLC–MS has often been used in the support of industrial hygiene studies and environmental risk assessments. The determination of biomarkers by HPLC–MS and examples of applications of this technique to occupational exposures will be the focus of this entry.

BACKGROUND ON BIOMONITORING AND BIOMARKERS

Biomonitoring generally refers to the periodic measurement of a biomarker to assess the internal dose and the health or health risk associated with exposure to a chemical. Biomonitoring or the monitoring of biomarkers has been used extensively during the past decade. The analysis of biomarkers of metabolic pathways for dysfunction has been used by both the scientific and the medical community for the determination of overall health or for use in health assessment. Biomarkers might indicate histopathologic changes, immunotoxicity, adverse biochemical alterations, and endocrine alterations. Monitoring of biomarkers, as well as the closely related field of metabolomics (the profiling of an organism's metabolites), has gained greater interest in recent years owing to the advances in analytical instrumentation and techniques. The hyphenated technique of combining liquid chromatography with MS detection is of major importance in biomarker research, and it can be considered the standard technique for biomarker identification and analysis.

The best review of the role of biomarkers in monitoring exposures to chemicals has been described by Watson and Mutti[1] and will not be repeated here in detail. Fig. 1 displays the general relation of events, such as exposure and biomarker classification.[2,3] The type of biomarkers with which this entry is concerned can generally be categorized as biomarkers of exposure, although metabolic changes can be detected by HPLC–MS and thus be a biomarker of effect. Biomarkers of susceptibility are outside the scope of this discussion and are related to effect-modifying factors, which include both genetic and

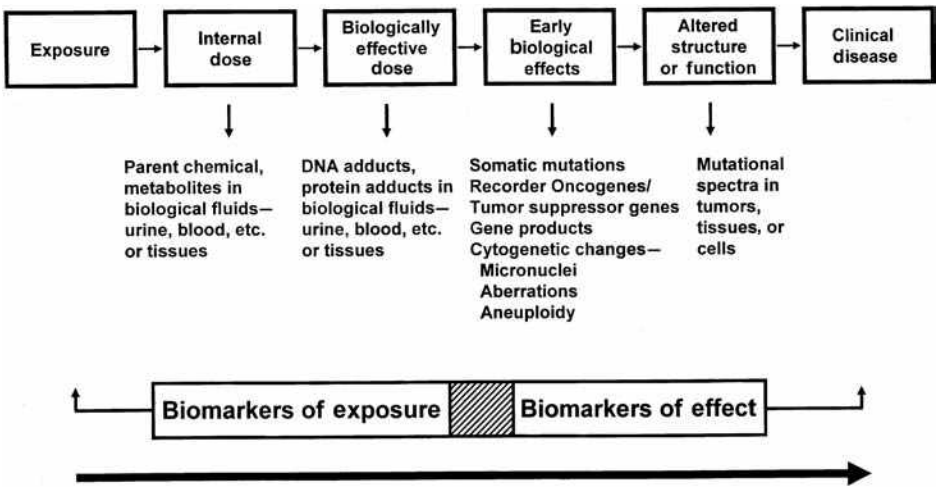

Fig. 1 The relation of events and biomarker classification.
Adapted from Watson & Mutti,[1] Albertini,[2] and Manini, Andreoli, & Niessen.[3]

acquired conditions. As the term implies, biomarkers of exposure are those related to exposure and the internal levels of some agent or chemical. Biomarkers of effect are those markers related to an early biological effect or altered structural function within an organism including any measurable biochemical or other physiological alteration that would be recognized as a potential impairment to health. In environmental or occupational health biomarker research, the major focus of interest has been on biomarkers of exposure. Parent chemicals, their metabolites, and the residues of adducted molecules are those biomarkers of exposure that can be detected and measured by HPLC–MS.[3–5] Common popular biomarker research has included various industrial chemicals, metals, pesticides, polycyclic aromatic hydrocarbons (PAHs), phthalates, acrylamide, benzene, and toluene, as well as biomarkers from tobacco smoke including cotinine, a metabolite of nicotine.

A good, well-chosen biomarker of exposure should have several qualities. One is it should be specific for the exposure of interest; some metabolites are common to multiple chemical substances and may not be a suitably specific biomarker. Even a small quantity of the biomarker should be easily detectable; therefore, high sensitivity is important. Also, the biomarker should be associated with exposure. Ideally, biomarkers should provide good predictive value to a specific health status and have reference values in the population if possible. Low overall analysis expense is another desirable characteristic of biomarker analysis for use in biomonitoring. The availability of suitable economical reference standards, as well as low-cost sample preparation, is an important consideration for extensive studies. This also implies that the analytical measurement procedure for the biomarker should have high throughput capability. Finally, measurements by non-invasive techniques are desirable. Urine-based biomarkers, either parent compounds or metabolites, are widely used in biomarker research today. Blood drawing is most often needed for the determination of macromolecular adducts such as protein adducts.

HPLC–MS

General Capabilities and Advantages

HPLC has many advantages and strengths as a separation technique. One is that solubility is the main requirement for sample introduction, unlike in gas chromatography (GC) where sample volatility is required. HPLC can avoid complicated derivatization procedures necessary for GC analysis of compounds that are not normally volatile. Thermal decomposition of analytes is also avoided by the use of HPLC, a requirement for many metabolic or protein-related biomarkers. Another important advantage of HPLC as a separation technique is in the general reproducibility and ruggedness of the procedure. Capillary electrophoresis (CE) has many unique separation qualities, including high plate number in the separation of analytes and electrophoretic separation of analytes, but it lacks the general ruggedness and reproducibility of HPLC. Also, CE is not as easily adaptable to interfaces with MS as is HPLC. This has made HPLC the preferred separation technique for metabolite analysis. The separation capabilities of HPLC with respect to urinary metabolites have been described by Waybright et al.[6] Reversed-phase HPLC is the most common mode of chromatography in metabolite and biomarker analysis. Small molecules require a C8 or a C18 stationary phase for good retention; larger molecules or proteins would typically require a C4 phase. Efficient chromatography of acidic metabolites often requires the use of buffered mobile phases, whereas retention of conjugated metabolites can be accomplished by ion-pair reversed-phase chromatographic systems. Gradient elution by increasing the organic modifier can greatly improve analyte resolution and reduce elution times for

well-retained analytes. In general, buffers used with the MS detector are chosen for their volatility and compatibility with the ionization source as well as chromatographic considerations.

MS detection has many strengths for use with HPLC, which have been described in the literature.[7,8] Tandem mass spectrometric (MS/MS) detection is considered the method of choice for the quantitative determination of metabolites in biological fluids.[8] MS possesses high sensitivity and also adds a higher degree of specificity (the ability of a technique to accurately measure the analyte in the presence of all potential sample components) to the detection technique. Limitations owing to low sensitivity and selectivity of UV detection can be overcome by more extensive sample cleanup and sample preconcentration, but MS offers overall method simplification by reducing those procedural steps. Unlike other forms of detection, MS measures specific mass-to-charge ratios of ions from the analytes, adding to method specificity. Therefore, HPLC–MS and HPLC–MS/MS can eliminate the numerous interferences typical of a sample derived from a biological matrix. Sample treatment is less complicated; moreover, the probability of having interfering components coeluting with analytes and having ions with the same mass-to-charge ratio is reduced. The MS detector also offers the possibility of identification of unknown compounds from fragmentation patterns; other HPLC detectors, such as UV, conductivity, fluorescence, or refractive index, lack that capability. The mass spectrometer may be considered as the instrument closest to the ideal universal HPLC detector. The only disadvantages of HPLC–MS are the high instrument cost and the requirement of highly qualified personnel to operate the mass spectrometer.

Mass Spectrometer

The basic function of the mass spectrometer is to measure the mass-to-charge ratios of analyte ions, and the various designs of mass spectrometers have been described in detail in the literature.[7,9] The HPLC–MS system has four main components consisting of a sample inlet, an ion source, a mass analyzer, and finally an ion detector. The sample introduction system vaporizes the HPLC column effluent. The ion source produces ions from the neutral analyte molecules in the vapor phase. Several designs of ion sources have been used over the past years including electrospray ionization (ESI), atmospheric pressure chemical ionization (APCI), thermospray ionization (TSP), continuous flow fast atom bombardment (FAB), and atmospheric pressure photoionization (APPI). The inductively coupled plasma (ICP) is a *hard* ionization source and is used specifically for the detection of metals and metals in adducts or in organometallic compounds. Generally, ICP–MS is used for elemental speciation analysis with HPLC, which has been described elsewhere in the literature[10] and will not be covered here. In recent years, ESI has become the most common ion source in HPLC–MS analysis of biomarkers, with the APCI source a close second. The third component of a mass spectrometer, the mass analyzer, separates the formed ions according to their mass-to-charge ratio (m/z ratio). The most widely used analyzer design is the quadrupole (or multipole) analyzer used either as a single stage or as a triple quadrupole combined with a soft ionization technique. In the triple quadrupole design with additional soft ionization, MS/MS can be accomplished. Other analyzer types, such as the time of flight (TOF), have been coupled to HPLC. The TOF analyzer has been used mainly for the analysis of proteins and other macromolecules. Magnetic sector design has been used when there was a need for high mass resolution capability or improved sensitivity. Ion trap has also been in common use with HPLC for the analysis of metabolites and biomarkers. Finally, the last component of the MS is the ion detector, which is necessary to record the separated ions. Multipliers are the most frequently used detectors in HPLC–MS commercial instruments.

Capabilities of the Common MS Ion Sources

The two most common ion sources for HPLC–MS determination and measurement of metabolites and biomarkers are ESI and APCI. Both have certain advantages. The ESI technique was invented by Nobel Prize winner John Fenn in 1992 and has become the ion source of choice for most HPLC–MS work. This technique has rapidly displaced TSP and continuous flow FAB in most HPLC–MS commercial systems. In ESI, the effluent from the HPLC system is passed through a small capillary or jet held at a high electrical potential (2000–5000 V). This results in electrostatic nebulization of the liquid. During desolvation of the droplets, the electric field increases in strength at the diminishing droplet surface and leads to the ejection of charged analyte ions upon final evaporation. The ESI source is a gentle ionization technique and does not cause thermal degradation as significant as that caused by other ion sources. It also exhibits a high level and efficiency of ionization, which leads to a high level of MS sensitivity. Finally, ESI can form multiple ions, which lower the m/z ratio of analytes, thus permitting the analysis of high molecular weight molecules typical of biological samples.

In APCI, the effluent from the HPLC is heated and sprayed with a high flow of nitrogen from a nebulizer, which generates an aerosol. This aerosol is subjected to a corona discharge to form ions of the sample components. In APCI, the ionization is in the gas phase, unlike ionization from the liquid phase in ESI. The APCI source allows improved analysis of non-polar and medium polar volatile compounds.

Mass Analyzer

The most common mass analyzer used in HPLC–MS analysis of metabolites is some variation of the quadrupole. A quadrupole consists of four parallel rods that utilize an oscillating electric field to select ions passing through the radio frequency field generated by the quadrupole. Many modern instruments actually use hexapoles and octapoles; they have a compact geometry using more rods, but operate under the same principle as the *quadrupole* and are often referred to as quadrupoles. In MS/MS, a *triple quadrupole* (TQ) mass spectrometer is used, which consists of three sets of quadrupoles that can either transmit all ions or function as a mass filter allowing ions of a specific *m*/*z* ratio to pass. The middle quadrupole of the TQ often serves as a collision cell and thus produces daughter ions to be filtered by the last quadrupole. Also, the ion trap in MS can be used for accumulation, fragmentation, and ejection of selected ions, thus allowing the analysis of molecular and daughter ions. These common mass analyzers have been described in detail elsewhere in the literature.[7,9]

COMMON PROBLEMS AND STRATEGIES OF HPLC–MS BIOMARKER ANALYSIS

The accurate determination of metabolites or biomarkers from complex biological samples, including biological fluids such as whole blood, plasma, urine, or extracts from tissue or structures such as fingernails, hair, or skin scrapings poses a complex set of problems for the analytical chemist. Some of these problems have been described in detail in the literature.[8,11] Although there is a common perception that the use of HPLC–MS, and especially HPLC–MS/MS, practically guarantees method specificity, in actual practice the quantitative determination of biomarkers from biological fluids has several pitfalls. Common possible problems include ion suppression or ion enhancement caused by the sample matrix and interferences from other metabolites within the sample. Ion effects have been reviewed in detail elsewhere[12] and will be summarized here. Matrix components may affect the response of the target analyte, either by reducing the efficiency of ionization and the MS response signal or sometimes by increasing or enhancing the signal. Hence, the assessment and elimination of any matrix effects from biological samples during the method development process is needed. Samples of biological origin generally contain hundreds or even thousands of components over a wide range of structural types and concentrations. Many of these components have variable or unknown MS responses, and most are unknown prior to the analysis.

Several strategies are generally incorporated into HPLC–MS method design and development to counter matrix effect problems. When the analytes are known, stable isotope-labeled internal standards (isotope dilution) can be used to counter matrix effects on ionization. Deuterated or carbon-13 analogues of the analytes can be spiked into the biological samples to counter or eliminate such effects. In the case of validated methods, the quality control or assurance samples can be prepared by spiking blank biological matrix samples with known concentrations of the analyte within the method's validated analyte concentration range. Also, the use of pooled urine samples from unexposed subjects represents the most widely used strategy to construct external calibration curves, which reduce the matrix effects found in biological samples. Finally, the importance of initial sample cleanup and good chromatographic separation cannot be overstated. Removal of inorganic salts from a sample matrix can reduce ion suppression of the ESI source. Liquid–liquid extraction (LLE) and solid-phase extraction (SPE) are commonly used for the sample cleanup of biological matrices. Also, the use of chromatographic gradients to increase the separation of sample components[6] can reduce the probability of the coelution of possible interferences.

APPLICATIONS OF HPLC–MS IN BIOMARKER ANALYSIS

As was mentioned in the previous section, HPLC–MS is widely used for the determination of biomarkers. Three specific applications of biomarker analysis using HPLC–MS are described in additional detail; they are acrylamide, common aromatic compounds such as toluene and benzene, and, finally, 1-bromopropane. These are common compounds found in general and work environments and are of interest for human exposure studies and health risk assessment.

Acrylamide

Acrylamide is a common industrial substance with many applications including its use as a polymerizing agent in grouts and in the preparation of laboratory gels for electrophoresis. Applications of the polymer form of acrylamide include water treatment, soil stabilization, and paper manufacture. Low levels of acrylamide have been detected in baked, fried, and roasted foods, largely derived from heat-induced Maillard reaction between asparagine and the carbonyl group of reducing sugars such as glucose during the process of cooking.[13] Acrylamide is a potent neurotoxicant in humans and is also a probable human carcinogen that makes exposure a concern for human health. The accepted metabolic scheme for acrylamide has been described in the literature[14] and is displayed in Fig. 2. Acrylamide forms several mercapturic acid metabolites that are useful urinary biomarkers in both animals and man. *N*-acetyl-*S*-(2-carbamoylethyl)cysteine (NACEC), acrylamide's primary urinary metabolite in both animals

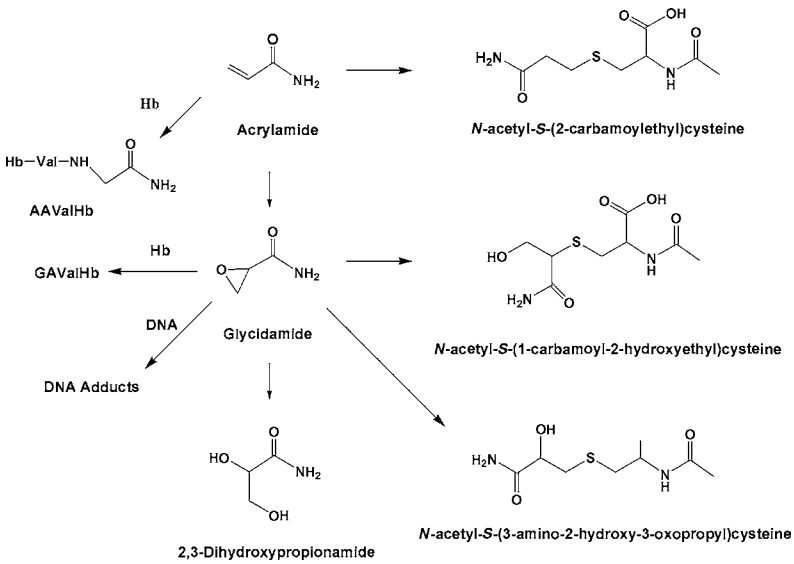

Fig. 2 A simplified metabolic scheme for acrylamide. *N*-acetyl-*S*-(2-carbamoylethyl)cysteine (NACEC) is the primary metabolite and is under study as a biomarker for acrylamide exposure.

and man, is formed by glutathione conjugation.[14–16] This is a first-order conjugation and is catalyzed by hepatic glutathione-*S*-transferase (GST). The other metabolic path, with glycidamide as an intermediate, leads to two other mercapturic acids, 2,3-dihydroxypropionamide as well as glycidamide–valine–hemoglobin adduct and DNA adducts. The glycidamide intermediate metabolite is also considered a toxicant. Formation of glycidamide from acrylamide is catalyzed by cytochrome P450; the two mercapturic acid metabolites of glycidamide, *N*-acetyl-*S*-(1-carbamoyl-2-hydroxyethyl)cysteine and *N*-acetyl-*S*-(3-amino-2-hydroxy-3-oxopropyl)cysteine, are GST catalyzed and are quantitatively minor metabolites. Both acrylamide and glycidamide react with proteins such as hemoglobin or albumin. Specifically, acrylamide reacts with the *N*-terminal valine amino acid of hemoglobin; the *N*-(2-carbamoylethyl)valine adducts are considered a biomarker of long-term acrylamide exposure.

The two main routes of biomarker analysis for acrylamide exposure involve the determination of either the valine adduct in hemoglobin or the urinary mercapturic acid metabolites.[14–16] The acrylamide–valine levels in hemoglobin are measured by hemolysis of the erythrocytes using a modified Edman degradation usually with pentafluorophenyl-isothiocyanate derivatization. This analysis is commonly performed by GC–MS[14] and will not be described in any further detail here. The mercapturic acid metabolites are commonly determined by HPLC–MS or HPLC–MS/MS.[14–16] The urinary NACEC metabolite has been determined using HPLC–MS in this laboratory; the metabolite was extracted from human urine by means of mixed-mode SPE, as has been reported in the literature by others.[16] Both the parent acrylamide and the NACEC metabolite were chromatographed using gradient reversed-phase HPLC. The chromatogram of a 10 μl injection prepared from spiked urine sample containing acrylamide, NACEC, and a deuterated analogue of NACEC is shown in Fig. 3. Specifically, a Phenomenex Synergi^{TM} 4 μ Hydro-RP 80 A (Torrance, California, U.S.A.) column with dimensions of 250 × 3 mm (I.D.) was used with a mobile phase consisting of 2/98/0.05% acetonitrile/water/formic acid held initially for 3 min, followed by a linear gradient for 15 min, and finishing with a mobile-phase composition of 80/20/0.05% acetonitrile/water/formic acid. The mobile-phase flow rate was 0.4 ml/min. The detector

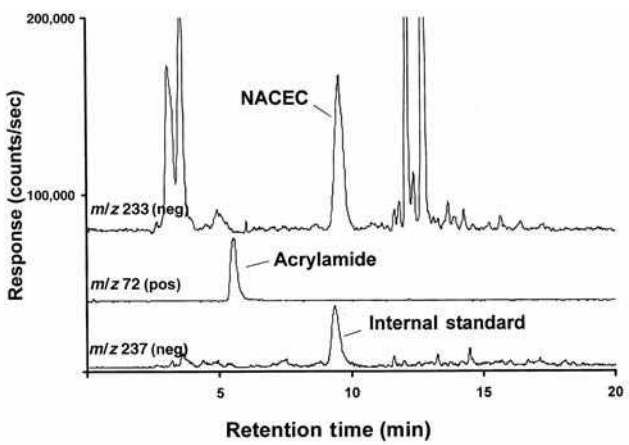

Fig. 3 The HPLC–MS chromatogram of a spiked urine sample containing acrylamide and the metabolite NACEC. Single-ion monitoring (SIM) at *m/z* 233 (negative mode) was used for NACEC, *m/z* 237 (negative mode) was used for the deuterated internal standard, and *m/z* 72 (positive mode) was used for the parent acrylamide. The urine sample was spiked at the 5 μg/ml level of acrylamide and NACEC and 2 μg/ml of the deuterated internal standard. For the chromatographic conditions used see the text or B'Hymer & Cheever.

Source: From Evaluation of extraction conditions and use of HPLC–MS for the simultaneous determination of acrylamide and its primary metabolite, *N*-acetyl-*S*-(2-carbamoylethyl)cysteine, in human urine, in J. Liq. Chromatogr. Relat. Technol. [17]

used was an Agilent Technologies (Palo Alto, California, U.S.A.) single lens (SL) mass selective detector (MSD) equipped with an ESI interface. Single-ion monitoring was used for quantification of the analytes; *m/z* 72 positive ion mode was used for the parent acrylamide, *m/z* 233 negative ion mode for NACEC, and *m/z* 237 negative ion mode was used for the deuterated NACEC internal standard. The use of a deuterated analogue of the metabolite of interest as the internal standard, a form of isotope dilution, is a common strategy in HPLC–MS biomarker analysis. The chromatographic system described was unique for acrylamide biomarker analysis in that both the parent acrylamide and its primary metabolite, NACEC, could be accurately determined simultaneously.[17] Other chromatographic systems that determined all the mercapturic acid metabolites of acrylamide have been described elsewhere.[14–16] As acrylamide is a potential carcinogen, these types of HPLC–MS methods have important applications in acrylamide biomarker research. The Urban et al.[14] study evaluated these metabolites with the dosimetry of acrylamide in smokers and non-smokers. Fennell et al.[15] used the mercapturic acid metabolites of acrylamide to study the kinetics of their elimination from urine in humans.

Common Aromatic Industrial Compounds

Toluene and benzene, as well as xylenes, are fairly common solvents encountered in the modern environment. These solvents are aromatic hydrocarbons frequently used as industrial chemicals. All are components of gasoline fuels, and our modern motor vehicle-based society represents one of the main emission sources. Benzene can also be released by several combustion reactions and can be found in tobacco smoke as well as in many consumer products. Benzene is a known human cancer hazard, and the hematotoxicity of benzene has been well elucidated during the past two decades. The acute internal dose of these aromatic compounds can be estimated by determining the amount of parent compound in blood, breath, or urine; however, the use of sensitive HPLC–MS procedures for measuring urinary metabolites has also been commonly reported in the literature.[18–21] Table 1 displays some of

Table 1 Structures and mass spectrometric behavior of phase I and II metabolites of some important aromatic industrial chemicals.

Parent compound	Metabolite[a]	Phase[b]	Structure	Ion mode	Ion,[c] *m/z*
Benzene	t,t-Muconic acid	I		Negative	141
	S-PMA	II		Negative	238
Toluene	Hippuric acid	I		Negative	178
	BMA	II		Negative	252
Xylene	MBAs	II		Negative	266
	DMPMAs	II		Negative	266

[a]Abbreviations: *S*-PMA, *S*-phenylmercapturic acid; BMA, benzylmercapturic acid; MBAs, methylbenzylmercapturic acids; DMPMAs, dimethylphenylmercapturic acids.
[b]Phase I (carboxylic acid) metabolites or phase II (mercapturic acid) metabolites.
[c]$[M - H]^-$ for negative ion mode.
Adapted from Manini, Andreoli, & Niessen.[3]

the metabolites of benzene, toluene, and xylene, many of which have been used as biomarkers of exposure. Phenol and its conjugates are the main biotransformation products for benzene; however, these compounds are not suitable as specific biomarkers for benzene because they are the products of other chemicals. Two other minor urinary benzene metabolites, *S*-phenylmercapturic acid (*S*-PMA) and *trans*,*trans*-muconic acid (see Table 1), are considered more suitable as specific biomarkers, and they are the better choice for biomonitoring studies. Similarly, the corresponding mercapturic acids of toluene, *S*-benzylmercapturic acid, and those of xylene are important biomarkers for these compounds (see Table 1).

Maestri et al.[18] describe an HPLC–MS method for the determination of urinary *S*-PMA acid. Sample cleanup and extraction utilized SPE C18 cartridges. The HPLC separation was performed on a reversed-phase column; specifically, a Waters (Milford, Massachusetts, U.S.A.) Symmetry C18 column (150 × 3 mm, 3.5 μm) was used with gradient elution by means of a methanol/water/acetic acid mobile phase. The MS detector was a single quadrupole design from Waters, the ZQ MS. Again, as in most methods described, an isotopic analogue of the target analyte was used as the internal standard; [^{13}C6]*S*-PMA was used in this case. Single-ion monitoring (ESI-negative mode) was used for quantitation of *S*-PMA; *S*-PMA molecular ions *m*/*z* 238 for *S*-PMA and *m*/*z* 244 for the internal standard were used. In a similar procedure developed by Li et al.[21] using a deuterated [^{2}H5] analogue of *S*-PMA as the internal standard, improved sensitivity with HPLC–MS/MS for the measurement of *S*-PMA was reported. Daughter ions *m*/*z* 109 for *S*-PMA and *m*/*z* 114 for the deuterated internal standard were used in this study.[21]

In an extensive study described by Manini, Andreoli, and Mutti,[19] both HPLC–MS and HPLC–MS/MS were used to develop methods to determine the metabolic biomarkers for numerous industrial chemicals including benzene and toluene. Either ESI or APCI was used as appropriate for each type of sample. The experimental evidence produced during this study demonstrated the need for carefully addressing the matrix effect of biological samples. Matrix effects were recorded not only for the type of sample matrix but also for individual subjects. The use of isotopically labeled internal standards is important for developing accurate HPLC–MS biomarker methods. This study also clearly showed the potential of HPLC–MS and HPLC–MS/MS in the determination of traditional biomarkers, as well as their possible use in metabolism studies aimed at investigating new and minor metabolic routes. The use of a methodology based on HPLC–MS for monitoring biomarkers from common industrial chemical exposure has been clearly demonstrated and will continue to grow in importance in the near future.

1-Bromopropane

1-Bromopropane (BP) is a widely used industrial solvent that has replaced many ozone-depleting chlorofluorocarbons. Applications of BP include metal and electronics, as a solvent in adhesive coatings and aerosol propellants. BP has been reported to cause central neurological and peripheral neuropathy disorders in workers and reproductive or hematopoietic problems in rats.[22] The metabolism of BP has been described in the literature,[23,24] and a simplified and condensed scheme is displayed in Fig. 4. Potential biomarkers for the evaluation of BP exposure, including urinary bromide, GC/electron capture detector (ECD) analysis of BP in breath, and GC–MS or HPLC–MS), analysis of BP metabolites, have been tried with varying degrees of success.[25] Several mercapturic acid metabolites in the urine of humans or animals have been suggested as biomarkers of exposure even though the majority of administered BP is exhaled or eliminated unchanged in the urine.[23] Although information on BP metabolism is somewhat limited, *N*-acetyl-*S*-(*n*-propyl)cysteine and *N*-acetyl-*S*-(2-hydroxyethyl)cysteine (i.e., 2-hydroxymercapturic acid or 2-HMA) are the

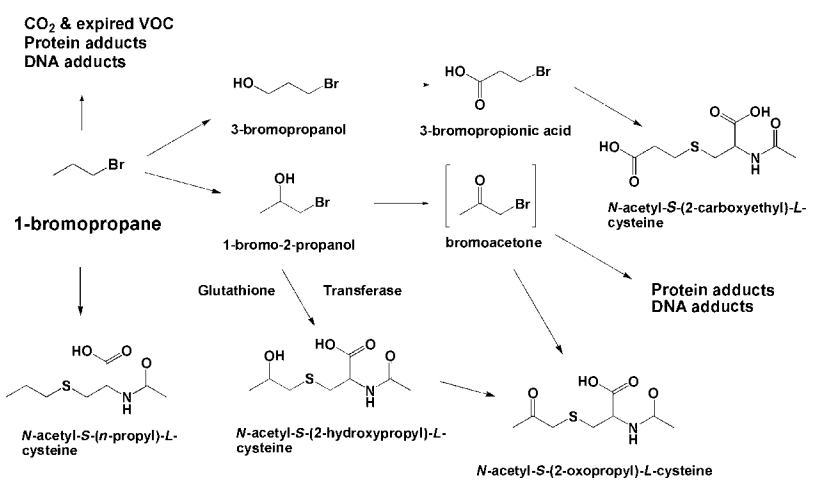

Fig. 4 A simplified metabolic scheme for 1-bromopropane. *N*-acetyl-*S*-(*n*-propyl)cysteine is a major metabolite and under study as a biomarker for 1-bromopropane exposure.

major metabolites in animals.[22] Other mercapturic acid metabolites have been reported for BP but several, including 2-HMA, *N*-acetyl-*S*-(2-carboxyethyl)cysteine, and *N*-acetyl-*S*-(2-oxopropyl)cysteine, are metabolites of related compounds and are not suitable as specific biomarkers of BP. *N*-acetyl-*S*-(*n*-propyl)cysteine is formed by glutathione conjugation; this metabolite may be further oxidized to the sulfoxide analogue, but this mercapturic acid oxide is not a major urinary metabolite. The other metabolic path, via P450 oxidation, may be important for low-level BP exposure with detectable amounts of bromide ion and 2-HMA found in the urine. However, with increasing exposure *N*-acetyl-*S*-(*n*-propyl)cysteine appears to be a likely biomarker candidate. The formation of reactive intermediates such as bromoacetone that would form DNA and protein adducts has been proposed[23] (see Fig. 4). In addition to non-specific biomarkers of BP exposure such as bromide ion, valine adducts from isolated hemoglobin or urinary *N*-acetyl-*S*-(*n*-propyl)cysteine have been considered possible biomarkers. The BP–valine adduct levels can be measured by high-resolution GC–MS. The modified Edman degradation of purified globin and the derivatization of valine adducts are expensive and time-consuming procedures, which would be most applicable to the detection of long-term exposures; it will not be described in further detail here.

Although mercapturic acids can be analyzed using GC–MS, derivatization would be required; however, *N*-acetyl-*S*-(*n*-propyl)cysteine can be more readily analyzed using HPLC–MS. The urinary *N*-acetyl-*S*-(*n*-propyl)cysteine metabolite of bromopropane has been determined in this laboratory, and a typical HPLC–MS chromatogram from this work is displayed in Fig. 5. Specifically, the metabolite was extracted from human urine using C18 reversed-phase SPE. Both *N*-acetyl-*S*-(*n*-propyl)cysteine and [d_7]-*N*-acetyl-*S*-(*n*-propyl)cysteine, the internal standard, were chromatographed using a Phenomenex Aqua 3 μm C18 125A column with dimensions of 150 × 2 mm (I.D.). A 10 min linear gradient (85:15 H_2O:MeOH 0.1% acetic acid to 100% MeOH 0.1% acetic acid) was used at a constant flow rate of 0.3 ml/min. The detector used was an Agilent Technologies 1100 SL mass spectrometer (MSD) equipped with an ESI interface. Single-ion (negative mode) monitoring was used for quantification of the analytes; *m/z* 204 was used for *N*-acetyl-*S*-(*n*-propyl)cysteine and *m/z* 211 was used for the [d_7]-*N*-acetyl-*S*-(*n*-propyl)cysteine internal standard (see Fig. 5). This specific example has important applications within this laboratory. These mercapturic acid metabolites are specific to 1-BP exposure. Worker exposure studies using total urinary bromide measurements[25] have been done; however, total urinary bromide is not specific and can be affected by diet. Therefore, the HPLC–MS methodology described, which measures the specific biomarkers of 1-BP, will obviously lead to more accurate human exposure assessment and improved industrial hygiene studies in the future.

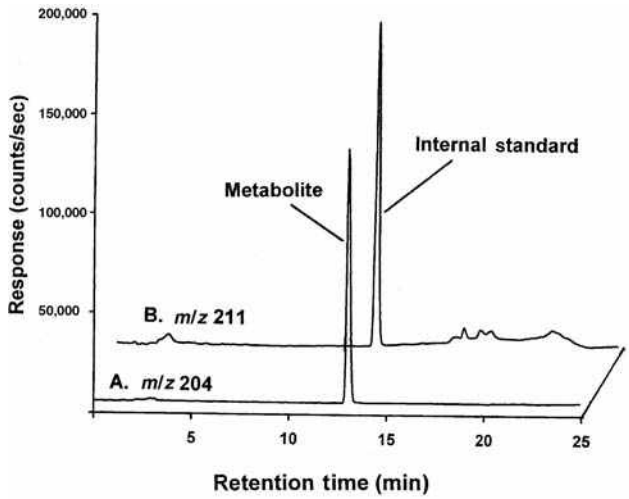

Fig. 5 The HPLC–MS chromatogram of a spiked urine sample containing the 1-bromopropane metabolite *N*-acetyl-*S*-(*n*-propyl)-cysteine (5 μg) and [d_7]-*N*-acetyl-*S*-(*n*-propyl)cysteine internal standard (10 μg). Single-ion monitoring (SIM) at *m/z* 204 (negative mode) was used for *N*-acetyl-*S*-(*n*-propyl)cysteine (A) and *m/z* 211 (negative mode) was used the deuterated internal standard (B). See the text for the chromatographic conditions used.

CONCLUSIONS

For biomarker and metabolite analysis HPLC–MS is a vital technique in biomonitoring and has been growing rapidly in the past decade. The inherent advantages of the mass spectrometer as a detector with high sensitivity and analyte specificity, combined with HPLC, make HPLC–MS one of the most valuable techniques for biomonitoring, metabolomics, and related bioanalytical fields. As more powerful commercial instrumentation becomes available at lower cost for the user, biomonitoring research will have continued rapid growth in the near future. For a more detailed description of HPLC–MS applications in occupational toxicology see Manini, Andreoli, and Niessen,[3] which provides a comprehensive review of biomarker and metabolite analysis for many common industrial chemicals.

Biopharmaceuticals: CE Analysis

Michel Girard
Bureau of Biologics and Radiopharmaceuticals, Health Canada, Ottawa, Ontario, Canada

INTRODUCTION

Capillary electrophoresis (CE) has rapidly established itself as one of the most versatile techniques for the analysis of biomolecules. In addition to providing exceptional separation efficiencies, it offers substantial advantages over conventional slab-gel electrophoretic techniques, namely, fast separation times, automation, reproducibility, and quantitative capabilities. Furthermore, owing to the different mechanisms by which products are separated in CE, data generated are generally complementary to those obtained by high-performance liquid chromatography (HPLC), thus allowing for more complete product characterization. CE methods can be successfully validated with respect to well-established analytical criteria (e.g., precision, accuracy, reproducibility, and linearity), making them a source of reliable information. These considerations are of key importance to the pharmaceutical industry in adopting CE as a frontline analytical technique for product characterization to meet the specific requirements associated with the manufacturing and testing of therapeutic substances.

Therapeutic biological compounds are collectively referred to as biopharmaceuticals and include recombinant proteins, monoclonal and polyclonal antibodies, antisense oligonucleotides, therapeutic genes, and recombinant and DNA vaccines. Although the majority of products on the market to date are proteins and antibodies, the first antisense oligonucleotide therapeutic, fomivirsen sodium, was approved in 1998 in the United States. Several other antisense and DNA-based products are being actively developed. Historically, biopharmaceuticals were obtained from biological sources, whether of human, animal, plant, or cellular origin, in the form of crude extracts or partially purified components of extracts. Because of the highly complex nature of these mixtures, only minimal physicochemical characterization could be carried out and product evaluation was generally based on biological response or surrogate bioassays. While a few traditional products remain in use today, newer production methods based on recombinant DNA or hybridoma technology are now being used for the large scale production of biopharmaceuticals. These developments have been paralleled by major advances in biomolecular separation and purification techniques and, consequently, have resulted in improvements in product development leading to the preparation of more consistent products with purity levels approaching those of conventional, small-molecule pharmaceuticals. A number of important therapeutics are produced in this manner. This is the case for somatropin human growth hormone (HGH), insulin, erythropoietin (EPO), several interferons (IFN-α, -β, and -γ), and hepatitis B vaccine, to name just a few. These products are currently used for diseases not otherwise well treated with small-molecule pharmaceuticals.

Despite these advances, the characterization of biopharmaceuticals remains a challenge. The inherent structural complexity of the therapeutic substance and the potential presence of numerous process- and product-related impurities and contaminants in the final product complicate the analysis. In addition, biological activity determination is still often performed using costly and imprecise animal testing. Nevertheless, the regulatory approval of biopharmaceuticals is based in part upon a comprehensive chemistry and manufacturing submission with a strong emphasis on high resolution analytical methodologies. The determination of the quality of a product through the verification of product identity, strength, stability, and consistency of manufacture and the quantitative evaluation of impurities and contaminants are of prime importance. Therefore, the establishment of more precise and selective methods of analysis is highly relevant to the pharmaceutical and regulatory sectors.

COMMON CE SEPARATION MODES FOR BIOPHARMACEUTICALS

There are several CE modes, based on different separation mechanisms, that, alone or in combination, are commonly used for the analysis of biopharmaceuticals (Table 1). Capillary zone electrophoresis (CZE) is the simplest and most commonly used CE mode for the analysis of peptides and proteins, including glycoproteins and monoclonal antibodies (MABs). In this mode, analytes migrate in a free solution according to their effective charge-to-size ratio. In capillary gel electrophoresis (CGE), analytes are separated according to their size through gel matrices by a molecular sieving mechanism analogous to that of polyacrylamide gel electrophoresis (PAGE). In capillary isoelectric focusing (CIEF), a stable pH gradient is formed inside the capillary and analytes migrate until they reach the pH equal to their isoelectric point (p*I*), at which time the net charge and mobility are zero and the analytes stop migrating. In micellar electrokinetic chromatography (MEKC),

Table 1 CE separation modes for the characterization of biopharmaceuticals.

Mode	Separation mechanism	Applications
CZE	Charge-to-size ratio	Proteins, peptides Glycoproteins MABs Peptide mapping Monosaccharides, oligosaccharides
CIEF	Isoelectric point (p*I*)	Proteins, peptides Glycoproteins MABs Isoelectric point determination Peptide mapping
CGE	Size	Protein MW determination Aggregates Oligonucleotides, DNA fragments Polysaccharides
MEKC	Partition	Proteins, peptides Peptide mapping Monosaccharides, oligosaccharides

analytes interact with micelles formed by adding surfactants to the running buffer at concentrations above the critical micelle concentration. The separation mechanism involves partition of the analyte between the micelle and the electrolyte.

PRODUCT CHARACTERIZATION

The characterization of biopharmaceuticals involves carrying out tests to demonstrate that a given product meets established criteria and that it remains safe and efficacious. There is a wide range of physicochemical methods that are frequently used for comprehensive characterization. Methods used include, among others, electrophoresis, HPLC, mass spectrometry (MS), UV spectrophotometry, nuclear magnetic resonance, sequencing, and amino acid analysis. CE is particularly well suited for the characterization of complex biomolecules, especially with regards to product identity and for assessing product heterogeneity arising from translational and post-translational modifications, degradation, or genetic variation. These considerations are particularly important for biopharmaceuticals, since they are inherently labile substances, especially when placed under non-physiological conditions. Consequently, the formation of impurities may occur throughout the manufacturing process and during the shelf life of the product.

Proteins are particularly susceptible to modification and degradation through a variety of pathways, leading to the formation of several types of variants. Some of the more commonly encountered pathways include deamidation, oxidation, dimerization/aggregation, peptide bond cleavage through proteolysis or hydrolysis, N- or C-terminal truncation, and disulfide scrambling (Table 2). These transformations have a significant impact on the physicochemical properties of the molecule by altering its size, charge, mass, hydrophobicity, or conformation. For example, deamidation leads to the formation of a more acidic variant from the transformation of the amide side chain in asparagine or glutamine residues into a carboxylic acid functional group. Furthermore, degradation may occur at more than one residue, a situation that leads to the formation of complex mixtures. Consequently, the choice of a separation mode or detection system depends mainly on an in-depth evaluation of the physicochemical properties of the product under study, that is, hydrophobicity, isoelectric point, size, post-translational modifications, and susceptibility to degradation/aggregation or conformational stability, and on the type of information required.

In the following sections, an overview of the use of CE for the characterization of selected classes of biopharmaceuticals is presented. The emphasis is placed on the relationship between the test performed and its intended purpose, that is, in terms of its usefulness for product identity or product purity determination.

In-Process Monitoring

CE has widespread applications in the biopharmaceutical industry owing, in large part, to the rapidity with which methods can be developed and to its versatility by virtue of the wide range of separation modes available. Besides its use in the development, quality control, and batch release stages,[1] CE is also commonly applied for in-process monitoring.[2] Manufacturing processes using recombinant DNA technology involve, as a first step, the large scale production of the desired protein in a suitable expression system

Table 2 Common protein modification and degradation pathways.

Pathways	Reaction	Reaction site
Deamidation	—$CONH_2$ → —COOH	Asn, Gln
Isomerization	Asn/Asp → isoAsp	Asn, Asp
Oxidation	—SR → —SOR, —SO_2R	Met
	—SH → —SS—	Cys
Dimerization/aggregation	Electrostatic, covalent, noncovalent bond formation	Various
Peptide bond proteolysis/hydrolysis	—CONH— → —COOH + NH_2^-	Various
N-, C-terminal truncation	Peptide bond cleavage	Various
Disulfide scrambling	R—SS—R′ → R—SS—R″	Disulfide bridge (—SS—)

through fermentation or cell cultivation. Experimental conditions are critical at this stage for ensuring the production of the required substance. As such, the detection of the product or its precursor at this early stage of the manufacturing process clearly confers an economic benefit. Conventional gel electrophoretic techniques cannot be readily applied since they are labor intensive and require considerable periods of time (e.g., staining/destaining procedures). CE methods have a clear advantage in these situations by providing fast analysis, sometimes in less than 5 min. In addition, apart from enabling the confirmation of the identity of the substance, they can provide a quantitative assessment of the process. Methods based on CZE, CGE, and CIEF are commonly used for the characterization of the product in fermentation broth or cell cultivation and during the various purification steps. Optimization includes attaining maximal separation of the reference compounds, such as the intact product or the pro-product, because the presence of impurities lowers resolution and selectivity.

Product Identity

One of the critical aspects to be considered during the manufacturing of any drug is product identity. While in itself it does not fulfill all of the requirements for a safe and effective drug, product identity testing provides assurance that the product generated is that which is intended and offers a measure of the consistency of the manufacturing process. CE-based methods are applied to confirm the product identity of biopharmaceuticals. Approaches usually involve the comparison of the property of the substrate to that of a pre-established, well-characterized reference standard with demonstrated quality, efficacy, and safety. In some instances, primary reference standards are available from official organizations such as the World Health Organization, the European Pharmacopoeia (EP), or the United States Pharmacopeia (USP). These preparations are established through international collaborative studies and are generally intended for use in the characterization of in-house reference standards. Aside from performing a simple identity test involving comigration of the substrate with the reference standard, a number of methods have been devised to provide qualitative and quantitative information with respect to specific structural features of the molecule such as primary sequence, molecular weight or size, and carbohydrate or isoform profile and distribution.

Peptide mapping is one of the most powerful tools for the identification of proteins and has been successfully adapted to CE.[3] It involves the cleavage of the amino acid chain at specific sites, using proteases or chemical reagents, to generate a mixture of smaller peptides. Different proteins generate different peptides after digestion, and separation of these peptides leads to a characteristic map or "fingerprint" of that protein. The analysis of peptide digests is generally carried out by CZE, where products are separated based on differences in charge-to-mass ratios. Peptide mapping by CZE is generally considered an orthogonal technique to HPLC. Peptide mapping by CZE is usually faster than by HPLC and typically provides greater resolution of a larger number of peptides. For instance, highly hydrophilic peptides are often poorly resolved or elute in the column dead volume by reversed phase HPLC. In CZE, these peptides migrate according to their charge-to-size ratio and are typically resolved. By contrast, peptides with similar net charges are not separated by CZE, and, in such cases, MEKC provides a useful alternative. The peptide map serves as a fingerprint of the substrate that, when compared to that of a reference standard, enables confirmation of the identity. Alternatively, it allows the detection and identification of amino acid and peptide modifications, which are indicative of the presence of product variants. In addition, it may be used to confirm the presence and position of disulfide bridges and glycosylation sites. Besides its application to simple proteins, peptide mapping by CZE can be particularly useful for the characterization of MABs.[4]

Several important therapeutic proteins are glycoproteins [e.g., EPO and tissue plasminogen (tPA)] that exist as mixtures of closely related species that differ in their glycosylation patterns (glycoforms). These differences are often the result of both compositional and sequence variations of the glycan chains. Moreover, the biological activity of glycoproteins is frequently linked to the presence of these carbohydrates, and, consequently, the characterization of glycoprotein microheterogeneity represents one of the more challenging tasks in identity testing. Several

CE approaches, based mostly on CZE and CIEF, have been devised.[5] For the frequently encountered sialoglycoproteins (i.e., sialic acid-containing glycoproteins), the analysis of the glycoform profile can be performed on the intact glycoprotein or on the glycopeptides obtained after the enzymatic digestion of the polypeptide chain. Alternatively, the analysis of the oligosaccharide profile can be performed following the chemical or enzymatic release of the glycan chains from the polypeptide backbone. In both cases, the profile obtained is an indication of the varying number of sialic acid residues on the oligosaccharide chains.

Carbohydrate analysis is essential to fully characterize a glycoprotein. CE methods are used for the analysis of the monosaccharide composition resulting from hydrolysis of the glycosylation chains. In those cases, monosaccharides must be derivatized with reagents such as 1-aminopyrene-3,6,8-trisulfonate (APTS) to provide both a readily ionizable group and a detectable chromophore. APTS has been used successfully for the derivatization of both oligosaccharides and monosaccharides and, coupled with CE/laser induced fluorescence (LIF), provides high sensitivity quantitative information with increased resolving power.

CE is a valuable tool for the confirmation of the structural integrity of biopharmaceuticals in final drug formulations.[6,7] Finished products generally contain low amounts of the active ingredient since the therapeutic effect can usually be achieved at low concentrations. In turn, formulations of low concentration proteins usually require the addition of large amounts of excipients to enhance product stability and to prevent nonspecific adsorption. Usual excipients include inorganic salts, amino acids, sugars, surfactants (e.g., polysorbate), and other proteins [e.g., human serum albumin (HSA)]. Typically, isotonic salt preparations are produced as most of these products are injectables and consequently high salt concentrations are present. Furthermore, many of these excipients may be present simultaneously, leading to complex mixtures. Such mixtures can interfere with traditional assay methodologies like HPLC or slab-gel electrophoresis. CZE is well suited for the direct analysis of products containing high salt concentrations, since conditions using highly concentrated buffer solutions increase the efficiency by contributing to the focusing effect. Fig. 1 shows the comparison of electropherograms obtained by reversed-polarity CZE[6] for a sample of formulated EPO-α (top trace) and a sample of its unformulated drug substance (bottom trace). Both traces show qualitatively similar glycoform profiles, a good indication of the structural integrity of the formulated product. These conditions also provide satisfactory results for assaying of the active ingredient and for quantitation of the glycoforms in the finished product.

In addition to other size-based analytical techniques such as size-exclusion HPLC or slab gel electrophoresis, CGE can be adequately used for the determination of a protein's apparent molecular weight.[8] Denaturing conditions are usually employed whereby sodium dodecyl sulfate (SDS)–protein complexes are formed with net overall negative charges that are proportional to their masses. These complexes migrate through the gel-filled capillary, acting as a sieving medium, in order of increasing molecular weight. The mobility of the substrate is used to estimate the molecular weight from a pre-established calibration plot of log molecular mass vs. mobility prepared from a series of protein standards of known molecular mass. CGE separation of SDS–proteins has the advantage over SDS–PAGE of giving higher resolution and requiring shorter analysis time. Oligonucleotides and DNA size determination is also achieved by CGE.[9] In these cases, the sieving matrix is required to separate the individual components since they have nearly identical charge-to-size ratios. Similarly, CIEF is used to determine the p*I* of a protein by interpolation from a p*I* calibration plot generated from a series of protein standards with known isoelectric points.[10]

Several MABs have been prepared for therapeutic purposes. They are among the most complex protein-based molecules, consisting of several light and heavy polypeptide chains, joined by multiple disulfide bridges, and containing a number of glycosylation sites of varying sequences and arrangements. Typically, MABs are very large molecules with molecular weights around 150,000 Da, a feature that, when combined with their structural complexity, makes high resolution chromatographic methods for the analysis of the intact molecule of little value. However, CE approaches have been highly successful for their characterization.[11] While all of the major CE separation modes have been applied, CIEF and CGE are particularly useful techniques. For instance, the high resolution achieved in CIEF allows monitoring of the profile of charge isoforms resulting from differential C-terminal processing (at lysine or arginine), a situation that frequently occurs in mammalian cell-derived products. CGE analysis under denaturing conditions has been used to estimate MAB molecular weight as well as the presence of aggregates. When performed under denaturing and reducing conditions, CGE provides an effective way to monitor the light and heavy chains that make up the typical antibody structure.

With the recent progress made on mass spectrometric ionization modes, large biomolecules can now be readily analyzed. The most widely used ionization mode for proteins and peptides characterization is electrospray ionization (ESI).[12] Molecular weights can be readily determined for large proteins with accuracies in the range of ±0.01–0.05%. The ESI method is sensitive, presently requiring samples in the 100 fmol–10 pmol range for proteins. As a result, the coupling of CE to MS provides an extremely powerful tool for the unambiguous structural confirmation or identification of biomolecules. A widely used approach consists in the analysis of intact proteins, which enables the determination of exact molecular

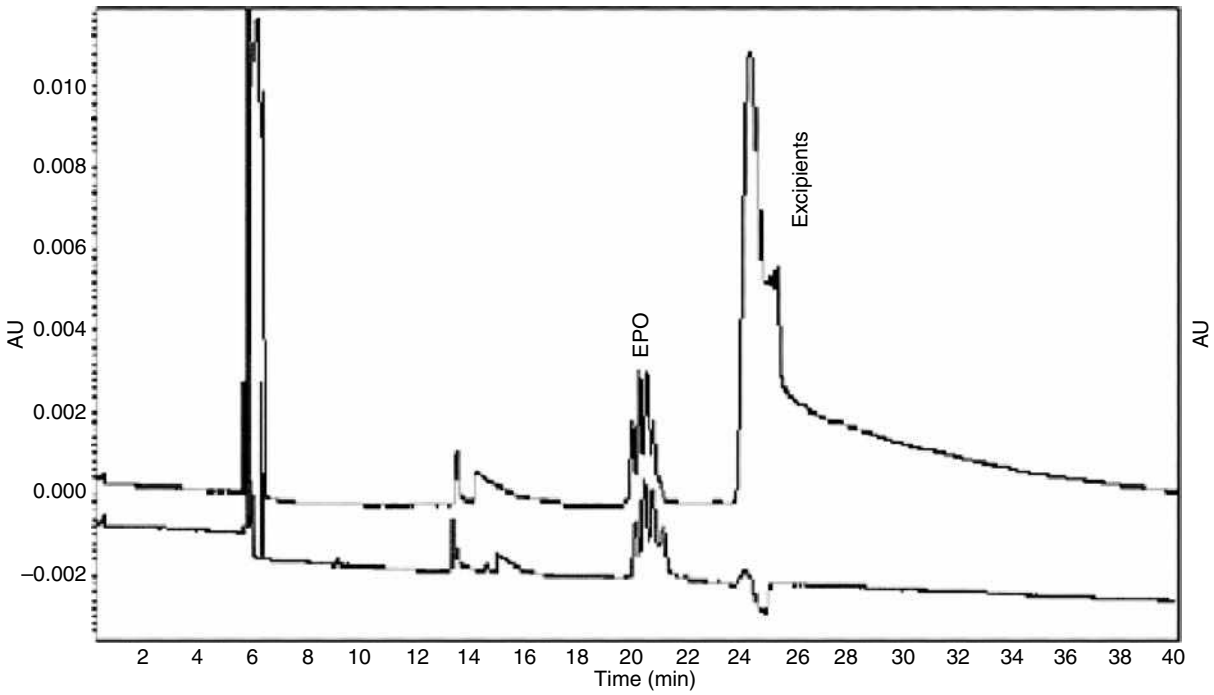

Fig. 1 Analysis of samples of EPO-α by reversed-polarity CZE: drug substance sample containing 8000 IU/ml (bottom trace) and drug product sample 10,000 IU/ml (top trace). Conditions were similar to those reported previously:[6] eCAP amine capillary (50 μm × 50 cm, 40 cm effective length); electrolyte: 200 m*M* sodium dihydrogen phosphate/1 m*M* nickel chloride, adjusted to pH 4.0 with acetic acid; 8 kV; UV detection at 200 nm.

weights. However, little or no fragmentation results from ESI and, as a consequence, no information on the sequence is obtained. An alternative, and more commonly used, approach for protein identification by MS is peptide mapping. In this approach, the peptide fragments separated by CE are analyzed by MS to determine their respective molecular weight. The protein is then identified through a database search from which two or more of the separated peptides can be matched to the predicted ones. In some cases, it may be necessary to obtain sequence information for a given peptide in order to ascertain its identity. This can be accomplished by using CE/MS/MS.

Product Purity

Purity determination is an essential component of the assessment of the quality of any drug. However, the purity determination of biopharmaceuticals is not as straightforward as that of small-molecule pharmaceuticals, since biopharmaceuticals are structurally complex and have a wide range of potential impurities. Approaches usually involve the judicious choice of a combination of methods that enable the detection and quantitation of impurities from which an overall purity assessment can be derived. As mentioned previously, proteins undergo degradation or modification through a number of pathways. Most of the more common variants encountered in protein preparations can be detected by CE methods.[13] The high efficiency and quantitative properties of CGE can be used to detect nondissociable aggregates and clipped forms in proteins. This separation mode also provides an effective means to monitor the presence of deletion sequences in oligonucleotides.[14] The separation and detection of charge variants such as deamidation products and clipped forms resulting from the proteolytic cleavage of the polypeptide chain are readily amenable using CE methods. In particular, CZE has proven to be highly effective for simple proteins having no carbohydrate-mediated heterogeneity present. The high efficiency of CZE, in some cases, allows the resolution of multiple charge variants, such as occur in HGH,[15] to be accomplished in a single run (Fig. 2). The coupling of CE to high sensitivity detection devices such as LIF detectors provides substantial enhancement of the detection limits of impurities.[16]

REGULATORY CONSIDERATIONS

CE is now recognized as a mature technique alongside HPLC and other modern analytical techniques. A harmonized general monograph[17] that presents both theoretical and practical considerations of the technique has been recently adopted by the Pharmacopoeial Discussion Group (PDG) for implementation into the USP, the

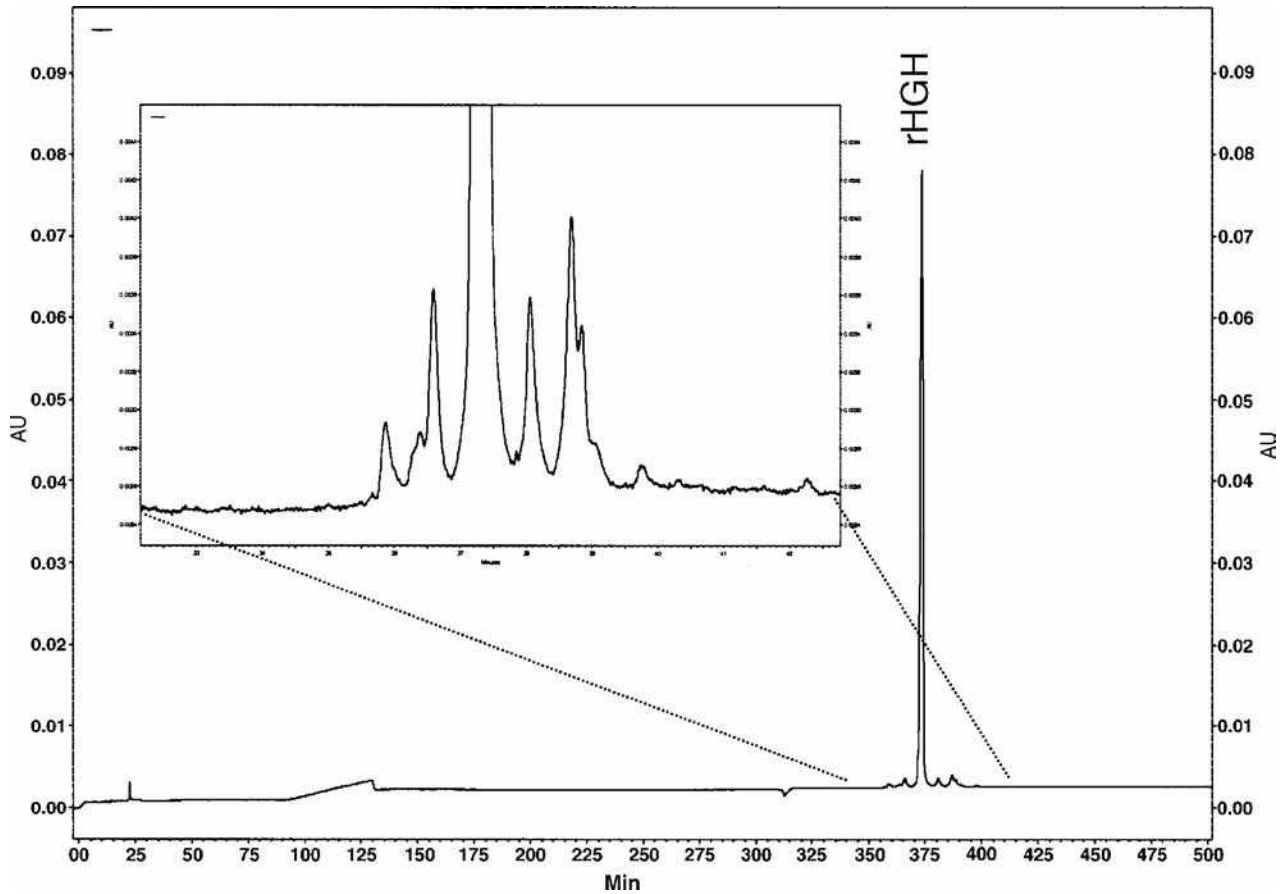

Fig. 2 Analysis of a sample of somatropin (recombinant HGH) by CZE. Inset: enlarged view showing the separation of impurities. Conditions were similar to those reported previously:[15] bare fused silica capillary (50 μm × 100 cm, 90 cm effective length); electrolyte: 0.1 *M* diammonium hydrogen phosphate, adjusted to pH 6.0 with phosphoric acid; 20 kV; UV detection at 200 nm.

Japanese Pharmacopoeia (JP), and the EP. In addition, a CZE method is currently used as an identification test for EPO concentrated solution in the EP.[18] This represents the first example of the use of CE for the monitoring of a biopharmaceutical by an official method. A second example is in the final stage of implementation and involves the determination by CZE of charge variants in somatropin preparations.[19] This test, which was found to provide more precise quantitative data, will replace the current isoelectric focusing method.

Regulatory agencies around the world are seeing an increasing number of drug manufacturers that include CE methods in drug submissions. While most regulatory agencies recognize the applicability of CE for biopharmaceuticals, they require the methods to be validated based on well-established parameters that include accuracy, precision, specificity, limit of detection, limit of quantitation, linearity, and range. There is considerable guidance available for the validation of analytical methods. The International Conference on Harmonisation (ICH) has published guidelines that refer specifically to biopharmaceuticals: Q6B—Specifications: Test Procedures and Acceptance Criteria for Biotechnological/Biological Products; Q5C: Quality of Biotechnological Products: Stability Testing of Biotechnological/Biological Products; Q5E: Comparability of Biotechnological/Biological Products Subject to Changes in Their Manufacturing Process; Q2A: Text on Validation of Analytical Procedures; Q2B: Validation of Analytical Procedures: Methodology. Guidelines are available on the ICH website.[20]

CONCLUSIONS

The use of CE has become an integral part of the study of biopharmaceuticals, especially for the monitoring of product identity and purity. It is a powerful technique that, in many instances, is superior to the more conventional electrophoretic techniques and complementary to the widely used high resolution chromatographic techniques. It is

particularly well suited to the study of complex mixtures of biomolecules such as glycoproteins and MABs.

Biopolymers and Pharmaceuticals: CEC

Ira S. Krull
Sarah Kazmi
Department of Chemistry, Northeastern University, Boston, Massachusetts, U.S.A.

INTRODUCTION

Capillary electrochromatography (CEC) has grown considerably over the past few years, due to the developments in column technology and the appearance of several articles demonstrating the high efficiencies possible with this technique.[1] The literature has shown that there can be numerous applications for this technology, which was not possible with the earlier separation methods.

CEC Technique

Tsuda published an article that discussed the CEC technique in detail.[2] The technique itself is a derivative of high-performance capillary electrophoresis (HPCE) and high-performance liquid chromatography (HPLC), where the separations are performed using fused-silica tubes of 50–100 μm inner diameter (I.D.), that are packed with either a monolithic packing or small (3 μm or smaller) silica-based particles.[3–5] The packing is similar to the conventional HPLC; however, the mobile phase is driven by electro-osmosis, which results from the electric field applied across the capillary rather than by pressurized flow. The mobile phase is made up of aqueous buffers and organic modifiers [e.g., (ACN)]. An electro-osmotic flow (EOF) of up to 3 mm/sec can be generated. It is a plug flow, where the linear velocity is independent of the channel width and there is no column back-pressure.[4] Partitioning or adsorption of the neutral analyte occurs in the same way as in HPLC. The analytes are separated while moving through the column with the EOF. Charged solutes have additional electrophoretic mobility in the applied electric field; therefore, the separation occurs by electrophoresis and partitioning. The selectivity in analysis of the charged analytes is increased by electromigration of the sample molecules. The flat flow profile results in a more efficient radial mass transport compared to the parabolic laminar flow in pressure-driven LC, and this results in a significant enhancement in separation performance and shorter analysis times.[1,5,6] The capillaries can be made shorter to offer the same plate count as HPLC, therefore reducing the back-pressure. The packing material is smaller compared to HPLC, so with the high electric fields, the efficiency of this technique is very high (up to about 500,000 plates/m),[1] the peaks are sharp, the resolution is high, and the process is highly selective. An article by Angus et al.[7] demonstrated the separation efficiencies of 200,000–260,000 plates/m that were obtained by CEC and were reproducible from column to column for structurally related, polar neutral compounds of pharmaceutical relevance. The sample capacity in CEC is 10–100 times higher than that of capillary electrophoresis (CE), and this means that more sample volume can be placed on the CEC column to give better sensitivity. The high capacity comes from the high column loadability that results from the stationary phase's retentive mechanism.[8] The absence of additives and predominantly organic mobile phases make CEC better suited for use in mass spectrometry (MS). In fact, non-aqueous CEC is already being practiced by analysts.[8] A recent article by Hansen and Helboe gives a detailed study of the possibility of using CEC to replace gradients or ion-pairing reagents. The group optimized the separation of six nucleotides using a background analyte consisting of 5 m*M* acetic acid, 3 m*M* triethylamine (TEA), and 98% acetonitrile and a C_{18} 3 μm column. This was accomplished in half the time taken for a similar separation in HPLC.[9]

A variation of gradient CEC is pressurized-flow CEC or PEC (pressurized flow electrochromatography). A pump forms the gradient and then allows part of this pressurized flow to pump the mobile phase through the packed bed. In this way, one can perform isocratic or gradient CEC with part of the mobile-phase driving force being pumped, part electrophoretic and part electro-osmotic flows.[1,8,10]

Detection of Biomolecules and Pharmaceuticals in CEC

There are many different types of detectors used for pharmaceutical applications in CEC. They vary from indicating just the presence of a sample [fluorescence (FL)], to giving some qualitative information about a sample [photodiode array UV/Vis detection (PDA)], to absolute sample determination of the analyte (MS). The methods can be on-column, off-column, and end-column. With on-column, the solutes are detected while still on the capillary, in off-column, the solute is transported from the outlet of the capillary to the detector, and end-column is done with the

detector placed right at the end of the capillary. Some modes of detection used in CEC are as follows:

1. UV/Vis absorbance detection is widely used in CE Absorptivity depends on the chromophore (light-absorbing part) of the solute, the wavelength of the incident light, and the pH and composition of the run buffer. A photodetector measures light intensities and the detector electronics convert this into absorbance.[11]
2. Fluorescence detection is based on the fact that, when light energy strikes a molecule, some of that energy may be given off as heat and some as light. Depending on the electronic transitions within a molecule, the light given off may be fluorescent or phosphorescent.[12] Fluorescence occurs when an electron drops from an excited singlet to the ground state, as opposed to phosphorescence, which occurs when an electron's transition is from an excited triplet to the ground state.
3. LIF detection, such as argon ion, helium–cadmium,[5] and helium–argon lasers, can be used for this detection method. The criterion for choosing the laser is that the wavelength should be at or near the excitation maxima for the solute to be determined. The higher the power of the laser, the higher the intensity and the peak height and the laser's ability to focus the beam to a small spot.
4. MS detection[4] is the only detector that has high sensitivity and selectivity and can be used universally, thus, the increased interest in interfacing this technology with CEC compared to other detection methods. It can detect all solutes that have a molecular weight within the mass range of the MS. In the selected ion-monitoring mode, it detects only solutes of a given mass, and in the total ion chromatogram mode, it detects all the solutes within a given mass range.

Current applications of CEC use on-column UV or laser-induced fluorescence detection; however, for UV, the path length is quite short, which limits sensitivity, although bubble, Z-shaped, and high-sensitivity cells have helped to improve detection limits. However, UV and fluorescence are only good for samples that fluoresce and absorb light or are amenable to derivatization with fluorescing or absorbing chromophores. These detectors impose difficult cell volumes and sample size limits if high separation efficiencies are to be realized, and they are very expensive. All of these drawbacks are non-existent for MS techniques, which are expensive but provide more structural information and high sensitivity and appear to have the greatest overall potential.[8]

According to an issue of LC/GC,[10] combining CEC with detection techniques such as MS, MS/MS, and inductively coupled plasma (ICP)-MS are easier to accomplish, as the flow rates are at nanoliter per minute levels. Analysts must add makeup solvent after the capillary separation for certain ionization methods, and, because it is added later, users can select solvents that are more compatible with the detection technique. CEC mobile phases have a high organic solvent content that is more amenable to MS. Also, the low CEC flow rates means less maintenance and downtime for MS source cleaning.

In the references to the application of CEC to biopolymers, most of the work discusses CEC–electrospray ionization (ESI)/MS, much less to direct CEC-UV/FL methods. However, much of the work has evolved from the use of commercially available, prepacked capillaries, such as C_{18} or ion exchange or a mixed mode containing both ion exchange and reversed phase (RP). There are very few articles that have actually attempted to develop new phases specifically for biopolymers.

When using MS, the actual CEC conditions never really need to be fully optimized because the MS accomplishes the additional resolution and specific identification, as needed. The specific mobile-phase conditions in CEC/MS may be quite different than for CEC-UV/FL or HPLC, and thus optimization of CEC/MS conditions will be somewhat different than for CEC-UV/FL. This would include, just as for LC/MS, the use of volatile organic solvents and organic buffers, low flow rates, no void volumes, or loss of resolution in the CEC/MS interface and the usual interfacing requirements already developed and optimized for CE/MS.[10,13–23]

Few descriptions of quantitation have been reported so far. Most of the literature is qualitative by nature, simply demonstrating suitable, if not fully optimized, experimental conditions that provide evidence of the presence of certain biopolymers and their high resolution from other components in that particular sample. Absolute quantitation and validation needs to be developed and fully optimized for CEC, to become a more valuable and applicable separation mode for biopolymers.

SEPARATION OF PROTEINS

Capillary electrochromatography can accomplish high plate counts, as mentioned earlier; this means a high peak capacity (number of peaks that can be fitted into a typical separation time for a given length of column), therefore highly complex materials can be separated. The implication of better peak capacities is a better resolution of the peaks in a complex analyte. Because of the frequent overlap of peaks due to components in a complex sample, it is difficult to demonstrate peak purity with other methods. It is possible in CEC to quantitatively determine the presence of a particular analyte. CEC techniques have produced the separation of the enantiomers of amino acids.[24–27] This is done with limited use of solvents, buffer additives, salts, organics, chiral species, packing materials, and total time

of analysis. Other groups have successfully utilized gradient elution to separate mixtures of dansylated amino acid mixtures on the ODS (octadecylsilane) stationary phase.[24] Also, microprocessor control of pressure flow and voltage, automated sample injection, automated data collection, automated capillary switching, and the ability to interface with a variety of detection instrumentation make CEC an appealing technique for protein separation and peptide mapping.

Proteins and peptides are water-soluble complex molecules that are composed of amino acids linked by peptidic and disulfide bonds. Proteins are really just larger peptides of higher molecular weight, and antibodies are larger proteins of specific conformations, shape, size and immunogenicity, together with antigenic recognition properties.[28–31] The type, number, and sequence of amino acids in the chain determine the chemical characteristics of a peptide. The amino acid sequence determines the electrophoretic properties of the peptide. In addition to the amine terminus of the sequence, the amine and the guanidine residues of lysine and arginine are the main carriers of the positive charges, and the negative charge contribution is associated with the carboxylic acid terminus and the acidic groups of the aspartic and glutamic acids. The isoelectric and isoionic points of the peptide are their important characteristics in electrophoresis. These points are similar in peptides but not identical; the isoelectric point is determined by the given aqueous medium, whereas the isoionic point is related to the interactions with protons. The relation of the electrophoretic mobility of the peptides and their relative molecular weight is described by Offord'sequation:

$$\mu_{\text{rel}} = \frac{Z}{[\sqrt[3]{(M^2)}]}$$

where μ_{rel} is the relative mobility, Z is the total net charge, and M is the molar mass in gram per mole. Calculation of the net charge cannot be done easily from the pK values of the acidic and basic groups for large peptides, but additional factors such as conformational differences, primary sequence, chirality, and so forth need to be considered.

The popular methods of analysis of proteins currently are HPLC, HPCE, and MS. However, due to the complexity of proteins, LC approaches show a single, broad, ragged peak, which indicates that the method is unable to resolve the individual species.[1] In CEC, the success of the protein separation requires that the capillary packing material meet certain properties. Depending on the ionic characteristics of the biopolymers, pH-dependent "ideal" packings would be either RP or ion-exchange chromatography (IEC) or a combination of both.[1,32–46] There are several references that detail the possible application of SEC packings in CEC, but these have mainly been applied to synthetic organic polymers and much less to biopolymers.[47–50] Regardless of which packing is actually utilized, it should contain a stationary (bonded, not coated) phase that can successfully interact with the biopolymers, as in RP-HPLC, and prevent any unwanted silanol interactions with the underlying silica or ionic sites. It must also provide additional or programable EOF, besides that from the uncoated fused-silica capillary walls. Perhaps an ideal packing would combine a cationic-exchange material (cationic-exchange chromatography (CIEC) together with RP, in order to allow separations based on RP (hydrophobicity) alone, a combination of RP and IEC, or just IEC alone, mobile phase (buffer) dependent. Also, that packing, be it single or mixed mode, should prevent unwanted biopolymer (e.g., peptide amino groups) interaction with the support, such as amine–silanol hydrogen-bonding in RP-HPLC for amine containing analytes (e.g., pharmaceuticals, peptides, and proteins). Additional articles on open tubular CEC (OT-CEC) applications, where a coating is applied on the inner surface of the capillary as in capillary GC have appeared.[51–54] There are articles on packed-bed CEC, where there is a real packing in the capillary.[55,56] Also, then there are methods that employ just CEC, without any additional, pressure-driven flow,[38,39] as well as pressurized CEC or PEC, with additional pressurized flow.[4,51–53] There is also electro-HPLC that utilizes gradient elution with an applied voltage, but it is mainly conventional HPLC with some voltage applied sporadically or continuously during the HPLC separation.[54]

CEC OF BIOPOLYMERS (PROTEINS, PEPTIDES, AND ANTIBODIES)

The majority of the applications of CEC for biopolymers have dealt with peptides, of varying sizes and complexity, utilizing different modes of CEC (OT–CEC, conventional isocratic CEC, gradient CEC, PEC, and others). The following accounts are listed according to the work of different authors in the field.

Palm and Novotny applied the polymeric gel beds (monoliths) for peptide resolutions in CEC.[5] The peptide separation used the above packing beds with 29% as the ligand. Additional CEC conditions are indicated in Fig. 1, which depicts the separation of a series of tyrosine-containing peptides, with detection at 270–280 nm. In this particular study, peptide elution patterns were very sensitive to changes in pH and ACN concentrations. A gradient elution technique, not employed here, would have been more appropriate for such samples of peptides having small differences in their constitution. Attempts to elute protein samples were unsuccessful with these particular gel matrices, perhaps due to the high hydrophobicity of the packings.[5]

Euerby et al. reported the separation of an *N*-methylated, C- and N-protected tetrapeptide from its non-methylated analog (Fig. 2).[38] These separations utilized a Spherisorb ODS-1, 3 μm packing material, without pressure-driven flow (true CEC using a commercially

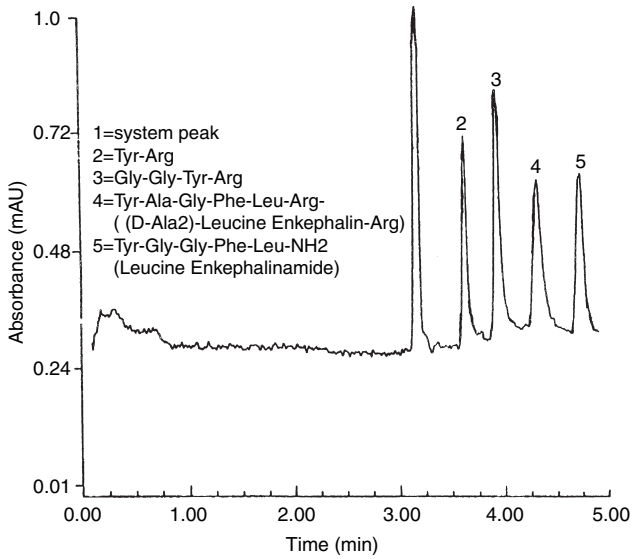

Fig. 1 Isocratic electrochromatography of peptides in a capillary filled with a macroporous polyacrylamide–polyethylene glycol matrix, derivatized with a C_{12} ligand (29%) and containing acrylic acid. Conditions: mobile phase, 47% acetonitrile in a buffer; voltage, 22.5 kV (900 V/cm), 7 μm; sample concentration, 4–10 mg/ml; detection, UV absorbance at 270 nm; other conditions are described in Ref.5

available CE instrument), and an ACN buffer. Using non-optimized, non-pressurized CEC conditions (non-PEC, non-pressure-driven CEC), separation of the two tetrapeptides could be achieved in a run time of 21 min with efficiency values of 124,000 and 131,000 plates/m. In comparison, when a pressurized CE (buffer reservoirs and capillary were pressurized, with pressure-driven flow of buffer) system was used, separation of the components was achieved within 3.5 min. According to Euerby et al. the separation of these two peptides using a pressure-driven HPLC gradient analysis took 30 min and gave comparable peak area results. Although this study illustrated the improved efficiency of both non-pressurized CEC and pressurized CEC over HPLC, no reasonable conclusions can be drawn from this work.

The attempts that have been made to utilize true chemometric optimization of operating conditions in CEC are unclear in most of the studies done utilizing CEC. This has been done for many years in GC and HPLC, as well as in CE, but there are no obvious articles that have appeared which have utilized true chemometric software approaches to optimization in CEC.[57–59] It is not clear that any true method optimization has been performed or what analytical figures of merit were used to define an optimized set of conditions for biopolymer analysis by CEC. It is also unclear as to why a specific stationary phase (packing) was finally selected as the optimal support in these particular CEC applications for biopolymers. In the future, it is hoped that more sophisticated optimization routines, especially computerized chemometrics (expert systems, theoretical software, or simplex/optiplex routines) will be employed from start to finish.

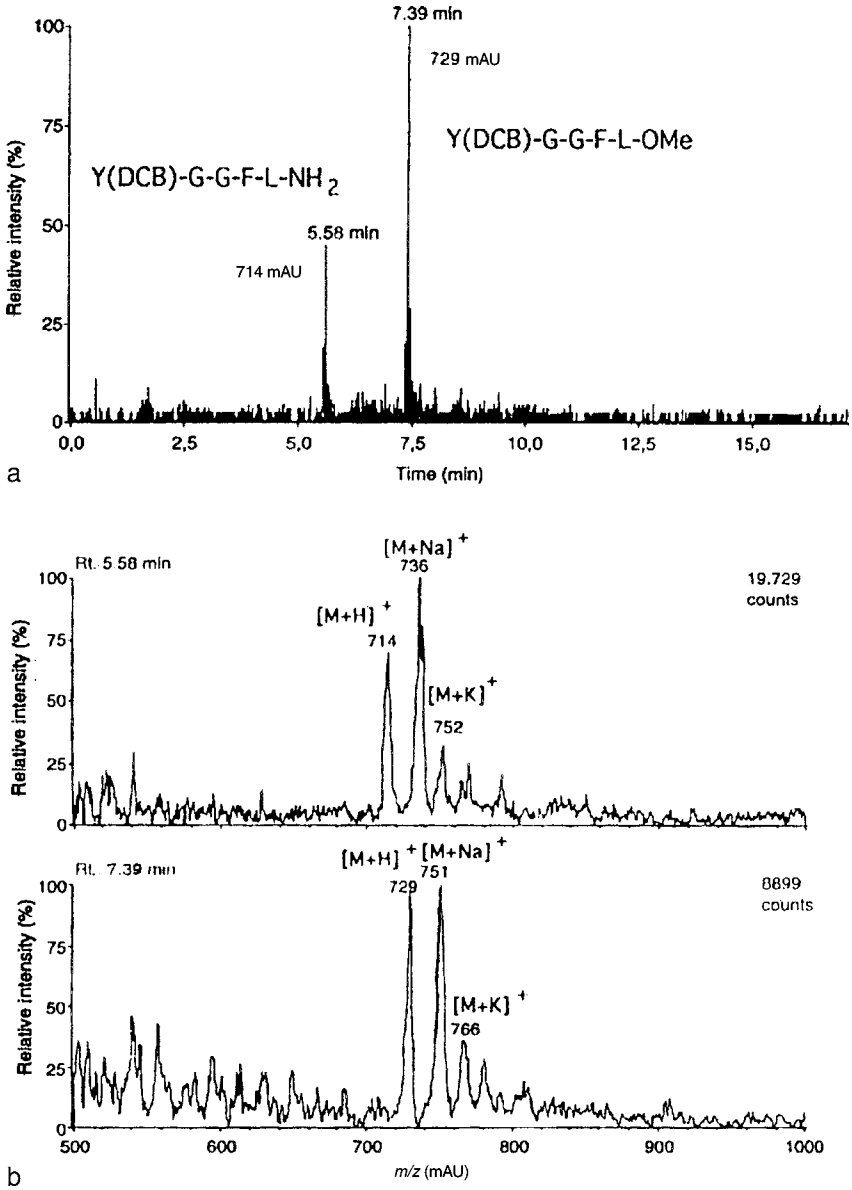

Fig. 3 Interfacing of pressure-driven CEC (PEC) for the separation of two simple peptides, enkephalin methyl ester (5.58 min) and enkephalin amide (7.39 min). (a) Extracted mass chromatogram of *m/z* 714 and 729 for the online peptide separation. Specific operating conditions are indicated in Ref. 4. (b) Mass spectra taken from the chromatographic peaks in (a), illustrating true M_r and the presence of M + H, M + Na, and M + K cations at appropriate *m/z* (amu) values.

The coupling of ESI and MS with a pressurized CEC system (PEC) has been shown to separate peptides.[4] This particular study of Schmeer et al. utilized a commercial RP silica gel, Gromsil ODS-2, 1.5 mm packing material, already utilized in capillary HPLC for peptide separations. It was never made perfectly clear why this particular packing material was selected or why PEC was selected for MS interfacing over conventional, isocratic CEC conditions. It is possible that the EOF alone with this packing material was insufficient to elute all peptides in a reasonable time frame and, thus, pressurized flow was introduced. No gradient elution PEC was demonstrated in this particular study. A mixture of enkephalin methyl ester and enkephalin amide was separated using the packed capillary column (Fig. 3a and b. The coupling of these two methods showed enhanced sensitivity and detectability. Like the Euerby study, this offered little insight into the capabilities of CEC to separate peptides; however, the study does provide a nice example of a peptide separation based on chromatographic and electrophoretic separation mechanisms, probably occurring simultaneously. This report also described the ability of easily interfacing CEC and PEC with ESI/MS.

The coupling of an MS with CEC or PEC provides several advantages. With the capillary columns of 100 mm inner diameter (I.D.), flow rates of 1–2 L/min are obtained, which are ideal for electrospray MS.[4] No interface like a liquid sheath flow is required and the sintered silica gel frits allow direct coupling of the packed capillary columns without additional transfer capillaries. The spray is therefore formed directly at the outlet side of the column. Verheij et al. carried out the first coupling of a

pseudoelectrochromatography system to a fast-atom bombardment (FAB)-MS in 1991.[6] However, this required transfer capillaries that caused a loss in efficiency, which was also a problem with other experimentations with this technique.

Lubman's group published several papers on the PEC/MS system.[51–54] RP open tubular columns (RP-OTC), which were prepared by a sol–gel process, were coated with an amine that enhanced the EOF in an acidic buffer solution and reduced the non-specific adsorption between the peptides and the column wall. A six-peptide mixture was separated to baseline within 3 min using this system coupled to an online ion-trap storage–time-of-flight mass spectrometer (ITS–TOF-MS). A full-range mass detection speed of 8 Hz was used in all these experiments, which was rapid to maintain the high efficiency and ultrafast separation. A high-quality total ion chromatogram could be obtained with only a couple of femtomoles of peptide samples, due to the high-duty cycle of the MS and the column path-length-independent and concentration-sensitive feature of the ESI process. The concentration limit of detection was also improved to about 1×10^{-6} *M* because of the preconcentration capability of the RP-CEC. A tryptic digest of horse myoglobin was successfully separated within 6 minon the gradient CEC system. The use of the MS increased the resolving power of this system by clearly identifying the coeluting components.

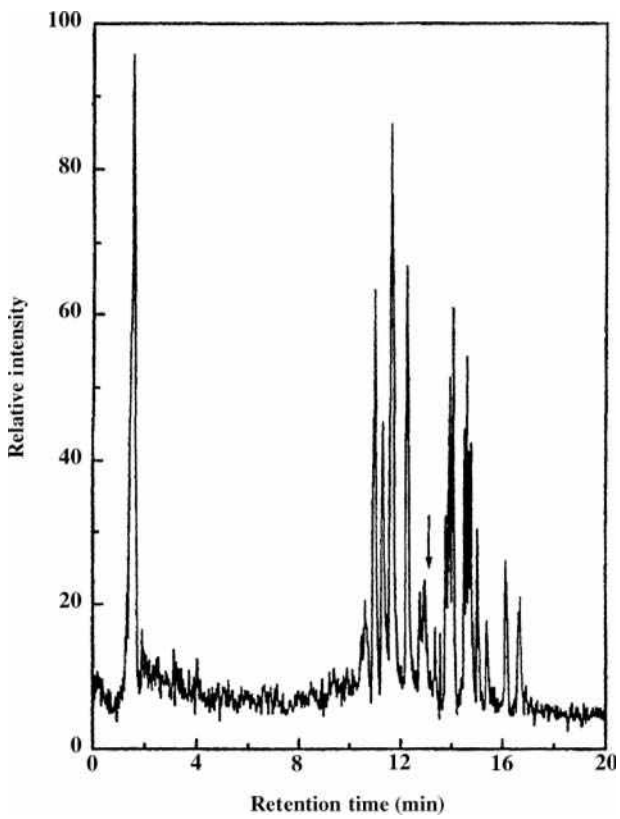

Fig. 4 The total ion chromatography (TIC) of the separation of a tryptic digest of chicken ovalbumin with a sample injection amount of 12 pmol corresponding to the original protein.[52] Column length, 6 cm. Conditions: 20 min, 0–40% acetonitrile gradient: 1000 V applied voltage with a 40-bar supplementary pressure.
Source: From Open-tubular capillary electrochromatography with an online Ion trap storage/reflectron time-of-flight mass detector for ultrafast peptide mixture analysis, in Anal. Chem.[52]; with permission of the authors and the American Chemical Society.

Another article by Wu et al.[52] dealt with a PEC coupled to an ion-trap storage/reflectron TOF-MS (RTOF-MS) for the analysis of peptide mixtures and protein digests. Taking advantage of the EOF, a high separation efficiency has been achieved in PEC due to a relatively flat flow profile and the use of smaller packing materials. With columns only 6 cm long, a tryptic digest of bovine cytochrome-c was successfully separated in about 14 min by properly tuning the applied voltage and the supplementary pressure. A relatively complex protein digest (tryptic digest) of chicken albumin gave 20 peaks (resolved) in the total ion current chromatogram in 17 min (Fig. 4). The sample concentrations were also on the order of about 1×10^{-5} *M*. The detector increased the resolving power of PEC by unambiguously identifying coeluting components. The CEC was directly interfaced to the MS via an ESI, which provided the molecular-weight information of the protein digest products and structural information via MS/MS (Table 1). The device uses a quadrupole ion trap as a front-end storage device, which converts a continuous electrospray beam for TOF analysis. The storage property of the ion trap provides ion integration for low-intensity signals, whereas the non-scanning property of the TOF-MS provides high sensitivity. A description of the MS is provided in an article by Wu et al.[54] According to an article by Verheij et al., problems that were encountered earlier, like formation of bubbles, have been overcome by using liquid junctions to apply the electric field over the column.[60]

A recent review article by the Lubman group points out that there are some serious advantages in using an open tubular column (OTC) for CEC as compared with packed-bed CEC.[54] OTCs with inner diameters around 10 μm have been found to have a smaller plate height when compared to packed columns. This is due to the lack of band-broadening effects associated with the presence of packing materials and end-column frits. OTC capillaries do not require end frits. High concentration sensitivity is another advantage of OTCs, as columns with very small dimensions are used. The small diameters of OTCs allow for the use of a higher voltage in CEC, without significant Joule heating. OTCs can also often provide more rapid separations than packed columns, by eliminating intraparticle diffusion, which is an important elimination for ultrafast separations in packed columns. However, there are some grave difficulties involved in using OTCs, perhaps because of the real difficulties with sample injection and detection. The injection volume of OTCs is in the low nanoliter or even picoliter range. The very small inner

diameters of most OTCs make optical detection difficult, but they are very compatible with a concentration-sensitive detection method, such as ESI–IT–TOF-MS. With peptide mixtures, however, gradient elution CEC, with or without pressure-driven flow, is almost required over isocratic or step-gradient methods, because small changes in the mobile phase composition results in large changes in peptide retention times.

In a later study, Pesek et al. reported the separation of other proteins using a diol stationary phase.[61–64] The use of a diol stationary phase should result in a surface that is more hydrophilic than a typical alkyl-bonded moiety, like C_{18} or C_8. The overall results showed significant variations in retention times due to differences in solute-bonded phase interactions. Other factors, such as pH, could also influence this interaction, due to its influence on charge and protein conformations. Combining all these factors in the separation of peptides and proteins provides an experimentalist with many decisions to be made in the optimized experimental conditions to be used. Other chemical modifications of etched fused silica need to be studied in order to provide a better understanding of their interactions with proteins and peptides, as well as other classes of biopolymers.

CONCLUSIONS

At the present time, although there are several applications of CEC/PEC to biopolymer classes, these are to be considered only preliminary and not necessarily fully optimized in all possible parameters. At times, significant improvements in peak shape, plate counts, resolutions, efficiency, and the time of analysis can be realized.

However, final optimizations of these separations have not been realized or possible. Some workers have utilized pressurized flow to solve the problems of obtaining reasonable EOF without silanol–analyte interaction; however, this does not solve the problem. It just forces the analyte to elute and approaches electro-HPLC, rather than true CEC. There are real differences between electro-HPLC, PEC, and CEC that need to be recognized. There does not, in general, seem to have been any serious attempt to utilize any chemometric software approaches in CEC/PEC for biopolymer separation optimizations or rationale for doing so. At this time, packings are simply used because they were on the shelf in a laboratory or commercially available and not necessarily because they were really the best for protein–peptide separations in PEC/CEC. There remains a need for research-oriented column choices from commercial vendors to avoid the need to pack capillaries in-house with commercial HPLC supports.

Biopolymers: CZE Analysis

Feng Xu
Yoshinobu Baba
Department of Medicinal Chemistry, University of Tokushima, Tokushima, Japan

INTRODUCTION

Since Jorgenson and Lukacs[1] separated peptides in 1981 using free zone electrophoresis in glass capillaries, capillary electrophoresis (CE) has become a highly efficient technique for the separation of biopolymers such as proteins, peptides, carbohydrates, and DNA. Free solution CE, or capillary zone electrophoresis (CZE), is an electrophoresis in free homogeneous solution.[2,3] Charged solutes are simply separated on the basis of the solute charge-to-mass (*m/z*) ratio, applied electric field, and the pH and ionic strength of the background electrolyte (BGE).

Separation of DNA is generally conducted by capillary gel electrophoresis (CGE), in which gel or polymer solutions act as sieving media, rather than by CZE, because each DNA has the same *m/z* ratio. The CZE separation of DNA can only be achieved by using some special modifications to break the charge-to-mass symmetry through either trapping analytes into sodium dodecyl sulfate (SDS) micelles or labeling analytes with large and weakly charged molecules at the DNA fragment ends (end-labeled free-solution electrophoresis).[4] Separation of DNA is not covered here. Interested readers are referred to our previous entries,[5,6] dealing with DNA size separation and sequencing, in the *Encyclopedia of Chromatography*. Here we concentrate on the CZE separations of three kinds of biopolymers (proteins, peptides, and carbohydrates), including the factors influencing the separations and the promising development of CZE in microchip and capillary array platforms.

PROTEINS AND PEPTIDES

Proteins are key participants in all biological activities. Peptides, generally shorter than proteins, have important biological functions, as hormones, neurotransmitters, etc. Owing to the similarity in structure, the general principles of the separations of proteins and peptides are alike. A semiempirical relation exists between mobility, charge, and size of a peptide or protein:

$$\mu = A\frac{q}{M^p} + B$$

where μ is mobility, q is charge, M is molecular mass, A and B denote empirical constants, and p varies from 1/3 to 2/3 as a function of the pH and ionic strength of BGE, and shape of peptides and proteins, etc. For a protein, the most difficult part is estimation of the charge.[7]

Sample Preconcentration

The CZE of a low concentration protein or peptide requires preconcentration of the sample before analysis, either off-line or online. Preconcentration is commonly performed by using solid-phase packing material at the inlet end of the capillary and is based on chromatographic or electrophoretic principle. Solid-phase extraction (SPE) on C_{18} or C_8 cartridges can be online connected to CZE and the concentrated non-specific analytes are released by an organic solvent (e.g., acetonitrile).[8] Alternatively, specific analytes can be concentrated by the use of antibody-containing cartridges and enzyme-immobilized microreactors. Desalting is important in protein processing. Microdialysis sampling can be used for the desalting of samples prior to introduction into electrospray ionization/mass spectrometry (ESI/MS). Capillary isoelectric focusing (CIEF), with slow ramping of voltage, can achieve online desalting of proteins in cerebrospinal fluid. Head column stacking has a long history and is now a popular technique in which the injected sample is simply dissolved in water and is focused at the interface between the sample plug and separation buffer, as a result of different mobilities in the two solutions. Capillary isotachophoresis (CITP) can also be utilized to achieve on-column sample preconcentration. The sample is introduced as a plug between a leading electrolyte, which has a higher mobility than the sample, and a trailing electrolyte, which has a lower mobility than the sample. After applying the voltage, the sample components are focused as a concentrated band. Very large sample zones can be accommodated by isotachophoresis to enhance the limit of detection (LOD).[9]

Detection

Peptide bonds enable proteins and peptides to be directly detected by ultraviolet (UV) radiation, at 200–220 nm, where the absorption is proportional to the number of peptide bonds. Sometimes, detection is performed around

254 or 280 nm, where proteins have modest absorbance in the presence of aromatic residues. However, the sensitivity of UV detection is relatively poor (to μM). Several commercially available Z-type cells and bubble-shaped cells can help, somewhat, in improving the sensitivity.

Laser-induced fluorescence (LIF) produces low LOD and a wide dynamic range. Native fluorescence of proteins is primarily associated with emission from tryptophan and tyrosine, between 300 and 400 nm. Proteins are easy to derivatize with a fluorescent reagent prior to electrophoresis. Postcolumn derivatization can be performed in sheath flow systems where the sheath flow cell acts as a postseparation labeling reactor. To avoid the formation of a mixture of multiply labeled products for originally single species, some special procedures utilizing Edman degradation chemistry or fluorescein isothiocyanate (FITC) labeling at lower than normal derivatization buffer pH have been developed. Noncovalent labeling is performed with dyes that interact with proteins, either by H bonding or through hydrophobic interactions. The sensitivity of LIF approaches the absolute LOD of a single molecule. A number of fluorescent dyes are widely used,[10] such as fluorescamine, 1-anilinonaphthalene-8-sulfonic acid, 4,4′-dianilino-1,1′-binaphthyl-5,5′-disulfonic acid, 2-(*p*-toluidino)naphthene-6-sulfonic acid, 3-(2-furoyl)quinoline-2-carboxaldehyde, naphthalene-2,3-dicarboxaldehyde, 4-chloro-7-nitrobenzofurazan, 4-fluro-7-nitrobenzofurazan, *O*-phthaldialdehyde-2-mercaptoethanol, and 3-(4-carboxybenzoyl)-2-quinolinecarboxaldehyde, etc.

Mass spectrometric detection has come into frequent use, as it provides significant information relating to the solute structure. Protein analysis using CZE/MS has been applied to abundant proteins in a single cell after the single intact cell was introduced into a separation capillary and after being lyzed. On the other hand, ESI/MS is a soft ionization technique that can form molecular ions. Online ESI detection requires an external interface and volatile buffers to avoid contamination of the ionization chamber. Proteins can also be off-line identified by matrix-assisted laser desorption ionization/time-of-flight mass spectrometry (MALDI/TOF/MS), in which the matrix utilizes a low-molecular-weight organic acid that absorbs laser light and dissipates the energy in such a way that protein is evaporated, usually in a single protonated form. Time of flight has an advantage of having no upper mass-to-charge limit.

Coatings and Additives

The interaction of proteins with the negative charges of the ionized silanol groups on the inner capillary wall should be overcome prior to separation. The interaction results in peak tailing, poor resolution, unstable electro-osmotic flow (EOF), and sample adsorption loss. A variety of approaches have been developed to overcome this problem, including the use of extreme buffer pH, coated capillaries, and additives in BGE.

The simplest way is to use extreme buffer pH, i.e., either a low pH at which the dissociation of silanol groups is suppressed so as to prevent their electrostatic interactions with positively charged polypeptides, or an alkaline pH that is at least two units above the isoelectric point of an analyzed polypeptide, which leads to electrostatic repulsion between the negatively charged polypeptide and the negatively charged silanol groups on the capillary wall. Unfortunately, even proteins that behave as anions still have a positively charged section on their surface that can interact with the capillary wall. In addition, more extreme pHs may denature proteins.

Static wall coatings are usually made by reacting the capillary wall with a small bifunctional reagent, which is then used to bind a polymer to the wall. The polymer is usually prepared in situ. γ-methacryloxypropyltrimethoxysilane is a classical bifunctional reagent, while polyacrylamide is a frequently used polymer for coatings. A variety of polymer coatings can be anchored onto capillaries, such as polystyrene, polybrene, polyvinyl alcohol, polyethyleneimine, polyethylene glycerol, polyvinylpyrrolidone, polyethylene oxide, and nonionic surfactant coatings. Hydrophilic coating, epoxy-poly(-dimethylacrylamide), can separate proteins over the range of pH 4–10 with the recovery of both cationic and anionic proteins over 90%.

Dynamic wall coatings are replaceable. There are two kinds of dynamic coatings: One is performed by introducing a neutral polymer to the BGE, and the other is performed by adding ions to the BGE. The neutral polymers not only shield capillary wall from interactions with solutes, but also increase the viscosity in the electric double layer and reduce EOF. Various cellulose derivatives and other hydrophilic polymers, such as polyvinyl alcohol, polyethyleneoxide, hydroxyethyl cellulose, copolymer of hydroxypropylcellulose and hydroxyethylmethacrylate, and polysaccharide guaran, have been used for this purpose. Ionic (mainly cationic) additives titrate the negative charge of the capillary wall so that the EOF is decreased, neutralized, or even reversed. Polyionic species reduce the pH dependence of the EOF if, for example, the coating contains sulfonic acid groups that are fully ionized over a wide pH range. One can also add, to the BGE,[11,12] oligoamines such as putrescine, spermine, and tetraethylene pentamine, cationic surfactants such as cetyltrimethylammonium bromide (CTAB) and didodecyldimethylammonium bromide (DDAB), high concentration of anionic surfactants such as SDS, zwitterionic phospholipids such as 1,2-dilauroyl-*sn*-phosphatidylcholine, high concentration of alkali salts and phytic acid, other compounds such as cyclodextrins, etc. A mixture of cationic and anionic fluorosurfactants produces efficient separations of acidic and basic proteins in a single run at neutral pH. Zwitterionic surfactants are typically superior to the non-ionogenic ones. The protein interactions with the capillary wall are inversely proportional to the critical micellar concentration (CMC) of surfactants.

In addition to reducing the adsorption, the dynamic additives also play important roles in selectivity enhancement. pH is an important option for protein and peptide separation. An increase in the buffer ionic strength can increase the resolution. Any ion that displays a preferential affinity with the peptides has a potential modifying effect on the selectivity. The addition of organic modifiers, e.g., methanol, ethanol, and acetonitrile, in the BGE, can induce different solvation of the peptide chains and modify the migration order and selectivity of peptides. For separation of very hydrophobic proteins, e.g., lipoproteins, surfactants can act as buffer additives to improve solubilization.

Using amphoteric, isoelectric buffers at pH close to their isoelectric points (p*I*), at which the electrolytes have a net charge of zero, is an efficient way to decrease the BGE conductivity and apply extremely high field strength. Thus the separation time can be reduced to the order of a few minutes, and high resolution is achieved as a result of minimal diffusion-driven peak spreading. Several acidic isoelectric buffers, such as cysteic acid (p*I*: 1.85), iminodiacetic acid (p*I*: 2.23), aspartic acid (p*I*: 2.77), and glutamic acid (p*I*: 3.22), all at 50 m*M* concentration,[13] have been used in CZE separation of proteins and peptides. Fig. 1 shows a decrease of total running time from 70 to 12 min when using an isoelectric solution.

CARBOHYDRATES

Carbohydrates are the third most important class of biopolymers, next to proteins and DNA. However, their analyses by CZE are still in infancy because of the complexity and diversity of their structures. In terms of ionization ability, carbohydrates may be divided into acidic and weakly ionizable classes. Acidic carbohydrates are negatively charged at neutral pH and can be conveniently separated. Weakly ionizable carbohydrates are neutral at mild pH, but deprotonate at extremely basic condition (e.g., pH $>$ 12).

Underivatized Carbohydrates

The borate buffer is the most effective buffer for the CZE separation of native (and derivatized) carbohydrates. Borate complexes with adjacent hydroxyl groups on carbohydrates to form a negatively charged complex, which has a 2- to 20-fold increased UV absorbance at 195 nm.[9] The stability of sugar–borate complexes increases with increasing pH and borate concentration, and depends on the number and configuration of the hydroxyl groups. The presence of a surfactant (e.g., tetrabutylammonium) in a borate buffer also enhances the solute selectivity by interacting with anionic borate–sugar complexes. Saccharides, e.g., sucrose, glucose, fructose, etc. can also be separated by chelating with Cu^{2+} present in the BGE. Elevated temperature up to 60°C facilitates the enhancement of resolution and efficiency.

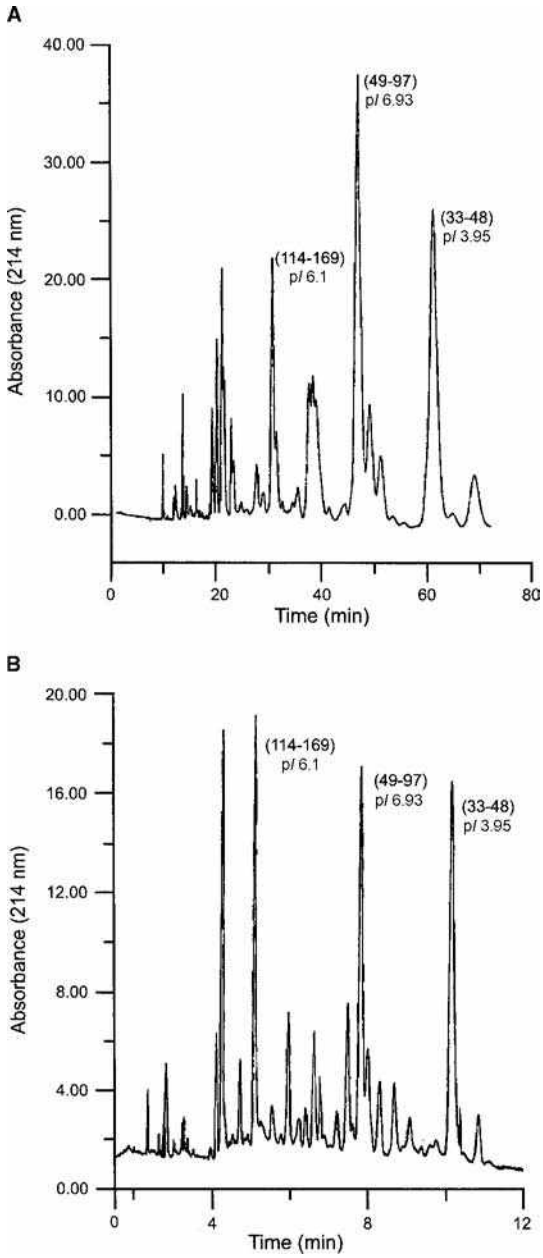

Fig. 1 CZE of tryptic digests of β-casein in 100 mm I.D. × 37 cm capillary. A, BGE: 80 m*M* phosphate buffer, pH 2.0; injection: 0.5 p.s.i. for 3 sec; applied field strength: 110 V/cm. The three major peaks are: 1) p*I* 6.1, fragment β-CN (114–169); 2) p*I* 6.93, fragment β-CN (49–97); and 3) p*I* 3.95, fragment β-CN (33–48). Note that the total running time is 70 min. B, BGE: 50 m*M* isoelectric aspartic acid (pH = p*I* = 2.77) added with 0.5% hydroxyethyl cellulose (HEC) (M_n 27,000 Da) and 5% trifluoroethanol; applied field strength: 600 V/cm.
Source: From Capillary electrophoresis of peptides in isoelectric buffers, in J. Chromatogr. A.[13]

Underivatized carbohydrates are mainly detected using low-wavelength UV (at 190–200 nm), indirect UV, or indirect LIF. The indirect method is based on the physical displacement of analytes with the added chromophoric or

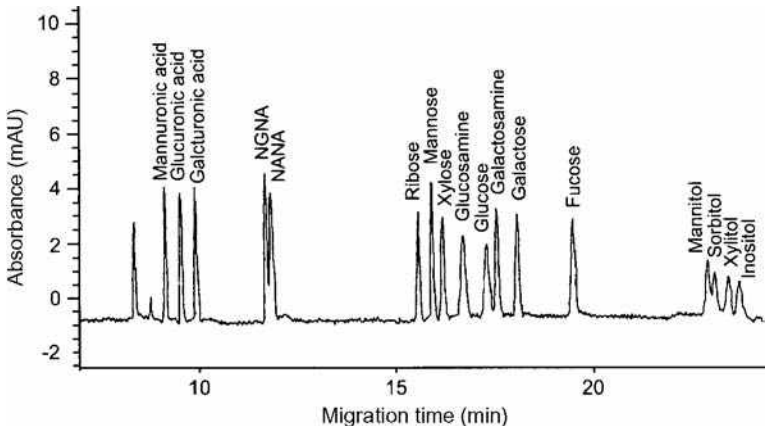

Fig. 2 Capillary zone electrophoresis of saccharides (1 m*M* each) standard mixture. Capillary: Fused silica, 50 μm I.D. × 80.5 cm (72 cm effective length); BGE: 20 m*M* 2,6-pyridinedicarboxylic acid (PDC) and 0.5 m*M* CTAB, pH 12.1; voltage: −25 kV. The signal wavelength was set at 350 nm with a reference at 275 nm.

flurophoric compounds in the BGE. Indirect UV detection, using sorbic acid as both carrier electrolyte and chromophore, and employing high pH to achieve ionization of saccharides, permits the analysis of underivatized saccharides in low concentration. Fig. 2 shows the separation of underivatized acidic, neutral, and amino sugars and sugar alcohols by CZE-indirect UV.[14] Capillary electrophoresis-pulsed amperometric detection (CE/PAD) in the analysis of oligosaccharides derived from glycopeptides provides structural information through simply modulating the detection potentials. Refractive index detection is a universal detection and is also useful for oligosaccharide analysis. However, the detection limit is rather poor.

Derivatized Carbohydrates

Derivatization provides the advantage of incorporating chromophoric or fluorophoric functions into carbohydrates to achieve highly sensitive detection. Electromigration can also be achieved by derivatization of neutral saccharides with reagents possessing ionizable functions. Derivatization of the reducing aldehyde and/or keto groups present in carbohydrates can be performed by reductive amination and condensation reaction.

The reaction of reductive amination is based on the reducing end of a saccharide reacting with the primary amino group of a chromophoric or fluorophoric reagent to form a Schiff base that is subsequently reduced to a stable secondary amine. For example, in the reductive amination of malto-oligosaccharides, 8-aminonaphthalene-1,3,6-trisulfonic acid (ANTS) introduces both electric charge and fluorescence to the saccharides.[15] The products are ionized at a pH as low as 2.5, allowing CZE of carbohydrates under conditions where both EOF and adsorption to the internal capillary wall are negligible, even in the absence of any coating. Aminobenzoic acid and related compounds have the merit to react with both ketoses and aldoses of oligosaccharides in less than 15 min at 90°C. Such fast reactions could be compatible with the CE separation speed. Other conventional fluorophores for carbohydrate labeling include 8-aminopyrene-1,3,6-trisulfonate (APTS), 7-amino-4-methylcoumarin, 3-(4-carboxybenzoyl)-2-quinolinecarboxaldehyde, 2-aminobenzamide, 4-aminobenzoate, 4-aminobenzonitrile, etc.

The derivatization of aldehydes in reducing carbohydrates can also be performed by a condensation reaction between the active hydrogens of 1-phenyl-3-methyl-5-pyrazolone (PMP) and the aldehyde functionality under slightly basic condition. The formed *bis*-PMP derivatives can be separated by CZE and detected by UV absorbance.[16] Oligosaccharides can also be separated as complexes with a variety of compounds, including acetate, molybdate, germanate, stannate, arsenite, wolframate, vanadate, and tellurate of various alkali and alkaline earth metal ions. In a BGE containing calcium, barium, or strontium acetate, a mixture of PMP-derivatized reducing carbohydrates such as arabinose, ribose, galactose, glucose, and mannose was fully resolved.[16]

Glycoprotein analysis requires both protein and glycan identification. CE/LIF is widely used in the fingerprinting of fluorescently labeled glycans and in detection differences in maps of the oligosaccharides released from glycoproteins. The analysis of the complete composition of saccharides occurring in glycoproteins can be performed by separating the hydrolyzed sugars using CZE. Useful information about the glycoprotein structure can be obtained by combining CZE with MALDI-MS and ESI–MS. The techniques are well suited for the sensitive determination of the degree of heterogeneity, the site of glycosylation in a protein, and the composition and branching patterns of *N*- and *O*-linked glycans.

CONCLUSIONS

CZE, with its automation, simplicity, and rapid method development, is an attractive choice for biopolymer separation. Future methodological advances include

novel capillary wall coatings, specific buffer additives, effective sample preconcentration, and highly sensitive detection. At the same time, CZE development will move toward two promising directions: High-throughput and ultrafast separations (in seconds not minutes). Previously, CZE was a sequential technique, which allowed analysis of one sample per analysis. One remedy to this problem is the use of the capillary array electrophoresis (CAE) technique. Array instruments use 100 or more capillaries in parallel, with the laser excited fluorescence signals from each channel simultaneously recorded, e.g., by a charge-coupled device (CCD) array. Another remedy for fast analysis is the use of microchip-based CE devices. All operations, e.g., sample manipulation, separation, and detection, are performed on the microstructures of the chips. The short sample injecting plug, essentially zero dead volume intersections, and high field strength result in extremely rapid and high efficient separation.[17] The advantage of microfabricated devices is also the potential of producing arrays of separation channels for high-throughput applications in a single run. After solving some technical problems, the microchip-based separations are expected to become a highly powerful tool in future separations of biopolymers.

INTRODUCTION

Endotoxin [lipopolysaccharides (LPSs)] is an integral part of the outer cellular membrane of Gram-negative bacteria and is responsible for organization and stability. In the biotechnology industry, Gram-negative bacteria are widely used to produce recombinant DNA products such as peptides and proteins. Thus these products are always contaminated with LPS. Such contaminants have to be removed from drugs and fluids before use in injections, because their potent biological activities cause pyrogenic reactions.

To achieve selective removal of LPS from final biological products, such as proteins and protective antigens, it is necessary to consider not only the chemical and physical structures of LPS, but also those of the adsorbents and proteins, as well as the solution conditions. In physiological solutions, LPS aggregates form supramolecular assemblies (M_w: 4×10^5 to 1×10^6) with phosphate groups as the head group and exhibit a net-negative charge because of their phosphate groups. However, as proteins may release LPS monomers from the aggregates, we assume that LPS aggregates comprise a wide range of molecular sizes, with M_w from 2×10^4 to 1×10^6 in physiological solutions. On the other hand, the molecular weights of proteins are generally about 1×10^4 to 5×10^5. Therefore, it is extremely difficult to separate LPS from protein solely by size-separation methods, such as size-exclusion chromatography (SEC) and ultrafiltration. Various procedures of LPS removal, such as ion-exchange membrane, ultrafiltration, and extraction, have been developed for pharmaproteins. These procedures, however, are unsatisfactory with respect to selectivity, adsorption capacity, and protein recovery.

For the removal of LPS from final solutions of bioproducts, selective adsorption has proven to be the most effective technique. Therefore considerable effort is being put into the development of adsorbents capable of retaining high LPS selectivity under physiological conditions (ionic strength of $\mu = 0.05$–0.2, neutral pH). Recently, numerous cationic polymer adsorbents have been developed for removing LPS from protein solutions. This entry will elucidate the chromatographic properties of various LPS adsorbents and will describe recent findings concerning methods for eliminating LPS from protein solutions using the adsorption technique.

CHROMATOGRAPHIC MATRICES WITH POLYCATIONIC LIGANDS

Lipopolysaccharide is an amphipathic substance[1–3] that has both an anionic region (the phosphoric acid groups) and a hydrophobic region (the lipophilic groups). From this point of view, an LPS-selective ligand should have, not only cationic properties, but also hydrophobic properties.[4–6] Fig. 1 shows structures of various cationic substances that are suitable as LPS-selective ligands. Through immobilization of polymyxin B on CNBr-activated Sepharose, Issekutz[7] created a polymyxin–Sepharose adsorbent for selective removal of LPS. This adsorbent is now commercially available. Although the polymyxin–Sepharose columns showed high LPS-adsorbing activity, protein losses during passage through the column have been noted (20% loss of BSA in Ref.[8]). This is due to the ionic interaction between the cationic region of the polymyxin B and the net-negatively charged proteins at low-ionic strengths. Furthermore, polymyxin B is not suitable as a ligand for LPS removal from a solution for intravenous injection because it could escape from the column and would be physiologically active in solution. If any polymyxin is to be released into a solution, it would be physiologically active. Poly(ethyleneimine) (PEI)-immobilized cellulose fibers have been prepared by Morimoto et al.[9] and the PEI fibers showed significant LPS-adsorbing capacity under physiological conditions (neutral and ionic strength of $\mu = 0.1$–0.2). In a more recent publication, poly(ε-lysine) (PL) was covalently immobilized onto cellulose spherical particles and used for selective adsorption of LPS from protein solutions.[10] In addition, the PL (degree of polymerization: 35, pK_a: 7.6) (Chisso)[11] produced by *Streptomyces albulus*, which has become commercially available as a safe food preservative, is more suitable as a ligand than is polymyxin B. The high LPS adsorption of chromatographic matrices having polycationic ligands, such as polymyxin B, PEI, or PL, is

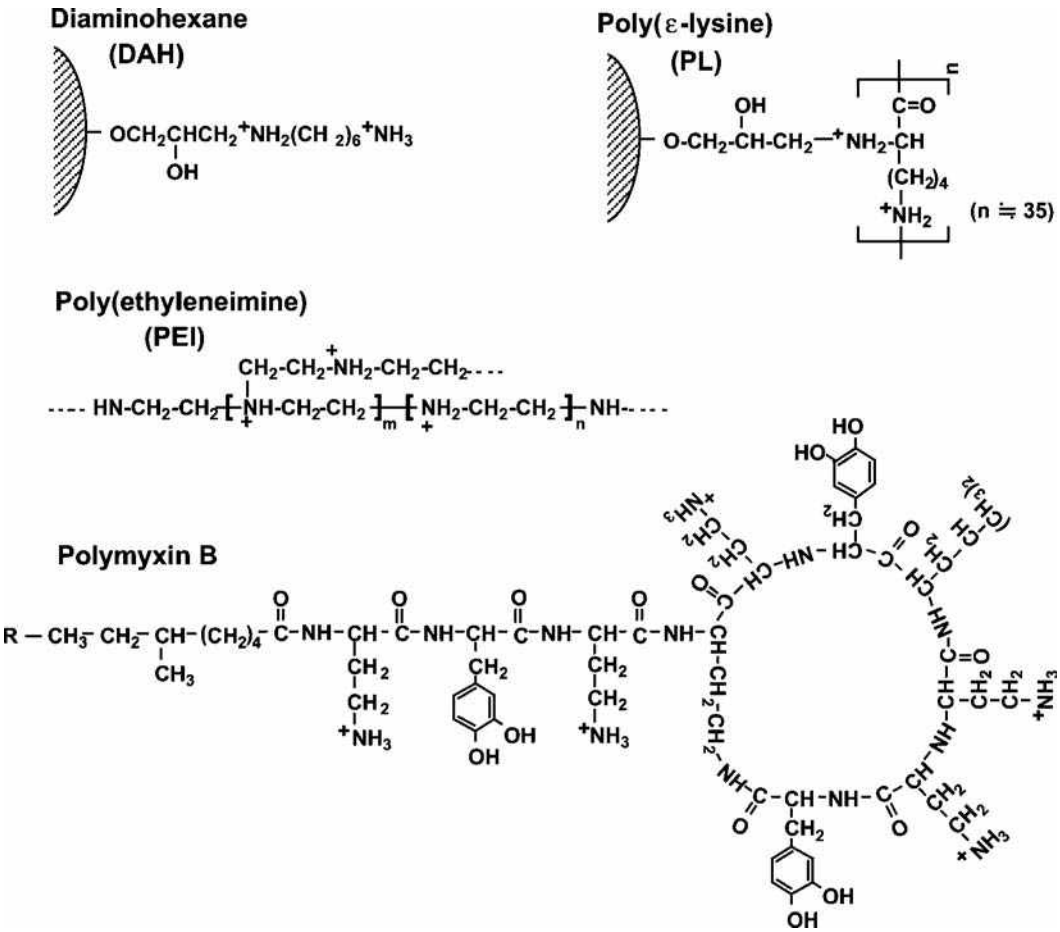

Fig. 1 Structure of LPS-selective ligands. Sepharose and cellulose particles are used as the matrix.

possibly due to the simultaneous effects of the cationic properties of the ligand and its hydrophobic properties.

EFFECTS OF VARIOUS FACTORS ON THE SEPARATION OF BIOPOLYMERS BY POLYCATIONIC ADSORBENTS

Effect of Pore Size of the Adsorbent on LPS Selectivity

To achieve the selective removal of LPS, it is important to determine the adsorbing activity of proteins. Table 1 shows the effect of the adsorbent pore size (molecular mass exclusion of polysaccharide, M_{lim})[12] on the adsorption of cellular products (biorelated polymers). The various PL-immobilized cellulose particles (PL cellulose) with pore sizes of M_{lim} 2×10^3 to $>2 \times 10^6$ were used as adsorbents. Lipopolysaccharide, DNA, and RNA, which are anionic biorelated polymers with phosphoric acid groups, were adsorbed very well by all the adsorbents. By contrast, the adsorption of protein was more dependent on the M_{lim} of the adsorbent than its anion-exchange capacity (AEC). The adsorption of bovine serum albumin (BSA) (M_w 6.9×10^4), an acidic protein, increased from 5% to 68% with an increase in the M_{lim} from 2×10^3 to 1×10^4. The adsorption of γ-globulin (M_w 1.6×10^5), a hydrophobic protein, increased from 2% to 22% with an increase in the M_{lim} from 1×10^4 to $>2 \times 10^6$. Polymyxin–Sepharose with large pore size ($M_{lim} > 2 \times 10^6$) also adsorbed BSA (78%) and γ-globulin (26%), as shown in Table 1. Very little of the other neutral or basic proteins adsorbed onto the adsorbents under similar conditions. As a result, only when the PL cellulose (10^3), with a M_{lim} of 2×10^3 and AEC of 0.6 meq/g, was used as the adsorbent at pH 7.0 and ionic strength of $\mu = 0.05$ were LPS and DNA selectively well adsorbed.

The results reported in Table 1 show that the adsorption of protein was caused, mainly, by the entry of the protein into the pores of the adsorbent. This indicates that both BSA and γ-globulin can readily penetrate into a particle with an M_{lim} of $> 2 \times 10^6$, but cannot penetrate into a particle with 2×10^3 (M_{lim}). On the other hand, it would also appear that LPS aggregates are not able to enter the pores of the adsorbents with 2×10^3 (M_{lim}) because their molecular weights (4×10^5 to

Table 1 Effect of adsorbent's pore size on adsorption of a bio-related polymer.

			Adsorption[a] (%)			
			PL-cellulose (10^3)[b]	PL-cellulose (10^4)[c]	PL-cellulose (10^6)[d]	Polymyxin–sepharose[e]

[g]Value deduced as molecular weight of polysaccharide.[12]

1×10^6)[13] are significantly larger than the M_{lim} of the adsorbent. Many of the standard LPS molecules (*Escherichia coli* O111:B4 and UKT-B), however, were well adsorbed even by the adsorbent with an M_{lim} of 2×10^3, as shown in Table 1. We previously reported[13] that the LPS molecules were adsorbed by aminated poly (γ-methyl L-glutamate) particles not only into the pores of the particles but also on their surfaces. Poly(ε-lysine)-immobilized cellulose particles have similar characteristics.

Effect of Degree of Ligand Polymerization on Adsorption of Biopolymer

For selective removal of LPS from a protein solution, it is also necessary to select the ligand of the adsorbent. Fig. 2 shows the effects of a buffer's ionic strength and pH on the adsorption of LPS by diaminohexane-(DAH), PL-, or PEI-immobilized cellulose particles. Diaminohexane monomer (M_w: 116), PL (degree of polymerization: 35, M_w: 4.0×10^3), and PEI (degree of polymerization: 1600, M_w: 7×10^4) were used respectively as adsorbent ligands, and cellulose particles with M_{lim} 2×10^3 (Cellufine GC-15) were used as the matrix. As shown in Fig. 2a, the higher the ionic strength of the buffer the lower the LPS-adsorbing activity of the adsorbent. Both PEI cellulose and PL cellulose always showed a greater LPS-adsorbing activity (99% to 82%) at a wide range of ionic strengths ($\mu = 0.05$–0.8). The adsorbing activity of DAH cellulose decreased markedly when the ionic strength was increased to 0.2 or higher.

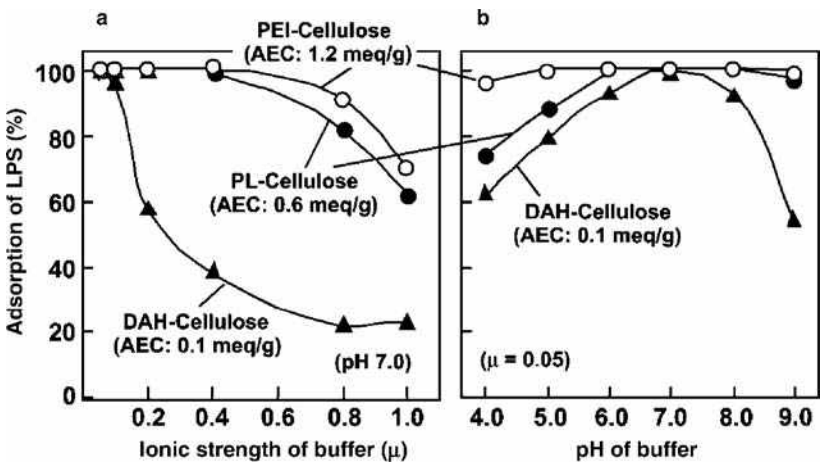

Fig. 2 Effects of a buffer's (a) ionic strength and (b) pH on the adsorption of LPS by various aminated cellulose adsorbents. The adsorption of LPS was determined using a batchwise method with 0.2 g of the wet adsorbent and 2 ml of a LPS (*E. coli* O111:B4, 1000 ng/ml) solution. Adsorbent and AEC of adsorbent: PEI-cellulose = poly(ethyleneimine)-immobilized Cellufine-GC15 (AEC:1.2 meq/g); PL-cellulose = poly(ε-lysine)-immobilized Cellufine-GC15 (AEC:0.6 meq/g); DAH-cellulose = diamino hexane-immobilized Cellufine-GC15 (AEC: 0.2 meq/g). M_{lim} of adsorbent: 2×10^3.

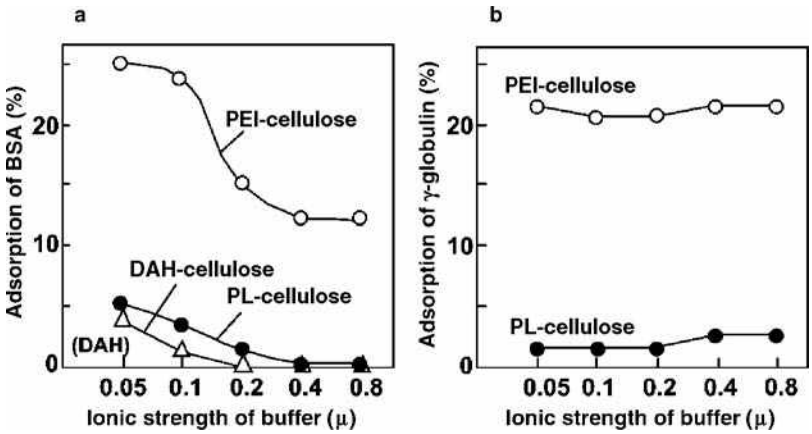

Fig. 3 Effect of a buffer's ionic strength on the adsorption of (a) BSA and (b) γ-globulin by various aminated cellulose adsorbents reported in Fig. 2. The adsorption of protein was determined using a batchwise method with 0.2 g of the wet adsorbent and 2 ml of a protein (100 μg/ml) solution.

Fig. 2b shows the effect of pH on the adsorption of LPS by various aminated cellulose adsorbents. The larger the molecular weight (polymerization degree) of an adsorbent's ligand the higher the LPS-adsorbing activity of the adsorbent. Over a wide pH range of 4.0–9.0 and at an ionic strength of $\mu = 0.05$, PEI cellulose (AEC:1.2 meq/g), with the largest polymerization degree of ligand, always showed the highest LPS-adsorbing activity (>98%). Poly(ε-lysine)-immobilized cellulose (AEC:0.6 meq/g) also showed a high activity (>97%) over a pH range from 6.0 to 9.0, although it decreased from 99% to 75% as the pH decreased from 6.0 to 4.0. On the other hand, DAH cellulose (AEC: 0.1 meq/g) showed high-adsorbing activity only at pH 7.0.

Fig. 3a and b shows the effect of a buffer's ionic strength on adsorption of BSA and γ-globulin, respectively, by aminated cellulose adsorbents. The stronger the ionic strength the lower the BSA-adsorbing activity of the adsorbent (Fig. 3a). By contrast, adsorption of BSA and γ-globulin is independent of ionic strength (Fig. 3b). Poly(ethyleneimine)-immobilized cellulose showed the highest adsorption of each protein among the three adsorbents.

From these results (Table 1, Figs. 2 and 3), we assumed that the adsorbing activity of aminated-cellulose adsorbents for biopolymers was induced by the simultaneous effects of their cationic properties and hydrophobic or other properties. The charge of LPS is anionic at pH values greater than its pK_a (pK_1 = 1.3[14]). The charge of BSA is also anionic at pH values greater than 4.9 (its pI). The adsorption of LPS and BSA increased with increasing AEC content of the adsorbent (Figs. 2 and 3). It is also dependent on the ionic strength and pH values (Fig. 2a and b, respectively). These results suggest that aminated-cellulose adsorbents adsorb LPS and BSA mainly by ionic interaction. On the other hand, the ionic interaction of the adsorbent with γ-globulin (pI: 7.4) is not induced at pH 7.0, as the charge of the protein is cationic at a pH under its pI value. γ-Globulin is a weakly hydrophobic protein. Its adsorption was independent of ionic strength and increased with an increase in the hydrophobicity (ligand-polymerization degree) of the adsorbent (Fig. 3b). Hou and Zaniewski[15] also reported that a hydrophobic bond was formed between LPS and the polymeric affinity matrix. These findings suggest the participation of hydrophobic binding. Furthermore, as shown in Table 1, polycation-immobilized cellulose adsorbents bind more strongly with LPS than protein. This is because the pK_a of the phosphate residues of LPS is lower than the pI of protein (pI: 4.6–11.0), and, probably, because the LPS is adsorbed by the adsorbent through its multipoint attachment onto the polycation chain of the adsorbent surface.

CHROMATOGRAPHIC RESULTS FOR SELECTIVE LPS REMOVAL

For selective LPS removal, it is necessary not only to select the ligand of the adsorbent, but also to control the conditions of the buffer (pH and ionic strength). The effect of ionic strength on the selective adsorption of LPS from a BSA-containing solution by various aminated cellulose adsorbents (M_{lim} 2×10^3) was examined (results are shown in Fig. 4a–c). A BSA solution, 500 μg/ml of BSA and 100 ng/ml of standard LPS, was used as a sample solution. The LPS-adsorbing activity of DAH cellulose decreased remarkably with an increase in the ionic strength. The DAH cellulose selectively adsorbed LPS only at $\mu = 0.05$ (Fig. 4a). Poly(ethyleneimine)-immobilized cellulose showed adsorbing activities for both LPS and BSA over a wide ionic strength, from $\mu = 0.05$ to 0.8 (Fig. 4c). It cannot therefore selectively adsorb LPS from the BSA solution at all ionic strengths. By contrast, PL cellulose selectively adsorbed LPS in the solution at ionic strengths of $\mu = 0.05$ to 0.4 and pH 7.0, without adsorption of BSA (Fig. 4b). The residual concentrations

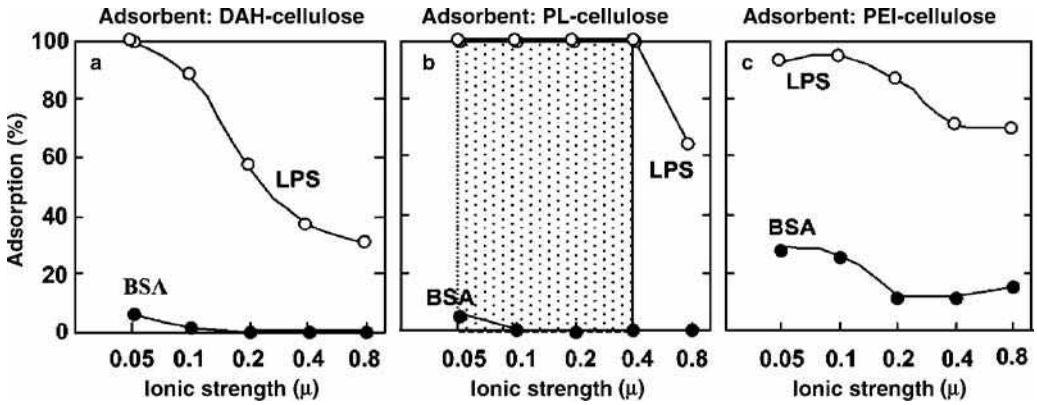

Fig. 4 Effects of ionic strength on selective adsorption of LPS from a BSA solution containing LPS by the various aminated cellulose adsorbents reported in Fig. 2. The selective adsorption of LPS was determined by a batchwise method with 0.2 g of the wet adsorbent and 2 ml of a sample solution [BSA: 500 μg/ml, LPS (*E. coli* O111:B4): 100 ng/ml, pH 7.0, and ionic strength of $\mu = 0.05$–0.8].

of LPS after treatment were less than 100 pg/ml [1 endotoxin unit (EU)/ml] and each BSA recovery was over 95%.[10] The threshold level for intravenous application is set to 5 EU per kg body weight per hour by all pharmacopoeias.[2] The PL-cellulose adsorbent was able to remove LPS from a BSA solution to a level below 1 EU/ml.

As regards the adsorbing capacity of LPS, the cationic polymers with large pore sizes show a greater capacity, because of the entry of LPS molecules into the large pores. We have already reported[10] that PL cellulose with $M_{lim} > 2 \times 10^6$ can reduce the concentration of LPS to 0.1 EU/ml or under in a LPS solution, at a neutral pH and $\mu = 0.05$–0.4. As shown in Table 1, Polymyxin B-Sepharose ($M_{lim} > 2 \times 10^6$) and PL cellulose (10^6) ($M_{lim} > 2 \times 10^6$) readily removed LPS from lysozyme and myoglobin solutions at pH 7 without a loss of protein. This is because the ionic interaction of the adsorbent with lysozyme (p*I*: 11.0) and myoglobin (p*I*: 6.8) is not induced at pH 7.0. Thus the cationic polymer particles having a large pore size are suitable as an adsorbent for removal of LPS from bioproducts (p*I*: 7.0–11.0) containing large quantities of LPS, such as a crude antigen solution originating from a Gram-negative bacterium.

CONCLUSIONS

The present results suggest that PL-cellulose spherical particles can reduce the concentrations of natural LPS to 1 EU/ml or lower in drugs and fluids used for intravenous injection, at a neutral pH and ionic strengths of $\mu = 0.05$–0.4. These processes did not affect the recovery, even of acidic proteins such as BSA. The high LPS-adsorbing activity of the PL cellulose is possibly due to the cationic properties of the ligand and its suitable hydrophobic properties. The high LPS selectivity of the particles with small pore size is due to the size-exclusion effects on protein molecules. By contrast, that of the particles with large pore sizes is due to the decreases in ionic interactions for net-negative charged proteins, which arise when the buffer's ionic strength is adjusted to 0.2 or stronger.

For practical application, ease of regeneration is very important. The PL-cellulose spherical particles can be completely regenerated by frontal chromatography with 0.2 *M* sodium hydroxide followed by 2.0 *M* sodium chloride.[10] Their stable structures, even under extreme pH values, are due to their –CHNH– bonds. Of course, the development of even better adsorbents should be pursued, by continuing this search for materials. To achieve selective removal of LPS, it is important to not only select a suitable ligand, but also to adjust the pore size of the matrix.

INTRODUCTION

Among various types of countercurrent chromatographic instruments developed in the past, the cross-axis coil planet centrifuge (cross-axis CPC) is one of the most useful systems for separation of numerous kinds of natural and synthetic products.[1–3]

The cross-axis CPC produces a unique mode of planetary motion, such that the column holder rotates about its horizontal axis while revolving around the vertical axis of the centrifuge.[4,5] This motion provides satisfactory retention of the stationary phase for viscous, low-interfacial tension, two-phase solvent systems, such as aqueous–aqueous polymer phase systems. Our previous studies demonstrated that the cross-axis CPC equipped with a pair of multiplayer coils or eccentric coil assemblies in the off-center position was very useful for the separation of proteins with polyethylene glycol-potassium phosphate solvent systems.[6–8] The apparatus is also useful for the separation of highly polar compounds such as sugars,[9] hippuric acid, and related compounds,[10] which require the use of polar two-phase solvent systems.

This entry illustrates the separation of biotic dicarboxylic acids using the cross-axis CPC with eccentric coil assemblies.[11]

CCC APPARATUS AND SEPARATION COLUMNS

The cross-axis CPC produces a synchronous planetary motion of the column holder, which rotates about its horizontal axis and simultaneously revolves around the vertical axis of the apparatus at the same angular velocity. In the $X - 1.5L$ type of the apparatus, the column holder was mounted at an off-center position ($X = 10$ cm and $L = 15$ cm), which provides efficient mixing of the two-phase solvent systems and stable retention of the stationary phase in the coiled column.

The separation column was prepared using a pair of eccentric coil assemblies, which were made by winding a 1 mm I.D. polytetrafluoroethylene (PTFE) tubing onto 7.6 cm long, 5 mm O.D. nylon pipes forming a series of tight left-handed coils. A set of these coil units was symmetrically arranged around the holder hub of 7.6 cm diameter in such a way that the axis of each coil unit is parallel to the axis of the holder. A pair of eccentric coil assemblies was mounted on the rotary frame, one on each side, and serially connected with a flow tube.

CCC SEPARATION OF DICARBOXYLIC ACIDS

The chemical structures of eight typical biotic dicarboxylic acids are shown in Fig. 1. They are extremely hydrophilic and require a specific reaction for detection using the color-producing reagent such as 2-nitrophenylhydrazine hydrochloride.[12–13]

Fig. 2 illustrates the partition coefficient (K) values for these dicarboxylic acid samples in the polar two-phase solvent systems composed of methyl *t*-butyl ether (MBE)/1-butanol/acetonitrile (ACN)/aqueous 0.1% trifluoroacetic acid (TFA), at various volume ratios. K values of the organic acids decreased as the hydrophobicity of the solvent system was increased, except for fumaric acid, which showed high K values regardless of the phase composition.

Fig. 3 illustrates the CCC chromatograms of dicarboxylic acids obtained with the above solvent system. In Fig. 3A, maleic acid and fumaric acid are separated at a volume ratio of 1 : 0 : 0 : 1, which is used for the separation of aromatic acids such as hippuric acid.[10] Using a more polar solvent system, at a volume ratio of 2 : 0 : 2 : 3, tartaric acid, succinic acid, and fumaric acid were well resolved by the lower aqueous mobile phase, as shown in Fig. 3B.

Fig. 4 illustrates a chromatogram of oxalic acid, malonic acid, and succinic acid obtained using the most polar

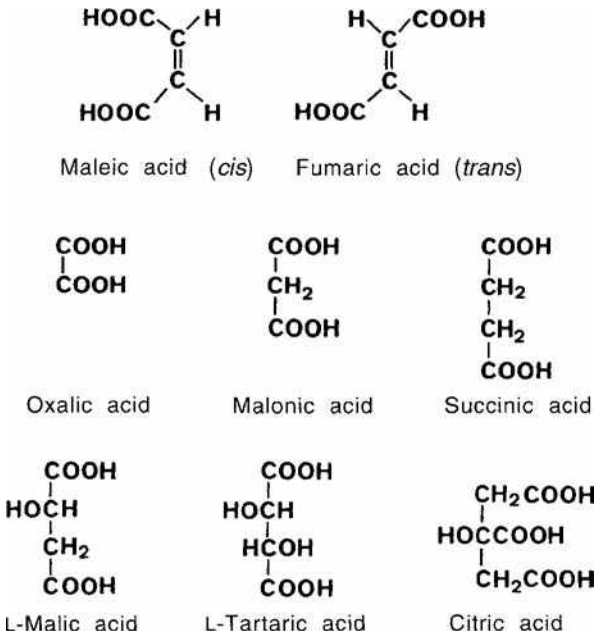

Fig. 1 Chemical structures of polar organic acids.

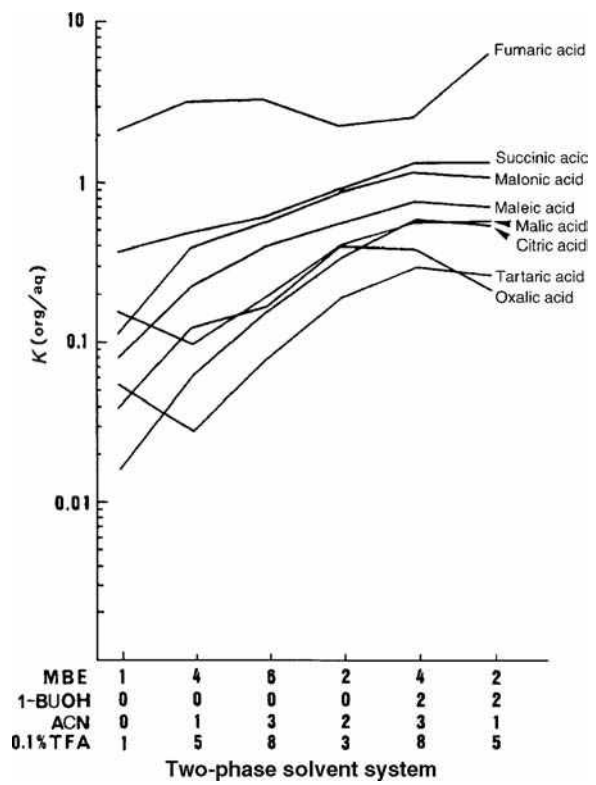

Fig. 2 Partition coefficients (K org/aq) of polar organic acids in methyl t-butyl ether/1-butanol/acetonitrile/aqueous 0.1% trifluoroacetic acid system. K is expressed by solute concentration in the organic phase divided by that in the aqueous phase. MBE = methyl t-butyl ether; 1-BuOH = 1-butanol; AcN = acetonitrile; TFA = trifluoroacetic acid.

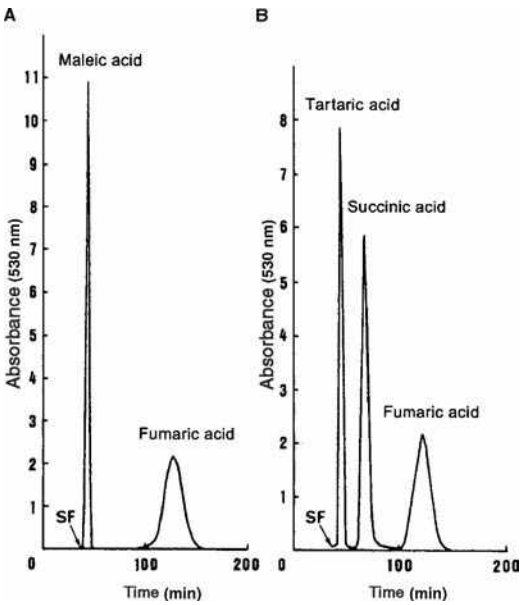

Fig. 3 CCC separation of polar organic acids by cross-axis CPC. Experimental conditions: apparatus, cross-axis CPC equipped with a pair of eccentric coil assemblies, 1 mm I.D. and 26.5 ml total column capacity; sample, (A) maleic acid (3 mg) and fumaric acid (3 mg); (B) tartaric acid (5 mg), succinic acid (5 mg), and fumaric acid (2.5 mg); solvent system, methyl t-butyl ether/1-butanol/acetonitrile/aqueous 0.1% trifluoroacetic acid (A) (1 : 0 : 0 : 1); (B) (2 : 0 : 2 : 3); mobile phase, lower phase; flow rate, 0.4 ml/min; revolution, 800 rpm. SF = solvent front.

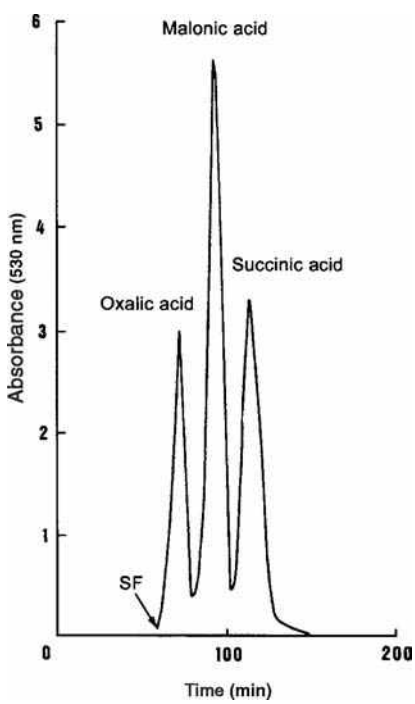

Fig. 4 CCC separation of oxalic acid, malonic acid, and succinic acid by cross-axis CPC. Experimental conditions: sample, 3 mg each; solvent system, 1-butanol/water; flow rate, 0.25 ml/min. For other experimental conditions, see the Fig. 3 caption. SF = solvent front.

binary solvent system, composed of 1-butanol/water. All components were well resolved from each other and eluted within 2.3 hr, using the lower-aqueous phase as the mobile phase.

As described above, various polar organic acids, such as dicarboxylic acids, can be separated with polar two-phase solvent systems, using the cross-axis CPC equipped with a pair of eccentric coil assemblies mounted in the off-center position.

Abstract
The demand for analytical methods suitable for accurate and reproducible determination of drugs and metabolites in biological samples has increased significantly in the past few years. High-performance liquid chromatography (HPLC) is the most important technique used for this purpose, but electromigration techniques represent a powerful alternative. We discuss here some fundamental aspects of capillary electrophoresis (CE) and related electrokinetic separation techniques applied to the analysis of drugs and metabolites in biological samples. In addition, recent developments in these techniques and important aspects that could be addressed to obtain reliable methods for bioanalysis are also discussed.

INTRODUCTION

The demand for analytical methods suitable for accurate and reproducible determination of drugs and their metabolites in biological samples has increased significantly during recent years, as the data obtained in this kind of analysis are essential for drug discovery, modern drug therapy, diagnosis, clinical and forensic toxicology, and for assessment of drug abuse.[1] High-performance liquid chromatography (HPLC) has been the main technique used for this purpose, but capillary electrophoresis (CE) and related techniques have begun to be explored extensively. Several review papers have appeared in recent literature.[2–6] In addition, routine CE methods have been successfully submitted to regulatory authorities, including the US Food and Drug Administration.[7]

CE has several advantages for the analysis of drugs in biological samples. High separation efficiency is the most important one, allowing the resolution of compounds with similar structures and preventing the interference of matrix compounds, metabolites, and other coadministered drugs. Due to the several separation mechanisms that are possible, CE is a versatile technique; it has been considered complementary to HPLC. For instance, CE is particularly attractive for the analysis of polar and/or basic drugs and their metabolites, including phase II metabolites such as glucoronides, sulfates, etc. that are not easily analyzed by chromatographic techniques. The simplicity of the instrumentation, the relatively easy method development, the speed of the analysis, the small amounts of samples (nanoliters), reduced operational costs, and the production of minimal amounts of waste, mostly of an aqueous buffer, are also important characteristics of this technique for biomedical applications. Owing to the limited sample volume analyzed and the short optical path length available when employing on-capillary detection, CE is characterized by relatively poor limits of detection. To minimize the impact of this feature, several approaches have been used, such as the use of more sensitive detection systems and concentration of the analyte by a suitable sample extraction procedure from the matrix or by online enrichment.[8]

We discuss here some fundamental aspects of CE and related electrokinetic separation techniques applied to the analysis of drugs and metabolites in biological samples. In addition, recent developments in these techniques and important aspects that could be addressed to obtain reliable methods for bioanalysis are also discussed.

ELECTROKINETIC TECHNIQUES FOR THE ANALYSIS OF DRUGS AND METABOLITES IN BODY FLUIDS

Free-solution capillary electrophoresis (FSCE) is the major technique used for drug analysis, considering the fact that many drugs have acidic or basic groups that allow them to analyzed as charged molecules. In this technique, the capillary is filled with a buffer solution and the separation is based on the different electrophoretic mobilities of the solutes. Separation of both anionic and cationic solutes is possible, owing to electro-osmotic flow (EOF). The pH of the buffer has a major influence on selectivity, but other factors such as buffer concentration, additives, etc. should also be considered during method development.[9]

Encyclopedia of Chromatography, Third Edition DOI: 10.1081/E-ECHR3-120045251

If the separation is not possible by FSCE, or if neutral drugs are to be analyzed, micellar electrokinetic capillary chromatography (MEKC) should be considered. In this case, a charged surfactant is added to the running buffer at a concentration above its critical micellar concentration; sodium dodecyl sulfate (SDS) is the main surfactant employed for this purpose. Neutral solutes partition with these micelles and their separation are based on their hydrophobic character. Charged solutes could also interact with the charged micelles. In addition to buffer type, concentration, and pH (typically between 7 and 10 for SDS), other parameters such as type and concentration of the surfactant, presence of organic solvent, urea, cyclodextrin or other additives, temperature, etc. should also be optimized.[9] Microemulsion electrokinetic chromatography (MEEKC) has recently appeared as a complementary technique to MEKC. In this case, the solutes interact with an oil droplet instead of a micelle.[10]

During recent years, there has been an increasing interest in using new electromigration technology for the analysis of drugs in biological samples. Capillary electrochromatography (CEC) is a hybrid technique that combines the advantages of CE with those of HPLC. It is similar to CE, as the separation is carried out in a capillary and the driving force for analyte movement is the EOF, resulting in reduced solvent consumption and high efficiency. The CEC also has features in common with HPLC, owing to the use of a stationary phase, providing additional selectivity and allowing the resolution of compounds not resolved by CE. Generally, the columns used in CEC have been classified into three types: packed, open-tubular, and continuous-bed or monolithic columns.[11] The major drawbacks associated with packed capillaries originate from the presence of frits, which retain the particles inside the column and can be responsible for bubble formation and zones of heterogeneities inside the packed capillary. These problems can be overcome by the use of monolithic stationary phases that eliminate the necessity for frits.[12] Monolithic stationary phases can be based on inorganic or organic polymers. The inorganic based monolithic phases are prepared by the sol–gel process whereas the monolithic phases based on organic polymers are generally made by in situ polymerization of monomers, cross-linkers, and porogens. Due to characteristics such as good permeability, high stability, fast mass transfer, and ease of modification, monolithic materials have been intensively used for both CEC and capillary liquid chromatography.

The use of organic solvents as the electrolyte medium is a relatively recent development in CE. Typically, the electrolytes are prepared in 100% organic solvents such as methanol or acetonitrile. The use of non-aqueous solvents affects the solvation of the charged molecules and also their pK_a values, providing additional selectivity to that obtained under aqueous conditions. Selectivity can also be altered by the use of additives such as ion-pair reagents, cyclodextrin, etc. Non-aqueous CE has also proved to be a powerful tool when the analyte has solubility and/or stability problems in aqueous solutions.[13]

Another direction in the development of electromigration techniques is the use of microchip technology. Microfabricated chips have advantages compared to conventional capillaries. They are disposable, rugged, and inexpensive. In addition, these systems can offer enhanced performance in terms of fast response and increased analysis speed. Through the use of chips with several separation microchannels, greater improvement in analysis speed is easily achieved. However, the applications of on-chip CE an on-chip CEC have centered on protein and DNA analysis.[13,14,15]

DETECTION

Detection in electromigration techniques is normally carried out by UV detection. In spite of its widespread use, UV detection offers limited concentration sensitivity for CE and related techniques, owing to the extremely short optical path lengths afforded by the small inner diameters of the capillaries. To maximize sensitivity, detection is often performed at low wavelengths such as 200 nm or using an extended light path (bubble cell) or high sensitivity cells.[16,17]

In addition to UV detection, two other more sensitive and selective detection systems have attracted attention for the analysis of drugs and metabolites in biological samples: laser-induced fluorescence (LIF) and mass spectrometry (MS). A powerful detection system is that which is based on LIF. The LIF detection provides extremely high mass sensitivity, but it is only applicable to some analytes that absorb in the 325 nm (helium–cadmium) or 488 nm (argon) region, as lasers are only commercially available for these wavelengths. Derivatization with fluorescent tags is an alternative for non-fluorescent species.[16,17]

The development of electrospray ionization–mass spectrometry (ESI–MS) has had a dramatic impact on the practice of bioanalytical chemistry by providing great selectivity and more sensitivity, thereby reducing, significantly, the time necessary for method development. ESI–MS has been successfully coupled to HPLC and, more recently, to CE and CEC systems.[18] The advantages of the system providing either selectivity/sensitivity or additional information for structural elucidation have increased the interest in this technique for biomedical applications. However, interfacing CE or CEC systems to MS is a difficult task due to limitations on the composition of the background electrolyte that could be used in the separation; in addition, the flow rates required to maintain a stable electrospray could only be supplied under conditions giving a maximized

EOF. The use of a flowing sheath liquid was offered as a solution to these problems and this design is most commonly used in commercial interfaces.[19]

SOME IMPORTANT ASPECTS FOR THE ANALYSIS OF DRUGS AND METABOLITES IN BODY FLUIDS

Sample Preparation and Concentration

When the concentration of the analyte is high enough, small amounts of biological samples such as serum, plasma, urine, etc., can be directly injected into the capillary, mainly when using MEKC, owing to the use of surfactants that solubilize proteins. However, the analysis of high-ionic-strength matrices can result in bandspreading, while proteins can be adsorbed onto the capillary walls, affecting reproducibility of the analysis.

To avoid the problems related to proteins and high salt concentration and also to obtain the detection of analytes usually present in the nanogram per milliliter range, some kind of sample preparation is frequently used. Conventional off-line sample preparation techniques such as protein precipitation, liquid–liquid extraction, and solid-phase extraction (SPE) have been used for sample preparation in several procedures described in the literature.[20] The main disadvantage of these off-line preconcentration methods is the inefficient use of the concentrated sample, because usually less than 1% of it is injected into the capillary. Regarding this aspect, solid-phase extraction has the advantage of easy automation; online SPE coupled to CE systems seems to be very attractive.[21] This technique is usually carried out using a short-length capillary packed with appropriate adsorbent material connected to the separation capillary.

Solid-phase microextraction (SPME)[20] and membrane microextraction[22] are new and very attractive sample preparation techniques because of low, or no, requirement of organic solvent. In SPME, a fiber coated with a stationary phase is used as the extraction medium. After extraction, the analytes could be desorbed into a suitable eluent and analyzed by CE. Membrane extractions have been performed using several systems. The most interesting one is based on the use of a hollow fiber. In this case, the hollow fiber is impregnated with an organic solvent and filled with an acceptor phase. When an aqueous solution is used as the acceptor phase, it can be directly analyzed by the CE system. Online extraction using these techniques is also possible. They are still less frequently used for the analysis of drugs in biological samples, but the interest in them has increased.

As pointed out previously, the lack of sensitivity in CE is the major concern when this technique is applied to the analysis of drugs in biological samples. One way to improve the sensitivity is to concentrate a large volume of sample introduced in the capillary (>5% of the capillary volume) using stacking techniques.[23] The simplest and most extensively used sample stacking effect is obtained by dissolving the extraction residue sample in diluted running buffer solution or in water. The stacking effect can also be observed when the sample is dissolved in acetonitrile or acetonitrile–water mixtures because of its low conductivity that can cause some stacking because of the high field strength. The stacking effect could also be obtained by injecting a small plug of water or other low conductivity solvent before the sample is injected electrokinetically, a procedure named field-amplified sample injection or head-column field-amplified sample stacking.[23]

Qualitative Aspects of CE-based Methods

As in related chromatographic methods, qualitative analysis is performed by comparing retention data and by using additional techniques. Migration times in CE are less reproducible than retention times (HPLC), owing to effects of analysis parameters on electro-osmosis and electrophoretic mobility. The use of internal markers has reduced the relative standard deviation (RSD) to acceptable values. The adsorption of proteins and other sample components onto the capillary wall also results in migration time variations. These retained compounds can be removed using a washing procedure between analyses. Another way to decrease protein adsorption onto the capillary is the use of dynamically or permanently coated capillaries. Capillaries coated with polyvinyl alcohol, cellulose derivatives, and polyacrylamide have been used.[8]

Another factor that can result in migration time variation is buffer electrolysis (buffer depletion). Several approaches have been used to reduce buffer depletion, such as the use of high concentration buffers with optimum buffer capacity, replenishment, changing the vials after a certain number of analyses, etc. During method development, buffer depletion should be investigated before the method is submitted to a validation procedure.[8]

Identification by comparing migration times (sometimes spiking the sample with a standard) is only suitable for non-complex samples and when the available information for the sample is enough for the analyst to have a certain degree of confidence. For really unknown samples, the confirmation of sample identity can be obtained using information from a diode array detector and MS detection.[13]

Quantitative Aspects of CE-based Methods

The quantification of drugs and metabolites in biological samples is performed by comparing peak areas or, less frequently, peak height of the analytes in the unknown sample with those obtained in quality control samples prepared by spiking the same matrix with known amounts of the analytes. The reproducibility of areas is mainly dependent on the volume of sample injected, which can

be affected by the temperature in hydrodynamic injection owing to changes in buffer viscosity. When using electrokinetic injection, the amount of sample introduced into the capillary depends on the EOF and the electrophoretic mobility of the analyte. Therefore, factors affecting the EOF, such as temperature, ionic strength, buffer composition, and pH will affect the precision of the sample volume introduced into the capillary. In addition, the amount of sample injected also depends on the sample composition as well as on the properties of the analytes.[24]

Advances in the development of equipment (better control of temperature and better injection systems) and the use of an internal standard to correct errors owing to sample preparation and injection have reduced the impact of injection variation on the final precision of the method.

The results obtained when analyzing a real sample using a specific analytical method can only be acceptable if the method is submitted to a reliable validation process. Method validation is particularly important for the analysis of drugs and metabolites in biological samples, as the results are used to adjust drug dosage [therapeutic drug monitoring (TDM)], to establish pharmacokinetics, metabolism, bioavailability, and stability parameters (accepted by health official authorities when a new drug is under the registration process), and for legal applications (forensic toxicology).

The most important parameters in method validation for bioanalysis applications are linearity, precision, accuracy, selectivity, and limits of detection and quantification. In addition to these parameters, other method properties should also be evaluated, such as recovery to establish the efficiency of the method used for sample preparation, sample stability to evaluate the period allowed for sample storage, and robustness.[25–26]

To evaluate the linearity of the method, drug-free matrix samples are spiked with known amounts of the drug. A minimum of five to eight calibration standards is required, including the concentration established as the quantification limit. Peak area is frequently used to establish the linear relationship between detector response and concentration because it is less influenced by peak distortion at high concentrations, which sometimes results in non-linear calibration curves when using peak height. In addition, peak area can be corrected (peak area/migration time ratio), avoiding any influence of drift of migration times.

The precision of a bioanalytical method is a measure of the random error and is defined as the agreement between replicate measurements of the same sample. It is expressed as an RSD. Precision can be evaluated by analyzing replicate samples on the same day (repeatability or within-day precision) or on different days (intermediate precision or between-day precision). The accuracy is defined as the agreement between the measured value and the true value. Accuracy is determined using reference samples, when available, or spiking a blank matrix with known amounts of the analyte and considering this value as the real concentration. Values lower than 15% for both precision and accuracy are considered acceptable for the analysis of drugs and metabolites in biological samples.

The sensitivity of the method is evaluated by the limit of detection and quantification. In general, there are no specific criteria for the limit of detection, but for bioanalysis purposes, the limit of quantification is established for the concentration with precision and accuracy lower than 20%. Limits of detection and quantification obtained in CE with UV detection are generally higher than in HPLC, owing to the small optical path in the detection window and injected volumes. As discussed previously, by using preconcentration procedures (off-line sample preparation and/or stacking sample injection techniques) and a more sensitive detection system, particularly LIF and MS detection, suitable detection or quantification limits could be obtained for the application of the methods to the analysis of real samples.

Selectivity is evaluated by analyzing the blank matrix and commonly used drugs and/or metabolites under the same conditions as developed for the analysis of the drug. Reproducibility in migration times is essential to evaluate the selectivity of the method. As peak width depends on the injected amount, the effects of sample overload must be investigated. Another way to validate the specificity is to assess peak purity using diode array or MS detection.

For robustness testing, several parameters are evaluated which are expected to vary slightly during routine use, such as age of the analytical solutions, buffer pH, temperature, rinse cycles, etc. It is important to observe the influence of all of these parameters on migration times, resolution of critical peak pairs, efficiencies, and peak areas.

Stability data are required to show that the concentration of the analyte in the sample at the time of analysis corresponds to the concentration of the analyte at the time of sampling. The stability test is carried out by evaluating the stability of standard solutions and the analyte in the biological sample and in the processed sample.

APPLICATIONS

Enantioselective Analysis of Drugs and Metabolites

Considering that a large number of drugs are chiral and used as racemic mixtures, and that the enantiomers may have very different pharmacokinetic and pharmacodynamic properties, there is an increased interest in the production of chiral drugs as single enantiomers as well as in the evaluation of the stereoselective properties of drugs that have already been used as racemates. This new trend has resulted in an increase in the demand for enantioselective methods for the analysis of chiral drugs and metabolites in biological fluids to permit pharmacokinetic and

metabolic studies. The main advantages of CE for the enantioselective analysis of chiral drugs are the extremely high efficiency, instrumentation simplicity, low sample and reagent consumption, and speed in method development and analysis. Although chiral CE separations can be carried out in different modes, FSCE, EKC, and, more recently, CEC are the most widely used methods. The separation of enantiomers by FSCE and EKC is possible by the addition of chiral selectors to the running buffer. The most common chiral selectors are cyclodextrins and their derivatives. In CEC, the capillary is packed or coated with a chiral stationary phase. The most common application of chiral CE is in the chiral purity testing of drug substance material, but the number of applications involving the analysis of the enantiomers in biological fluids has grown rapidly in recent years.[27]

Pharmacokinetics and Metabolic Studies

Emphasis has recently been placed on the importance of performing well-designed pharmacokinetics–pharmacodynamic, as well as metabolic studies, as early as possible in the process of new drug development. Advantages of this approach include greater efficiency in establishing effective dosage regimens, increased understanding of drug action, and identification of metabolites and their pharmacological activity. In addition, the influence of age, disease, sex, and genetic and other factors on drug disposition must also be evaluated, including the drugs already marketed, to make them safer. The high resolving power of the electrophoretic techniques, including for phase II metabolites, is the main advantage for pharmacokinetic and metabolic studies. The low requirement of sample volume is also very attractive for certain studies such as investigations involving pediatric patients. Unfortunately, the low concentration sensitivity of CE with UV detection has limited its application in this area. The use of LIF and MS detection seems to be the appropriate direction for the evolution of applications of CE in pharmacokinetic studies. MS detection is also important for the identification of unknown metabolites in in vitro and in vivo metabolism studies.[6]

Forensic Applications

CE is also useful in forensic toxicology laboratories to screen urine for drugs of abuse such as opiates, barbiturates, benzodiazepines, amphetamines, morphine, etc. and also for screening postmortem fluids for illicit drugs or elevated levels of legal drugs. When coupled to MS, CE is a powerful tool in the confirmation of positive results.[4]

CONCLUSIONS

Electromigration techniques represent a powerful alternative to the well-established HPLC based methods for the analysis of drugs and their metabolites in biological samples, with the advantages of high resolution power, low cost, low-waste production, short analysis time, and easy method development. The general direction of developments for CE is toward ultrafast separations using microchip technologies, high-efficiency analysis employing narrow capillaries, and high-throughput analyses using array systems. In addition, coupled systems, mainly CE–MS or CEC–MS, will be routinely used for the separation and identification of complex mixtures in the near future. Among these, the use of electrophoretic techniques coupled to MS detections seems to be the logical further step for the analysis of drugs in biological fluids.

Bonded Phases in HPLC

Joseph J. Pesek

Department of Chemistry, San Jose State University, San Jose, California, U.S.A.

INTRODUCTION

The development of chemically bonded stationary phases is one of the major factors that lead to the growth of high-performance liquid chromatography (HPLC) and is responsible for its importance as a separation technique.

HISTORICAL BACKGROUND

In its earliest form, gravity flow moved the mobile phase through the column which was generally packed with a solid adsorbent such as silica or alumina. In a few instances, a high-molecular-weight liquid was coated on the solid particle to provide different types of selectivity. Under these circumstances, the column was similar to those used in gas chromatography (GC), where a liquid stationary phase was held in place by physical forces alone. In GC, the requirement for the stationary phase to remain in place for a long time is low volatility. In liquid chromatography (LC), the requirement for durability is insolubility in the mobile phase. However, with the development of reliable high-pressure pumps that could produce stable flow rates for long periods of time, immiscibility with the mobile phase is not sufficient. At the pressures used to force solvents through most packed HPLC columns (from tens to a few hundred atmospheres), the shear forces developed at the interface between the stationary and the mobile phases are high enough to remove even insoluble liquids from the surface of the solid support. The stationary phase then is forced out of the column as an insoluble droplet. Removal of the stationary phase from a chromatography column is usually referred to as "column bleed." Therefore, it was necessary to develop a means of fixing the stationary phase on the solid support through a chemical bond. If the chemical bond between the surface of the solid support and the compound used as the stationary phase is stable under the experimental conditions of the HPLC experiment (temperature and mobile-phase composition), then column bleed will be avoided.

Fortunately, the most common support material used in LC experiments was silica. The chemistry of silica had been investigated for many years so a considerable amount of information was available about possible reactions on its surface. Silica can be considered as a polymer of silicic acid (H_2SiO_3). The terminal groups of the polymer located on the surface of the solid are hydroxide groups. These Si–OH functions are referred to as silanols. Because they come from an acid precursor, they are acidic themselves and generally have a pK_a near 5. This value is variable, depending on other constituents in the silica matrix such as metals. The structure of silica, including its major chemical features, are shown in Fig. 1. The polymeric unit consists of a series of siloxane bonds (–Si–O–Si–) that are slightly hydrophobic in nature. What is generally regarded as the most prominent feature on the surface is the silanol group, as indicated earlier. In a few cases, a single silicon atom will have two hydroxyl groups, which is called a geminal silanol. The silanols exist in two forms. First, they can be independent of other entities around them and are thus referred to as free or isolated silanols. If they are close enough to interact with a neighboring silanol, then these moieties become hydrogen-bonded or associated silanols. All forms of silanol are polar hydrophilic species. The relative number of free versus hydrogen-bonded silanols also has an influence on the pK_a value of the silica. Finally, because of the polar and hydrogen-bonding characteristics of the silanols, water is strongly adsorbed to the surface. This water is not easily removed, even at prolonged heating above 100°C. It is this complex matrix that must undergo a chemical reaction in order to attach a moiety to the surface as a stationary phase. According to the findings of early investigations on the reactivity of silica, it was determined that the silanol groups were the site of chemical modification on the surface.

The concept of attaching an organic moiety as a stationary phase to a silica surface was first applied in packed-column GC. The rationale for developing these materials was to prevent column bleed at the high temperatures required for some separations in GC. As long as the chemical bond was stable, the organic moiety would remain fixed to the surface. Some of the reactions utilized for the attachment of organic compounds in the synthesis of bonded stationary phases were originally developed for the modification of ordinary glass surfaces. Therefore, it was known that most of these modified surfaces were reasonably temperature stable and should be applicable to the bonding of organic groups onto the porous silica particles used as supports in chromatography.

The first reaction used for the modification of porous silica in chromatography involves an alcohol as the organic

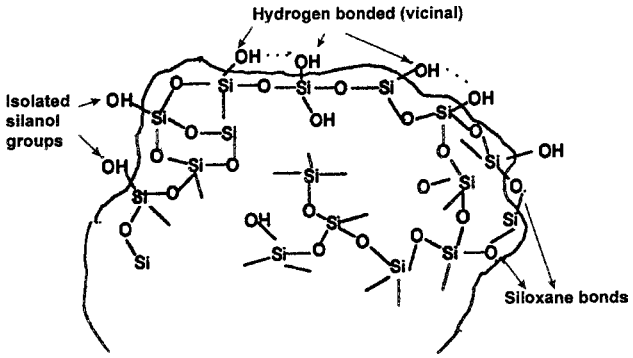

Fig. 1 Structure of silica showing the surface chemical features.

species. This process is referred to as an esterification reaction. This may seem like incorrect nomenclature in order to describe the chemical process taking place between the silianol (Si–OH) and the organic compound (R–OH). However, the OH of the silanol is an acidic species, so the reaction taking place involves an acid and an alcohol, which, in typical organic chemistry nomenclature, is an esterification. The chemical reaction is illustrated in Fig. 2. The product of this reaction can be used as a stationary phase in GC because the material is thermally stable up to temperatures of approximately 300°C. However, the Si–O–C bond that exists between the surface and the bonded moiety is hydrolytically unstable in the presence of relatively small amounts of water. Therefore, these materials cannot be used for stationary phases in LC, where water comprises even a small fraction of the mobile phase.

The second reaction shown in Fig. 2 is the most common means used for the modification of silica surfaces. This method is referred to as organosilanization. Within this general reaction scheme, there are two possible approaches, as shown in Fig. 2. The first possibility involves the use of an organosilane reagent (RR′R′SiX) with only a single reactive group (X). The substituents on the silicon atom are as follows: X is a halide, most often Cl, methoxy or ethoxy; R is the organic moiety giving the surface the desired properties (i.e., hydrophobic, hydrophilic, ionic, etc.), and R′ is a small organic group, typically methyl. This reaction leads to a single siloxane bond between the reagent and the surface. Because of the single point of attachment of the reagent, the resulting bonded material is referred to as a monomeric phase. The second approach to organosilanization involves a reagent with the general formula $RSiX_3$. The substituents on the silicon atom in this reagent are defined as above. The basic difference between the approaches (as shown in Fig. 2) is that the reagent with three reactive groups results in bonding to the surface as well as cross-linking among adjacent bonded moieties and is referred to as a polymeric phase. This cross-linking effect provides extra stability to the bonded moiety but is less reproducible than the monomeric method. The one-step organosilanization procedure

REACTION TYPE	REACTION	SURFACE LINKAGES
ESTERIFICATION	$Si\text{-}OH + R\text{-}OH \rightarrow Si\text{-}OR + H_2O$	Si - O - C
ORGANOSILANE	$Si\text{-}OH + X\text{-}SiR'_2R \rightarrow Si\text{-}O\text{-}SiR'_2R + HX$ $\equiv Si\text{-}OH + X_3Si\text{-}R \rightarrow \equiv Si\text{-}O\text{-}Si(\equiv)_2\text{-}R + 3HX$	Si - O - Si - C
CHLORINATION FOLLOWED BY REACTION OF GRIGNARD REAGENTS OR ORGANOLITHIUM COMPOUNDS	$Si\text{-}OH + SOCl_2 \xrightarrow{\text{Toluene}} Si\text{-}Cl + SO_2 + HCl$ a). $Si\text{-}Cl + BrMgR \rightarrow Si\text{-}R + MgClBr$ or b). $Si\text{-}Cl + Li\text{-}R \rightarrow Si\text{-}R + LiCl$	Si - C
a). TES SILANIZATION	a). $\equiv Si\text{-}OH + \equiv Si\text{-}OH + \equiv Si\text{-}OH \rightarrow \equiv Si\text{-}O\text{-}Si(\equiv)_2\text{-}H$	a). Si - H monolayer
b). HYDROSILATION	b). $Si\text{-}H + CH_2 = CH\text{-}R \xrightarrow{\text{Catalyst}} Si\text{-}CH_2\text{-}CH_2\text{-}R$	b). Si - C

Fig. 2 Reactions for the modification of silica surfaces.

is relatively easy and the modification of the surface can be done by stirring the reagent continuously with the porous silica support. The reaction mixture is heated for about 1–2 hr, then the reagent solution is removed, usually by centrifugation and/or filtration. The bonded phase is then washed with several solvents and dried under vacuum to remove as much of the rinse solutions as possible. Organosilanization accounts for virtually all of the commercially available chemically bonded stationary phases.

Another method that has been reported for the modification of silica supports is based on a chlorination/organometalation two-step reaction sequence. This process is also depicted in Fig. 2. In the first step, the silanols on the porous silica surface are converted to chlorides via a reaction with thionyl chloride. This step must be done under extremely dry conditions because the presence of any water results in the reversal of the reaction with hydroxyl replacing the chloride (Si–Cl), resulting in the regeneration of silanols (Si–OH). If the chlorinated material can be preserved (usually done in a closed vessel purged with a dry gas like nitrogen), then an organic group can be attached to the surface via a Grignard reaction or an organolithium reaction. The main advantage of this process is that it produces a very stable silicon–carbon linkage at the surface. However, the stringent reaction conditions for the first step and the possibility of forming salts that could affect chromatographic properties as by-products in the second reaction have resulted in relatively little commercial use of this process.

The final method shown in Fig. 2 involves, first, silanization of the silica surface, followed by attachment of the organic group through a hydrosilation reaction. In the first step, the use of triethoxysilane under controlled conditions results in a monolayer of the cross-linked reagent being deposited on the surface. This reaction results in the replacement of hydroxides by hydrides. In the second step, an organic moiety is attached to the surface via the hydride moiety by a hydrosilation reaction using a catalyst such as hexachloroplatinic acid (Speier's catalyst), but other transition metal complexes or a free-radical initiator have been reported as well. This process also results in a silicon–carbon bond at the surface, does not require dry conditions (water is required as a catalyst in the first step), and is applicable to a variety of unsaturated functional groups in the hydrosilation reaction, although terminal olefins are the most common. The silanization/hydrosilation method also has seen limited commercial utilization to date.

In all of the reactions described, the choice of the organic moiety on the reagent (R group) determines the properties of the material as a stationary phase. Therefore, selection of a hydrophobic moiety where R is typically an alkyl group leads to a stationary phase that selectively retains non-polar analytes. These materials are typically used in reversed-phase chromatography. If the organic moiety contains a polar functional group such as amine, cyano, or diol, then the stationary phase selectively retains polar compounds. These materials are typically used in normal-phase chromatography.

The bonding of the organic group on the surface results in the replacement of silanols whose adsorptive properties are strong, especially for bases, and often non-reproducible. Although it is impossible to replace all silanols, the remaining Si–OH groups are often shielded from solutes by the steric hindrance of the bonded organic moiety. In many cases though, some silanols are accessible to typical solutes. In order to inhibit the interaction between analytes and residual silanols, the bonded phase is subjected to an additional reaction referred to as endcapping. In this case, a small organosilane, often trimethylchlorosilane, penetrates into the spaces between the bonded groups to react with the most accessible silanols. This process generally greatly reduces or eliminates solute interactions with silanols.

After the bonded phase is prepared, it must be packed into a column, usually a stainless-steel tube. In order for the material to form a uniform bed of high density that will not form voids after prolonged use, the packing process must be done under high pressure (>500 atm). The stationary phase is mixed with a solvent of approximately the same density as silica, so that a slurry is formed. This slurry is then forced into the column at high pressure with another solvent, usually methanol. After packing, most stationary phases require several hours of conditioning, with the mobile phase passing through the column at normal flow rates, before actual chromatographic analysis can begin.

Buffer Systems in CE

Robert Weinberger
CE Technologies, Inc., Chappaqua, New York, U.S.A.

INTRODUCTION

The solution contained within the capillary in which the separation occurs is known as the background electrolyte (BGE), carrier electrolyte, or, simply, the buffer. The BGE always contains a buffer because pH control is the most important parameter in electrophoresis. The pH may affect the charge and thus the mobility of an ionizable solute. The electro-osmotic flow (EOF) is also affected by the buffer pH. Table 1 contains a list of buffers that may prove useful in high-performance capillary electrophoresis (HPCE). As will be seen later, only a few of these buffers are necessary for most separations.

Other reagents, known as additives, are often added to the BGE to adjust selectivity (secondary equilibrium), modify the EOF, maintain solubility, and reduce the adherence of the solute or sample matrix components to the capillary wall. Table 2 provides these applications, along with some of the commonly used reagents.

BUFFERS

The selection of the appropriate buffer is usually straightforward. For acids, start with a borate buffer (pH 9.3), and for bases, a phosphate buffer (pH 2.5). These two buffer systems, along with the appropriate additives will work well for most applications. Both buffers have good buffer capacity and the ultraviolet (UV) absorbance of each is low. If bases are not soluble in phosphate buffer, acetate buffer (pH 4) may be more effective. Higher pHs may be required for basic proteins to avoid solute adherence to the capillary wall. If pH 7 is desired, the phosphate buffer works well at that pH. If necessary, the buffer pH can be fine-tuned using a mobility plot.

Alternative buffer systems include zwitterions and dual-buffering reagents. Zwitterionic buffers such as bicine, tricine, N-cyclohexyl-3-aminopropanesulfonic acid (CAPS), morpholino ethane sulfonic acid (MES) and Tris may be useful for protein and peptide separations. An advantage of a zwitterionic buffer is low conductivity when the buffer pH is adjusted to its pI. There is little buffer capacity when the pK_a and pI are separated by more than 2 pH units. When the pI and pK_a are close together, the buffer is known as an isoelectric buffer.[1]

Selection of the appropriate counterion is also important. Lithium ion has the lowest mobility of the alkali earth metals. Its use provides for a low-conductivity buffer. Sodium salts are used more frequently due to purity and availability. It makes little sense to ever use a potassium salt. Dual-buffering systems with low-mobility ions and counterions (Tris-phosphate, Tris-borate, aminomethyl-propanediol–cacodylic acid) are effective in minimizing buffer conductivity. These buffers are often used in the slab–gel, where low conductivity is particularly important.

The buffer concentration plays an important role in the separation. Typical buffer concentrations range from 20 to 150 mM. At the higher buffer concentrations, the production of heat may require the use of lower field strength or smaller-diameter capillaries (25 μm instead of 50 μm). An Ohm's law plot is used to select the appropriate voltage. The advantages of high-concentration buffers include improved peak shape, fewer wall effects, and increased sample stacking.

Low-concentration buffers (less that 20 mM) provide the fastest separations because solute mobility and EOF is inversely proportional to the square root of the buffer concentration. Because the conductivity of a dilute buffer is low, a high electric field strength can be used as well. Problems with low-concentration buffers are loading capacity, wall effects, and poor stacking. Sawtooth-shaped peaks from a process known as electrodispersion may occur whenever the solute concentration approaches the BGE concentration. It also becomes more likely that proteins will adhere to the capillary wall when the buffer concentration is low. Ionic-strength-mediated sample stacking relies on a high-conductivity BGE and a low-conductivity sample.[2] This important process is less effective at low buffer concentrations. When indirect detection is employed, the buffer (indirect detection reagent) concentration must be kept low to optimize sensitivity.[3] Sawtooth peaks are often observed when this technique is used.

It is important to refresh the BGE reservoirs frequently to avoid a process known as buffer depletion.[4] Electrolysis at the respective electrodes produces protons and hydroxide ions. This can cause pH changes in the buffer reservoirs.

High-pH buffers (>pH 11) are used for certain small ion separations and for the separation of carbohydrates using indirect detection. Adsorption of carbon dioxide can cause the buffer pH to decline. It is best to use small containers filled to the top when storing these buffers.

BUFFER ADDITIVES

Secondary Equilibrium

If two solutes are inseparable based on pH alone, secondary equilibrium can be employed to effect a separation. The following equilibrium expressions can be written.[5]

$$A^+ + R \overset{K_A}{\rightleftharpoons} A^+R \quad (1)$$

$$B^+ + R \overset{K_B}{\rightleftharpoons} B^+R \quad (2)$$

If the equilibrium is pushed too far to the left, no separation can occur because A^+ and B^+ are inseparable. When the reagent interacts with the solute, the mobility decreases because the neutral reagent contributes mass without charge. However, if the equilibrium is pushed too far to the right, no separation occurs because A^+R and B^+R are inseparable. Separation only occurs when two conditions are met:

1. K_A does not equal K_B.
2. The equilibrium is not pushed to either extreme.

The next feature to consider is the charge of the reagent and solute. To separate charged solutes, the reagent can be charged or neutral. When the solute is neutral, the reagent must be charged.

Micelles and cyclodextrins are the most common reagents used for this technique. Micellar capillary electrokinetic chromatography (MECC) or MEKC is generally used for the separation of small molecules.[6] Sodium dodecyl sulfate at concentrations from 20 to 150 m*M* in conjunction with 20 m*M* borate buffer (pH 9.3) or phosphate buffer (pH 7.0) represent the most common operating conditions. The mechanism of separation is related to reversed-phase liquid chromatography (LC), at least for neutral solutes. Organic solvents such as 5–20% methanol or acetonitrile are useful to modify selectivity when there is too much "retention" in the system. Alternative surfactants such as bile salts (sodium cholate), cationic surfactants (cetyltrimethylammonium bromide), non-ionic surfactants (polyoxyethylene-23-lauryl ether), and alkyl glucosides can be used as well.

Cyclodextrins (CD) are frequently used for chiral recognition,[7] although they are quite useful for achiral applications as well. Many classes have been used including native, functionalized, sulfobutylether, and highly sulfated CDs. The latter two are generally most effective for chiral and structural isomer separations. The typical CD concentrations range from 1 to 20 m*M* in 20–50 m*M* of borate (pH 9.3) or phosphate buffer (pH 2.5). Other reagents useful for chiral recognition include macrocyclic antibiotics, bile salts, chiral surfactants, non-cyclic oligosaccharides and polysaccharides, and crown ethers.

Additional reagents useful for secondary equilibrium include borate buffer for carbohydrates, chelating agents for transition metals, ion-pair reagents for acids and bases, transition metals for proteins and peptides, silver ion for alkenes, and Mg^{2+} for nucleosides.

Electro-Osmotic Flow Control

The control of EOF is critical to the migration time precision of the separation. Among the factors affecting the EOF are buffer pH, buffer concentration, buffer viscosity, temperature, organic modifiers, cationic surfactants or protonated amines, polymer additives, field strength, and the nature of the capillary surface.

Table 2 Buffer additives.

Purpose	Reagent	Mechanism
Modify mobility	Borate	Complex with carbohydrates, diols
	Calixarenes	Inclusion complex
	Chelating agents	Complex formation with metals
	Crown ethers	Inclusion complex
	Cyclodextrins	Inclusion complex
	Dendrimers	Inclusion complex
	Macrocyclic antibiotics	Inclusion complex
	Organic solvents	Solvation
	Sulfonic acids	Ion-pair formation
	Surfactants	Micelle interaction
	Transition metals	Complex formation
	Quaternary amines	Ion-pair formation
Modify EOF	Cationic surfactant	Dynamic coating, EOF reversal
	Linear polymers	Dynamic coating
	Organic solvents	Affects viscosity
Reduce wall effects	Cationic surfactant	Dynamic coating, EOF reversal
	Linear polymers	Dynamic coating
Polyamines		Covers silanols
Maintain solubility	Organic solvents	Hydrophobicity
	Urea	"Iceberg effect"

At pH 2.5, the EOF is approximately 10^{-5} $cm^2/V/s$ in 50 m*M* buffer. At pH 7, it is an order of magnitude higher. The EOF is inversely proportional to BGE viscosity and is proportional to temperature, up until the point where heat dissipation is inadequate. Organic modifiers such as methanol decrease the EOF because hydro-organic mixtures have higher viscosity compared to water alone. Acetonitrile does not strongly affect the EOF. Polymer additives such as methylcellulose derivatives increase viscosity as well as coat the capillary wall.

Cationic surfactants and protonated polyamines may reverse the direction of the EOF as they impart a positive charge on the capillary wall. This technique is used to prevent wall interactions with cationic proteins. Changing the direction of the EOF is important in anion analysis where comigration of anions and the EOF is required. Otherwise, highly mobile anions such as chloride migrate toward the anode, whereas lower mobility anions are swept by the EOF toward the cathode.

A new series of reagents (CElixir, MicroSOLV, Long Branch, New Jersey, U.S.A.) have been shown to dramatically stabilize the EOF, resulting in highly reproducible run-to-run and capillary-to-capillary migration times.[8] First, a capillary is treated as usual with 0.1*N* sodium hydroxide, followed by a rinse with a polycation solution. Then, a second layer consisting of a polyanion in a buffer at the desired pH is flushed through the capillary. Replicate runs are virtually superimposible, yielding reproducibility seldom found in HPCE. The reagents have been shown to work best for bases below at a pH below the pK_a.

Maintaining Solubility

All solutes and matrix components must remain in solution for an effective separation to occur. In aqueous systems, surfactants and urea are the most useful reagents. Organic solvents can be used as well, but this is less desirable because of evaporation. It can be difficult to separate solutes with widely different solubilities in a single run. In some cases, non-aqueous separations are necessary.

Reducing Wall Effects

Wall effects, or the adherence of material to the bare silica capillary wall, has been a difficult problem since the early days of HPCE, particularly for large molecules such as proteins. Small molecules can have, at most, one point of attachment to the wall and the kinetics of adsorption/desorption are rapid. Large molecules can have multiple points of attachment resulting in slow kinetics. Several solutions have been proposed, including the use of: (a) extreme-pH buffers; (b) high-concentration buffers; (c) amine modifiers; (d) dynamically coated capillaries; and (e) treated or functionalized capillaries.

In the first case, it was recognized that if the buffer pH is greater that 2 units above the protein, the anionic protein

would be repelled from the anionic capillary wall.[9] At a pH < 2, the capillary wall is neutral and does not attract the cationic protein. The problem with this approach is that a wide range of pHs are not available for use and separations of similar proteins may not occur. For high-p*I* proteins such as histones, a buffer pH of 13 is required. The conductivity and UV background of such an electrolyte is too high to be generally applicable.

The use of high-concentration buffers is effective in reducing wall effects. This includes electrolytes containing up to 250 m*M* added salt. The problem with this approach is the high conductivity of the BGE. This requires a reduction in field strength resulting in lengthy separations. Zwitterionic buffers titrated to their p*I* can be used as well at concentrations approaching 1 *M*. At that concentration, it is important to select a reagent with low UV absorption.

The latter three cases are most commonly employed to reduce wall effects. In the third case, amine modifiers such as polyamines are added to the BGE at concentrations ranging from 1 to 60 m*M*.[10] These reagents coat the free silanols and reduce wall interactions. Now, any pH electrolyte can be employed. Diaminobutane, otherwise known as putrecein, is the preferred reagent because it is less volatile compared to diaminopropane. Monovalent amines such as triethanolamine are not as effective in this regard.

Dynamically coated capillaries (case d) are often used to reduce wall effects.[11] The mechanism of charge reversal is as follows. Ion-pair formation between the cationic head group of the surfactant and the anionic silanol group naturally occurs. The hydrophobic surfactant tail extending into the bulk solution is poorly solvated by water. The molecular need for solvation is satisfied by binding to the tail of another surfactant molecule. The cationic head group of the second surfactant molecule now extends into the bulk solution. The capillary wall becomes positively charged and the EOF is directed toward the anode. Separations are performed using the reversed-polarity mode (inlet side negative). Following this approach, a buffer pH is selected that is below the p*I* of the target protein. The cationic protein is now repelled from the cationic wall.

When coated capillaries are employed (case e), conventional buffers without additives to reduce wall effects are used. Urea and/or organic solvents can be added to aid solubility. Reagents for secondary equilibrium can be used as well. It is best to operate at a pH below 8 to maximize the stability of the often labile coating material. Coated capillaries are also used simply to eliminate the EOF in some applications.

Buffer Type and Concentration: Mobility, Selectivity, and Resolution in CE

Ernst Kenndler
Institute for Analytical Chemistry, University of Vienna, Vienna, Austria

INTRODUCTION

Resolution in capillary zone electrophoresis (CZE) is, as in elution chromatography, a quantity that describes the extent of the separation of two consecutively migrating compounds, *i* and *j*. It is the result of the counterplay of two effects: migration and zone dispersion. The different migration velocities of the two separands lead (at least potentially) to the separation of the sample zones. The simultaneous mixing of the samples with the background electrolyte (BGE), caused by a number of processes, results in zone broadening and counteracts separation. Both effects determine the overall degree of separation. A quantitative measure that describes this degree is the resolution a dimensionless number. It is expressed by the difference of the apex of the two peaks, on the one hand. It is of advantage not to measure this difference in an absolute scale (e.g., in seconds when the electropherogram is depicted in the time domain). In fact, a relative scale is taken, which is based on the widths of the peaks. We define the resolution as the difference in migration times, *t*, related to the peak width, taken, for example, by the mean standard deviation of the Gaussian peaks, as the scaling unit:

$$R_{ji} \equiv \frac{t_j - t_i}{2(\sigma_{t,i} + \sigma_{t,j})} \tag{1}$$

Baseline separation is achieved for two peaks with the same area when the resolution is 1.5. For peak area ratios larger than unity, the resolution must be larger.

SELECTIVITY AND EFFICIENCY

This definitional Eq. 1 is not very operative and is, thus, transformed to an expression which more clearly visualizes the dependence of the resolution on sample properties and experimental variables. The migration times are substituted for by the mobilities of the separands, and the standard deviations by the plate height, *H*, or the plate number, *N*, respectively.

The resulting resolution is then

$$R_{ji} = \frac{1}{4}\frac{\mu_i - \mu_j}{\bar{\mu}}\sqrt{\frac{L}{\bar{H}}} = \frac{1}{4}\frac{\Delta\mu}{\bar{\mu}}\sqrt{\bar{N}} \tag{2}$$

where $\bar{\mu}$, $\bar{H}$, and $\bar{N}$ are the average values; *L* is the migration distance.

The resolution consists of two terms, the selectivity term, $\Delta\mu/\bar{\mu}$, with the relative difference of the mobilities, and the efficiency term, the square root of the mean plate number. It must be pointed out that the plate height, $\bar{H}$, on which this plate number is based consists of all the contributions to peak broadening.

At this point, a differentiation should be made between two cases: the simple one, where migration is only caused by the electric force on the ionic separands, and the second, where an additional migration due to the occurrence of an electro-osmotic flow (EOF) takes place.

RESOLUTION IN ABSENCE OF EOF

Two main parameters determine the resolution: the effective mobility and the plate number. The effective mobility of a simple ion (e.g., the anion from a monovalent weak acid) is given by

$$\mu_{\text{eff}} = \frac{\mu_{\text{act}}}{1 + 10^{\text{p}K_a - \text{pH}}} \tag{3}$$

We take, here, only protolysis into consideration and do not discuss such important other equilibria such as complexation or interactions with pseudo-stationary phases. It follows from Eq. 3 that the effective mobility depends on the actual mobility (that of the fully charged particle at the ionic strength of the experiment), on the pK_a value of the analyte, and on the pH of the BGE. It follows that all these properties determine the selectivity term in the resolution.

The actual mobility depends on the following:

1. *The solvent*. There is a more or less pronounced influence of the solvent viscosity, reflected by Walden's rule. However, this rule is obeyed in rare cases; mainly in some mixed aqueous–organic solutions is an acceptable agreement found. On the other hand, in very viscous aqueous solutions of water-soluble polymers, such as poly(ethylene glycol), it was found that the actual mobility is independent of the viscosity.
2. *The size of the solvated ion*. Here, we must note that water is an excellent solvator for anions and cations

Encyclopedia of Chromatography, Third Edition DOI: 10.1081/E-ECHR3-120039897

as well, compared to most organic solvents. Only few exceptions for preferred solvation of the organic solvents are found (e.g., for Ag^+ and acetonitrile).

3. *The ionic strength of the BGE*. The dependence of the mobility on the ionic strength is expressed for simple systems (and simple ions) by the theory of Debye, Hückel, and Onsager. Without going into detail, we can state that the mobility decreases, in all cases, with increasing ionic strength of the BGE, and the decrease is more pronounced the higher the charge number of the ion.
4. *On the temperature*. In aqueous solutions, the mobility increases with temperature roughly by about 3% per degree. This is a strong effect as, for example, a temperature difference of only 5 K between the center and the wall of the separation capillary leads to a mobility difference of about 15%.

The pK_a value is also a function, mainly, of the solvent. Note that the pH scale is strongly dependent on the kind of solvent. Restricting the discussion to protolysis, it can be followed that the pH of the buffer has the most pronounced effect on the effective mobility, because the other effects change the mobility roughly in parallel for all separands. Again, it must be pointed out that other equilibria have an enormous potential to affect the effective mobility (cf. e.g., the use of cyclodextrins to introduce selectivity for the separation of enantiomers).

How is the efficiency influenced by the BGE? Peak broadening is the result of different processes in CZE occurring during migration [in addition, extracolumn effects contribute to peak width (e.g., that stemming from the width and shape of the injection zone, or the aperture of the detector cell)]. If the system behaves linearly, the individual peak variances (the second moments), are additive according to

$$\sigma_{\text{tot}}{}^2 = \Sigma\sigma_{\text{ind}}{}^2 = \sigma_{\text{extr}}{}^2 + \sigma_{\text{dif}}{}^2 + \sigma_{\text{Joule}}{}^2 + \sigma_{\text{conc}}2 + \sigma_{\text{ads}}{}^2 \quad (4)$$

where the subscripts extr, dif, Joule, conc, and ads indicate the contributions from extracolumn dispersion, longitudinal diffusion, Joule self-heating, concentration overload, and wall adsorption, respectively. All but one effect might be eliminated: The longitudinal diffusion is inevitable. Plate number expressing this contribution is dependent on the voltage, U, applied and on the charge number, z_i, of the analytes according to

$$N_i \approx 20 z_i U \quad (5)$$

at 20°C. It is obvious that the charge number depends on the pH of the BGE, as it is related to the degree of ionization. It follows that the plate number is a function of the pH as well. Thus, the resolution is influenced by the pH of the BGE twofold: via the selectivity, on the one hand, and via the plate number, on the other hand.

In conclusion, it follows for the limiting case of longitudinal diffusion as the only peak-broadening effect, that the resolution depends on the following:

- Instrumental variables: U and T.
- Analyte parameters: μ_{act} and pK_a.
- Chemical conditions determining the degree of ionization, α, or charge number z.

RESOLUTION IN PRESENCE OF EOF

The EOF brings an additional, unspecific velocity vector to the electrophoretic migration of the separands. The total migration velocity of the analyte, i, is then

$$\nu_{i,\text{tot}} = (\mu_{i,\text{eff}} + \mu_{\text{EOF}})E \quad (6)$$

Note that the mobilities are taken as signed quantities. By convention, cations have positive electrophoretic mobilities and those of anions are negative. The mobility of the EOF when directed toward the cathode has positive sign, and vice versa.

The effect of the EOF on migration time and selectivity depends on the mutual signs of the mobilities of analytes and EOF, respectively. Concerning the change in separation selectivity, we refer to the expression of the selectivity term in the resolution equation. The difference between the mobilities of the two separands, i and j, will not be influenced by the EOF. However, the mean mobility is larger for the case of comigration. This means that the selectivity term in the expression for the resolution is always reduced in this case. In practice, selectivity is lost for cation separation when the EOF is directed, as is usual in uncoated fused-silica capillaries, toward the cathode. For this reason, cationic additives are applied in the BGE to reverse the EOF direction.

The effect of the EOF on separation selectivity (in comparison with the situation without EOF) can be quantified by the so-called electromigration factor, or reduced mobility, $\mu_i{}^*$, defined as

$$\mu_i{}^* = \frac{\mu_{i,\text{eff}}}{\mu_{i,\text{eff}} + \mu_{\text{EOF}}} \quad (7)$$

The change of the selectivity term in the resolution is directly expressible by $\mu_j{}^*$. Interestingly, the effect of the EOF on the dispersion effects, expressed by the plate height H, also depends directly on μ^*. For longitudinal diffusion, Joule self-heating, and concentration overload, the variation of the plate height in the presence of the EOF is directly dependent upon this reduced mobility according to

$$H^{\text{EOF}} = H^0\mu^* \quad (8)$$

where the superscript 0 indicates the system without EOF. For wall adsorption, the corresponding effect is related to the reciprocal of μ^*.

An analysis of the effect of the EOF on the resolution brings the following result: For comigration of the analyte and EOF, the efficiency always increases and the selectivity term always decreases. As the decrease is directly proportional to μ^* but the gain in plate number is only increasing with the square root of μ^*, the resolution is always worse than without comigrating EOF.

For the case of countermigration, the situation is more complicated, because the overall effect depends on the magnitude of the mobility of analyte and that of the EOF. Roughly, it can be concluded that the resolution is increased for a given pair of analytes when the EOF is counterdirected, and it has a lower mobility than the analytes. Here, efficiency is lost, but selectivity is gained overproportionally. When the EOF mobility reaches a value that is twice as large as the analyte mobility (note that the signs of the mobilities are different), an analogous situation is found as without EOF. At mobilities of the EOF larger than twice the analyte mobility (conditions not impossible for high pH values of the BGE), resolution is worse here than without EOF, but the analysis time is shorter than in all other cases. It should be pointed out that all of these effects can be quantified by the reduced mobility defined in Eq. 7.

Capacity

M. Caude
A. Jardy
Analytical Chemistry Department, City of Paris Industrial Physics and Chemistry Higher Educational Institution (ESPCI), Paris, France

INTRODUCTION

The capacity is closely related to the number of active sites of the stationary phase per volume or mass unit. Practically, there are two definitions corresponding to two different approaches to the problem. On the one hand, there is the linear capacity and, on the other, the maximum available capacity.

DISCUSSION

It is well known that when increasing the injected sample quantity, whether in volume or in concentration, peaks are distorted and/or shifted beyond a certain limit; the column is said to be overloaded. To quantify how much sample can be injected into a column without altering the resolution, it is convenient to define the column linear capacity. It is well known, for small injected quantities, that solute retention times and column efficiency are not affected by the sample size. However, above a critical sample size, a noticeable decrease in retention time and column efficiency are always observed.

Snyder has defined[1] the adsorbent linear capacity as the ratio (weight sample)/(weight stationary phase) giving a value of k' (or V_R) reduced by 10% relative to the constant k' values measured for smaller samples (Fig. 1). In Fig. 1, the adsorbent (Silica Davison) has a linear capacity close to 0.5 mg of dibenzyl per gram of silica. When the linear capacity of the column is exceeded, qualitative and quantitative analyses become much more complicated. Retention factors vary according to the injected solute quantity and the column efficiency can be tremendously decreased, entailing a degradation of resolution. Therefore, for analytical separations, it is always preferable to choose operating conditions corresponding to the linear capacity (k' and N values are constant whatever the injected sample sizes).

However, the practical interest of column linear capacity is very limited because its value varies according to various parameters: solute nature and retention and, even for the same quantity of injected solute, both the injected volume and the solute concentration of the injected solution. Thus, although widely accepted, the column linear capacity is misleading because it characterizes not only the thermodynamic nature of the chromatographic system but also the kinetic conditions (in term of column efficiency).

Consequently, it is preferable, according to Gareil et al.,[2] to define the concept of maximum available capacity C_D for a stationary phase:mass of solute entailing the saturation of the mass m of stationary phase contained in the column for given operating conditions:

$$C_D = \frac{Qs}{m} \tag{1}$$

with

$$k' = \frac{Qs}{Qm} = \frac{Qs}{V_m C_0} \tag{2}$$

The combination of Eqs. 1 and 2 gives

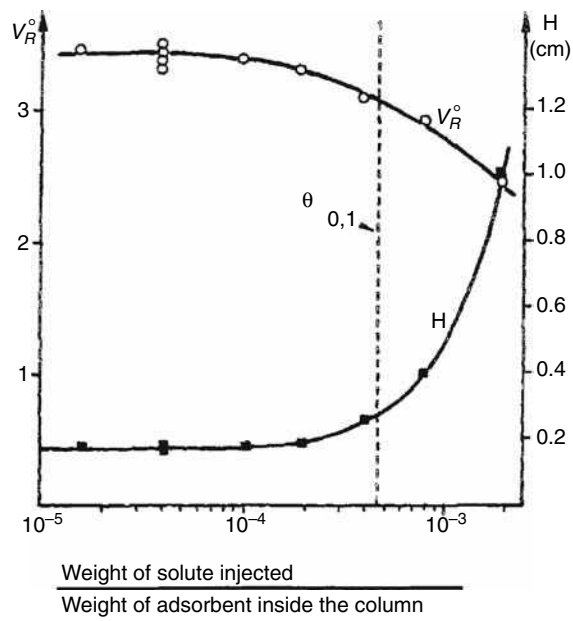

Fig. 1 Variation of the specific retention volume $V_R{}^0$ and of the height equivalent to a theoretical plate H as a function of the weight of injected solute (dibenzyl) related to the weight of adsorbent inside the column.
Source: From Column efficiency in liquid-solid adsorption chromatography. H.E.T.P. [height equivalent to a theoretical plate] values as a function of separation condition, in Anal. Chem.[1]

Encyclopedia of Chromatography, Third Edition DOI: 10.1081/E-ECHR3-120039900

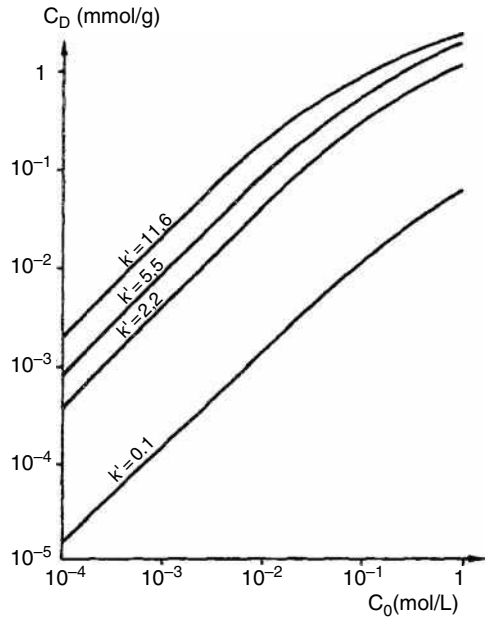

Fig. 2 Variation of the available capacity C_D as a function of the solute concentration in the module-phase C_0 (logarithm scales). In the case of RP chromatography, the stationary phase is *n*-octyl-bonded silica Lichroprep R.P.8 with 11.6% of carbon, the mobile phases are water-methanol mixtures, and the solute is phenol.

$$C_D = \frac{k' V_m C_0}{m}$$

where k' is the solute retention factor measured for an analytical injection, V_M is the mobile-phase volume contained in the column, and C_0 is the solute concentrationin the mobile phase.

Fig. 2 shows, for various retention factors, the available capacity variation versus the solution concentration in the mobile phase in (RP) chromatography. These curves, called distribution isotherms, can be divided into two parts. In the first part, a linear variation of C_D versus C_0 is observed (bilogarithm scale); in the second part, a plateau is reached. In the first part and for the same retention (k' constant), the available capacity is independent of the solute nature.

The maximum available capacity is defined as the C_D limit value when both C_0 and k' are high ($C_0 \cong 1$ mol/L, $k' \geq 10$). This value does not vary either with or k', or the solute nature (for the same family).

The maximum available capacity depends on the nature of the stationary phase:specific area for adsorption, the ion-exchange capacity for ion-exchange capacity, and the bonded rate for partition chromatography.

As a general rule, the maximum values of available capacity vary from 1.2 mmol/g (silica having a specific area close to 400 m^2/g) to 5 mEq/g for the cation exchanger (sulfonate groups).

Capillary Isoelectric Focusing

Robert Weinberger
CE Technologies, Inc., Chappaqua, New York, U.S.A.

Abstract
Capillary isoelectric focusing (CIEF) is designed to separate solutes based on their p*I*, the pH where they are electrically neutral. Because solutes do not migrate when they are neutral, the mobilization step distinguishes CIEF from other capillary electrophoretic techniques. This entry reviews the basis for CIEF including pH gradient formation, mobilization techniques, additives, and applications.

INTRODUCTION

Capillary isoelectric focusing (CIEF) employs a pH gradient developed within the capillary to separate zwitterions, usually proteins and peptides, based on each solute's p*I*. The technique is analogous to slab–gel CIEF[1] with several important differences: a) Slab–gel IEF is a non-elution process. After running the electrophoretic step, the proteins are detected by staining. CIEF is usually an elution technique. The contents of the capillary are mobilized to pass through the detector region. b) In the slab–gel, detection is by Commassie or silver staining. In CIEF, detection is by ultraviolet (UV) absorbance at 280 nm. c) In the capillary format, no gel is required because mechanical stability is provided by the rigid capillary walls. d) The field strength is at least an order of magnitude higher in the capillary format compared to the slab–gel.

The usual advantages of capillary electrophoresis apply equally to CIEF. Slab–gel IEF is extremely labor intensive and time-consuming. CIEF is simple to run, fully automated, and high speed and provides improved quantitative results compared to slab–gel IEF. This topic has been recently reviewed,[2] and is usually covered as a chapter in many high-performance capillary electrophoresis textbooks.

pH GRADIENT FORMATION

A solution containing 0.5–2.0% carrier ampholytes and 0.1–0.4% methylcellulose (1500 cP for a 2% solution) is filled into the capillary. A coated capillary is used to suppress the electro-osmotic flow (EOF) in conjunction with the methylcellulose solution. The sample (protein) concentration in the ampholyte blend is usually between 50 and 200 μg/ml. The inlet reservoir (anolyte) is filled with 10 m*M* phosphoric acid in methylcellulose solution. The outlet reservoir (catholyte) contains 20 m*M* sodium hydroxide. Higher concentrations of acid and base may be used to further stabilize the pH gradient.

The condition of the capillary immediately upon activation of the voltage is illustrated at the top of Fig. 1. In this case, the capillary is filled with a p*I* 3–10 mixture of ampholytes. Assuming the pH of the solution is 7, charges have been assigned to the individual ampholytes. The ampholyte charge dictates the direction of migration. Should any ampholyte migrate into a reservoir, the extreme pH conditions cause immediate charge reversal. Likewise, as the steady state is approached, should an ampholyte migrate into a more acidic or basic zone, charge reversal occurs as well. The result is the formation of a pH gradient as indicated at the bottom of Fig. 1. As each ampholyte approaches a pH equal to its individual p*I*, migration slows and then ceases. Because overlapping Gaussian zones of each ampholyte are formed, the gradient is smooth and linear.

The conventional pH range for CIEF is pH 3–10. Narrow-range gradients can be created by selecting custom ampholyte blends (e.g., pH 6–8). To avoid problems such as a step-gradient or the creation of water zones, the narrow-range ampholyte solution is usually supplemented with 20% pH 3–10 ampholytes. This ensures that there are sufficient ampholyte species to produce Gaussian overlaps.

The focusing step takes 2–5 min at a field strength of 500–1000 V/cm. Overfocusing causes precipitation of proteins and can damage the capillary as well. Initially, the current is high as ampholytes and proteins are highly charged. As their p*I*'s are approached, the current declines and reaches 1–4 μA when focusing is complete.

The 2:1 ratio of base:acid in the reservoirs is not coincidental. It is selected to minimize drift of the pH gradient. The pH of the anolyte must be lower than that of the most acidic ampholyte; likewise, the pH of the catholyte must be higher than the most basic ampholyte. Otherwise, ampholytes will migrate into the reservoirs and cause gradient drift. If the EOF is not reduced, a form of cathodic drift occurs as well. An exception to this is when one-step mobilization is employed.

Internal standards are always used to calibrate the pH gradient. This is important because the salt content of the

Encyclopedia of Chromatography, Third Edition DOI: 10.1081/E-ECHR3-120045233

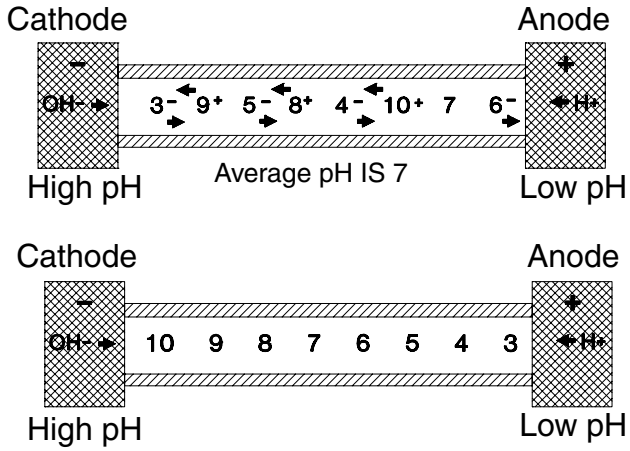

Fig. 1 Illustration of the process of pH gradient formation.

sample can compress the gradient. The ideal internal standard absorbs at a wavelength other than 280 nm. It can then be added to the ampholytes and monitored without producing interference. In this case, photodiode array detection is used for multiwavelength monitoring. Methyl red, p*I* 3.8, is ideal in this regard, but other such markers have not been identified. Aminomethylphenyl dyes are often used with monitoring at 400 nm, but they have some absorbance at 280 nm.

To prevent focused zones from reaching the blind side of the capillary past the detector, the ampholytes are either filled just prior to the detector or the reagent TEMED (*N,N,N,N*-tetramethylenediamine) is added to the blend at the appropriate concentration (0.5–2.0%). TEMED, a basic amine, then occupies that space past the detector window.

RESOLVING POWER

The resolving power, ΔpI of CIEF is described by

$$\Delta pI = 3\sqrt{\frac{D\left(\frac{dpH}{dx}\right)}{E\left(\frac{d\mu}{dpH}\right)}} \quad (1)$$

where D is the diffusion coefficient, E is the field strength, μ is the mobility of the protein, and $d\mu/dpH$ describes the mobility–pH relationship. The term dpH/dx represents the change in the buffer pH per unit of capillary length. This adjustable parameter is controlled by selecting an appropriate ampholyte pH range as well as the capillary length. Under optimal conditions, a resolution of 0.02 pH units is possible.

MOBILIZATION

There are three ways of mobilizing the contents of the capillary: a) chemical (salt) mobilization, b) electro-osmotic (one-step) mobilization, and c) hydrodynamic mobilization. Hydrodynamic mobilization is the simplest and most widely used method. Low pressure is used to evacuate the capillary with the voltage activated. Laminar band broadening is minimized by simultaneous focusing. In one-step mobilization, the EOF is reduced but not absent. If done correctly, focusing occurs prior to any proteins reaching the detector. This is the fastest method but has lower resolution and linearity compared to hydrodynamic mobilization. Salt mobilization is infrequently used today, but it produces the highest resolution at the expense of run time and gradient linearity. The mobilization step is time consuming and may reduce the overall resolution of the separation. Imaged detection permits the entire capillary to be monitored in real time.[3] The disadvantage of this technique is the requirement for a dedicated CIEF instrument that is available from only one manufacturer.

DETECTION

Because the ampholytes absorb below 250, 280 nm detection is required. It is critical to run ampholyte blanks because the reagents are not checked by the manufacturers for UV absorption at 280 nm. The limit of detection is a few micrograms per milliliter of protein and this is usually limited by the UV reagent background. Proteins that are deficient in aromatic amino acids are poorly detected. Different lots of ampholytes from various manufacturers show variation in the UV background.

The combination of CIEF and mass spectrometry is analogous to two-dimensional (2-D) electrophoresis.[4] In this case, the mass spectrometer provides the molecular-weight information instead of sodium dodecyl sulfate–polyacrylamide gel electrophoresis. This information can be obtained by online CIEF/MS[5] or by using CIEF as a micropreparative technique.[6]

For the online system, CIEF is performed conventionally in a 20 cm capillary mounted inside an electrospray probe. After focusing, the outlet reservoir (catholyte) is removed and the capillary tip set to 0.5 mm outside of the probe. A sheath liquid of 50% methanol, 49% water, and 1% acetic acid (pH 2.6) pumped with a syringe pump at 3 μl/min produces a stable electrospray. Cathodic mobilization is produced by changing the anolyte to the sheath liquid. The ampholyte ions were observed up to m/z 800 and thus did not interfere with the protein signals.

CIEF IN MICROFABRICATED SYSTEMS

Adaptation of CIEF to the microchip format can provide higher performance compared to conventional capillaries.[7] Whole channel imaging can be performed, thereby eliminating the need for mobilization. The chip can be interfaced to the mass spectrometer while maintaining the short length of the separation channel which is a distinct advantage compared to the conventional capillary.

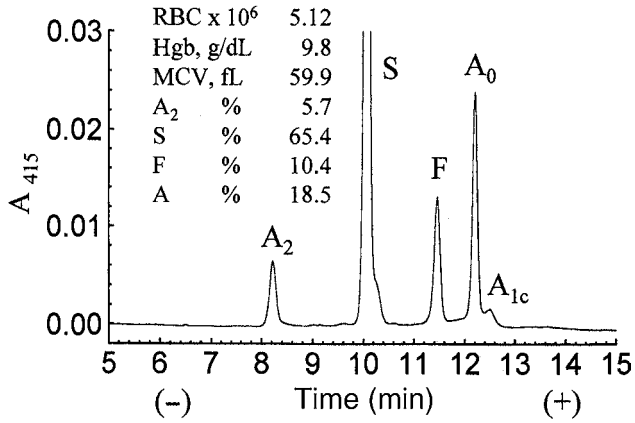

Fig. 2 Separation of hemoglobins by CIEF in blood from a patient suffering Hb *S*/β+ from thalessemia. Capillary: 27 cm (20 cm to detector) × 50 μm I.D. DB-1 (J & W Scientific); ampholytes: 2% pH 6–8:10–3 (10:1) Pharmalytes (Pharmaceia Biotech) and 0.375% methylcellulose; catholyte: 20 m*M* sodium hydroxide; anolyte: 100 m*M* phosphoric acid in 0.375% methylcellulose; focusing: 5 min at 30 kV; mobilization: low pressure (0.5 psi) for 10 min at 30 kV; detection: UV, 415 nm.
Source: From Capillary isoelectric focusing of hemoglobin variants in the pediatric clinical laboratory, in Electrophoresis.[11]

ADDITIVES FOR HYDROPHOBIC PROTEINS

The tendency of hydrophobic proteins to aggregate and precipitate is a major problem in IEF whether in the slab–gel or capillary format. The focusing power of CIEF produces an increase in solute concentration by a factor of over 200.[8] Proteins also readily precipitate as the p*I* is approached because their charge and, thus, electrostatic repulsion approach zero.

Protein precipitation is indicated first by spikes in the electropherogram followed by clogging of the capillary. Additives are required to suppress the aggregation of hydrophobic proteins to keep them in solution. Two excellent review articles describe this in detail.[9–10]

Among the reagents used to prevent aggregation are urea, non-ionic surfactants such as Brij-35, zwitterionic detergents such as sulfobetains, polyols such as ethyleneglycol, glycerol, and sorbitol or non-reducing sugars. A strategy of mixing polyols and zwitterions is often successful in dealing with solubility problems. Urea is often used to keep some monoclonal antibodies in solution.

APPLICATIONS

CIEF has been employed for separations of many proteins, recombinant proteins, monoclonal antibodies, and protein glycoforms. The most widely used method employing isoelectric focusing is the neonatal determination of hemoglobin variants for the screening of genetic disorders, including sickle cell anemia, thalassemias, and other hemoglobinopathies. Fig. 2 illustrates the separation of hemoglobins in a patient with S/β thalassemia. Eventually, this application will be performed clinically using microfabricated systems.

CONCLUSIONS

CIEF is a charge-based method that is orthogonal to ion-exchange chromatography. Of the CE methods, CIEF is more difficult to implement. The method works best on a dedicated instrument that uses whole capillary imaging instead of the classical mobilization step. The technique has gained general acceptance within the biopharmaceutical industry primarily for checking monoclonal antibody purity.

Capillary Isotachophoresis

Ernst Kenndler
Institute for Analytical Chemistry, University of Vienna, Vienna, Austria

INTRODUCTION

Three analytical electrophoretic techniques can be distinguished. They differ in the kind of background electrolyte (BGE) and in its arrangements. Zone electrophoresis has a uniform BGE without a gradient; in isoelectric focusing, the separation is established by the aid of a BGE forming a continuous (linear) pH gradient. In contrast, isotachophoresis (ITP) is an electrophoretic method with a stepwise gradient of the background electrolyte.

ISOTACHOPHORESIS

In ITP, samples of only one charge type are separated in the same run (i.e., either anions or cations). The BGE in ITP is selected in the way that (the anion or cation of) the leading (L) and the terminating (T) electrolyte will have a higher and a lower mobility, μ, respectively, than the analytes of interest. Thus, the prerequisite for separation by ITP is that $\mu_L > \mu_{analytes} > \mu_T$.

Consider the case that the sample ions are anions (consisting of analytes A^- and B^-), and that the ions exhibit mobilities in the sequence $\mu_L > \mu_A > \mu_B > \mu_T$. The capillary is filled with and separated by a sharp boundary, and the sample is injected between the two electrolyte zones (for simplicity, it is assumed that the counterions, Q^+, are all the same). After application of an electric field, a certain field strength is established in the zones as depicted in Fig. 1 (it is assumed that the capillary has uniform diameter). Across the individual zone, the field strength is constant, but it increases due to the decreasing mobility (and increasing electrical resistance) from L to T. Across the zone of the mixed sample (A + B) it is constant as well, with strength E_{mix}. In this zone, the two analytes A and B are moving with different migration velocities, ν, according to $\nu_A = \mu_A E_{mix}$ and $\nu_B = \mu_B E_{mix}$. Due to the higher mobility of A, this analyte moves faster here than B: $\mu_A E_{mix} > \mu_B E_{mix}$. This effect leads to the migration of ions out of the mixed zone, forming a separate zone in front with pure A^- (which is always placed behind the zone of the leading electrolyte). For B^- the analogous situation occurs; it is moving slower in the mixed zone and forms a separate zone at the rear side (but in front of T). The formation of zones of pure analyte ions (obviously with counterions, Q^+, the counterions of the leading electrolyte) is, therefore, observed. Five zones can be differentiated in this transient state: L^-, pure A^-, mixed $A^- + B^-$, pure B^-, and T^-. Due to the different mobilities, the field strength increases in this sequence. Separation takes place as long as the mixed zone exists. Finally, this zone disappears and the isotachophoretic condition is established: All zones and zone boundaries migrate with the same mean velocity ("isotachophoresis"); consequently,

$$\mu_L E_L = \mu_A E_A = \mu_B E_B = \mu_T E_T \quad (1)$$

This is the isotachophoretic condition. The conditions of electroneutrality must be fulfilled as well, which means, in the case considered, that in each zone the concentration of ions and counterions is equal. The third condition is Ohm's law, stating that (for given constant current) the product of electrical conductivity and field strength in each zone is equal. The combination of these conditions leads to the so-called regulation function (Kohlrausch), which reads in a simplified form (for monovalent strong electrolytes):

$$c_A = c_L \frac{\mu_A(\mu_L + \mu_Q)}{\mu_L(\mu_A + \mu_Q)} \quad (2)$$

It relates the concentration of a species in its own zone to the concentration of the species in the subsequent zone and, as a consequence, to the concentration of the first zone, the leading ion. It is also a function of the mobility of the ions involved: the analyte, the leading ion, and the counterion. This function allows two conclusions as follows.

As for given conditions, the mobilities in Eq. 2 are constant under ITP conditions; the concentration of the sample in its zone is constant as well. The concentration distribution is, therefore, given by a rectangular function. It follows that the temperature and the pH within the particular zone is constant, too, and changes stepwise at the boundary to the neighboring zone.

The concentration depends only on that of the leading ion; it is independent of the initial concentration in the sample. Therefore, ITP can act as an enrichment

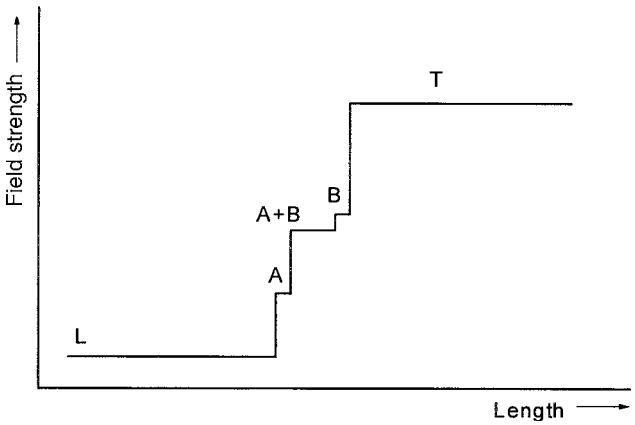

Fig. 1 Electrical field strength in the zones of the leading electrolyte, L, the sample consisting of A and B, and the termination electrolyte, T.

method, analogous to displacement chromatography and in contrast to zone electrophoresis and elution chromatography. The concentration in the steady state is adjusted to the value given in Eq. 2. If the concentration of the analyte species is lower in the initial sample, the higher steady-state concentration is established. This concentration is independent of the migration distance: there is no dilution with a BGE as there is in capillary zone electrophoresis (CZE).

The adjustment of the steady-state concentration to a certain constant value has the consequence that the zone length of an analyte depends on the amount present in the sample. Increasing the amount results in an increase of the zone length under ITP conditions. The length is, therefore, the parameter for quantitative analysis.

The stepwise gradient of the electrical field at the zone boundary is the source of the "self-sharpening" effect in ITP. When, by diffusion, an ion migrates out of its own zone, into a neighboring zone (where the field strength is higher or lower, respectively), the condition given in Eq. 1 is not fulfilled any more. Therefore, the velocity of the considered ion is either accelerated or retarded, and the ion is pushed back into its initial zone. As a consequence, the boundary between the zones remains sharp and its shape is not dependent on the migration distance.

Isotachophoresis might have several advantages compared to zone electrophoresis. The adaptation to a considerably high concentration of the sample components in their own zones in the absence of further BGE favors the use of the electrical conductivity detector. The high concentration and the long sample zone have also some advantage in combining capillary electrophoresis with, for example, MS. Also, ITP can be used as an enrichment technique prior to zone electrophoretic separation, a phenomenon that is applied routinely in sodium dodecyl sulfate–polyacrylamide gel electrophoresis using a discontinuous buffer for sample introduction, and a technique called sample stacking in CZE. In fact, both methods rely on an isotachophoretic principle.

Carbohydrates: Affinity Ligands

I. Bataille
D. Muller
Galilee Institute, University of North Paris, Villetaneuse, France

INTRODUCTION

Since its conception 30 years ago, affinity chromatography has been a powerful technique to separate or purify biological compounds, but also a method to study the interactions between living systems and molecules of biological or therapeutical interest. Among these molecules, oses, polysaccharides, or more complex molecules such as glycosaminoglycans constitute a family of potential ligands.

DISCUSSION

The majority of applications of affinity chromatography has been, for quite some time, in the field of protein purification. For example, some of the most rewarding applications have been in the area of purification of hormone and drug receptors. Among these drugs, carbohydrate-based structures are well known for their biological activity (e.g., their anticoagulant or antiproliferative properties). Although some of these biological properties are widely used in medical applications, the mechanisms of action at the molecular level is not accurately determined.

An example of the use of carbohydrate-based affinity chromatography is, thus, the separation of proteins that are responsible for the action of bioactive polysaccharides or oses. The strategy consists in the immobilization of these carbohydrates on classical low- or high-pressure affinity phases. We will distinguish two types of ligands: those based on osidic structures and those prepared from glycosaminoglycans or polysaccharides.

OSIDIC LIGANDS

All osidic structures that can interact with proteins implicated in biological responses or phenomenons are, a priori, candidates as ligands in affinity chromatography. Here, we give some examples of oses which have been successfully immobilized to make selective chromatographic supports.

Sialic Acid (*N*-Acetylneuraminic Acid)

Purification of immunoglobulins G is of great interest in biological science. Among other separation methods, affinity chromatography has been used in different ways. Affinity supports were first prepared using protein A or protein G, whose affinity constants take different values according to the IgG subclasses (IgG1, 2, 3, or 4). Among interesting carbohydrates, sialic acid is known to specifically interact with IgGs. Indeed, immunoglobulins are able to react to the presence of tumoral cells. The antigens that are suspected to promote this reaction are gangliosids. Beyond a ceramide molecule, some oses are present in gangliosids, among which are included between one and three sialic acids.

The hypothesis has been made that sialic acid may lead to the formation of specific interactions with immunoglobulins G. Some workers have, thus, developed affinity supports bearing sialic acid in order to purify IgGs. Sialic acid can be extracted from swallow nests and coupled on activated coated silica. This support has been found to possess a good specificity for IgGs, in particular for the subclass IgG3.[1]

Supports prepared with sialic acid have also been used in the purification of insulin, as this sugar and *N*-acetylglucosamine have been found to take part in the interaction between insulin and its glycosylated receptor. The affinity between insulin and sialic acid-bearing supports has been found to be rather strong ($K_a \sim 10^9/M$) and the system allows the separation of beef and pig insulins,[2] which differ by only two amino acids.

N-Acetylglucosamine

N-Acetylglucosamine also shows a specific interaction with insulin. Affinity chromatography experiments have evidenced results very close to those observed in the case of sialic acid. An interesting result is that the improvement of both affinity and capacity of supports bearing both sugars.[3] These supports are supposed to more accurately mimic the structure of insulin receptor.

Mannose and Derivatives

Mannose has been immobilized in order to separate mannose-binding proteins such as mannose-binding lectin. When grafted onto agarose, it constitutes a purification step of a specific lectin that does not bind to DEAE–cellulose or Affi-gel Blue gel.[4] Another way to obtain mannose-binding lectin is to perform expanded-bed

affinity chromatography by immobilizing mannose on a DEAE Streamline support.[5] Affinity agarose supports, grafted with pentamannosyl phosphate, allowed the testing of the functionality (in terms of ligand binding) of truncated and glycosylation-deficient forms of the mannose 6-phosphate receptor from insect cells.[6] Phosphomannan affinity chromatography has been used to purify a human insulinlike growth factor II mannose 6-phosphate receptor.[7]

GLYCOSAMINOGLYCANS AND POLYSACCHARIDES

One of the most used glycosaminoglycans is heparin because of its anticoagulant properties. Other glycosaminoglycans or polysaccharides have also shown such properties; among them, sulfated dextran derivatives and naturally sulfated polysaccharides extracted from algae (fucans) will be discussed further.

Heparin

Anticoagulant properties are due to the formation of a complex between heparin and antithrombin (ATIII); heparin increases ATIII activity, inhibiting thrombin, which is responsible for the formation of the clot.[8] Although this complex is already characterized by a weak affinity, the exact mechanism of association between heparin and antithrombin is not exactly known. A multistep protocol of immobilization of heparin on silica beads permitted high-performance chromatographic phases to be obtained. Thus, it has been possible to evidence a slightly stronger affinity of heparin for antithrombin than for thrombin.

ATIII has been also used as a model protein to test a novel affinity chromatographic system: capillary affinity chromatography.[9] Separation quality has been found equivalent to that observed with classical affinity chromatography, whereas the necessary protein amount is strongly reduced to the nanogram level.

Heparin possesses an affinity for many molecules, among which is a phospholipid-binding protein, annexin V. Affinity chromatography evidenced the Ca^{2+} dependence of the binding mechanism;[10] von Willebrand factors with high and low molecular weights have been separated using their different affinities toward heparin.[11]

Heparin has been used in enzyme purification such as recombinant human mast cell tryptase. The purified enzyme is fully active.[12] Heparin-based affinity chromatography also permitted the isolation of growth factors such as basic fibroblast growth factor (bFGF). The affinity is lower when bFGF is complexed with acidic gelatin.[13] The elution of synthetic TFPI (tissue factor pathway inhibitor) peptidic fragments on immobilized heparin has allowed one to find the peptidic sequence responsible for the TFPI-heparin interaction.[14]

Heparin is able to inhibit smooth-muscle cell (SMC) proliferation in vitro. SMCs are present in blood vessel walls and may proliferate in the case of an internal injury. The antiproliferative action of heparin is due to its internalization in SMCs, which is probably mediated by membrane receptors. Heparin-based affinity chromatography of SMC membrane extracts allowed the separation of a few proteins, which could be implicated in the growth inhibition.[15]

The different actions taking place in the overall affinity mechanism of immobilized heparin for different biological compounds are not yet elucidated, but the influence of ionic strength demonstrates the important contribution of ionic interactions in this mechanism. However, the large spectrum of biological activities of heparin is also a limit for its specificity.

Other Glycosaminoglycans

Dermatan sulfate is known to specifically catalyze thrombin inhibition by the plasmatic inhibitor heparin cofactor II (HCII). Dermatan sulfate has been immobilized on a dextran- or agarose-coated silica matrix. These systems were tested as high-performance chromatographic supports for the purification of HCII from human plasma. The eluted HCII was obtained with no contamination of ATIII, the other main thrombin inhibitor.[16]

DEXTRAN DERIVATIVES

Phosphorylated dextran derivatives, called phosphodextrans, possess a strong affinity for K-vitamin-dependent coagulation factors, like factor II or prothrombin. This property was used to separate them by affinity chromatography on phosphodextrans, which interact in a similar way as phospholipids from the cell membrane.[17]

Heparinlike sulfated dextran derivatives, like carboxymethyldextran benzylamide sulfonates (CMDBS), have been immobilized on silica beads. By high-performance liquid affinity chromatography (HPLAC), they allow a good recovery of thrombin, with a yield of 80%. The affinity constant was estimated ($K_a \sim 10^5/M$) and was found superior to the value obtained between thrombin and heparin. On the contrary, the affinity of dextran derivatives for ATIII is estimated at a lower value than that of heparin.[17]

FUCANS

Fucan is a sulfated polysaccharide, naturally present in algae such as *Fucus vesiculosus* or *Ascophyllum nodosum*. Fucan is a general name for a mixture of three polysaccharides; among them, fucoidan (or homofucan) can be theoretically considered as an homopolymer of α-1,2

L-fucose-4-sulfate and has been studied as a ligand in the same way as fucan itself. Their interaction with two proteins implicated in the coagulation process (thrombin and antithrombin) has been studied and is at least partially ionic. However, the dissociation of the complex fucan–antithrombin seems to include a slower step which could be attributed to a conformation change of the fucan.[18]

Fucan was also used as ligand for HPLAC. In the same way as dextran derivatives, a good separation was obtained for thrombin, with a yield of 80%. The affinity constant was estimated in the same order as that obtained for CMDBS ($K_a \sim 10^5/M$) and superior to the value obtained for heparin.[17]

CONCLUSIONS

In this entry, we have described several uses of carbohydrate compounds as affinity ligands. These few examples clearly demonstrate the importance of such affinity supports in the separation of biological products. Affinity chromatography is also able to help in the determination of the interaction mechanisms of carbohydrate derivatives in biological reactions. This developing field of research will lead to improved quality and specificity of affinity-chromatographic phases.

Carbohydrates: CE Analysis

Oliver Schmitz
Division of Molecular Toxicology, German Cancer Research Center, Heidelberg, Germany

INTRODUCTION

Carbohydrates play an important role in many research and industrial domains. The huge number of stereoisomers, the immense combination possibilities of carbohydrate monomers in oligosaccharides, and the lack of chromophores are the major problems in the analysis of carbohydrates. Capillary electrophoresis (CE), in its various modes of operation, has been developed as a very useful tool in the analysis of carbohydrate species such as monosaccharides and oligosaccharides, glycoproteins, and glycopeptides.

DISCUSSION

Some simple sugar mixtures, such as monosaccharides and oligosaccharides, consisting of not more than about 15 monomer units, can be separated in free solution due to their mass-to-charge ratio (*m/z*). For an increase in selectivity or for analyzing neutral carbohydrates, MEKC can be used for analysis. In this case, charged amphiphilic molecules containing both hydrophilic and hydrophobic regions (e.g., sodium dodecyl sulfate) are used as buffer surfactants.

Higher oligosaccharides or polysaccharides possess unfavorable mass-to-charge ratios, preventing their effective resolution in open tubes. The separation of these carbohydrates is possible with capillary gel electrophoresis (CGE). The analytes are selectively retarded by a sieving network (gel or polymer matrix) due to differences in their sizes and structural conformations.

Complex carbohydrates (in particular, glycoproteins) play an important role in various biological processes and in biotechnological production of glycoproteinaceous pharmaceuticals. To elucidate the relationship between bioactivity and structures of complex carbohydrates, it is necessary to determine the sites of attachment of the oligosaccharide chains to the polypeptide backbone and to characterize the oligosaccharide class (N- or O-linked, high mannose, hybrid, etc.).

For this reason, glycoproteins must first be isolated from the biological matrix by dialysis, preparative chromatography, isoelectric focusing, and so forth or by a combination of several methods. For a structural determination, degradation steps such as a site-specific proteolysis (e.g., with trypsin), removal of oligosaccharides from the polypeptide (by an enzymatic hydrolysis or hydrazine treatment), or chemical hydrolysis, yielding a monosaccharide mixture may be applied. Then, the CE can function as a powerful end method in analytical and structural glycobiology. Due to the complexity of the carbohydrate-dependent microheterogeneity of glycoproteins, several electrophoretic techniques are usually needed, in concert, to characterize the various glycoforms of a given glycoprotein.

For detection of carbohydrates in principle, ultraviolet (UV), laser-induced fluorescence, refractive index, electrochemical, amperometric, and mass spectrometric detection can be used. Mass spectrometry (MS), with its various ionization methods, has traditionally been one of the key techniques for the structural determination of proteins and carbohydrates. Fast-atom bombardment (FAB) and electrospray ionization (ESI) are the two online ionization methods used for carbohydrate analysis. The ESI principle has truly revolutionized the modern MS of biological molecules, due to its high sensitivity and ability to record large molecule entities within a relatively small-mass scale.

The refractive index detection (RID), often used in high-performance liquid chromatography (HPLC), is an interesting detection method in CE with a laser light source and a limit of detection (LOD) in the micromolar range. Electrochemical detection (ECD) and pulsed amperometric detection (PAD) of sugars are common and effective methods used in HPLC. Some recent communications show that the sensitivity of these detection methods in CE have an approximately 1000-fold better LOD than RID. Unfortunately, these detectors (RID, ECD, and PAD) are not commercially available for CE at the moment.

Indirect detection methods are a viable alternative for compounds lacking a chromophoric or a fluorophoric group. An electrolyte containing a chromophore or fluorophore allows the indirect detection of carbohydrates. This method is based on the displacement of the background electrolyte (BGE) by carbohydrates, which are dissociated in strongly alkaline electrolytes. The LOD with indirect LIF detection is in the nanometer range, but the lack of any specificity is a great disadvantage of this detection method, because all sample compounds displace the BGE and the peak identification is only possible by the migration time.

Direct UV detection is the most versatile detection method in CE and is implemented in every commercial CE system. Unfortunately, its use for carbohydrates detection is restricted because of their lack of conjugated p-electron systems and, consequently, the relatively low

extinction coefficients. Despite this fact, it is possible to detect carbohydrates with UV detection without any derivatization at 200 nm. Sensitivity and selectivity can be increased by the use of an alkaline borate buffer as the electrolyte by in situ complexation with the tetrahydroxyborate ion rather than the boric acid (Fig. 1A). The LOD is between micromolar and nanomolar. A further advantage of very high pH values (>10) is the negative charge of the carbohydrates, which are repelled by the negatively charged surface. Consequently, the surface problems in high-performance CE are much lower in carbohydrate analysis than in the analysis of proteins. Therefore, simple carbohydrates are often analyzed in uncoated fused-silica capillaries. Unlike the analysis of simple carbohydrates, for glycopeptides and glycoproteins, the use of coated capillaries such as hydroxypropylcellulose, hydroxyethylmethacrylate, polyether, or other commercially available coated fused-silica capillaries is necessary to achieve high resolution and reproducibility.

In complex matrices, the insufficient specificity at 200 nm and the low sensitivity of direct UV detection make the analysis of carbohydrates more difficult. Therefore, derivatization of carbohydrates with a suitable agents is still a preferred approach for the detection of monosaccharides and oligosaccharides. Derivatization agents like 2-aminopyridine, 8-aminonaphthalein-1,3,6-trisulfonate

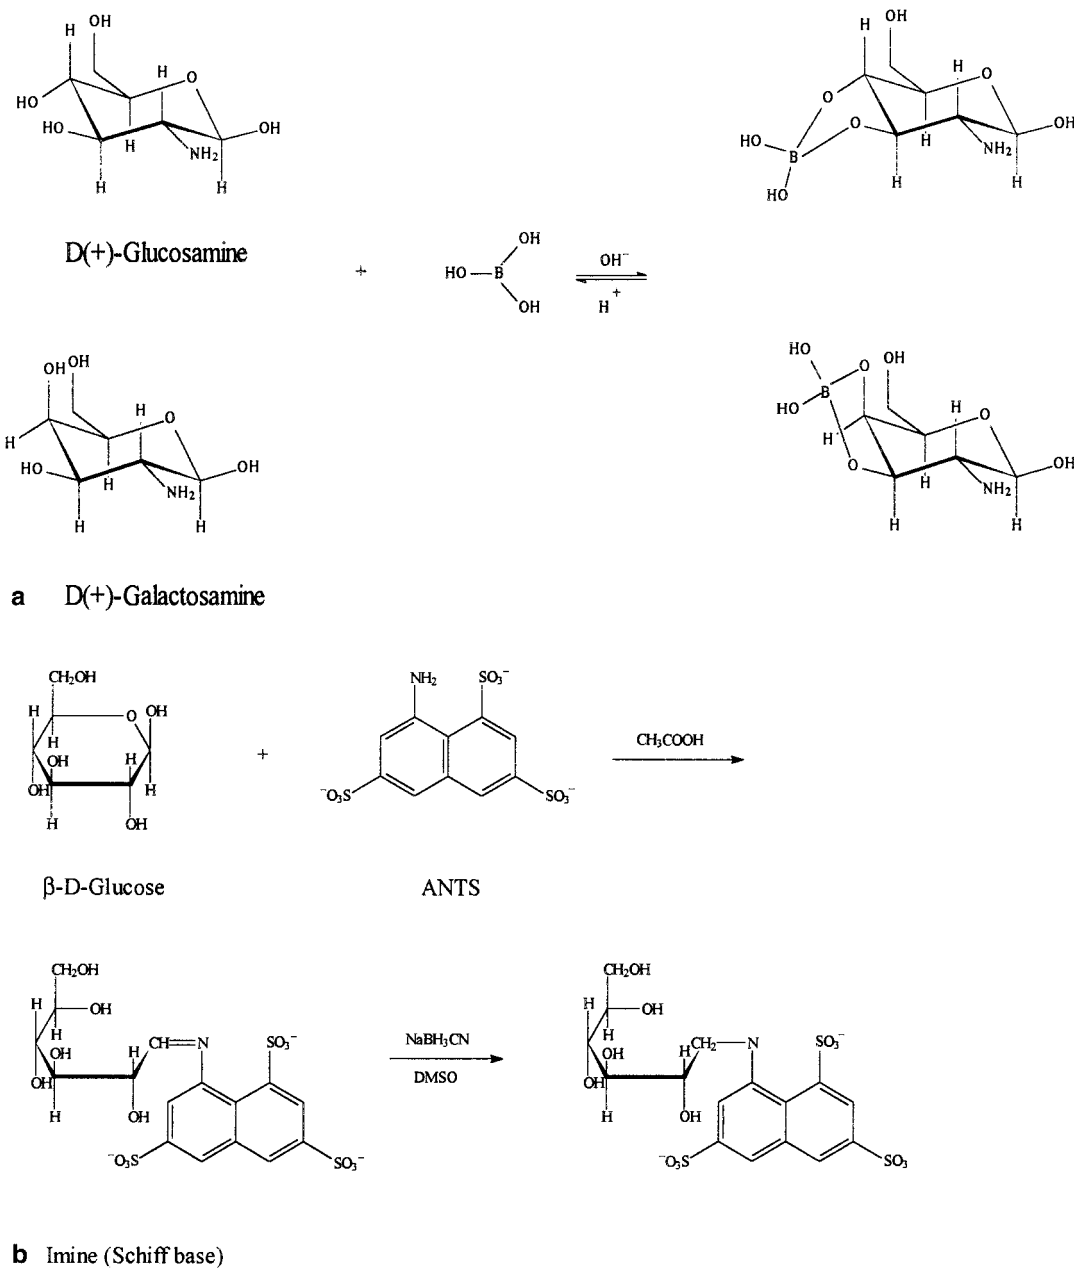

Fig. 1 Derivatization of Carbohydrates.

(ANTS) or 8-aminopyren-1,3,6-trisulfonate (APTS) can be introduced mostly by reductive amination. This reaction is based on imine formation (Schiff base) by the condensation of the aldehyde group in a carbohydrate with the amino group in a primary amine (fluorescent tag), followed by reduction to an N-substituted glycamine with a reductant like sodium cyanoborohydride (see Fig. 1b). Selection of the suitable derivatization reagent is important, because the electrophoretic migration of the carbohydrates and, therefore, the separation power is influenced by the properties of the tags. Fluorescent dyes are better suitable than UV-active derivatization reagents, because CE analysis permits the use of laser-induced-fluorescence (LIF) detection with excellent sensitivity up to the femtomolar-level.

CONCLUSIONS

CE in carbohydrate analysis has advantages in both separation and detection over other techniques of electrophoresis, as well as chromatography. It allows high efficiency (up to a few million plate numbers) and very good sensitivities (up to femtomolar). In addition, CE permits analysis by a variety of separation modes simply by changing the electrolyte (capillary zone electrophoresis, micellar electrokinetic chromatography (MEKC), capillary gel electrophoresis (CGE)).

Carbohydrates: Derivatization for GC Analysis

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

As a result of the development of special bonded phases, carbohydrates or their derivatives are usually separated by liquid chromatography (LC). However, certain carbohydrate samples are still analyzed by gas chromatography (GC) due to the inherent high efficiencies obtainable from the technique and to the associated short elution times. In addition, gas chromatography (GC)/ mass spectrometry (MS) is a particularly powerful analytical technique for carbohydrates, especially for their identification. As a consequence, appropriate derivatives must be formed to render them sufficiently volatile but still easily recognizable from their mass spectra.

DISCUSSION

It is relatively easy to form the trimethylsilyl derivatives, employing standard silyl reagents such as trimethylchlorsilane or hexamethyltrisilazane, and the reactions normally can be made to proceed to completion. However, there is a major problem associated with the derivatization of natural sugars which arises from the formation of anomers and the pyranose–furanose interconversion. Reducing sugars in solution (e.g., glucose) exist as an equilibrium mixture of anomers. Consequently, each sugar produces five tautomeric forms—two pyranose, two furanose, and one open-chain form. In general, all the anomers can be separated by GC. This autoconversion can be minimized by mild and rapid derivatization. Equilibrium mixtures are to be expected from reducing sugars isolated from natural products.

Mixtures of hexamethyltrisilazane and trimethylchlorsilane are frequently used to derivatize sugars. Pure sugars (e.g., glucose, mannose, and xylose) can be readily derivatized using a mixture of hexamethyltrisilazane : trimethylchlorsilane : pyridine (2:1:10 v/v/v), giving single GC peaks; however, if the proportion of trimethylchlorsilane is doubled, small amounts of the anomeric forins are observed. One disadvantage of this procedure is the formation of an ammonium chloride precipitate, which, if injected directly onto the column, can cause column contamination and eventually column blockage. The formation of ammonium chloride can be avoided by extracting the derivative into hexane or by the use of an alternative derivatizing agent.

N,*O*-Bistrimethylsilyltrifluoroacetamide, usually combined with trimethylchlorosilane (10:1, v/v) is also a popular derivatizing agent for carbohydrates and the reaction mixture can be injected directly onto the column without fear of column contamination. The formation of anomers can also be avoided by preparing the alditols by treating with sodium borohydride. The alditols can then be separated after derivatizing with trimethylchlorosilane, a procedure that is considered preferable to the preparation of their acetates. The rapid preparation of trimethylsilylalidtols using trimethylsilylimidazole in pyridine mixtures at room temperature has the advantage over other methods, which require longer reaction times and higher temperatures. The use of silylaldolnitrile derivatives has been reported for the separation of aldoses. The sugars are reacted with hydroxylamine-*O*-sulfonic acid to form aldonitriles which are then silanated with *N*,*O*-bistrimethylsilyltrifluoroacetamide : pyridine (1:1 v/v). The silylaldonitrile derivatives are readily separated on open tubular columns.

Another silanization procedure for the derivatization of carbohydrates is the formation of trimethylsilyl oximes. The methyloxime is heated with hexarnethyldisilazane : trifluoroacetic anhydride (9:1 v/v) for 1 hr at 100°C. Anthrone *O*-glucoside is an important ingredient in skin care cosmetics and can be fully silylated by reaction with *N*,*O*-bistrimethylsilylacetamide : acetonitrile mixture (1:1 v/v) for 1 hr at 90°C, and subsequently separated by GC.

CONCLUSIONS

Acetylation and the use of trifluoroacetates, originally the more popular derivatives for the separation of carbohydrates by GC, are still used on occasion, but the various silanization methods are, today, the most common and considered the most effective for GC carbohydrate analysis.

Carbohydrates: HPLC Analysis

Juan G. Alvarez
Department of Obstetrics and Gynecology, Beth Israel Deaconess Medical Center, Boston, Massachusetts, U.S.A.

INTRODUCTION

Carbohydrates are widely distributed molecules in biological systems and pharmaceutical products, not only in free form but also in conjugated form. Because they are present in various forms and there are isomers and analogs, the separation of carbohydrates involves more difficult problems than those of proteins or nucleic acids. Difficulties are also found in detection, especially in biochemical and biomedical analyses due to their low abundance and the fact that photometric and fluorimetric methods cannot be applied directly because of the lack of chromophores and fluorophores.

Analysis of carbohydrates in body fluids by high-performance liquid chromatography (HPLC) using anion-exchange columns was first reported in the 1970s.[1–5] This method has been greatly improved by the use of packing materials of fine, spherical particles and by the development of photometric and fluorimetric postcolumn labeling systems for sensitive detection. Honda et al. established rapid automated methods for microanalysis of aldoses,[6] uronic acids,[7] and sialic acids using a Hitachi 2633 anion-exchange resin and a photometric and fluorimetric postcolumn labeling system with 2-cyanoacetamide. Alditols[8] were fluorescence labeled by the use of sequential periodate oxidation and the Hantzsch reaction. Microanalysis of aminosugars was successful when their borate complexes were separated in the cation-exchange mode and detected by fluorescence generated either by the reaction with 2-cyanoacetamide[9] or by the Hantzsch reaction.[10] All these methods are suitable for routine analysis of clinical samples because of their speed of analysis and high sensitivity.

The United States Food and Drug Administration and the regulatory agencies in other countries require that pharmaceutical products be tested for composition to verify their identity, strength, quality, and purity. Recently, attention has been given to inactive ingredients as well as active ingredients. Some of these ingredients are non-chromophoric and cannot be detected by absorbance. Some non-chromophoric ingredients, such as carbohydrates, glycols, sugar, alcohols, amines, and sulfur-containing compounds, can be oxidized and, therefore, can be detected using amperometric detection. This detection method is specific for those analytes that can be oxidized at the selected potential, leaving all other non-oxidizable compounds transparent.[11] Amperometric detection is a powerful detection technique with a broad linear range and very low detection limits.

This review outlines current chromatographic methods utilized in the analysis of carbohydrates in biological systems and pharmaceutical products.

ANALYSIS OF CARBOHYDRATES BY PARTITION HPLC

Partition HPLC is an important type of chromatography for the analysis of monosaccharides and oligosaccharides. Analysis in this mode has the advantages that it requires a shorter analysis time and gives sharper peaks than anion-exchange chromatography of borate complexes, although it has the drawback of low sensitivity, as detection is usually performed by refractometry. Generally, silica gel whose silanol groups are substituted by alkyl or aminoalkyl groups is used as the stationary phase. HPLC separations using such a stationary phase has been applied successfully to separate oligosaccharides liberated from glycoproteins with hydrazine or borohydride in alkali, permitting quick separation within 60 min.[12–14] Previously, such oligosaccharides were separated and purified by tedious procedures involving gel permeation chromatography on Bio-Gel P-2 or P-4, paper chromatography, and paper electrophoresis. However, modified silica, especially amine-modified silica, has difficulties in durability, being unsuitable for routine analysis.

ANALYSIS OF CARBOHYDRATES BY ANION-EXCHANGE HPLC

The introduction in the 1980s by Honda and Suzuki[15] of the anion-exchange resin resulted in a significant improvement in the separation of carbohydrates by HPLC using the partition mode. Honda and Suzuki, using this mode, established analytical conditions common to aldoses, amino sugars, and sialic acids. Aldoses in the intact state, amino acids as their *N*-acetates, and sialic acids as *N*-acylmannosamines were separated on a column of a proton-formed, sulfonated styrene–divinylbenzene copolymer and detected by measuring absorption at 280 nm after postcolumn labeling with 2-cyanoacetamide.

Postcolumn labeling is a characteristic feature of carbohydrate analysis in which no direct physical methods are available for sensitive detection. Many labeling methods have hitherto been developed. The methods with phenol in

sulfuric acid,[16] orcinol in sulfuric acid,[17] anthrone in sulfuric acid,[18] tetrazolium blue in alkali,[19] copper(II)-2-2′-bicinchonitate,[20] and 2-cyanoacetamide[21] are used for photometric detection. The methods with 2-cyanoacetamide,[6] ethylenediamine,[22] ethanolamine,[23] taurine,[24] and arginine[25] are used for fluorimetric detection. Some labeling methods for electrochemical detection were reported by Honda and Suzuki in 1984.[26,27]

Quantification of Carbohydrates by Anion-Exchange HPLC and Amperometric Detection

Two main columns are used in the analysis of carbohydrates by amperometric detection: the CarboPac™ PA10 and the CarboPac MA1 anion-exchange columns. The CarboPac PA10 column packing consists of a non-porous, highly cross-linked polystyrene–divinylbenzene substrate agglomerated with 460 nm-diameter latex. The MicroBead™ latex is functionalized with quaternary ammonium ions, which create a thin surface-rich anion-exchange site. The packing is specifically designed to have a high selectivity for carbohydrates. The PA10 has an anion-exchange capacity of approximately 100 μEq/column.

The CarboPac MA1 resin is composed of a polystyrene–divinylbenzene polymeric core. The surface is grafted with quaternary ammonium anion-exchange functional groups. Its macroporous structure provides an extremely high anion-exchange capacity of 1450 μEq/column. The CarboPac MA1 column is designed specifically for sugar alcohol and glycol separations. The PA10 but not the MA1 is compatible with eluents containing organic solvents, which can be used to clean these columns.

The equipment used for the analysis of carbohydrates by anion exchange and amperometric detection include a Dionex DX-500 system consisting of a GP40 gradient pump, an ED40 electrochemical detector, a LC30 chromatography oven, and a PeakNet chromatography workstation. A gold electrode is used for both column applications. The flow rate used for the PA10 column is 1.5 ml/min and 0.4 ml/min for the MA1. Injection volumes are typically 10 μl and the oven temperature 30°C. Eluent components include water and 200 m*M* sodium hydroxide for the PA10 column and water and 480 m*M* sodium hydroxide for the MA1 column. Eluent concentration for the PA10 column starts at 91% water/9% 200 m*M* sodium hydroxide for up to 11 min, 100% 200 m*M* sodium hydroxide from 11.1 to 17.6 min, and 91% water/9% 200 m*M* sodium hydroxide from 17.7 to 40.0 min. Eluent concentration for the MA1 column system starts at 52% water/48% 480 m*M* sodium hydroxide and is maintained for up to 60 min.

Table 1 shows the separation of alcohols (2,3-butanediol, ethanol, methanol), glycols (glycerol), alditols (erythritol, arabitol, sorbitol, galactitol, mannitol), and carbohydrates (rhamnose, arabinose, glucose, galactose, lactose, sucrose, raffinose, maltose) using a CarboPac MA1 column set with 480 m*M* sodium hydroxide eluent flowing at 0.4 ml/min. The alcohols, sugar alcohols (alditols), glycols, and carbohydrates are well resolved. Maltose elutes at about 60 min.

Table 1 Separation of carbohydrates, alditols, alcohols, and glycols using a CarboPac MA1 column and pulsed amperometry.

Analyte	Retention time (min)
2,3-Butanediol	7.4
Ethanol	7.6
Methanol	7.8

Carbonyls: Derivatization for GC Analysis

Igor G. Zenkevich
Chemical Research Institute, St. Petersburg State University, St. Petersburg, Russia

Abstract
The carbonyl group in aldehydes (RCHO) and ketones (RCOR′) is one of the frequently encountered functionalities in the composition of organic compounds. This group has no active hydrogen atoms, excluding the cases of high content of enols for β-dicarbonyl compounds (β-diketones, esters of β-ketocarboxylic acids, etc.); hence the simplest carbonyl compounds are volatile enough to be analyzed with gas chromatography (GC) in their native forms. Nevertheless, if any other polar groups are present in the molecules of analytes, the conversion of all of them into less polar fragments is recommended. The most important type of organic reactions used in derivatization of carbonyl compounds is condensation with different nucleophilic reagents having primary amino groups, i.e., -NH_2 (aryl hydrazines, *O*-alkyl hydroxylamines, etc.).

INTRODUCTION

The carbonyl group in aldehydes (RCHO) and ketones (RCOR′) is one of the frequently encountered functional groups in organic compounds. This group has no active hydrogen atoms, excluding the enol tautomers in β-dicarbonyl compounds (β-diketones, esters of β-ketocarboxylic acids, etc.). In these cases enol tautomers are stabilized by intramolecular hydrogen bond, as it is shown in Fig. 1.

The carbonyl fragment is present in more complex functional groups like carboxyl (–COOH) in organic acids or (–CO–NRR′) in amides. Owing to the different chemical properties, these classes of carbonyl compounds are considered independently.

One of the general objectives of derivatization is to replace active hydrogen atoms in different functional groups by less polar fragments (see *Derivatization of Analytes: General Aspects*, p. 562). However, in accordance with this aim, the derivatization of monofunctional carbonyl compounds is not an obligatory stage of sample preparation before gas chromatography (GC) analysis. Nevertheless, the main reasons for their derivatization are the following:

1. The simple aldehydes and ketones are slightly polar low boiling substances with small retention indices (RIs) both on standard non-polar and on polar stationary phases (Table 1).

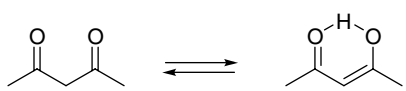

Fig. 1 Appearance of active hydrogen atoms in the molecules of β-diketones in a result of keto-enol tautomerism.

From these data it is easy to conclude that RIs of both aldehydes and ketones exceed these parameters for *n*-alkanes with the same number of carbon atoms only at 176 ± 5 retention index units (i.u.) on standard non-polar phases. This small ΔRI value indicates that these compounds belong to the group of only slightly polar chemicals. At the same time, the average difference of RIs of carbonyl compounds on standard polar polyethylene glycols and non-polar polydimethyl siloxanes is 293 ± 15 (aldehydes) and 282 ± 39 (ketones), which is only slightly more than, for example, the corresponding ΔRI value for alkyl-substituted arenes (246 ± 30) (they are not classified as polar compounds).[1]

However, in the numerous GC analytical procedures, the first part of chromatograms very often can be overloaded by intense poorly resolved peaks of auxiliary compounds (solvents, by-products, etc.). The optimization of the determination of target carbonyl compounds usually needs the "replacement" of their analytical signals into less "populated" areas of chromatograms (the

Compound	$RI_{non\text{-}polar}$	RI_{polar}
Aldehyde		
Ethanal	369 ± 7	701 ± 14
Propanal	479 ± 9	794 ± 9
Ketone		
Acetone	472 ± 12	820 ± 14
2-Butanone	578 ± 12	907 ± 14

Table 2 Comparison of dipole moments of structurally related alkanals, 1-alkanols, and alkanecarboxylic acids.

Compound	μ, D	Compound	μ, D
Ethanal	2.7	Propanal	2.6
Ethanol	1.7	1-Propanol	1.7
Acetic acid	1.7	Propionic acid	1.7

derivatives with retention parameters that exceed those for initial analytes).

At the same time it is interesting to note one paradox connected with the term "polarity." If we consider such characteristics of polarity as dipole moment (D), commonly accepted in chemistry, we should conclude that simplest carbonyl compounds (RCHO) are more polar as corresponding aliphatic alcohols (RCH_2OH) and, moreover, carboxylic acids (RCO_2H) (Table 2). Hence, it is not the dipole moment, but just the presence of active hydrogen atoms in the molecules of alcohols and carboxylic acids that is responsible for the chromatographic polarity of analytes and in that sense polarity in organic chemistry and chromatography are not equivalent to each other.

However, instead of interpretation of a term as ambiguous as polarity, it is better to bear in mind the structural features of molecules of analytes (presence or absence of functional groups with active hydrogen atoms).

2. The simplest monofunctional compounds with active hydrogens in the functional groups OH, NH_2, and so forth are typically volatile enough for their direct GC determination. However, the presence of any additional polar fragments (including C═O) in the molecules makes GC analysis of these compounds difficult, and they usually need derivatization of one or (better) both polar functional groups. Thus, in many cases, the necessity of derivatization of the carbonyl fragment in polyfunctional compounds is a secondary procedure that is required because of the presence of other functional groups.

   More importantly, some silylating reagents used for protection of functional groups with active hydrogen atoms can react with carbonyl fragments with the formation of trimethylsilyl (TMS) derivatives of enols. If such unpredictable mode of derivatization is undesirable, all carbonyl fragments should be protected before silylation, for example, by conversion into alkoxyimino groups (alkyl ethers of oximes, see below).
3. Both aliphatic and aromatic aldehydes are compounds that are easily oxidized even by atmospheric oxygen dissolved in the liquid samples. Hence, one of the aims of their derivatization is to prevent the oxidation of analytes.

METHODS OF DERIVATIZATION OF CARBONYL COMPOUNDS

Some methods for derivatizing carbonyl compounds have been known in "classical" organic chemistry since the 19th century. Their predestination was the identification of such compounds by simple comparison of melting points of purified solid derivatives with reference data. These derivatives are, for example, semicarbazones $RR'C{=}NNHCONH_2$, thiosemicarbazones $RR'C{=}NNHCSNH_2$, 2,4-dinitrophenyl hydrazones $RR'C{=}NNHC_6H_3(NO_2)_2$, and so forth. However, most of these derivatives are not volatile for their direct GC analysis owing to the presence of active hydrogen atoms. The convenient derivatives for GC determination should include not more than one of these atoms (as in monosubstituted aryl hydrazones) or they need to be free of them (*O*-alkyl or *O*-benzyl ethers of oximes).[2–6] The oximes themselves can be synthesized by the reaction of carbonyl compounds with hydroxylamine, but they are usually used in GC practice in the form of *O*-TMS ethers.

$$RR'CO + H_2NNHAr \rightarrow RR'C = NNHAr$$
$$RR'CO + H_2N - OR'' \rightarrow RR'C = N - OR''$$
$$RR'CO + H_2NOH \rightarrow RR'C = NOH \rightarrow RR'C = N - OSi(CH_3)_3$$

Formation of 2,4-dinitrophenylhydrazones of carbonyl compounds is a "popular" method for their derivatization. However, owing to low volatility of these derivatives, their reversed-phase high-performance liquid chromatography (HPLC) analysis seems more preferable than GC analysis.[7]

Other types of carbonyl derivatives are acetals or ketals, including their thio- and aza-analogues, preferably cyclic 1,3-dioxolanes, 1,3-oxothiolanes, or thiazolidines. The last method of derivatization with 2-aminoethanethiol has been proposed for sampling and GC determination of volatile aliphatic aldehydes (see Fig. 2).[8]

All the above-mentioned processes are classified as reactions of condensation. Hence, in all cases, the target derivatives are theoretically the sole components of reaction mixtures and no other detectable by-products excluding water (which has no influence on the results of GC analysis) are formed. However, some features of these reactions should be mentioned:

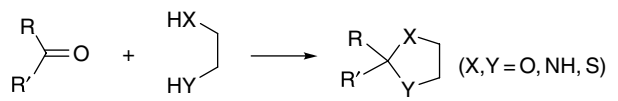

Fig. 2 Derivatization of carbonyl compounds with formation of heterocyclic products.

Table 3 Statistically processed differences of GC retention indices (ΔRIs) between products of some derivatization reactions and initial carbonyl compounds on standard non-polar phases.

Scheme of reaction	ΔMW	ΔRI
$RR'CO \rightarrow RR'C{=}NNHCH_3$	28	229 ± 23
$ArRCO \rightarrow ArRC{=}NNHCH_3$	28	320 ± 30
$RR'CO \rightarrow RR'C{=}NN(CH_3)_2$	42	302 ± 20
$RR'CO \rightarrow RR'C{=}NNHC_2H_5$	42	345 ± 16
$RR'CO \rightarrow RR'C{=}NNHC_6H_5$	90	858 ± 22
$ROH \rightarrow ROSi(CH_3)_3$ (for comparison)	72	119 ± 18

1. Some reagents, especially aryl hydrazines in the form of free bases, are slightly oxidized compounds. Their salts with inorganic acids are more stable, but even in this case, the presence of any oxidizers in the reaction mixtures must be prevented. Nevertheless, in practice, these mixtures very often contain some oxidation by-products (e.g., $ArNH_2$, ArOH, ArH). Usually, it is not difficult to obtain their chromatographic peaks, because all of them have lower retention parameters than that for initial reagents and, moreover, all target derivatives.
2. The condensation reaction of considered type can be characterized by statistically processed differences of RIs of products and initial substrates.[9] This additive scheme mode permits us to estimate these analytical parameters for any new derivatives of monocarbonyl compounds of standard non-polar polydimethyl siloxanes. For the simplest reaction scheme A + L → B + M, we have the following ΔRI = RI(B) – RI(A) values [ΔMW = MW(B) – MW(A)] (Table 3):

   This set of ΔRI values illustrates that the simplest alkyl hydrazones (methyl, ethyl, dimethyl, etc.) have appropriate GC retention parameters and theoretically can be recommended as the derivatives of carbonyl compounds. But in real analytical practice, these hydrazones are not used because of their low yields for aliphatic ketones.
3. All considered condensation reactions have some anomalies for the α,β-unsaturated carbonyl compounds. Most reagents with active hydrogen atoms can react not only with carbonyl groups, but also with polarized conjugated C=C double bond (absence of regioselectivity). As a result of this feature, three products instead of the estimated one target derivative (pair of *syn*- and *anti*-isomers) can be formed in the reactions of α,β-unsaturated carbonyl compounds with *O*-alkyl hydroxylamines, like it is illustrated by scheme presented in Fig. 3.[10]

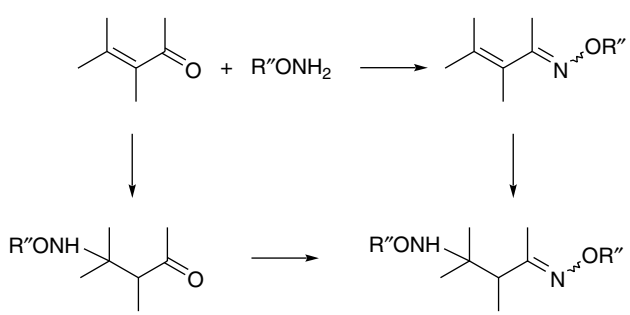

Fig. 3 Anomalous interaction of α,β-unsaturated carbonyl compounds with *O*-alkyl hydroxylamines.

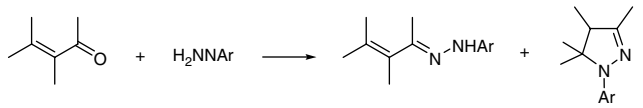

Fig. 4 Formation of two alternative products in the reaction of α,β-unsaturated carbonyl compounds with aryl hydrazines.

The relative ratio of these products depends on the excess of derivatization reagent and pH of reaction mixtures. The chemical origin of products of the reaction of aryl hydrazines with unsaturated carbonyl compounds depends on the same factors and, moreover, on the order of component mixing (it exerts influence on the current pH of reaction media). Thus, 2-pyrazolines have resulted in some cases as the predominant products instead of hydrazones (see scheme in Fig. 4).

The formation of different products means that the quantitative yields of each of them are not enough, as is necessary for GC analysis of derivatives. It is quite probable that the same anomalies can take place in the reactions of unsaturated carbonyls with other reagents. This fact is reflected by the small number of published RI data for the derivatives of these compounds and it explains the necessity to search for new types of derivatization reactions for them.

Both *O*-ethers of oximes and some disubstituted hydrazones of asymmetrical carbonyl compounds exist in two isomeric structures with slightly different GC retention parameters (Fig. 5).

Hence, most of these derivatives give two analytical signals on the chromatograms. *Anti*-isomers typically

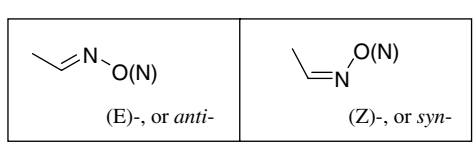

Fig. 5 *Syn-anti* isomerism of *O*-alkyl ethers of oximes (hydrazones).

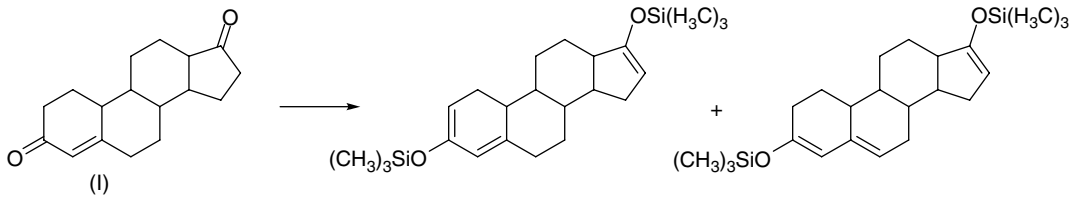

Fig. 6 Formation of two silylation products from androst-5-en-3,17-dione.

are more stable and their peaks prevail over those of the *syn*-forms. If the assignment of these two peaks to the isomeric compounds is not obvious, in accordance with the usual chromatographic practice they can be marked by symbols #1 and #2 (in order of chromatographic elution). The same duplication of analytical signals takes place, for example, during RP HPLC analysis of 2,4-dinitriphenylhydrazones (2,4-DNPHs).

The condensation reaction of carbonyl compounds with halogen-containing derivatization chemicals (so-called electroforic reagents like pentafluorophenyl hydrazine, 2,4,6-trichlorophenyl hydrazines)[11] and, especially, pentafluorobenzyl hydroxylamine (PFBHA)[12–14] that has been considered can provide the possibility of their selective GC determination with electron capture detectors. For GC analysis of monosaccharides (an important group of hydroxy carbonyl compounds), many combinations of derivatization reagents have been proposed, but most of them are based on the conversion of carbonyl group into hydroxyimino (>C=NOH) with following silylation, and alkoxy (methoxy)imino (>C=NOR).[15]

For polyfunctional organic compounds, the condensation reactions of carbonyls considered should be combined with different derivatization of other functional groups. The "standard" method for the derivatization of hydroxysteroids for GC analysis is their two-stage treatment by *O*-methyl hydroxylamine, followed by silylation of OH groups. The resulting trimethylsilylated methyl oxime derivatives (MO-TMS) of compounds of this class are well characterized by standard mass spectra and GC RIs on standard non-polar phases for their identification. The use of most active silylating agents permits us to exclude the stage of *O*-methyl oxime formation, as long as ketosteroids can form the enol-TMS ethers. For example, androst-5-en-3,17-dione (I, no hydroxyl groups present in the molecule) after silylation by MSTFA/AcOK or ethyl (trimethylsilyl)acetate [$(CH_3)_3SiCH_2CO_2C_2H_5$] forms the *bis*-*O*-TMS derivative of *bis*-enol.[16] The enolization of the carbonyl group in the third position in similar structures can lead to the formation of a conjugate system of C=C double bonds in enol not only in positions 2,4, but also in positions 3,5 (see Fig. 6). These isomeric TMS-enol derivatives have different retention parameters[17] that should be kept in mind during interpretation of the results (duplication of analytical signals for the single precursor). Because of the presence of p-π-(d) conjugated systems C=C–O–(Si), these enol-TMS derivatives indicate intense signals of the molecular ions in their mass spectra.

To minimize the risk of accessory reactions during silylation of α,β-unsaturated carbonyl compounds and, hence, the uncertainty in the structures of derivatives, some original recommendations have been proposed. One of them implies the use of mixed reagent MSTFA + I_2, that provides silylation of carbonyl enols accomplished by entering of *N*-containing fragment from TMS-carrier in the α-position of carbonyl compound in the result of nucleophilic substitution (it is recommended just for steroidal 3-ketones with C=C double bond in the position 4).[18] However, this proposition remains discussible at first in respect of the yield of the derivatization and regioselectivity of the reaction.

Sometimes the products of carbonyl compounds silylation are not TMS-enols, but *bis*-TMS derivatives of hydrated carbonyls, $RR'C=O \leftrightarrows RR'C(OH)_2 \rightarrow RR'C(OTMS)_2$.[19] More unpredictable products can be formed during silylation of α-ketocarboxylic acids. For example, ketomalonic acid (II) besides the normal *bis*-TMS ester gives an unusual TMS derivative of the enol-hydrate form[20] (see Fig. 7).

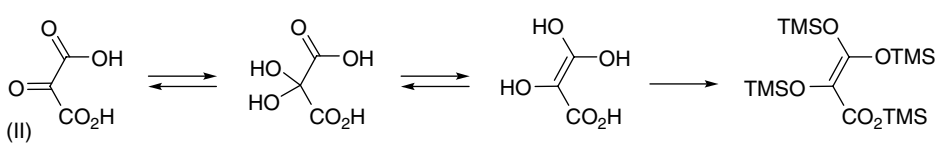

Fig. 7 Example of unusual silylation of ketomalonic acid with formation of tetrakis-TMS derivative instead of normal *bis*-TMS ester.

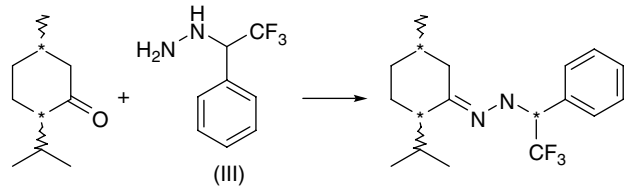

Fig. 8 Example of formation diastereomeric derivatives from chiral carbonyl compound and derivatization reagent.

The formation of volatile acetals or ketals from carbonyl compounds requires acid catalysis and (sometimes) the presence of water-coupling reagents. This reaction accomplishes alkylation of carboxyl groups when ketocarboxylic acids are derivatized by this method.[21,22] The conversion of aliphatic aldehydes into dimethyl acetals only slightly increases the retention parameters of analytes ($\Delta RI = 189 \pm 17$). Cyclic ethylene derivatives (1,3-dioxolanes, $\Delta RI = 212 \pm 23$ for acyclic carbonyl compounds) are more resistant to hydrolysis and used in GC practice preferably. Their important advantage for gas chromatography–mass spectrometry (GC–MS) analysis is the very specific fragmentation of molecular ions with the loss of substituents R and R′ in the second position of the cycle (see Fig. 3) and the formation of daughter ions $[M\text{-}R]^+$ and $[M\text{-}R']^+$, which gives useful information for the determination of the initial carbonyl compound structure. The use of 2-aminoethanethiol instead of ethylene glycol in this reaction leads to the formation of thiazolidines, which indicate intense signals of molecular ions in mass spectra. It is noteworthy that the latter reagent (solid substance with high melting point) contains two polar functional groups (NH_2 and SH) with active hydrogen atoms in the molecule and its GC analysis without derivatization is impossible.

The GC separation of chiral carbonyl compounds (at first natural terpenoids) on the non-chiral phases can be carried out in accordance with the same principles as those for enantiomers of other classes. Their conversion to diastereomers by reaction with chiral derivatization reagents is necessary. An example is the reaction of stereochemically pure α-trifluoromethylbenzyl hydrazine (III) with isomeric menthones; symbol (*) in the Fig. 8 means the chiral center in the molecule.

Principal physicochemical and gas chromatographic properties of some reagents for derivatization of carbonyl compounds are summarized in Table 4.

Table 4 Physicochemical and gas chromatographic properties of some reagents for derivatization of carbonyl compounds.

Reagent	Abbreviation	MW	T_b, °C (m.p., °C)	$RI_{non\text{-}polar}$
Phenyl hydrazine	—	108	244	1157 ± 11
Pentafluorophenyl hydrazine	PFPH	198	(74–75)	1164 ± 16

CONCLUSIONS

Monofunctional carbonyl compounds belong to the group of slightly polar organic substances and typically need no derivatization prior to GC analysis. However, the carbonyl functional group is one of the most encountered fragments in the composition of organic compounds. In accordance with general principles of derivatization, all the polar groups present in molecules should be transformed into less polar fragments having no active hydrogen atoms. Following this concept, numerous methods have been proposed for the derivatization at first of polyfunctional carbonyl compounds.

Some special methods for derivatization of simple low boiling aldehydes and ketones are used for the "displacement" of their analytical signals into less "populated" parts of chromatograms. It increases the resulting selectivity for determining target analytes.

Catalysts: Reversed-Flow GC

Dimitrios Gavril
Physical Chemistry Laboratory, Department of Chemistry, University of Patras, Patras, Greece

Abstract
Reversed-flow gas chromatography (RF-GC) has been used to study the kinetics of surface-catalyzed reactions and the nature of the active sites. RF-GC is technically very simple and it is combined with a mathematical analysis that gives the possibility for the estimation of various physicochemical parameters related to catalyst characterization in a simple experiment under conditions compatible with the operation of real catalysts. The experimental findings of RF-GC for the oxidation of CO over well-studied silica-supported platinum–rhodium bimetallic catalysts are in agreement with the results of other workers using different techniques ascertaining that RF-GC methodologies can be used for the characterization of various solids with simplicity and accuracy.

INTRODUCTION

During the last four decades, various chemical reactions concerning processes of technological and environmental interest have been related to the development of catalysts. Catalyst characterization is a necessary step and it usually involves activity tests and investigation of the kinetics of the related reactions as well as of the nature of the active sites.

Diffusion, adsorption, and surface reaction are closely interconnected in heterogeneous catalysis characterization studies. Chromatographic separation is a physicochemical process also based on diffusion, adsorption as well as liquid dissolution. Based on the broadening factors embraced by the van Deemter equation, precise and accurate physicochemical measurements have been made by gas chromatography, using relatively cheap instrumentation and a very simple experimental setup.

Reversed-flow gas chromatography (RF-GC) is another gas chromatographic technique based on the perturbation of the carrier gas flow, which has been utilized for the measurement of physicochemical parameters. The fundamental difference of RF-GC from classic GC is the use of a T-form system of chromatographic columns (sampling and diffusion columns) placed perpendicularly one in the middle of the other. The carrier gas flows continuously through the sampling column, while it is stagnant in the diffusion column. The solid catalyst under study is placed either near the injection point at the closed end of the diffusion column, for experiments under *non-steady-state* conditions, or at the middle of the sampling column, for experiments under *steady-state* conditions, as is shown in Fig. 1. The fact that the solid material is under investigation also classifies RF-GC as an inverse gas chromatographic (IGC) methodology. The reversing of the carrier gas flow for short time intervals results in extra chromatographic peaks on the continuous concentration–time curve. Thus, a repeated sampling of the physicochemical phenomena occurring into the diffusion column is achieved, and by using appropriate mathematical analysis the values of the relevant physicochemical quantities are determined.

EXPERIMENTAL

The experimental setup of RF-GC for the study of catalytic processes has been presented elsewhere,[1–21] and it is very simple. It comprises of a conventional gas chromatograph equipped with the appropriate detector (e.g., flame ionization, thermal conductivity) depending on the reactant(s) and product(s). A separation column L' can also be incorporated in the GC oven. The separation column can be filled with the appropriate material for the separation of the reactants and products and it can be heated at the same or at a temperature different from that of the sampling cell. The "sampling cell" is formed by the sampling column $l' + l$ and the diffusion column L, which is connected perpendicularly to the middle of the sampling column. The ends D_1 and D_2 of the sampling column are connected through a four-port valve, to the carrier gas inlet and the detector, as shown in Fig. 1.

When flow perturbations are performed, negative and positive abrupt fronts appear in the chromatogram, forming the so-called *sampling peaks* like those shown in Fig. 2.[1] The volumetric carrier gas flow rate does not affect the physicochemical phenomena occurring in the diffusion column, but affects only the speed of the sampling procedure.

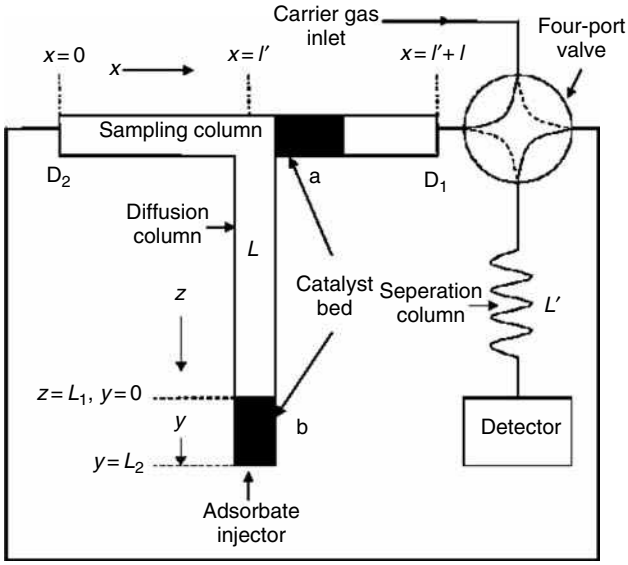

Fig. 1 Experimental setup used from RF-GC for the characterization of solid catalysts: a) Under steady-state conditions, with catalyst bed being put at a short length of sampling column *l*, near the junction of diffusion and sampling columns; b) Under non-steady-state conditions, with catalytic bed being put at the top of diffusion column *L*.

THEORETICAL

The sampling peaks are predicted theoretically by the "chromatographic sampling equation," describing the concentration–time curve of the sampling peaks created by the flow reversals. The area or the height H, of the sampling peaks is proportional to the concentration of the substance under study at the junction $x = l'$ of the sampling cell at time t from the beginning of the experiment. If ln H is plotted against time t for each solute, the so-called diffusion band, is obtained. An example is shown in Fig. 3.[1]

Under Steady-State Conditions

By placing the catalyst bed at a short length of the sampling column l near the junction of the diffusion and sampling column (cf. Fig. 1), the catalytic behavior under steady-state conditions can be studied. In this case, time-dependent fractional conversions X_t are determined from the heights or the areas of the sampling peaks obtained after each flow reversal, and overall conversions X can be calculated from the total areas of the diffusion bands corresponding to reactants and products.[1]

Under Non-Steady-State Conditions

The catalytic behavior under non-steady-state conditions can be studied by placing the catalyst bed at a short length at the entrance of the diffusion column L (cf. Fig. 1). In this case not only conversions but also a large number of physicochemical parameters related to the interaction of the studied catalyst with the injected adsorbate can be determined. The whole treatment of experimental data is based on the fact that the heights of the "sampling peaks" are described by a clear function of time comprising the sum of 2–4 exponentials.

$$H^{1/M} = \sum_i A_i \exp(B_i t) \tag{1}$$

where H is the height of the experimentally obtained chromatographic peaks, M the response factor of the detector, and t the time from the beginning of the experiment. Eq. 1 is not an a priori assumption, but results from the solution of the mathematical model. The values of the pre-exponential factors A_i and the corresponding coefficients of time B_i are easily and accurately determined from the chromatogram by PC programmes of non-linear least-squares regression (cf. Appendix of Ref. 13).

The experimental pairs H, t are the variables of Eq. 1. By introducing them into the data lines of the GWBASIC program as given in Appendix of Ref. 12, together with other easily obtained quantities required by the input lines (such as the geometric details of the diffusion column, mass and porosity of the catalyst bed, solute amount as well as its diffusion coefficient in the carrier gas, and the carrier gas flow rate), the various physicochemical parameters related to the studied catalyst are calculated.

POTENTIAL OF THE METHODOLOGY AND INDICATIVE RESULTS

RF-GC methodologies have been utilized for the investigation of various catalytic processes and a large amount of physicochemical quantities related to the kinetics of the elementary steps (adsorption, desorption, surface reaction) and the nature of the active sites have been determined. These parameters are summarized as follows:

1. Time-dependent, X_t, and overall, X, conversions, either under steady- or non-steady-state conditions.[1,2,17,21]
2. Adsorption, k_1, desorption, k_{-1}, and surface reaction, k_2, rate constants and the respective activation energies, E_a.[3,4,5,15]
3. Local adsorption energies, ε, local adsorption isotherms, $\theta(p, T,\varepsilon)$, local monolayer capacities, c^*_{max}, and adsorption energy distribution functions, $f(\varepsilon)$, for the adsorption of gases on heterogeneous surfaces circumventing altogether the integral equation:[6,7]

$$\theta(p,T) = \int_0^\infty \theta(\varepsilon,p,T) f(\varepsilon) d\varepsilon \qquad (2)$$

where (p,T) is the overall experimental adsorption isotherm.

4. The energy of the lateral molecular interactions on heterogeneous surfaces in a time-resolved procedure.[8,12,18,19]
5. Surface diffusion coefficients for physically adsorbed or chemisorbed species on heterogeneous surfaces in a time-resolved procedure.[9,20]
6. Standard free energy of adsorption and its probability density function over time, together with the geometrical mean of the London parts of the total surface free energy $(\gamma_1^L\gamma_2^L)^{\frac{1}{2}}$ of the adsorbed probe and the solid surface, accompanied by the relevant probability density functions over time.[10,11]
7. Investigation of the nature of the various groups of active sites of solid catalysts.[12,18,19]
8. Study of the competition between mass transfer and kinetics of solid catalysts.[14]
9. Adsorption entropy, Gibbs free energy, and enthalpy for the adsorption of gases on heterogeneous surfaces.[16]

The question naturally arising is how reliable are the physicochemical quantities determined by means of RF-GC. For this reason, the adsorption of CO, O_2, and CO_2 as well as the oxidation of CO have been studied over well-studied silica-supported Pt–Rh bimetallic catalysts. Indicative conclusions extracted by using RF-GC, which are in agreement with the observation of other techniques, are the following:

Table 1 Rate constants for the adsorption (k_1), desorption (k_{-1}), and disproportionation reaction (k_2) of carbon monoxide over a Pt/SiO_2 catalyst, determined by reversed-flow gas chromatography, at various temperatures.

a. The experimental data for carbon monoxide adsorption over the studied catalysts (in the absence of oxygen in the carrier gas), at temperatures higher than 300°C, suggest that the adsorption of CO is a dissociative process.[2,4]
b. There is a characteristic temperature of maximum catalytic activity, T_{max}, for every bimetallic catalyst. The temperatures found by RF-GC are very close to those found for the same catalysts by using different techniques.[1–4]
c. The bimetallic catalysts exhibit higher catalytic activity at lower temperatures in comparison to pure Pt and Rh ones, as shown in Fig. 2. Other workers have also observed this synergism for Pt–Rh bimetallic catalysts.[1–4]
d. The rate constants found by the RF-GC technique, as those in Table 1, are very close to those determined experimentally by the frequency response method[2,4,5] for the adsorption of CO on Pt/SiO_2.
e. The values of the estimated activation energies for CO-dissociative adsorption, shown in Table 2, are low. Low activation energy values are indicative of

Table 2 Activation energies (kJ/mol) corresponding to the adsorption, E_{a1}, desorption, E_{a-1} and disproportionation reaction, E_{a2}, of carbon monoxide over silica supported Pt, Rh, and $Pt_{0.50}$–$Rh_{0.50}$ alloy catalysts.

corrugated surfaces. From the difference noticed in the energy barriers, it is also concluded that CO adsorption is the rate-determining step for CO-dissociative adsorption, followed by the dissociation step. These findings suggest a precursor-mediated mechanism for CO-dissociative adsorption.[2]

f. The nature of the different groups of active sites for the catalytic oxidation of CO has also been investigated from the experimentally determined energy distribution functions. The existence of three groups of active sites is observed as is shown in Figs. 3 and 4,[12] which is also expected from thermal desorption spectroscopy (TDS) for the adsorption of CO over group VIII noble metals.

Group A active sites correspond to β states of TDS, arising from CO-dissociative adsorption. The topography of these active sites is random, as the values of the lateral interaction energy, β, are negative. The B and C groups of active sites shown in our plots correspond to α states of TDS. They are characterized by positive values of β, which means that they have a patchwise topography. Group C active sites correspond to higher β values, in comparison with B group active sites. They are indicative of CO island formation. The experimental results also explain the superior activity of the $Pt_{0.25} + Rh_{0.75}$ alloy catalyst (synergism) as a result not only of its capacity to adsorb higher amount of carbon monoxide at lower temperatures, but also due to the fact that this catalyst is characterized by a more random topography in contrast with the other studied silica supported pure Pt and Rh catalysts.

The utilization of RF-GC methodologies has been extended in the study of the surface properties of various solids and related processes. Novel methodologies of RF-GC have been developed for the study of the competition between mass transfer and kinetics[14] as well as to measure the adsorption entropy.[16] It should be noted that in contrast with other IGC methods, which determine the standard entropy at zero surface coverage, the present method operates over a wide range of surface coverage taking into account not only the adsorbate–adsorbent interaction, but also the adsorbate–adsorbate interaction.

Moreover, in recent works the effect of the presence of hydrogen on the adsorptive behavior of monometallic Rh, bimetallic Pt–Rh/SiO_2,[13,15,18] and Au/γ–Al_2O_3 catalysts[17,19,21] was studied, since the selective CO oxidation (SCO) in a rich hydrogen atmosphere is a process of great technological and environmental interest, as it is related to the development of proton exchange membrane (PEM) fuel cells.

CO adsorption, being an elementary step of SCO, was studied over silica-supported monometallic Rh and $Rh_{0.50}$ + $Pt_{0.50}$ alloy catalysts, under various atmospheres ranging from 25% to 75% H_2.[15] The variation of the experimentally determined rate constants and the activation energies against the nature of the used catalyst (monometallic or alloy) and the amount of hydrogen in the carrier gas gives useful information about the selectivity as well as the activity of SCO. At low temperatures and under H_2-rich conditions, compatible with the operation of PEM fuel cells, the activity of the monometallic and the alloy catalysts is expected to be similar; however, the selectivity of $Rh_{0.50}$ + $Pt_{0.50}$ alloy catalyst is expected to be higher, making the Pt–Rh alloy catalyst a better candidate for CO-preferential oxidation. The determined desorption barriers were in any case much lower than the respective activation energies found for CO desorption in the absence of hydrogen, indicating H_2-induced desorption, which explains the observed in the literature rate enhancement of SCO oxidation.

Then, the effect of hydrogen in the "topography" of the active sites related to CO adsorption was studied on a silica-supported Rh catalyst, at 90°C.[18] It was found that the topography of the catalyst in the absence of hydrogen consists of both random and islands of CO bound over chemisorbed CO molecules. In contrast, under H_2-rich conditions, the topography observed was almost entirely patchwise ascribed to long-range lateral attractions between adsorbate molecules as shown in Fig. 5.[18] In excess of hydrogen, CO adsorption is shifted at higher lateral attractions values, β, which correspond to weaker adsorbate–adsorbent interactions and lower surface coverage. This provides an indication of a H_2-induced desorption, which can be attributed to the formation of an H–CO complex desorbing from the catalyst surface below the temperature required for CO desorption, in the absence of H_2, and could explain the well-known in the literature enhancement of SCO rate by H_2.

Recently, new findings giving further information on the mechanism of CO oxidation over γ-alumina-supported nanoparticle-sized gold catalysts were found, utilizing, among other techniques, RF-GC[17,21]: 1) CO_2 formation, increasing with rising temperature, was observed in the absence of hydrogen and oxygen pointing to a model of active sites consisting of an ensemble of metallic Au atoms and a cationic Au with a hydroxyl group; 2) at high temperatures (>200°C) in excess of H_2, reversed water gas shift (RWGS) reaction results in CO_2 consumption toward CO and H_2O formation; 3) hydrogen strongly influences the interaction of CO on Au/γ–Al_2O_3, by weakening the CO adsorption. The presence of hydrogen plays an important role in both decreasing the strength of CO bonding and preventing deactivation and regeneration.

The study of the nature of the active sites related to CO adsorption over Au/γ–Al_2O_3 both in the presence and in the absence of hydrogen in a wide temperature range has revealed[19] the following: 1) higher amounts of CO can be bound on the catalyst active sites, at conditions compatible with the operation of PEM-FCs; 2) at rising temperatures, catalyst adsorptive capacity decreases while the degree of surface heterogeneity increases since new groups of active sites appear, both in the presence and in the absence of hydrogen; 3) the experimentally observed high activity of Au/γ–Al_2O_3 for SCO at ambient temperatures can be explained as a consequence of weaker CO bonding over metallic Au active sites in comparison to stronger CO bonding taking place at active sites located on γ-Al_2O_3 support, which is related to deactivation.

CONCLUSIONS

The usual IGC, in which the stationary phase is the main object of investigation, is a classical elution method that neglects the mass transfer phenomena; it does not take into account the sorption effect and is also influenced by the carrier gas flow. In contrast to the integration method, the new methodology of RF-GC, although being an IGC technique, is a differential method not depending either on retention times and net retention volumes or on broadening factors and statistical moments of the elution bands.

The RF-GC methodology is technically very simple and it is combined with mathematical analysis for estimating various physicochemical parameters related to solid catalysts' characterization in a simple experiment under conditions compatible with the operation of real catalysts. The experimentally determined kinetic quantities are not only consistent with the results of other techniques but they can also give important information about the mechanism of the relevant processes, the nature of the active sites, and the topography of the heterogeneous surfaces. The utilization of RF-GC methodologies can be extended to the study of the surface properties of various solids of technological and environmental interest.

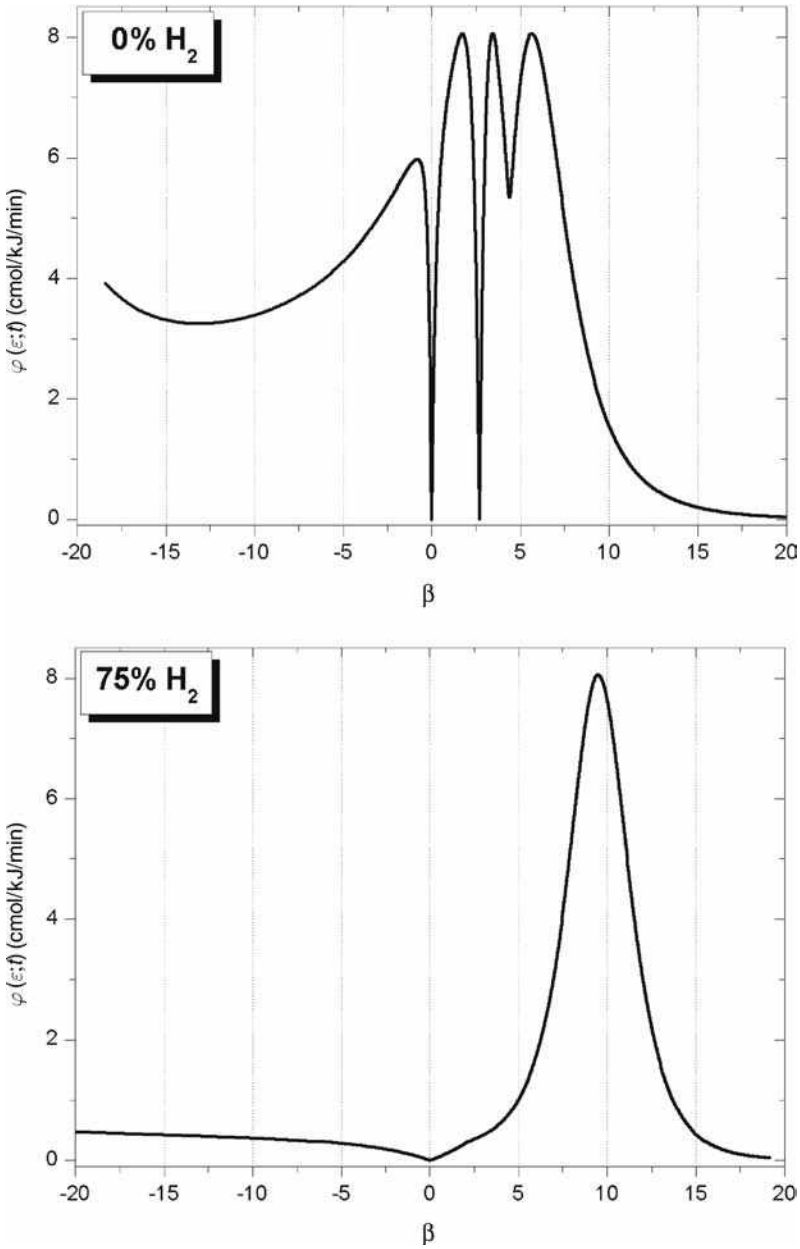

Fig. 5 Comparative study of the energy distribution functions $\varphi(\varepsilon;t)$ against the lateral interaction energy β, for CO adsorption on Rh/SiO_2 catalysts, at 90°C, in the absence of hydrogen (0% H_2) and in excess of hydrogen (75% H_2).

INTRODUCTION

Countercurrent chromatography (CCC) is a unique liquid–liquid partition technique which does not require the use of a solid support,[1–5] hence eliminating various complications associated with conventional LC, such as tailing of solute peaks, adsorptive sample loss and deactivation, contamination, and so forth. Since 1970, the CCC technology has advanced in various directions, including preparative and trace analysis, dual CCC, foam CCC, and, more recently, partition of macromolecules with polymerphase systems. However, most of these methods were only suitable for preparative applications due to relatively long separation times required. In order to fully explore the potential of CCC, efforts have been made to develop analytical high-speed CCC (HSCCC) by designing a miniature multilayer coil planet centrifuge; interfacing analytical HSCCC to a mass spectrometer (HSCCC/MS) began in the late 1980s.

Integration of the high-purity eluate of HSCCC with a low detection limit of MS has led to the identification of a number of natural products, as shown in Table 1.[6–10]

Various HSCCC/MS techniques and their applications are described herein.

INTERFACING HSCCC TO THERMOSPRAY MS

HSCCC/thermospray (TSP) MS was initiated using an analytical HSCCC apparatus of a 5-cm revolution radius, equipped with a 0.85 mm inner diameter (I.D.) polytetrafluoroethylene (PTFE) column at 2000 rpm.[6–8] Directly interfacing HSCCC to the MS produced, however, a problem in that the high back-pressure generated by the TSP vaporizer often damaged the HSCCC column. To overcome this problem, an additional high-performance liquid chromatography (HPLC) pump was inserted at the interface junction between HSCCC and MS to protect the column against high back-pressures. The effluent from the HSCCC column (0.8 ml/min) was introduced into the HPLC pump through a zero-dead-volume tee fitted with a reservoir supplying extra solvent or venting excess solvent from the HSCCC system. The effluent from the HPLC pump, after being mixed with 0.3 *M* ammonium acetate at a rate of 0.3 ml/min, was introduced into the TSP interface. This system has been successfully applied to the analyses of alkaloids,[6] triterpenoic acids,[7] and lignans[8] from plant natural products, thereby providing useful structural information. However, a large dead space in the pump at the interface junction adversely affected the resulting chromatogram, as evidenced by loss of a minor peak when HSCCC/UV and HSCCC/TSP–MS total ion current (TIC) chromatograms of plant alkaloids were compared.

In the subsequently developed techniques, the HSCCC effluent is directly introduced into the MS to preserve the peak resolution. Direct HSCCC/MS techniques have many advantages over the HSCCC/TSP method as follows:

1. High enrichment of sample in the ion source
2. High yield of sample reaching the MS
3. No peak broadening
4. High applicability to non-volatile samples

Various types of HSCCC/MS have been developed using frit fast-atom bombardment (FAB) including continuous flow (CF) FAB, frit electron ionization (EI), frit chemical ionization (CI), TSP, atmospheric pressure chemical ionization (APCI), and electrospray ionization (ESI). Each interface has its specific features. Among those, frit MS and ESI are particularly suitable for directly interfacing to HSCCC, because they generate low back-pressures of approximately 2 kg/cm^2, which is only one-tenth of that produced by TSP.

INTERFACING OF HSCCC TO FRIT EI, CI, AND FAB–MS

In our laboratory, separations were conducted by newly developed HSCCC-4000 with a 2.5 cm revolution radius, equipped with a 0.3 mm or 0.55 mm I.D. multilayer coil at a maximum revolution speed of 4000 rpm.[9] The system produced an excellent partition efficiency at a flow rate ranging between 0.1 and 0.2 ml/min, whereas the suitable

Table 1 Summary of previously reported HSCCC/MS conditions.

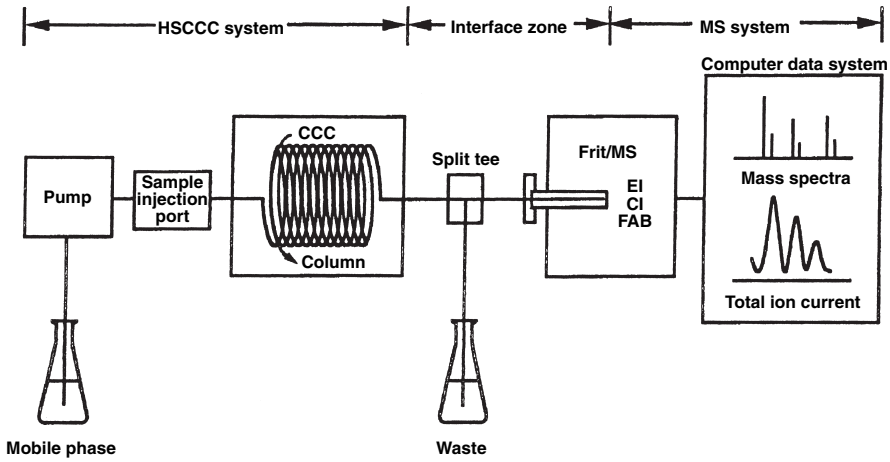

Fig. 1 HSCCC/frit MS system.

flow rate for HSCCC/frit MS is between 1 and 5 μl/min. Therefore, the effluent of the HSCCC column was introduced into the MS through a splitting tee which was adjusted to a split ratio of 1 : 40 to meet the above requirement. A 0.06 mm I.D. fused-silica tube was led to the MS and a 0.5 mm I.D. stainless-steel tube was connected to the HSCCC column. The other side of the fused-silica tube extended deeply into the stainless-steel tube to receive a small portion of the effluent from the HSCCC column, and the rest of the effluent was discarded through a 0.1 mm I.D. PTFE tube. The split ratio of the effluent depended on the flow rate of the effluent and the length of the 0.1 mm I.D. tube. For adjusting the split ratio at 40 : 1, a 2-cm length of the 0.1 mm I.D. tube was needed. Fig. 1 shows the HSCCC/MS system, including an HPLC pump, sample injection port, HSCCC/4000, the split tee, and mass spectrometer.[9]

In order to demonstrate the potential of HSCCC/frit MS, indole auxins, mycinamicins (macrolide antibiotics), and colistin complex (peptide antibiotics) were analyzed under HSCCC–frit, EI, CI, and FAB–MS conditions.

Three indole auxins, including indole-3-acetamide (IA, MW: 174), indole-3-acetic acid (IAA, MW: 175), and indole-3-butyric acid (IBA, MW: 203) were analyzed under frit EI–MS conditions. In comparison of a TIC with a UV chromatogram, both showed similar chromatographic resolution with excellent theoretical plate numbers ranging from 12,000 to 5500. The results indicate that MS interfacing does not adversely affect chromatographic resolution. In frit EI–MS, the mobile phase behaves like a reagent gas in CI–MS. Both molecular ions and protonated molecules appear in all mass spectra and these data are very useful for the estimation of the molecular weight. Common fragment ions originating from the indole nuclei are found at *m/z* 116 and 130.

A mixture of mycinamicins was analyzed under HSCCC/frit CI–MS conditions. Mycinamicins consist of six components, mycinamicins I to VI, and isolated mycinamicins IV (MN-IV, MW: 695) and V (MN-V, MW: 711) were used. The structural difference is derived from the hydroxyl group at C-14. These antibiotics were detected under CI conditions, but a reagent gas such as methane, isobutane, or ammonia was not introduced, because the mobile phase behaves like a reagent gas, as described earlier. Both UV and TIC chromatograms showed similar efficiencies, indicating that the MS interfacing does not affect peak resolution, as demonstrated in the analysis of indole auxins. An applicability of this HSCCC/MS system to less volatile compounds was examined under frit FAB–MS conditions.

A peptide antibiotic colistin complex consisting of two major components of colistins A (CL-A, MW: 1168) and B (CL-B, MW: 1154) is difficult to ionize by CI and EI–MS. For HSCCC analysis of these polar compounds, a wider column of 0.55 mm I.D. (instead of 0.3 mm I.D.) was used to achieve satisfactory retention of the stationary phase for a polar *n*-butanol–trifluoroacetic acid (TFA) solvent system. In addition, for obtaining FAB mass spectra, it is necessary to introduce a sample with an appropriate matrix such as glycerol, thioglycerol, and *m*-nitrobenzyl alcohol into the FAB–MS ion source. In the present study, glycerol was added as a matrix to the mobile phase at a concentration of 1%. Although a two-phase solvent system containing glycerol was the first trial for a HSCCC study, similarly satisfactory results were obtained in both retention and separation efficiency. Because of the use of a wider column with a viscous *n*-butanol–aqueous TFA solvent system, the separation was less efficient compared with those obtained from the above two experiments, but the peaks corresponding to CL-A and CL-B were clearly resolved. Mass chromatograms at individual protonated molecules showed symmetrical peaks without a significant loss of peak resolution due to MS interfacing. In all spectra, protonated molecules appeared well above the chemical noise to indicate the molecular weights. These experiments demonstrated that the present HSCCC/frit MS system including EI, CI, and FAB is very potent and is applicable to various

analytes having a broad range of polarity. For a non-volatile, thermally labile and/or polar compound, HSCCC–frit FAB is most suitable, whereas both HSCCC–frit EI and CI can be effectively used for a relatively non-polar compound.

INTERFACING HSCCC TO ESI–MS

The experiment was carried out using a small analytical coiled column (17 ml) at 1200 rpm. The effluent from the CCC column at 800 μl/min was split at a 1 : 7 ratio to introduce the smaller portion of the effluent into ESI–MS using a tee adaptor, as described earlier.

The performance of HSCCC–ESI–MS was evaluated by analyzing erythromycins and didemnins.[10] Because erythromycins (macrolide antibiotics) show weak UV absorbance and cannot be detected easily with a conventional UV detector, mass spectrometric detection is a very useful technique for analysis of these antibiotics. A mixture of erythromycin A (Er-A, MW: 733), erythromycin estolate (Er-E, MW: 789), and erythromycin ethyl succinate (Er-S, MW: 789) was analyzed using HSCCC–ESI–MS with a two-phase solvent system composed of *n*-hexane–ethyl acetate–methanol–water (4 : 7 : 4 : 3). TIC showed, clearly, four peaks corresponding to Er-A, Er-E, Er-S, and an unknown substance. The mass spectra of Er-E and Er-S gave $[M + H]^+$ at *m/z* 862 and 789 and $[M + H - H_2O]^+$ at *m/z* 844 and 772, respectively. In the mass spectrum of Er-A, $[M + H - H_2O]^+$ was observed at *m/z* 761; however, no $[M + H]$ was given. The mass spectrum of the unknown peak indicated that it consists of two components with molecular weights of 843 and 772, which correspond to dehydrated Er-S and Er-E, respectively.

Didemnin A (Did-A, MW: 942) is one of the main components of didemnins (cyclic depsipeptides) and is a precursor for synthesis of other didemnins which exhibit antiviral, antitumor, and immunosuppressive activities. Therefore, its purification is very important in the field of pharmaceutical science. However, largescale purification of Did-A using conventional LC is difficult due to the presence of nordidemnin A (Nordid-A), which contaminates the target fraction. HSCCC–ESI–MS has been successfully applied to the separation and detection of didemnins. Three peaks were observed on TIC corresponding to didemnins A and B and nordidemnin A. Their mass spectra gave only protonated molecules without fragmentation. The first eluted peak was didemnin B, which gave $[M + H]^+$ and $[M + Na]^+$ at *m/z* 1112 and 1134, respectively. Did-A appeared as the second peak with $[M + H]^+$ at *m/z* 943 and $[M + Na]^+$ at *m/z* 965. The third peak was Nordid-A, showing $[M + H]^+$ at *m/z* 929 and $[M + Na]^+$ at *m/z* 951. The results indicated that Did-A can be isolated by HSCCC.

FUTURE PROSPECTS

HSCCC/MS has many desirable features for performing the separation and identification of natural and synthetic products, because it eliminates various complications arising from the use of solid support and offers a powerful identification capacity of MS with its low detection limit. We believe that the combination of these two methods, HSCCC–MS, has great a potential for screening, identification, and structural characterization of natural products and will contribute to a rapid advance in natural products chemistry.

INTRODUCTION

Countercurrent chromatography (CCC) is a support-free liquid–liquid partition system where solutes are partitioned between the mobile and stationary liquid phases in an open column space. The instrumentation, therefore, requires a unique approach for achieving both retention of the stationary phase and high partition efficiency in the absence of a solid support. The variety of existing CCC systems may be divided into two classes,[1] i.e., hydrostatic and hydrodynamic equilibrium systems. The principle of each system can be illustrated by a simple coil, as shown in Fig. 1.

TWO BASIC CCC SYSTEMS

The basic hydrostatic equilibrium system (Fig. 1, left) utilizes a stationary coil. The mobile phase is introduced at the inlet of the coil, which has been filled with the stationary phase. The mobile phase then displaces the stationary phase completely on one side of the coil (dead space), but only partially displaces it on the other side due to the effect of gravity. This process continues until the mobile phase elutes from the coil. Once this hydrostatic equilibrium state is established throughout the column, the mobile phase only displaces the same phase while leaving the stationary phase permanently in the coil. Consequently, the solutes locally introduced at the inlet of the coil are subjected to a continuous partition process between two phases at each helical turn and separated according to their partition coefficients in the absence of a solid support.

The basic hydrodynamic equilibrium system (Fig. 1, right) uses a rotating coil, which generates an Archimedean screw effect, whereby all objects of different densities in the coil are driven toward one end, conventionally called "head," the other end being the tail. The mobile phase introduced through the head of the coil is mixed with the stationary phase to establish hydrodynamic equilibrium, with a portion of the stationary phase retained in each turn of the coil. This process continues until the mobile phase elutes from the tail of the coil. After hydrodynamic equilibrium is established throughout the coil, the mobile phase displaces only the same phase while leaving the other phase stationary in the coil. Consequently, solutes introduced locally at the head of the coil are subjected to an efficient partition process between the two phases and separated according to their partition coefficients.

Each basic system has its specific advantages as well as disadvantages. The hydrostatic system provides stable retention of the stationary phase but has relatively low partition efficiency due to the limited degree of mixing. The hydrodynamic system, on the other hand, has a high partition efficiency in a short elution time, but the retention of the stationary phase tends to become unstable due to violent mixing, often resulting in emulsification and extensive carryover of the stationary phase.

DEVELOPMENT OF HYDROSTATIC CCC SYSTEMS

In the early 1970s, the hydrostatic system was quickly developed into several efficient CCC schemes, as shown in Fig. 2.[2] The development has been done by utilizing unit gravity (Fig. 2, top) or centrifugal force (Fig. 2, bottom).

In droplet CCC, which utilizes unit gravity, one side of the coil (Fig. 1, left), entirely occupied by the mobile phase, is reduced to a fine flow tube, while the other side of the coil is replaced by a straight tubular column. The column is first filled with the stationary phase and the mobile phase is introduced into the column in a proper direction so that it forms a string of droplets in the stationary phase by the effect of gravity. The system necessitates the formation of droplets, which limits the choice of solvent system. In order to allow more universal application of solvent systems, a locular column was devised by inserting centrally perforated disks into the tube at regular intervals to form a number of compartments called "locules." The locular column is held at an angle and rotated along its axis to mix the two phases in each locule. As in droplet CCC, the lower phase is eluted from the upper end of the locular column and the upper phase from the lower end for better retention of the stationary phase.

In the toroidal coil CCC (helix CCC) system, operated under a centrifugal force, the dimensions of the coil are reduced (Fig. 2, lower left). The coil is mounted around the periphery of a centrifuge bowl so that the stable, radially acting centrifugal force field retains the stationary phase,

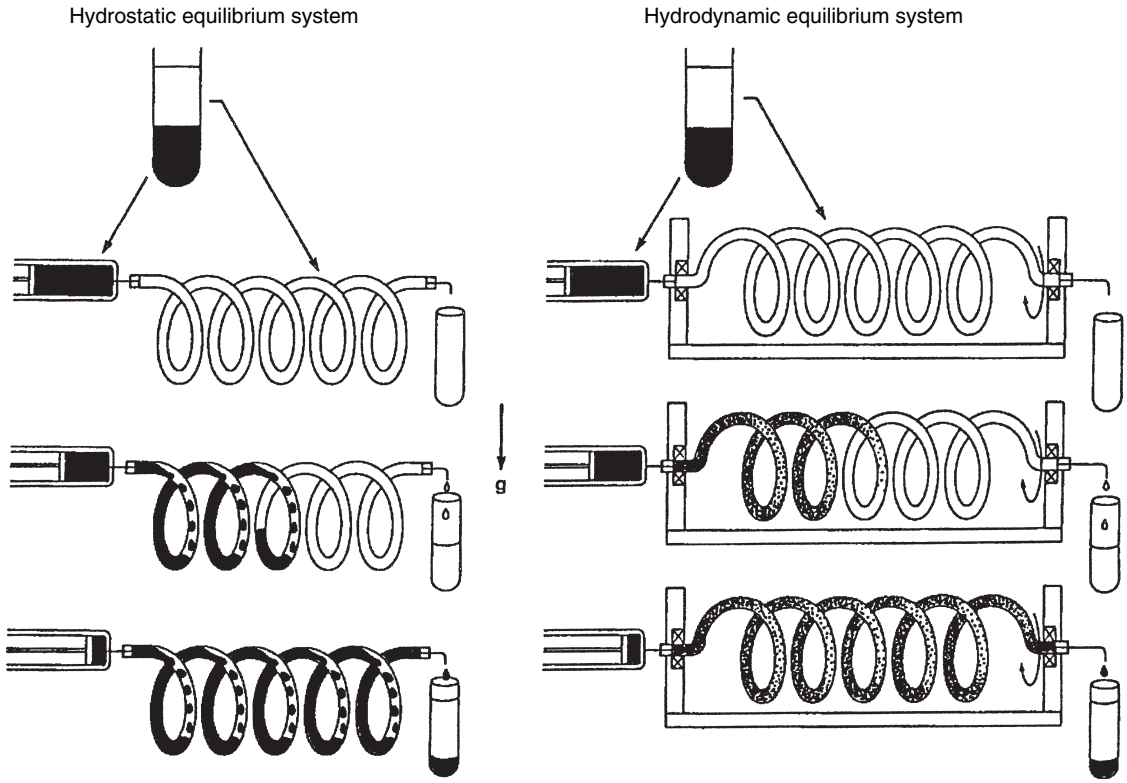

Fig. 1 Two basic CCC systems: hydrostatic equilibrium system (left) and hydrodynamic equilibrium system (right).

either upper or lower, on one side of the coil, as in the basic hydrostatic system (Fig. 1, left). The effective column capacity and retention of the stationary phase can be increased by replacing the coil with a locular column arrangement (centrifugal partition chromatography).

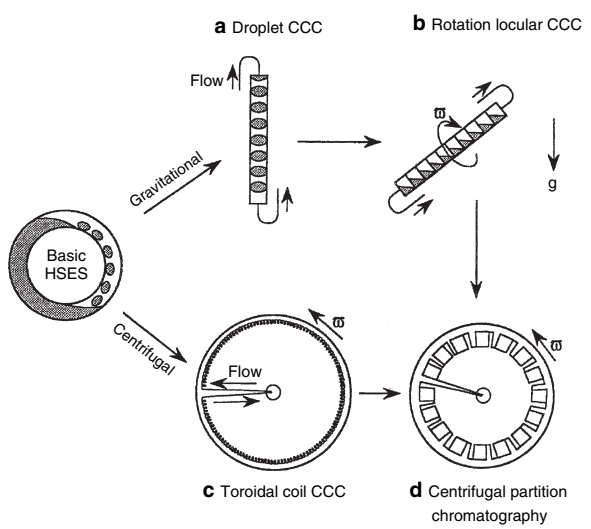

Fig. 2 Development of hydrostatic CCC systems.

INSTRUMENTATION OF HYDROSTATIC CCC SYSTEMS

Helix CCC (Toroidal Coil CCC)

Fig. 3A shows the design of the original helix CCC centrifuge rotor. A long helical column (typically 0.2–0.3 mm I.D. × 40 m length coiled onto a 0.85 mm xdO.D. tube making ~8000 turns) is accommodated around the periphery of the rotor. The mobile phase is introduced into the coil from a rotating syringe mounted at the center of the rotor, while the effluent from the outlet of the coil is collected through a rotary seal at the upper end of the syringe plunger. The system has a high partition efficiency of several thousand theoretical plates.[3]

The above original design has been improved using a seal-free centrifuge system based on non-planetary motion (Fig. 5, bottom middle). Fig. 3B shows a cross-sectional view of the seal-free toroidal coil centrifuge. A long helical tube is accommodated around the periphery of the column holder. The seal-free (non-planetary) motion of the column is achieved by a set of four miter gears: When the motor drives the gear box with a pair of toothed pulleys and a toothed belt, a pair of idler miter gears, engaged with the stationary miter gear at the bottom, rotate about their own axis at the same speed in a revolving gear box. This motion is further conveyed to the top miter gear, which is directly

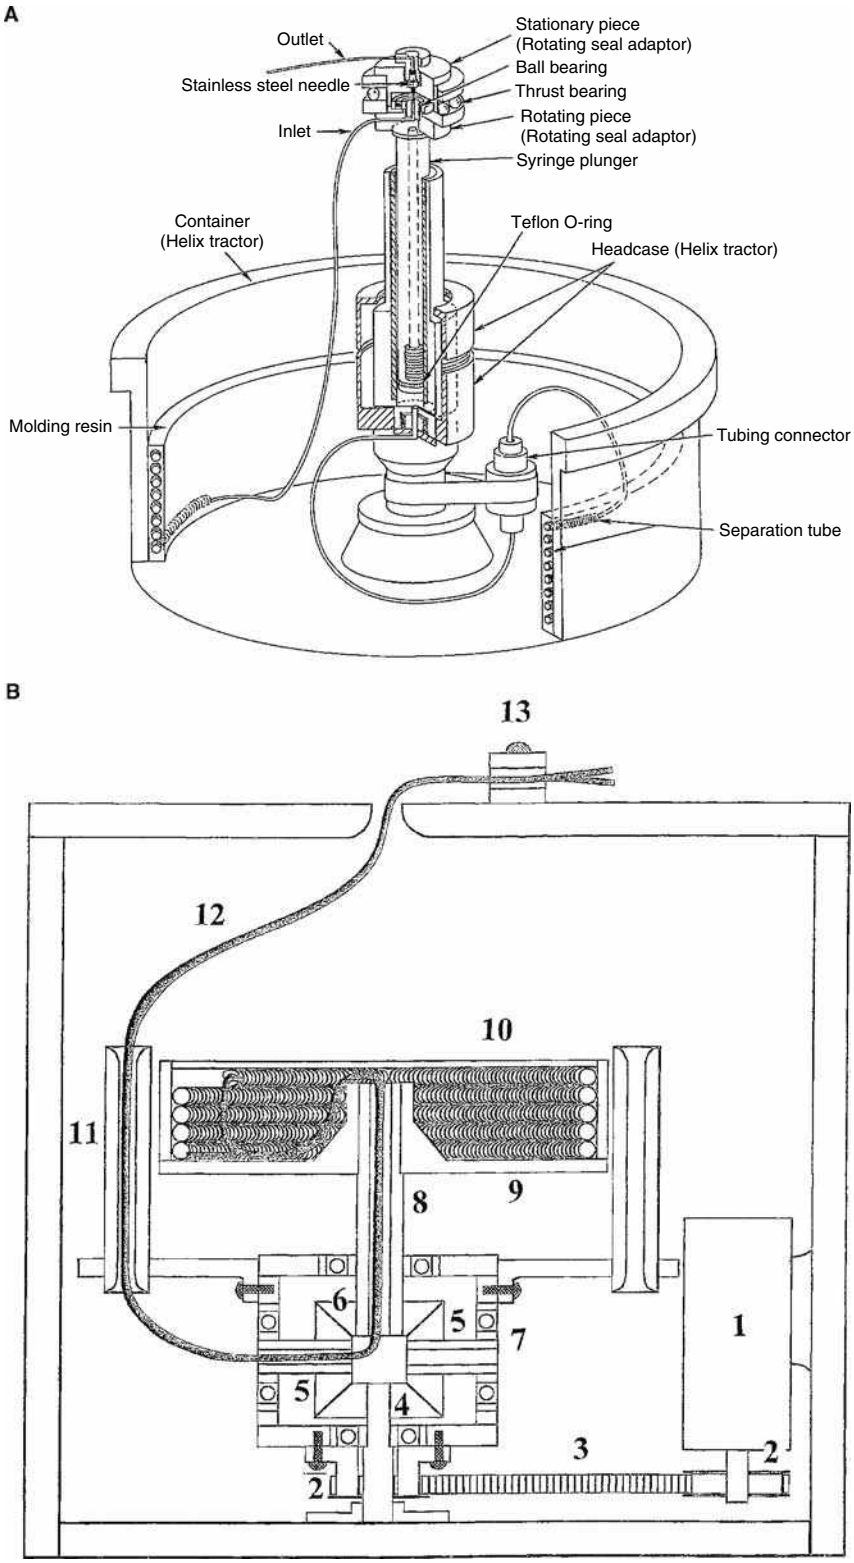

Fig. 3 Design of helix CCC (toroidal coil CCC) apparatus. A, Schematic drawing of centrifuge head of original helix CCC apparatus; B, cross-sectional view of advanced design of helix CCC equipped with seal-free flow-through device. 1, Motor; 2, toothed pulleys; 3, toothed belt; 4, stationary miter gear; 5, horizontal idler miter gear; 6, inverted upper miter gear mounted at bottom of column holder shaft (8); 7, gear box; 9, column holder; 10, coiled separation column; 11, hollow tube support; 12, flow tubes; and 13, clamps.

mounted at the lower end of the column holder shaft. Consequently, the column holder rotates at double the speed of an ordinary flow-through centrifuge system but without the need for the conventional rotary seal device. A pair of flow tubes from the coiled column pass through the holder shaft downward, through the horizontal shaft of an idler miter gear, and then through the vertical tube support (left) to exit the system at the center of the centrifuge cover, where they are tightly fixed with a pair of clamps, as indicated in the diagram. Because of the

near-symmetrical arrangement of the design, the system is well balanced and the column can be rotated at a high speed up to 2000 rpm, while the elution can be performed through its seal-free flow-through system to eliminate complications, such as leakage of solvent and cross-contamination of solutes, that are often caused by the use of a conventional rotary seal device.[4]

Centrifugal Partition Chromatography

Fig. 4 schematically shows a design of the centrifugal partition chromatographic system (see Fig. 2). The separation disk has a series of partition chambers connected by narrow ducts. The disk is rotated up to 2000 rpm. The flow-through system is made by a pair of rotary seals, which can maintain leak-free elution up to 60 bar (~ 800 psi), although the seals should be kept clean. The system is computerized and the operation is programed as in an high-performance liquid chromatography (HPLC) system.[5]

DEVELOPMENT OF HYDRODYNAMIC CCC SYSTEMS

The performance of the basic hydrodynamic CCC system (Fig. 1, right) is remarkably improved by rotating the coil in a centrifugal force field, i.e., by applying a planetary motion to the coil. During the 1970s, a series of flow-through centrifuge schemes has been developed for performing CCC. In these centrifuge systems, the use of the conventional rotary seal devise is eliminated, since it leads to various complications such as leakage, clogging, and cross-contamination. These seal-less flow-through centrifuge schemes are divided into three classes: synchronous, non-planetary, and non-synchronous, according to the mode of planetary motion (Fig. 5).

In type I synchronous planetary motion (Fig. 5, upper left), a vertical holder revolves around the central axis of the centrifuge while it counter-rotates around its own axis at the same angular velocity. This counter-rotation of the holder unwinds the twist of the tube bundle caused by revolution, thus eliminating the need for the rotary seal. This principle works well for the rest of the synchronous schemes with tilted (types I-L and I-X), horizontal (types L and X), inversely tilted (types J-L and J-X), and even inverted orientation (type J) of the holder. When a holder of type I is moved to the center of the centrifuge, the counter-rotation of the holder cancels out the revolution effect, resulting in no rotation (Fig. 5, upper center). In contrast, when this shift is applied to type J planetary motion, the rotation of the holder is added to the revolution, resulting in the rotation of the holder at doubled speed, while the tube bundle revolves around the holder to unwind the twisting (Fig. 5, bottom center). This non-planetary scheme is a transitional form to non-synchronous planetary motion. On the basis of the non-planetary scheme, the holder is again shifted toward the periphery to undergo a synchronous planetary motion. Since the net revolution

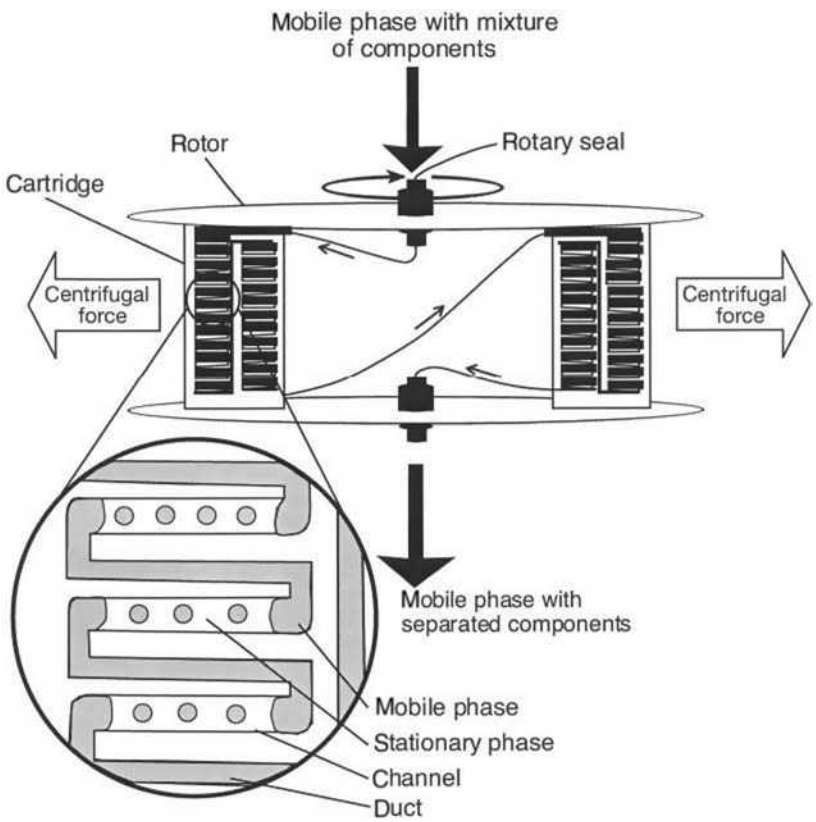

Fig. 4 Design of centrifugal partition chromatography.

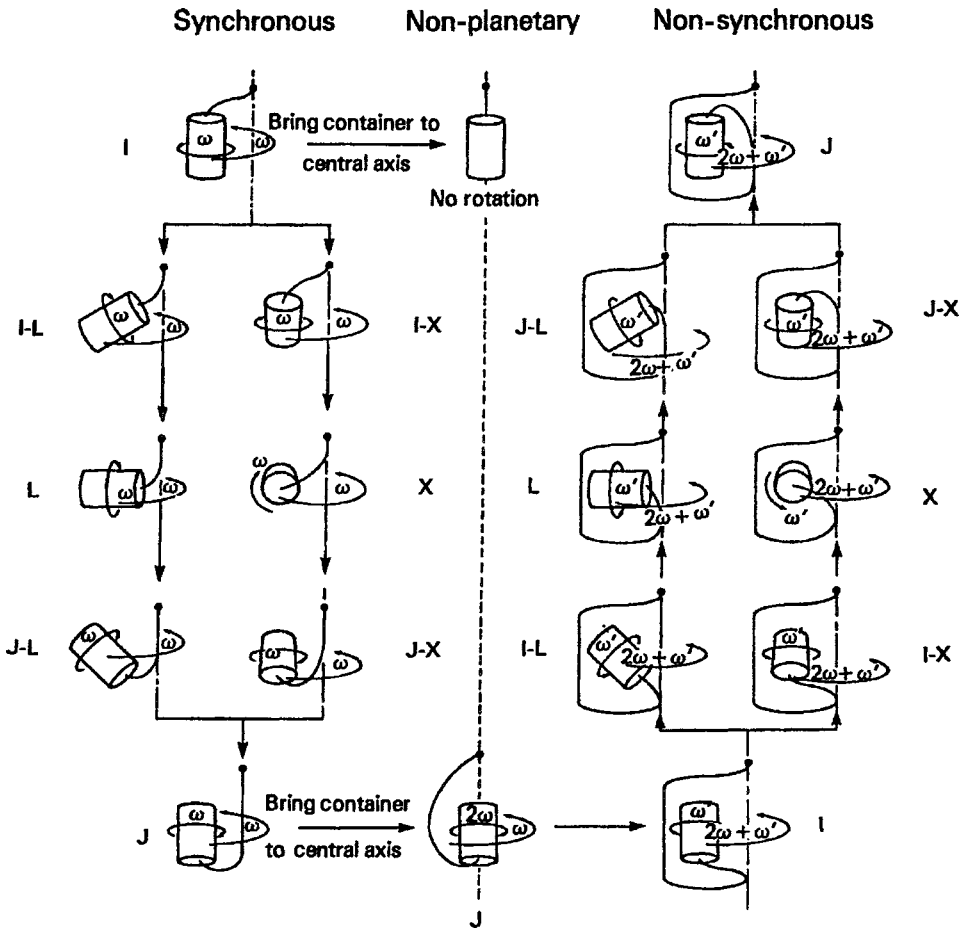

Fig. 5 Series of seal-less flow-through centrifuge systems for performing CCC.

speed of the coil is the sum of the non-planetary and synchronous planetary motions, the ratio of the rotation and revolution becomes freely adjustable.

Several useful CCC systems have been developed from these centrifuge schemes. The non-planetary scheme has been used for toroidal coil CCC,[4,6] centrifugal precipitation chromatography,[7,8] and online apheresis in blood banks.[9,10] The non-synchronous scheme has been applied to the partitioning of cells with polymer phase systems and also to cell elutriation with physiological solutions.[11,12] The type J synchronous scheme has been further developed into a highly efficient CCC system called high-speed CCC.[13,14]

Development of High-Speed Countercurrent Chromatography (HSCCC)

The development of HSCCC was initiated by the discovery that when type J planetary motion is applied to an end-closed coil coaxially mounted on a holder (Fig. 6A), the two solvent phases are completely separated in such a way that one phase occupies the head side and the other phase the tail side of the coil.

This bilateral hydrodynamic distribution can be utilized for performing CCC, as illustrated in Fig. 6B, where each of the coils is schematically shown as a straight tube to indicate the overall distribution of the two phases. The top coil shows the bilateral distribution of the two phases as mentioned above, with the white phase occupying the head side and the black phase the tail side. This hydrodynamic distribution of the two phases can be utilized for performing CCC. In the middle diagram, the upper coil is filled with the white phase and the black phase is introduced from the head end. The mobile black phase then rapidly travels through the coil, leaving a large volume of the white phase stationary in the coil. Similarly, the lower coil is filled with the black phase and the white phase is introduced from the tail end. The mobile white phase then travels through the coil, leaving a large volume of the black phase stationary in the coil. In either case, solutes locally injected at the inlet of the coil are efficiently partitioned between the two phases and quickly eluted from the coil in the order of their partition coefficients, thus yielding high partition efficiency in a short elution time.

The present system also permits simultaneous introduction of the two phases through the respective terminals, as illustrated in the bottom coil. This dual countercurrent

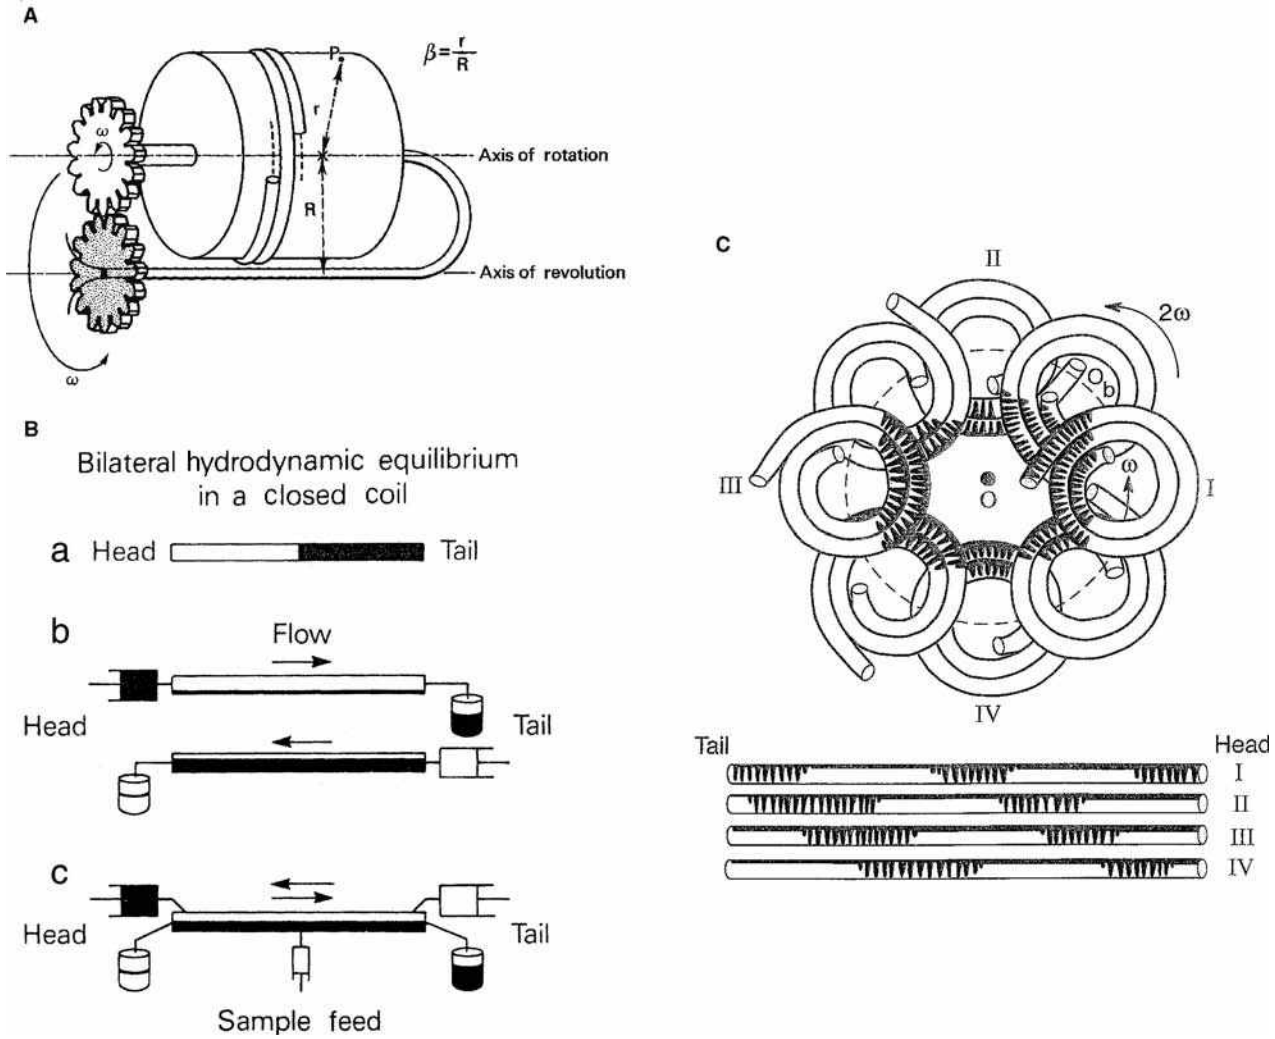

Fig. 6 Principle and mechanism of high-speed CCC. A, Coaxial coil orientation on holder of type J coil planet centrifuge; B, mechanism of high-speed CCC; and C, distribution of mixing and settling zones in spiral column undergoing type J synchronous planetary motion.

operation requires an additional flow tube at each terminal to collect the effluent, and if desired, a sample injection port is created at the middle portion of the coil. This system has been effectively applied to foam CCC[15,16] and dual CCC.[17]

The hydrodynamic motion of the two solvent phases in the rotating spiral column has been observed under stroboscopic illumination (Fig. 6C). As shown in the upper diagram, the spiral column is divided into two areas, a mixing zone near the center of the centrifuge and a settling zone in the rest of the area. The lower diagram shows the motion of the mixing zone by stretching the spiral column from position I to IV. It demonstrates that the mixing zones travel through the spiral column at a rate of one round per revolution. This implies high efficiency of this system: Solutes present in any portion in the column are subjected to an efficient partition cycle of repeating mixing and settling at an enormously high frequency (13 cycles/sec at 800 rpm of column revolution).

INSTRUMENTATION OF HYDRODYNAMIC CCC SYSTEMS

Type J HSCCC

Fig. 7A shows a cross-sectional view of the original design of the HSCCC centrifuge.[18] The rotary frame holds a large multilayer coil holder and a counterweight mass symmetrically to balance the centrifuge system. Twist-free type J synchronous planetary motion is provided by coupling a pair of identical gears, the planetary gear mounted on the column holder flange and the

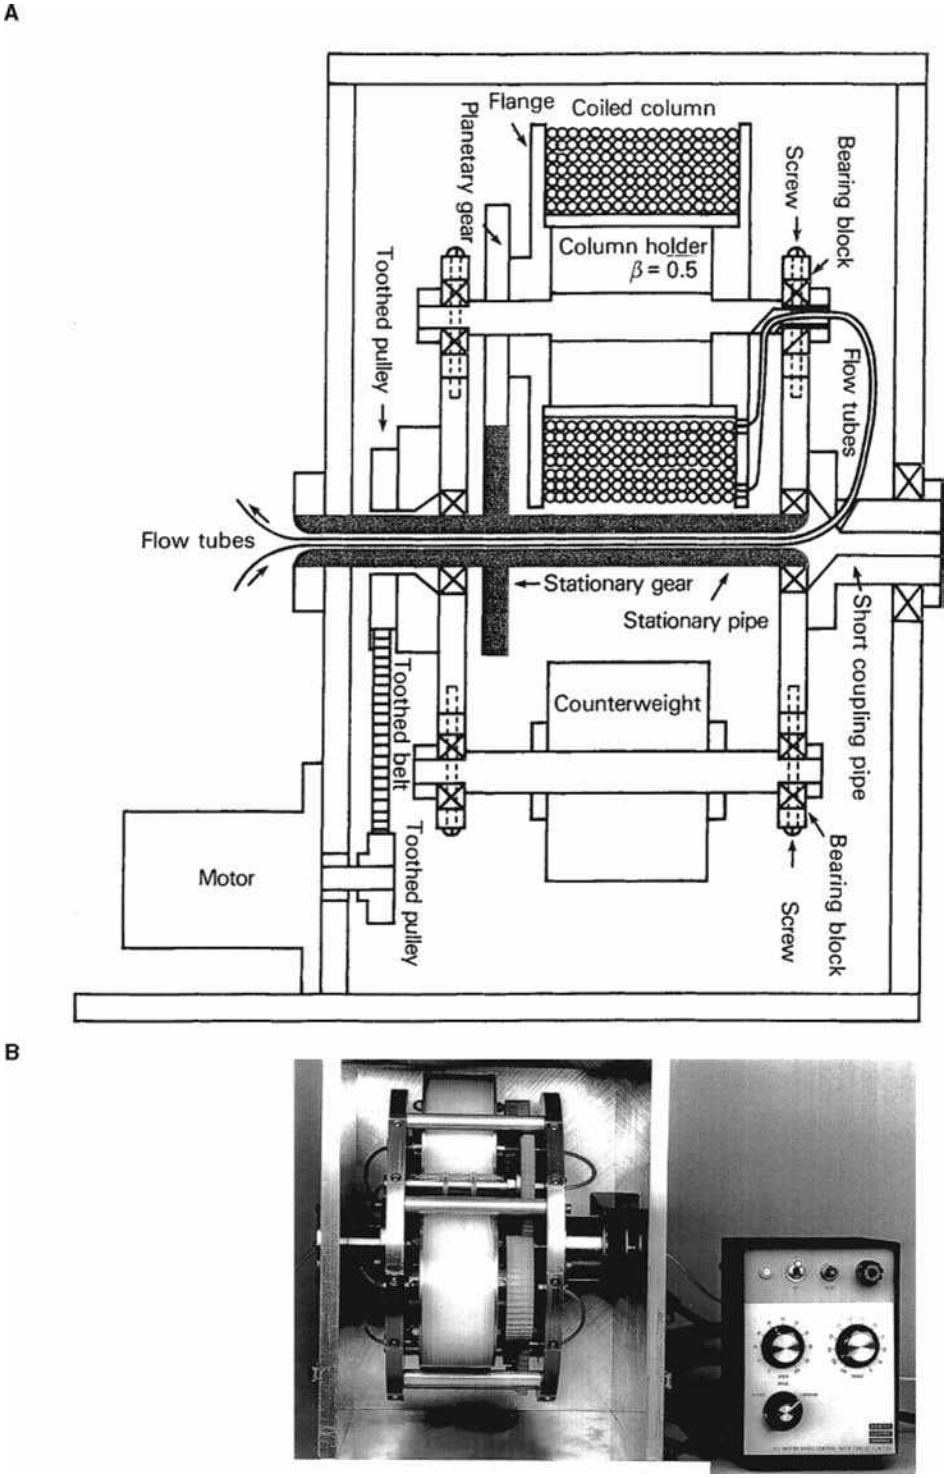

Fig. 7 Design of high-speed CCC apparatus. A, Original multilayer coil planet centrifuge: cross-sectional view through center of apparatus; B, photograph of most advanced prototype of high-speed CCC centrifuge equipped with a set of three multilayer coils connected in series.

stationary sun gear (shaded) on the centrifuge axis. The flow tubes from the separation column first pass through the center of the holder and then, forming an arch, enter the central stationary pipe (shaded) via a side hole made in the short rotary shaft (right). These tubes can maintain their integrity for many runs when protected with a short segment of Tygon tubing to avoid direct contact with metal parts.

Later, the above original design was improved by eliminating the counterweight mass and arranging two to three identical columns symmetrically around the rotary frame. Fig. 7B shows the most advanced form of high-speed CCC centrifuge, equipped with a set of three multilayer coil separation columns. All three columns are serially connected with flow tubes through a counter-rotation hollow pipe to prevent twisting.

This type J high-speed CCC system equipped with the multilayer coil separation column can separate a variety of natural and synthetic products with high partition efficiency using organic–aqueous two-phase solvent systems. The system, however, fails to retain a satisfactory amount of stationary phase in low interfacial aqueous–aqueous polymer phase systems due to intensive emulsification.

Cross-Axis Coil Planet Centrifuge (X-Axis CPC)

In this CCC system, the column holder revolves around the vertical axis of the centrifuge while it rotates about its horizontal axis at the same angular velocity.[19] This second HSCCC system is based on a hybrid between type *L* and *X* synchronous systems (Fig. 5), and it leads to bilateral hydrodynamic distribution of the two phases in an end-closed coaxial multilayer coil as in the type J HSCCC (Fig. 6B). However, in contrast to type J synchronous planetary motion, the centrifugal vectors fluctuate in a three-dimensional space where one component steadily acts across the diameter of the tube to stabilize the retention of the stationary phase. This stabilizing effect becomes greater as the hybrid approaches the type *L* synchronous system, while the phase-mixing effect is reduced. The optimum column position for separating proteins with a polyethylene glycol (PEG) and potassium phosphate system is at around $L/X = 1.5$ (Fig. 8), where X is the distance from the axis of the holder to the central axis of the centrifuge and L the length of column shift from the center along the rotary shaft. For highly viscous and very low interfacial tension polymer phase systems such as dextran/PEG, $L/X = 3$ provides satisfactory retention of the stationary phase. Fig. 8 shows a cross-sectional view through the horizontal plane of the *X*-axis CPC ($L/X = 1.5$). A pair of column holders is mounted symmetrically around the rotary frame. When the motor (not shown) drives the rotary frame around the centrifuge axis, a pair of horizontal miter gears engaged with a stationary sun gear (center) rotates about their own axes on the rotating frame. This motion is further conveyed to each column holder by coupling with a pair of pulleys, one at the end of the gear shaft and the other mounted on the flange of the column holder, with a toothed belt. The flow tubes leading from each holder, as indicated in the diagram, are not twisted when they are supported at the center of the centrifuge cover. These tubes maintain their integrity for many runs when lubricated with grease and protected with a short sheath of Tygon tubing to prevent direct contact with metal parts. This apparatus has been successfully used for the purification of various kinds of proteins with PEG/potassium phosphate systems.

CCC: Solvent Systems

T. Maryutina
Boris Ya. Spivakov

INTRODUCTION

Countercurrent chromatography (CCC) has been mainly developed and used for preparative and analytical separations of organic and bio-organic substances.[1] The studies of the last several years have shown that the technique can be applied to analytical and radiochemical separation, preconcentration, and purification of inorganic substances in solutions on a laboratory scale by the use of various two-phase liquid systems.[2] Success in CCC separation depends on choosing a two-phase solvent system that provides the proper partition coefficient values for the compounds to be separated and satisfactory retention of the stationary phase. The number of potentially suitable CCC solvent systems can be so great that it may be difficult to select the most proper one.

DISCUSSION

Recent studies have made it possible to classify water-organic solvent systems in CCC for separation of organic substances on the basis of the liquid-phase density difference, the solvent polarity, and other parameters from the point of view of stationary-phase retention in a CCC column.[1,3–9] Ito[1] classified some liquid systems as hydrophobic (such as heptane–water or chloroform–water), intermediate (chloroform–acetic acid–water and *n*-butanol–water) and hydrophilic (such as *n*-butanol–acetic acid–water) according to the hydrophobicity of the non-aqueous phase. Thirteen two-phase solvent systems were evaluated for relative polarity by using Reichardt's dye to measure solvachromatic shifts and using the solubility of index compounds.[6]

However, the systems for inorganic separations are very different from those for organic separations, as, in most cases, they contain a complexing (extracting) reagent (ligand) in the organic phase and mineral salts and/or acids or bases in the aqueous phase. Thus, the complexation process, its rate, and the masstransfer rate can play a significant role in the separation process.[9] There are three important criteria for choosing a two-phase liquid system.

First, the systems must be composed of two immiscible phases. Each solvent mixture should be thoroughly equilibrated in a separatory funnel at room temperature and the two phases separated after the two clear phases have been formed. When the nature of the organic sample to be separated is known, one may find a suitable solvent system by searching the literature for solvent systems that have been successfully applied to similar compounds.[1,3–8] In the case of organic-aqueous two-phase systems, the organic phase consists of one solvent or of a mixture of different solvents. Various non-aqueous–non-aqueous two-phase solvent systems have been used for separation of non-polar compounds and/or compounds that are unstable in aqueous solutions. Separation of macromolecules and cell particles can be performed with a variety of aqueous–aqueous polymer-phase systems. Among the various polymer-phase systems available, the following two types are the most versatile for performing CCC.[1,8] Poly (ethylene glycol) (PEG)–potassium phosphate systems provide a convenient means of adjusting the partition coefficient of macromolecules by changing the molecular weight of PEG and/or the pH of the phosphate buffer. The PEG 6000–Dextran 500 systems provide a physiological environment, suitable for separation of mammalian cells by optimizing osmolarity and pH with electrolytes.

For preconcentration and separation of inorganic species, a stationary phase containing extracting reagents of different types (cation-exchange, anion-exchange, and neutral) in an organic solvent should be usually applied.[2,9–12] The mobile-phase components should not interfere with the subsequent analysis. Solutions of inorganic acids and their salts are most often used.The mobile phase may also contain specific complexing agents, which can bind one or several elements under separation.

Second, one of the phases (stationary one) must be retained in the rotating column to a required extent. The most important factor, which determines the separation efficiency and peak resolution for both organic and inorganic compounds, is the ratio of the stationary-phase volume retained in a column to the total column volume. The volume of the stationary phase retained in the column depends on various factors, such as the physical properties of the two-phase solvent system, flow rate of the mobile phase, and applied centrifugal force field. In droplet CCC, where the separation is performed in a stationary column, a large density

difference between the stationary solvent phases becomes the predominant factor for the retention of the stationary phase. In other CCC schemes, various types of two-phase solvent systems can be used under optimized experimental conditions. The influence of planetary centrifuge parameters and operation conditions on the stationary-phase retention have been well studied for some simple two-phase liquid systems consisting of water and one or two organic solvents.[1,3–8]

According to Ito's classifications,[1,3] hydrophobic organic phases are easily retained by all types of CCC apparatus. Intermediate solvent systems involve a more hydrophilic organic phase. Their tendency to evolve, after mixing, to a more stable emulsion than the hydrophobic systems decreases the retention of stationary phase. The hydrophilic two-phase systems containing a polar phase are even less retained in the column.

However, the addition of extracting reagents and mineral salts to a two-phase system (in case of inorganic separations) can strongly affect the physicochemical properties of liquid systems and, consequently, their hydrodynamic behavior and S_f value. Varying concentrations of the system constituents used for inorganic separation allows selective changing of a certain physicochemical parameter (interfacial tension γ, density difference between two liquid phases $\Delta\rho$ and viscosity of the organic stationary phase η_{org}). The type of the solvent may often have a great effect on the stationary-phase retention and, consequently, on the chromatographic process. The correlations between the physicochemical parameters of the complex liquid systems under investigation and their behavior in coiled columns are described in detail.[10] The composition and physicochemical properties of the organic phase in inorganic analysis were modified by adding an extracting reagent [e.g., di-2-ethylhexylphosphoric acid (D2EHPA), tri-*n*-butyl phosphate, trioctylamine].[2,10] The density and viscosity of the organic phase were varied by changing the amount of reagents in the stationary phase. For example, a small addition (5%) of D2EHPA in an organic solvent (*n*-decane, *n*-hexane, chloroform, and carbon tetrachloride) leads to a considerable increase in the factor in the organic solvent—$(NH_4)_2SO_4$—water systems (from 0 to 0.73 in the case of carbon tetrachloride).[10]

Third, the stationary phase should permit separate elution of the substances into the mobile phase and the selectivity toward samples of interest has to be sufficient to lead to separations with good resolution. The selectivity of solvent systems can be estimated by determination of the partition coefficients for each substance. The batch partition coefficients D^{bat} are calculated as the ratio of the component concentration in the organic phase to that in the aqueous phase. The dynamic partition coefficients of compounds are determined from an experimental elution curve.[7] Several solvent systems for organic separation were investigated.[4–8] The most efficient evolution usually occurs when the value of the partition coefficient is equal 1. However, in some CCC schemes, the best results are obtained with lower partition coefficient values of 0.3–0.5.[1,4]

CONCLUSIONS

In inorganic analysis with the use of CCC, the stationary phase should provide preconcentration of the elements to be determined, if necessary. It should be noted that the element elution depends on the operation conditions for the planetary centrifuge, which influence the quantity of the stationary phase in the column. A chromatographic peak shifts to left and narrows if the volume of the stationary phase lowers (all the other factors being the same).[2] The reagent concentration in the organic solvent also affects the elution curve shape and, therefore, the dynamic partition coefficient values. An increase of the reagent concentration in the organic phase leads to higher partition coefficients for the elements, and a better separation is achieved. However, a rather large volume of the mobile phase can be required for the elution of elements from the column.

The composition of the mobile phase also has an influence on the partition coefficients of inorganic substances and the separation efficiency. Concentrations of the mobile-phase constituents should provide partition coefficient values needed for the enrichment or separation of components under investigation. If a step-elution mode is used, partition coefficients higher than 10 and less than 0.1 are favorable for the enrichment of components into the stationary phase and their recovery into the mobile phase, respectively. Chemical kinetics factors may also play an important role in the separation of inorganic species by CCC.[9] It has been shown that the values of masstransfer coefficients determine the type of elution (isocratic or step), which is necessary for the element separation. The data on batch extraction (mass-transfer coefficients and partition coefficients) and parameters of chromatographic peaks (half-widths) can be interrelated by some empirical expressions.[9] The application of CCC in inorganic analysis looks promising because various two-phase liquid systems, providing the separation of a variety of inorganic species, may be used for the separation of trace elements.

INTRODUCTION

Electrophoresis has been used as a separation technique for decades, particularly by biochemists, in the open-bed format. In this mode, a layer of a gel is formed on a flat-bed support which is in contact with an electrolyte and two electrodes are situated at either end of the open slab. The sample is placed at one end of the separation medium, and when voltage is applied, the molecules migrate through the gel by electrophoresis. The components in the sample are separated based on their differences in electrophoretic mobility. The electrophoretic mobility is controlled by molecular parameters such as charge, size, and shape. After the electric field is turned off, the separation is evaluated by spraying the plate with a dye and the bands of the sample components become visible, similar to the detection format used in paper or thin-layer chromatography.

DISCUSSION

Although the basic principle was conceived many years ago, the practical development of electrophoresis experiments in a closed or tubular format was only begun a little more than a decade ago. The main problem of the closed system is that the application of high voltages leads to the generation of Joule heat as current flows through the electrolyte solution. The heat generated can often cause sample decomposition or, more frequently, result in a large increase in molecular diffusion, leading to zone broadening that obliterates the separation between adjacent bands. Therefore, for these experiments to work in a tubular format, it is necessary to use capillary tubes with diameters of 100 μm or less in most cases. The answer to overcoming the Joule heat problem is to use fused-silica tubes, similar to those developed for capillary gas chromatography but having a smaller internal diameter. A second advantage of the fused-silica capillary is that it is suitable for direct online detection because it is optically transparent to ultraviolet (UV) and visible light. Typical dimensions for the capillary under experimental conditions are an outer diameter (O.D.) of ~375 μm, an inner diameter (I.D.) of 50–100 μm, and an overall length of 50–100 cm. To protect the fragile fused-silica tube, the capillary is coated with an external layer of polyimide, allowing it to be flexible and manipulated into a variety of instrumental geometries. A detection window can be made by removing a small amount of the protective coating.

The fused-silica surface also provides another mechanism, electro-osmosis, which drives solutes through the tube under the influence of an electric field. The principle of electro-osmotic flow (EOF) is illustrated in Fig. 1. The inner wall of the capillary contains silanol groups on the surface that become ionized as the pH is raised above about 3.0. This creates an electrical double layer in the presence of an applied electric field so that the positively charged species of the buffer which are surrounded by a hydrated layer carry solvent toward the cathode (negatively charged electrode). This results in a net movement of solvent toward the cathode that will carry solutes in the same direction as if the solvent were pumped through the capillary. This electrically driven solvent pumping mechanism results in a flat flow profile in contrast to the laminar one (parabolic) obtained from mechanical pumps such as those used in high-performance liquid chromatography (HPLC). However, EOF is uniform throughout the capillary and does not depend on any solute properties. All solutes are affected by EOF uniformly and this process does not contribute to the separation mechanism. Therefore, only differences in electrophoretic velocity are responsible for the separation of charged compounds in a fused-silica capillary in the presence of an applied electric field. In fact, EOF is detrimental to the separation process because it moves positively charged species through the capillary faster, thus allowing less time for differences in electrophoretic velocity to separate two species with similar mobilities. This effect can be described mathematically by the following equation:

$$v_{tot} = v_{ep} + v_{EOF}$$

where v_{tot} is the total velocity of the charged species, v_{ep} is the electrophoretic velocity of that species, and v_{EOF} is the electro-osmotic velocity. In a typical experiment, sample migration rates through the capillary are as follows: cationic species > neutral compounds > anionic species. Because both cationic and anionic compounds can have different electrophoretic mobilities, they can be separated within the capillary. However, neutral species are carried through the capillary only by EOF, so these compounds will all migrate at the same rate and, therefore, cannot by separated by capillary electrophoresis (CE).

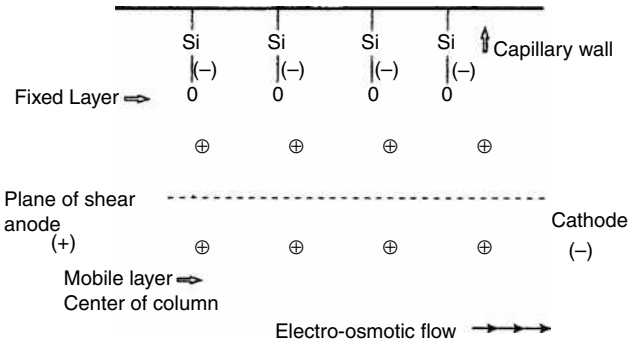

Fig. 1 Principle of electro-osmotic flow.

The basic apparatus necessary for a CE system is shown in Fig. 2. The instrument must have the following components: power supply, electrodes (anode and cathode), vials for electrodes and buffers, separation capillary, detector, and data system or recorder (not shown). The function of each of these components is as follows:

- Power Supply. This device supplies the high voltage to the system. Typically, experiments are run at several kilovolts up to 30 kV or more. Most power supplies will also have an ammeter to measure the current flowing through the system.
- Electrodes. These components are generally platinum wires which serve as the contact point between the liquid (buffer solutions) in the system and the high-voltage power supply. An inert metal is desirable to avoid an electrochemical reaction or excessive fouling of the electrode surface that would disrupt current flow in the system.
- Buffer Reservoirs. These containers hold the buffer solution that provides for a complete electrical circuit through the capillary and connection to the high-voltage supply. Due to EOF as described earlier, the vials also serve as reservoirs to maintain electroneutrality in the system.

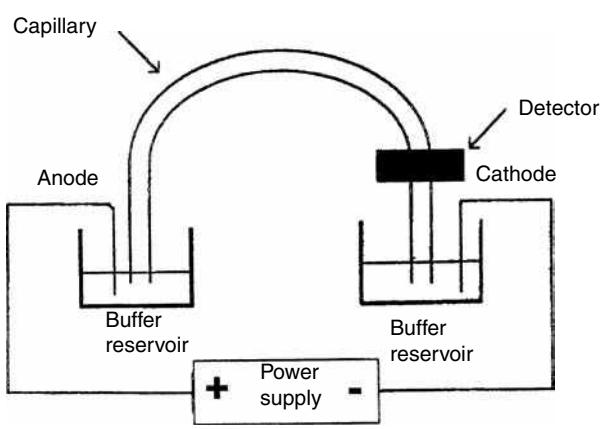

Fig. 2 Basic apparatus for capillary electrophoresis.

- Separation Capillary. The fused-silica capillary tube is the focal point in the instrument because sample separation takes place here. The length is typically 50–100 cm and the ends are placed in the buffer reservoirs. The capillary is filled with the running buffer before the analysis begins.
- Detector. This device measures a property of the solute in order to determine when each compound has passed through a significant portion of the capillary to the detection window. The detector is not placed at the end of the capillary, as this part of the tube must be in the buffer solution. Solute properties most often used for detection are absorbance and fluorescence, although CE can also be coupled to a mass spectrometer.
- Data System/Recorder. The simplest device for output is an ordinary recorder. However, an integrator will provide more information about the peaks (time and area). The most sophisticated apparatus is a computer, which can be used to process and evaluate the data. The computer can also be used to control the operations of the instrument.

The sample can be introduced into the capillary by several methods. The simplest approach is to remove the end of the capillary from the anode buffer reservoir and place it in the sample vial that has been elevated slightly above the level of the cathode buffer container. Gravity flow for several seconds will move some of the sample in the separation capillary. Another approach is to place the anode end of the capillary into the sample vial and apply pressure to the analyte solution. The next method involves placing the anode end of the capillary in the sample vial and applying a vacuum to the cathodic side of the capillary to draw solution into the tube. The previous three means of sample introduction are referred to as hydrodynamic modes of injection. The last method involves placing the anodic end of the capillary in the sample vial and applying a low voltage for several seconds. This approach is referred to as electrokinetic injection.

Information about the analyte can be qualitative and/or quantitative, with the data resembling a chromatogram. The output from the recorder/integrator/data system is in the form of peaks which are indicated by a time (migration time) from the start of the experiment. The migration time is analogous to the retention time in a chromatographic separation and provides qualitative information by comparison to a known compound under identical experimental conditions. Because the majority of detection in CE is by spectroscopic means, the area under the peak is proportional to the concentration. Therefore, quantitative information can be obtained by making a calibration curve from a plot of peak area vs. concentration.

Even though CE is a relatively simple method, several formats exist that allow for analyses of different types of samples or to take advantage of certain solute properties. The primary modes of CE are as follows:

- Capillary Zone Electrophoresis. The most fundamental approach that involves the use of a fused-silica capillary placed between the two buffer vials so that separation of the sample component occurs after an electric field (voltage) is applied to the system. Separation of the analytes is based on differences in electrophoretic mobility. Only charged compounds, both large and small, can be separated in this format.
- Capillary Gel Electrophoresis. In this mode, molecules are separated according to size as they migrate through a polymer matrix. The polymer can be in solution, physically coated on the capillary wall, or chemically bonded to the capillary wall. This mode is primarily used for the separation of large molecules like proteins, peptides, and DNA species.
- Capillary Isoelectric Focusing. In this approach, the capillary contains a pH gradient. When the sample is introduced and voltage is applied, it migrates to the point in the capillary where it has zero net charge (isoelectric point). The analytes are removed from the capillary by adding a salt to one of the reservoirs and then applying voltage again. The solutes will then migrate past the detector, with the time being related to its position in the capillary.
- Capillary Isotachophoresis. In isotachophoresis, the capillary is first filled with a buffer of higher mobility than any of the solutes, then the sample, and, finally, a second buffer with lower mobility than any of the analytes. Separation occurs in the zone formed between the two electrolytes.
- Micellar Electrokinetic Capillary Chromatography. Surfactants that form micelles in solution are added to the buffer in the capillary. When the solute is injected, it partitions itself between the buffer and the micelle. Migration of the solute depends on the amount of time it spends in the micelle vs. the time it spends in the buffer. Therefore, the separation of analytes occurs due to differences in the partition coefficient between the two phases, much like in a chromatographic process.

CONCLUSION

CE is still an emerging technology. Rapid development is occurring in separation capillaries, detector technology, and applications.

CE in Nonaqueous Media

Ernst Kenndler
Institute for Analytical Chemistry, University of Vienna, Vienna, Austria

INTRODUCTION

Organic solvents are used in capillary electrophoresis (CE) for several reasons:

1. To increase the solubility of lipophilic analytes.
2. To affect the actual mobilities of the analytes (those of the fully charged species at the ionic strength of the solution).
3. To change the pK values of the analytes.
4. To influence the magnitude of the electro-osmotic flow.
5. To influence the equilibrium constant of association reactions between analytes and additives (e.g., for the adjustment of the degree of complexation; an important example is the separation of chiral compounds by the use of cyclodextrins).
6. In some rare cases, to allow homoconjunction or heteroconjugation of the analytes with other species present and, thus, enable separation. For such interactions, a low dielectric constant of the solvent is a prerequisite.

APPLICATION OF NONAQUEOUS SOLVENTS

The organic solvents are applied in many cases in order to enhance the separation selectivity by changing the effective mobilities of the analytes. They are either applied as pure solvents, or as nonaqueous mixtures, or as constituents of mixed aqueous–organic systems. Solvents used for CE, as described in the literature, are methanol, ethanol, propanol, acetonitrile, tetrahydrofuran, formamide, *N*-methylformamide, *N*,*N*-dimethylformamide, *N*,*N*-dimethylacetamide, dimethylsulfoxide, acetone, ethylacetate, and 2,2,2- trifluoroethanol.

Organic solvents have relevance in many fields of application: for the separation of inorganic ions, organic anions and cations, pharmaceuticals and drugs, amino acids, peptides, and proteins.

There are some practical restrictions for the use of organic solvents:

1. Many organic solvents have a significant ultraviolet (UV) absorbance in the range of wavelengths that are normally also used for the detection of the analytes. This property leads to a poor signal-to-noise ratio or limits the applicability to solutes with UV absorbances at a higher wavelength.
2. Many electrolytes cannot be used as buffers, due to their low solubilities in organic solvents.
3. The low dielectric constant of solvents suppresses ion dissociation and favors ion-pair formation.
4. Important physicochemical properties (e.g., ionization constants of weak acids and bases) are often not known, which leads to a more or less random experimental approach for the optimization of the resolution.
5. In this context, it should be mentioned that the clear determination of the pH scale in these solvents is not a straightforward task, which may introduce a certain inaccuracy for the description of the experimental conditions. As this aspect is not adequately considered in many articles on CE in nonaqueous solvents, it is discussed here in more detail.

ACIDITY SCALES IN ORGANIC SOLVENTS

When investigating the effect of organic solvents on the pK_a of an acid, the significance of the pH scale in this solvent must be questioned. We base such scales on the measurement of the activity of the solvated proton. We define the activity, a_i, of a particle, i, the proton in the case of interest, by the difference between the chemical potential, ω_i in the given and in a standard state (indicated by superscript 0)

$$\omega_i = \omega_i^{\,0} + RT \ln a_i$$

In practice, we therefore differentiate a number of acidity scales: the standard, the conventional, the operational, and the absolute (thermodynamic) scale.

STANDARD ACIDITY SCALE

The standard state might be chosen in various ways (e.g., as the state at infinitely diluted solution). The resulting standard acidity scale is characterized by the activity of the proton solvated by the given solvent, HS, according to

$$\mathrm{pH} = -\log a_{\mathrm{SH}_2^1} \qquad (1)$$

The range of this scale is defined by the ionic product of the solvent, pK_{HS}.

Measurements in the standard acidity scale are carried out in cells without liquid junctions (e.g., with the following setup: $Pt/H_2/HCl$ in SH/AgCl/Ag). It is assumed, here, that the activities of the solvated proton and the counterion, chloride, are equal. In this case, the electromotive force (emf) of the cell can be expressed by

$$E = E_S^0 - \frac{RT}{F}\ln a_{SH_2} - a_{Cl^-} = E_S^0 - \frac{2RT}{F}\ln\left(c_{HCl}\gamma_{HCl}\right) \quad (2)$$

where is c_{HCl} the concentration γ_{HCl} and is the mean activity coefficient of HCl. $E_S{}^0$ is the standard potential of the silver chloride electrode in the given solvent, S, after extrapolation of the measured emf to zero ionic strength. Rearrangement leads to the expression of the pH in the standard scale:

$$\mathrm{pH} = -\frac{(E - E_S^0)F}{2.3RT} + \log c_{Cl^-} + \log \gamma_{Cl^-} \quad (3)$$

CONVENTIONAL ACIDITY SCALE

The standard acidity scale, although well defined theoretically, has the limitation in practice that only the mean activity coefficient, but not the single-ion activity coefficient, is thermodynamically assessible. The single-ion coefficient depends on the composition of the solution as well. One way to circumvent this problem would be to have a defined value of the activity coefficient for one selected ion. Given that, all other activity coefficients could be obtained from the activity coefficients of the particular electrolytes and that special single-ion coefficient. The value of this selected coefficient could be used, then, as the base of the conventional acidity scale. This single-ion activity coefficient is derived for chloride by the Debye–Hückel theory. This choice is made by convention, initially proposed for aqueous solutions; it is accepted also for other amphiprotic, polar solvents. Note that the measurements of the proton activity are carried out in cells without liquid junction.

OPERATIONAL ACIDITY SCALE

Due to the disadvantage of working with cells without liquid junctions, in practice the operational scale uses buffer solutions with known conventional pH for the calibration of cells with liquid junction [e.g., the convenient glass electrode (with the calomel or silver electrode, respectively, as reference)]. After calibration of the measuring cell (with a buffer of known conventional pH), the acidities of unknown samples can be measured in the same solvent. It is clear that for the standard buffers used, the conventional and the operational pH are identical. However, we cannot assume such an identity for the unknown samples. This is because the activities and the mobilities of the different ionic species might change the potential on the boundary with all liquid junctions (even without taking effect of the non-electrolytes into account).

ABSOLUTE (THERMODYNAMIC) SCALE AND MEDIUM EFFECT

This scale, in fact, would allow comparing the basicities of the different solvents in a general way. It is based on the question of the chemical potential of the proton (as a single-ion species) in water, W, and the organic solvent, S. Taking the hypothetical 1 *M* solution as the standard state, the chemical potential is given, according to Eq. 1, as

$$\omega_{H^+} = \omega_{H^+}^0 + RT\ln m_{H^+} + RT\ln\gamma_{H^+} \quad (4)$$

where *m* is the molal concentration. The so-called medium effect on the proton is given by

$$\ln {}_W\gamma_{H^+} - \ln {}_S\gamma_{H^-} = \ln\left(\frac{{}_W\gamma_{H^-}}{{}_S\gamma_{H^+}}\right) = \ln {}_m\gamma_{H^+} = \frac{{}_S\omega_{H^+}^0 - {}_W\omega_{H^+}^0}{RT} \quad (5)$$

${}_m\gamma_{H^+}$ is named the transfer activity coefficient. The medium effect is proportional to the reversible work of transfer of 1 mol of protons in water to the solvent, S (in both solutions at infinite dilution). If the medium effect is negative, the proton is more stable in the solvent, S. It is, thus, an unequivocal measure of the basicity of the solvent, compared to water, as it allows us to establish a universal pH scale due to

$$-\log {}_W a_{H^+} = -\log {}_S a_{H^+} - -\log {}_m a_{H^+} \quad (6)$$

It is a serious drawback that it is not possible to determine the transfer activity coefficient of the proton (or of any other single-ion species) directly by thermodynamic methods, because only the values for both the proton and its counterion are obtained. Therefore, approximation methods are used to separate the medium effect on the proton. One is based on the simple *sphere-in-continuum* model of Born, calculating the electrostatic contribution of the Gibb's free energy of transfer. This approach is clearly too weak, because it does not consider solvation effects. Different extrathermodynamic approximation methods, unfortunately, lead not only to different values of the medium effect but also to different signs in some cases. Some examples are given in the following: ${}_m\gamma_{H^+}$ for methanol +1.7 (standard deviation 0.4); ethanol +2.5 (1.8), *n*-butanol +2.3 (2.0), dimethyl

sulfoxide −3.6 (2.0), acetonitrile + 4.3 (1.5), formic acid +7.9 (1.7), NH_3 −16. From these data, it can be seen that methanol has about the same basicity as water; the other alcohols are less basic, as is acetonitrile. Dimethyl sulfoxide, on the other hand, is more basic than water. However, the basicity of the solvent is not the only property that is important for the change of the p*K* values of weak acids in comparison to water. The stabilization of the other particles that are present in the acido-basic equilibrium is decisive as well.

CE on Chips

Christa L. Colyer
Department of Chemistry, Wake Forest University, Winston-Salem, North Carolina, U.S.A.

INTRODUCTION

It is no wonder that capillary electrophoresis (CE) has evolved into one of the premier separation techniques in use today, due to its extremely high efficiencies, fast analysis times, reduced sample and reagent consumption, and vast array of operating modes. The transposition of CE methods from conventional capillaries to channels on planar chip substrates is a more recent phenomenon and has been driven by several factors, including, but not limited to, the need for ever-more sensitive and selective assays, the need to manipulate increasingly smaller samples, and the desire to process many samples in parallel.[1] Perhaps of greater significance to the rapid development of this important field, however, is its amenability to the assimilation of multiple components of an assay—beyond simple separation of analytes—into a single, fully integrated device. The promise of the "lab-on-a-chip," although seemingly ambitious in concept, is clearly attainable, and microchip capillary electrophoresis (μ-chip CE) has quickly established itself as one of the most fundamental constituents of such systems.

One of the first published demonstrations of capillary electrophoresis on a chip appeared in 1992, when Harrison et al. separated a mixture of fluorescein and calcein.[2] Although separation efficiencies and analysis times in this pioneering work did not represent significant improvements over those achievable by way of conventional CE, this work demonstrated the feasibility of miniaturizing a chemical analysis system involving electrokinetic phenomena for sample injection, separation, and solvent pumping. Within 2 years of the appearance of this seminal paper, analysis times on the order of seconds and even milliseconds had been demonstrated with similar μ-chip systems, and efficiencies in excess of 100,000 theoretical plates were routinely obtained. Subsequently, the integration of other functionalities, such as sample manipulations and chemical reactions, alongside the CE separation, has vaulted CE-on-a-chip to new heights.

CHIP FABRICATION TECHNOLOGY

The evolution of CE on a chip has directly benefited from the tremendous advances in semiconductor microfabrication technologies that have taken place over the past two decades. Although semiconducting substrates are not ideally suited to CE applications due to the high voltages applied for separation and fluid manipulation, many of the established semiconductor microfabrication techniques can be modified for the insulating glass or quartz substrates most commonly encountered in μ-chip CE. Here, the name μ-chip refers to the channel dimensions as opposed to the actual substrate dimensions, which commonly are on the order of 0.5 mm thick and anywhere from 3 to 10 cm in length and width (or diameter for circular substrates).

In many cases, standard photolithographic and wetetching techniques are employed in the manufacture of CE chips. To begin, the clean glass or quartz substrate is uniformly coated with sequential thin layers of chromium/gold and positive photoresist by sputtercoating and spin-coating methods, respectively. The design for the CE channel structure is then transferred to the substrate by exposure of the photoresist to ultraviolet (UV) light through a photomask of the channel pattern. After photoresist development, a series of wet etches are employed, first to remove the metal etch mask and, second, to etch the channels into the substrate. Channels created in this fashion are trapezoidal in profile due to the isotropic etching of amorphous materials. Typical channel dimensions range from 5 to 40 μm deep and 20 to 100 μm wide (at half the channel depth). Residual photoresist and metal film are stripped from the etched substrate prior to thermal bonding of a cover plate, thereby forming closed channels suitable for electrophoresis. Access to the channels is most commonly gained through holes drilled in the cover plate prior to bonding.

Capillary electrophoresis chips so created are quite rugged due to the monolithic nature of their structure, and they can withstand applied voltages in the same range (up to 30 kV) as those commonly encountered in conventional CE. In addition, they offer greater heat dissipation than conventional CE capillaries, thereby allowing for operation under conditions of higher power. Although quartz substrates have superior optical properties relative to their glass counterparts, both present an optically flat surface for detection schemes, which is a definite advantage over the curvature inherent to conventional capillary walls. As well, the void volumes associated with channel intersections on-chip are virtually non-existent. Despite their many advantages, these chips are time-consuming and expensive to fabricate. As such, alternative methods for CE chip fabrication are being developed, such as the creation of channels in polymeric materials by casting, molding, and

imprinting techniques. The success of these methods will rely, in part, on the concomitant development of suitable surface modification procedures to successfully manage channel wall properties.

INJECTION ON CHIPS

Clever chip design permits the integration of the sample injector directly on the chip, thereby combining injection and separation functions by default on a single substrate. Most commonly, the injector is fashioned as a simple cross or "double-T" arrangement of etched channels, as shown in Fig. 1. One branch of this cross serves as the sample channel, and the other serves as the separation channel. Fluid flow is manipulated through this cross, just as with all other fluid manipulations on chip, by control of electrokinetic phenomena: electrophoresis and electro-osmosis. By first applying the appropriate voltage between the sample and sample waste reservoirs (Fig. 1a), the sample solution crosses the separation channel, filling the double-T intersection. Consequently, injection volumes are defined by the injector geometry. Typical sample plug volumes and lengths are on the order of about 10–100 pl and 50–200 μm, respectively. Provided the injection field strength and time are sufficient to ensure that the least mobile sample component has moved through the channel intersection, this method results in an unbiased injection, with all sample components represented in the intersection volume according to their original proportions. Having thus formed a sample plug, the voltage is switched so as to generate electro-osmotic flow EOF along the separation channel (Fig. 1b), sweeping the sample plug out of the

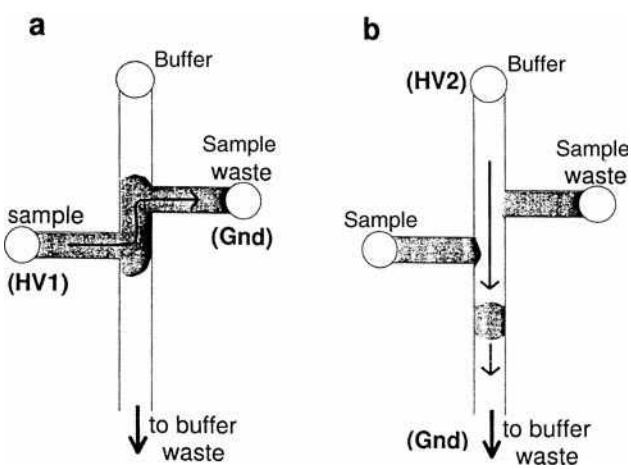

Fig. 1 Illustration of a μ-chip CE sample injector. Injection consists of (a) sample loading across the separation channel by application of a high voltage (HV1) across the sample and sample waste reservoirs, followed by (b) mobilization of the sample plug along the separation channel by application of HV2 across the buffer and buffer waste reservoirs.

double-T injector and initiating separation along the second branch of the injector. This branch—the separation channel—typically ranges from 1 to 10 cm in length. Further control of sample plug size and shape and prevention of sample leakage can be effected by carefully controlling voltages applied to all four arms of the cross simultaneously during injection and separation phases.

DETECTION ON CHIPS

It is not surprising that the requirements for detection on chips are very stringent, especially given the extremely small sample sizes discussed earlier. This need for sensitivity, along with the optically flat chip surface, makes laser-induced fluorescence (LIF) detection a natural choice; consequently, LIF detection on chips is the most widespread of all detection types. However, because relatively few analytes are natively fluorescent, LIF detection necessitates the development of selective and sensitive labeling strategies for each assay. Other detection methods, such as UV-Vis absorption, chemiluminescence, and electrochemical, are less commonly encountered in chip CE, but they have been successfully demonstrated. Recently, the ability to generate an electrospray from the edge of a CE chip[3] has spawned a flurry of additional work in the area of electrospray ionization–mass spectrometry (ESI–MS) detection for CE chips. This promises to be a particularly powerful and exciting advance, as both quantitative and qualitative information can be provided simultaneously by this method of detection.

BEYOND CE: SAMPLE MANIPULATIONS

The most fundamental purpose of a CE chip is, of course, the separation and subsequent detection of analytes within a manifold of micromachined channels on a miniaturized substrate. This separation may take place as a result of basic electrokinetic phenomena or it may be enhanced or assisted by implementation of any one of various other separation techniques, such as isotachophoresis, micellar electrokinetic chromatography, isoelectric focusing, or capillary gel electrophoresis, all of which have been successfully demonstrated on-chip. However, the feature that truly distinguishes μ-chip CE from its conventional capillary counterpart is not its separative ability but, rather, its facility to integrate other functions onto the chip alongside the separation. This has already been discussed with respect to the sample injector and it is equally applicable to various sample preparation techniques. For example, controlled sample dilution, achieved by mixing buffer and sample streams directly on-chip, was first shown by Harrison et al.[4] By increasing the voltage applied to a buffer reservoir while holding the voltage applied to a fluorescein dye sample reservoir constant, a controlled

decrease in fluorescence intensity, corresponding to increasingly greater dilutions of the fluorescein, was observed downstream at the detector.

Preconcentration is another commonly encountered sample pretreatment method that has been successfully integrated onto a CE chip. Ramsey and coworkers incorporated a porous membrane structure into a microfabricated injection valve, enabling electrokinetic concentration of DNA samples using homogeneous buffer conditions.[5] Sample preconcentration in non-homogeneous buffer systems—a technique known as sample stacking—has also been achieved on-chip.[6]

Filtration is yet another pretreatment technique commonly encountered in CE. The reduced dimensions of fluid channels on chip substrates make the need for solution filtration all the more critical in this work. Until very recently, filtration was exclusively conducted "off-line" (i.e., before the sample and/or buffer solution was ever introduced to the chip). However, Regnier and coworkers recently micromachined solvent and reagent filters into quartz substrates using deep reactive ion etching.[7] Flow through these microfabricated lateral percolation filters was driven by EOF, thus making them compatible with other fluidic processes in a chip CE system. The on-chip filters were shown to be capable of removing a variety of particulate materials, ranging from dust to cells. Surface fouling and loss of cationic proteins from analyte streams were minimized by applying a polyacrylamide coating to the filter surfaces. Hence, these selected examples of the transposition of some traditional sample pretreatment methods onto chip substrates and their compatibility with on-chip CE separations illustrate the potential for achieving a fully integrated lab-on-a-chip.

BEYOND CE: CHEMICAL REACTIONS ON CHIP

Full functionality of these chips cannot be realized by the integration of sample pretreatment, injection, and separation methods alone. Additionally, the ability to carry out chemical reactions on-chip must be included in the list of integrated functions in order to extend the utility of these systems. Indeed, a wide variety of on-chip chemical reactions coupled to CE separations have been successfully demonstrated, including fluorescent derivatization, digestion of DNA and proteins, affinity-type reactions, and the polymerase chain reaction (PCR) for DNA amplification. The first of these reactions is necessitated by the laser-induced fluorescence detection schemes commonly used with CE chips. Because few analytes are natively fluorescent, it is often necessary to either (a) react the analyte with a fluorescent tag prior to separation (preseparation or precolumn labeling) or (b) separate the analyte first, followed by reaction of the separated zones with a derivatizing agent (postseparation or postcolumn labeling). The former, although leading to greater sensitivity, often suffers from increased band broadening and reduced separation efficiencies. The latter, although leading to higher efficiencies, offers reduced sensitivity and requires very fast labeling kinetics. Preseparation and postseparation labeling schemes were the first reactions demonstrated in conjunction with CE separations on chip substrates. Although the initial on-chip reactors suffered from inefficient mixing, and therefore inefficient reactions, improvements in channel structures and geometries along with optimization of solution conditions soon led to satisfactory results. The geometry of one such "second-generation" CE reactor chip is shown in Fig. 2, along with the electropherogram generated by postseparation labeling of amino acids with *O*-phthaldialdehyde (OPA). Despite the fact that the amino acids, once separated, had to mix and react with OPA in order to be rendered fluorescent, their corresponding peaks remained as sharp and well-defined as the peak obtained

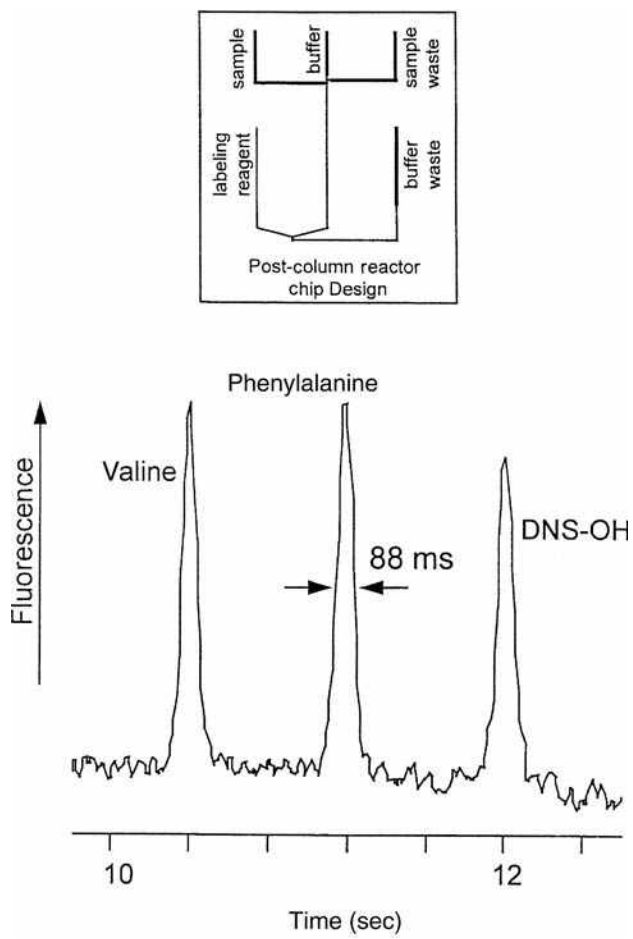

Fig. 2 Electrokinetically driven on-chip reaction in a CE-based system. Postseparation labeling of amino acids with OPA. Sample contained 200 μm each of phenylalanine and valine, and 10 μm of hydrolyzed dansyl chloride. The postcolumn reactor chip design is shown in the inset.
Source: From Clinical potential of microchip capillary electrophoresis systems, in Electrophoresis.[13]

for hydrolyzed dansylchloride (DNS–OH), which did not react with OPA.[8]

The products of digestion reactions involving either protein or DNA substrates are conveniently separated and detected by CE on a chip. Improvements in digestion product assays should, therefore, be realized by marrying the digestion reaction and separation on a single chip. Jacobson and Ramsey demonstrated one such marriage by fabricating a chip device capable of both digesting a DNA sample with a restriction enzyme and separating the resulting DNA fragments using electrophoresis in a sieving matrix. Subsequent detection of the DNA restriction fragments was achieved by way of LIF using an intercalating dye that was introduced to the fragments on-chip.[9] In some cases, the products of a digestion reaction may not, in themselves, be of interest, but, rather, they may be used to determine information about the digestion enzyme itself. In one such chip assay, the reaction kinetics for the enzyme β-galactosidase were determined using resorufin β-D-galactopyranoside, a substrate that is hydrolyzed to resorufin, a fluorescent product.[10] Precise concentrations of substrate, enzyme, and inhibitor (phenylethyl β-D-thiogalactoside) were mixed on-chip, and the entire integrated assay was conducted in a 20 min period using only 120 pg of enzyme and 7.5 ng of substrate. Thus, the facility to perform digestion reactions directly on chip prior to separation and detection of digestion products necessarily improves the efficiency of these assay methods and represents a powerful new tool in the area of biochemical analysis.

Affinity-type reactions, which involve an analyte's affinity for a conjugate molecule, such as antibody–antigen interactions, form an important part of biochemical research. CE on a chip provides for the separation of complexes of the analyte with its conjugate from uncomplexed reagents. However, the ability to carry out the reaction between the analyte and its conjugate to form a complex directly on-chip, in conjunction with electrophoretic separation, is an important advance, and many examples of such on-chip affinity reactions exist. In one such example, Chiem and Harrison presented a μ-chip CE device capable of functioning as a complete immunoreactor for the determination of serum theophylline, a therapeutic drug for asthma treatment.[11] In this competitive immunoassay, a serum sample containing theophylline was mixed, directly on the chip, with fluorescently labeled theophylline tracer prior to introducing a limited amount of anti-theophylline antibody, also on-chip. The products of this immunoassay were subsequently separated by electrophoresis and detected by LIF on-chip. As the concentration of theophylline in the serum increased, this competitive assay led to an increase in signal for free, labeled theophylline and a corresponding decrease in signal for the labeled theophylline–antibody complex. Total analysis time, including on-chip reagent mixing, reaction, separation, and detection, was 150 sec per sample, demonstrating one of the obvious advantages (along with reduced reagent consumption and increased sensitivity) of being able to conduct reactions on-chip alongside CE separations and other functions.

Another important reaction that has found a place on CE chips is the PCR, which is used to amplify DNA and which is critical to high-throughput genetic analyses. With the demonstrated ability of CE chips to integrate chemical reactions alongside high-speed separations, it is perhaps not surprising that μ-chip devices capable of genetic analysis would be fabricated. For example, a single monolithic chip capable of PCR amplification of up to four DNA samples, followed by product analysis has been demonstrated.[12] Integrated onto this chip are the facilities to thermally lyse cells to release DNA, standard PCR protocols to amplify DNA, gel electrophoresis to separate PCR products, intercalation of a fluorescent dye into PCR products, and detection of labeled products by LIF. The level of sophistication in a device such as this clearly illustrates the reality of the lab-on-a-chip concept: A concept that is founded upon the many advantages of μ-chip CE.

CONCLUSIONS AND FUTURE DIRECTIONS

The advantages typically associated with capillary electrophoresis, such as reduced sample and reagent consumption, reduced analysis time, and increased separation efficiency, are augmented when the CE system is transposed to a chip substrate. More importantly, however, μ-chip CE offers the further advantage of integrating analytical processes beyond separation. Sample preparation, injection, reaction, and detection can be seamlessly tied to the electrophoretic separation stage of the analysis. The monolithic CE chips capable of separation coupled to some of these other analytical steps are precursors to the ultimate "lab-on-a-chip," which promises high-throughput sensitive analyses with minimal user intervention. Applications of such devices in biochemical, clinical, forensic, and environmental analyses are seemingly unlimited. However, several challenges remain despite the great promise of these devices. In order to fully realize the advantages offered by the microfluidics regime of the chip, methods of addressing these microvolumes and of interfacing them to the macroscale world beyond the chip must be carefully managed. Although chip fabrication techniques are now well established, they are by no means accessible to the majority of analysts. Fabrication processes that rely less heavily on high-tech processing facilities must be developed or, more realistically, the chips themselves must be made available inexpensively and in a variety of application designs for all potential users. Miniaturization or careful arrangement of the apparatus accompanying the CE chip, including power supplies, detection components, and computer controllers, into a compact and robust system must be considered in order to take full advantage of the chip's

inherently small size. Finally, true parallel processing facilities must be routinely developed on single chips in order to increase sample throughput and increase the applicability of these systems to large-scale analytical problems. These challenges, although formidable, are worthy of solutions in order to successfully build labs-on-a-chip around the cornerstone of CE on a chip.

CE/MS: Large Molecule Applications

Ping Cao
Biology Department, Tularik, Inc., South San Francisco, California, U.S.A.

INTRODUCTION

Capillary electrophoresis (CE) is a modern analytical technique which permits rapid and efficient separation of charged components present in small-sample volumes. Separation occurs due to differences in electrophoretic mobilities of ions inside small capillaries. The impetus for CE method developments focused primarily on the separation of larger biopolymers such as polypeptides, proteins, oligonucleotides, DNA, RNA, and oligosaccharides.[1] Mass Spectrometry (MS) has long been recognized as the most selective and broadly applicable detector for analytical separations. Currently, electrospray ionization (ESI) serves as the most common interface between CE and MS. Generation of multiply-charged species with an ESI extends the applicability of conventional mass analyzers of limited mass-to-charge (m/z) ranges to molecular mass and structure determination of larger biopolymers. CE/MS combines the advantages of CE and MS so that information on both high efficiency and molecular masses and/or fragmentation can be obtained in one analysis. This entry focuses on larger-molecular analysis by online CE/MS interfaced via ESI sources.[2,3] However, CE/MS using continuous-flow – fast atom bombardment (CF–FAB) sources employing either "liquid-junction" or "coaxial" interfaces and several off-line CE/MS combination should be noted.

When ESI–MS is employed as detector, the proper choice of a suitable electrolyte system is essential to both a successful CE separation and good quality ESI mass spectra. Even though a wide range of CE buffers were successfully electrosprayed when the liquid-junction and sheath flow CE/MS interfaces were employed since the low CE effluent flow is effectively diluted by a much large volume of sheath liquid;[4] the best detector response is produced by volatile electrolyte systems at the lowest practical concentration and ion strength and by minimizing other non-volatile and charge-carrying components. Volatile reagents like ammonium acetate (pH 3.5–5.5) or formate (pH 2.5–5; both adjustable to high pH) and ammonium bicarbonate have been proven to be well suited for CE/ESI/MS.

Due to the inherent tendency to adsorb strongly to the inner walls of the fused-silica capillary, the analysis of proteins and peptides by CE has presented unique challenges to the analyst because this phenomenon gives rise to substantial peak broading and loss of separation efficiency. Successful separations of proteins and peptides by CE involve efficient suppression of adsorption to the fused-silica wall. Basically, there are two approaches to prevent protein adsorption: modification of the fused-silica surface by dynamic or static coating or by performing analysis under experimental conditions that minimize adsorption.[5] The static coating capillary is preferred under CE/ESI/MS analysis of large molecules because the CE buffer composition is simplified. This entry is meant only to provide the reader with a description of most common approaches taken to analyze large molecules, especially polypeptides and proteins, by CE/ESI/MS.

LARGE-MOLECULE ANALYSIS OF CE/MS BY NEUTRAL CAPILLARY

Because there is no ionizable groups of the coating in the neutral capillary, the interaction between charged molecules with ionic capillary surface is eliminated. Also, the electro-osmotic flow (EOF) of a neutral capillary is eliminated. However, a continuous and adequate flow of the buffer solution toward the CE capillary outlet is an important factor for routine and reproducible CE/ESI/MS analysis; in order to maintain a stable ESI operation, some low pressure applied to the CE capillary inlet is usually needed, especially when the sheathless interface is employed. The disadvantage of the pressure-assisted CE/ESI/MS is the loss of some resolution because the flat flow profile of the EOF is partially replaced by the laminar flow profile of the pressure-driven system. A typical neutral capillary is a linear polyacrylamide (LPA)-treated capillary. Karger and coworkers[6] used mixtures of model proteins, a coaxial sheath flow ESI interface, and a 75 μm inner diameter (I.D.), 360 μm outer diameter (O.D.), 50 cm-long LPA-coated capillary to evaluate CE/MS, capillary isotachophoresis (CITP)–MS, and the on-column combination of CITP/CE/MS. In the CE/MS experimental, 0.02 M 6-aminohexanoic acid + acetic acid (pH 4.4) was employed and a 18 kV constant voltage was applied during the experiment. Seven model proteins were well resolved. They showed that the sample concentration necessary to obtain a reliable full-scan spectrum was in the range of 10^{-5} M. However, by proper selection of the running buffers, they demonstrated that the on-column combination of both CITP and capillary zone electrophoresis (CZE) can improve the concentration detection limits for a full-scan CE/MS analysis to approximately 10^{-7} M.

LARGE-MOLECULE ANALYSIS OF CE/MS BY A POSITIVELY CHARGED CAPILLARY

To help overcome adsorption, positively charged coatings have been employed for the separation of positively charged solutes. In this approach, positively charged proteins are electrostatically repelled from the positively charged capillary inner wall. Two examples of such coatings are aminopropyltrimethoxysilane (APS) and polybrene, a cationic polymer. These coatings reverse the charge at the column–buffer interface and, thus, the direction of the EOF compared to uncoated capillaries.

The CE/MS analysis of the venom of the snake *Dendroaspis polylepis polylepis*, the black mamba, is reported by Tomer and coworkers.[7] A VG 12-250 quadrupole equipped with a Vestec ESI source (coaxial sheath flow interface) was employed for this experiment. The sheath fluid was a 50 : 50 methanol : 3% aqueous acetic acid solution. The CE voltage was set at −30 kV during the analysis and the ESI needle was held at +3 kV. The CE running buffer used was 0.01 *M* acetic acid at pH 3.5. The APS column was flushed with buffer solution for 10 min prior to sample analysis. The snake venom was dissolved in water at a concentration of 1 mg/ml and 50 nl of the analyte solution was injected into the column. They demonstrated the existence of at least 70 proteins from this venom.

One interesting example of intact protein analysis was described by Smith and coworkers.[8] They used the high sensitivity and mass accuracy of a Fourier transform ion cyclotron resonance (FTICR) MS detector to analyze hemoglobin α and β in a single human erythrocyte. Human erythrocytes were obtained from the plasma of a healthy adult male. A small drop of blood diluted with saline solution (pH 7.4) was placed on a microscope slide. With the help of a stereomicroscope and a micromanipulator, the etched terminus of the CE capillary was positioned within a few microns of the cell to be injected. Following electro-osmotic injection of the cell, the end of the CE capillary was placed in a vial containing the CE running buffer (10 m*M* acetic acid, pH 3.4), and the cell membrane was lysed via osmotic shock from the running buffer and the cellular contents of the cell released for subsequent CE separation and mass analysis. A 1 m APS column and a sheathless interface employing a gold-coated capillary with −30 kV CE separation and +3.8 kV ESI voltage were used for this study. They demonstrated that adequate sensitivity needed to characterize the hemoglobin from a single human erythrocyte (~450 μmol) and mass spectra with average mass resolution in excess of 45,000 (full width at half-maximum) were obtained for both the α- and β-chain of hemoglobin. Fig. 1 shows the mass spectra obtained from this experiment.

In order to overcome the bubble formation associated with the sheathless CE/MS interface and quick degradation of the coated capillary, Moini et al.[9] introduced hydroquinone (HQ) as a buffer additive to suppress the bubbles formed due to the electrochemical oxidation of the CE buffer at the outlet electrode. The oxidation of water ($2H_2O(l) \leftrightarrow O_2\ (g) + 4H^+\ 4e$) was replaced with that of more easily oxidized HQ (hydroquinone ↔ *p*-benzoquinone + $2H^+ + 2e$). Formation of *p*-benzoquinone, other than the formation of oxygen gas, effectively suppresses gas bubble formation. The APS-coated capillaries and 10 m*M* acetic acid CE running buffer containing 10 or 20 m*M* HQ were used for the experiments. The CE outlet/ESI electrode was maintained at +2 kV and the CEinlet electrode was held at −30 kV. Tryptic digest of cytochrome-*c* and hemoglobin were used as model proteins. They demonstrated that the combination of the in-capillary electrode sheathless interface using a platinum wire, HQ as a buffer additive, and

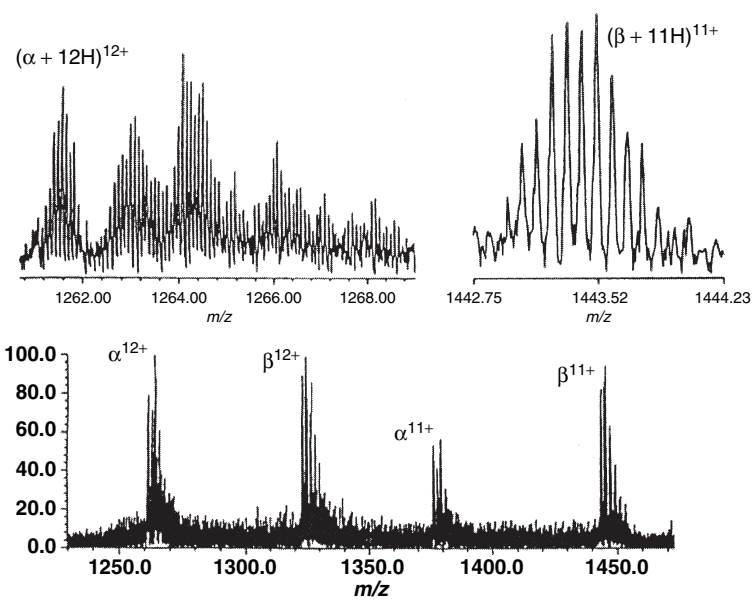

Fig. 1 Mass spectra obtained from CE/MS analysis of a single human erythrocyte using an FTICR mass analyzer.

Source: From The charaterization of snake venoms using capillary electrophoresis in conjuction with electrospray mass spectronetry: Black Mambas, in Electrophoresis.[7]

pressure programming at the CE inlet provides a rugged high-efficiency setup for analysis of peptide mixtures.

Because the concentration limits of detection of CE are often inadequate for most practical applications (approximately 10^{-6} *M*), several analyte concentration techniques have been developed, including combining CITP with CE, transient isotachophoresis (TITP) in a single capillary, analyte stacking, and field amplification. Such electrophoretic techniques have extended the applicability of CE for the analysis of dilute analyte solutions. Chromatographic online sample concentration has been achieved by using an extraction cartridge which contains a bed of reversed-phase packing[10] or a membrane[11] with properties. Accumulated analyte on the cartridge can be prewashed to remove salts and buffers that are not suited for CE separation or ESI operation. Figeys and Aebersold[12] designed the solid-phase extraction (SPE)/CE/MS/MS system which consists of a small cartridge C_{18} of extraction material immobilized in a Teflon sleeve. Solutions of peptide mixtures typically derived by proteolysis of gel-separated proteins were forced through the capillary by applying positive pressure at the inlet and the peptides were concentrated on the SPE device. After equilibration with an electrophoresis buffer compatible with ESI, eluted peptides were separated by CE and analyzed by ESI/MS. A detection limit of 400 αmol tryptic digest of bovine serum albumin (20 μl of solution at a concentration of 20 αmol/μl was applied) was achieved in the ion trap mass spectrometer-based system. This method was successfully applied to the identification of yeast proteins separated by two-dimensional gel electrophoresis.

Applications of CE/MS to large molecules are progressing rapidly. As biology enters an era of large-scale systematic analysis of biological systems as a consequence of genome sequencing projects, rapid and sensitive identifications of large-scale (proteomewide) proteins that constitute a biological system is essential. CE/MS with its high separation efficiency, rapid separation, and economy of sample size is complementary to microcolumn high-performance liquid chromatography (μHPLC)/MS. In addition, high-resolution, multiple-dimensional separations become increasingly attractive. HPLC/CE/MS, affinity CE/MS, capillary microreactor on line with CE/MS, and microchip based separations will be used in a broad range of future applications.

CE: ICP/MS

Clayton B'Hymer
National Institute for Occupational Safety and Health, Centers for Disease Control and Prevention, U.S. Department of Health and Human Services, Cincinnati, Ohio, U.S.A.

INTRODUCTION

Capillary electrophoresis (CE) has many well-known advantages including low-sample-volume requirements, high plate number (i.e., peak efficiency), the ability to separate positive, neutral, and negatively charged species in a single run, and, when properly developed, relatively short analysis times. The ability of CE to separate ionic multispecies and to have low operational costs makes the technique superior in certain specific applications to conventional high-performance liquid chromatography (HPLC). The inductively coupled plasma-mass spectrometer (ICP–MS) has the advantages of possessing low detection limits for the majority of the chemical elements. The ICP–MS detector has other additional positive attributes including linearity over a wide dynamic range, multielement detection capability, and the ability to perform isotopic analysis. Also, the ICP–MS is known to have minimal matrix-effect problems when compared to other detection systems. Sample matrix-effect problems are further reduced in CE–ICP–MS analysis owing to the small sample size and flow rates associated with CE. With all of these strong points, CE–ICP–MS is a rapidly growing hyphenated technique; the separation capability of CE is combined with the highly sensitive, element-specific detection system of ICP–MS.

HISTORICAL BACKGROUND AND USE

The first research papers describing CE–ICP–MS were written in 1995 by the Olesik, Lopez-Avila, and Barnes research groups.[1–3] The coupling of the ICP–MS detector with CE and HPLC has become the dominant analysis technique for elemental speciation analysis. Elemental speciation analysis is defined as the separation, identification, and quantification of the different chemical forms (organometallic and inorganic) and oxidation states of specific elements in a given sample. Information on elemental speciation in clinical and environmental material is vital in the study of mechanisms of element transport within living as well as environmental systems, elemental bioavailability, metabolic pathways within living organisms, and toxicology.

THE FUNDAMENTALS OF CAPILLARY ELECTROPHORESIS–INDUCTIVELY COUPLED PLASMA–MS

The Inductively Coupled Plasma–MS Detector

MS has established itself as the detection system of choice for CE of trace metals and metalloids, as well as their chemical species. The ICP–MS has dominated CE analysis methods in recent years. The ICP–MS differs from the more commonly used electrospray or ion-spray mass spectrometer method of ion generation. The electrospray MS can be described as using a "soft" ion source; that is, structural information can be obtained from molecular fragments. The ICP-MS is a "hard" ion source; that is, the plasma generally operates at an approximate temperature of 8000 K. Under these conditions, the ICP generates ions of elements and a few polyatomic ions. The ICP–MS has been well documented since its early development by both the Houk[4] and Gray[5] research groups over 20 years ago. A diagram of a typical commercial ICP–MS detector is shown in Fig. 1. The inductively coupled plasma is formed from a flow of gas, typically argon, through a series of concentric tubes made of quartz called the torch. The ICP torch is surrounded by a copper load coil. The load coil is connected to a radio-frequency generator, which operates between 27 and 40 MHz at a power of 700–1500 W.[6] This induces an oscillating magnetic field near the exit of the torch. A plasma is formed while a spark is applied to the flowing gas stream to form gaseous ions. The free electrons created during this process are accelerated by the magnetic field and bombard other gas atoms; this causes further ionization and produces the plasma. Sample introduction into the plasma is via a carrier argon gas flow through the central tube of the ICP torch. Liquid samples are nebulized into an aerosol before being carried into the ICP torch, a function performed by a nebulizer and spray chamber. The nebulizer produces the aerosol, and the spray chamber separates and removes the large droplets from the aerosol to form a more uniform mist. Once the fine aerosol sample reaches the plasma, vaporization, atomization, and ionization of the analyte to element ions occur almost simultaneously. Coolant and auxiliary gas are added to the ICP torch to keep the quartz

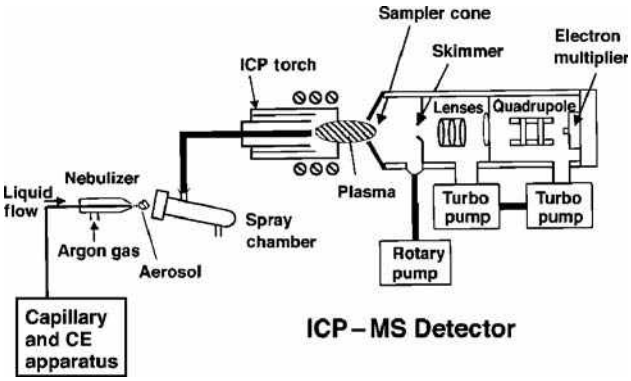

Fig. 1 The ICP–MS used as a detector for HPLC. The liquid sample passes through the capillary into a nebulizer where it is changed into an aerosol. The aerosol passes through a spray chamber and into the plasma. The analytes pass into the mass spectrometer. The CE interface is not in detail in this figure.

from melting and to provide a tangential flow of gas, which serves to center and stabilize the plasma.

Beyond the ICP torch are the sampler and skimmer cones of a typical mass spectrometer (Fig. 1). Ions generated from the sample pass through the aperture of the cones into low-pressure chambers. Ion lenses, which are actually a series of electrodes, are used to "focus" the ion path, before reaching the quadrupole mass analyzer. Ions of only one mass-to-charge ratio are transmitted at a time and impacted onto an electron multiplier detector. The electron pulse is amplified and this signal is then recorded by the instrument's data system. The diagram in Fig. 1 displays a quadrupole mass analyzer, but other spectrometers have been used with CE including scanning instruments such as the double-focusing and sector-field mass detectors, and for fast separations of multielement mixtures of chemical species, the time-of-flight (TOF) MS.

Alternative plasmas have been occasionally used for elemental speciation analysis, including the microwave-induced plasma (MIP), which has been reviewed in Ref.[7] and the low-power helium plasma. Both of these plasma sources have the advantage of reduced gas and power consumption over the traditional ICP; however, the use of these plasmas with interfaces with CE has been very infrequent and does not warrant further discussion in this entry. The MIP has been occasionally used with low flow rate liquid sample introduction. The low-power helium plasma has generally only been used with GC interfaces; their low-power levels are generally not capable of properly vaporizing and ionizing a liquid aerosol.

Interfacing Capillary Electrophoresis to the Inductively Coupled Plasma–MS

Overview of design considerations

The main design challenge of CE–ICP–MS is in the actual interface. In the typical practice of CE, a fused silica capillary filled with a buffer has both ends submerged or in physical contact with two buffer reservoirs. Electrodes placed in the buffer reservoir provide the application of a high electrical potential through the capillary. When attempting to interface CE to an ICP–MS, several problems need to be overcome. One is that CE has an extremely low flow rate (approximately 1 μl/min or less). This requires the use of a low liquid flow nebulizer to be used in the interface. A low liquid flow rate nebulizer is required that maintains a high transport efficiency and delivers a large quantity of analyte to the plasma. The ICP–MS detector sensitivity is based on mass of the analytes, not concentration of the solution. Because CE injection volumes are low, high transport efficiency by the nebulizer is vital to reduce analyte loss to the MS detector. The second problem with CE–ICP–MS interfacing is that an electrical connection must be maintained to the end of the fused silica capillary, yet the capillary must still introduce the CE buffer flow into the nebulizer and produce a uniform aerosol for the analysis system. This problem has been solved by various designs, which usually involves the addition of a "make-up" buffer or sheath electrolyte added near the end of the fused silica capillary. Interfacing CE with ICP–MS has the advantage of requiring a low liquid flow rate, and therefore places a small demand on the desolvation and solvent load capacity of the inductively coupled plasma. This makes a more stable plasma less subject to long-term signal drift over the course of several CE runs. Two other design considerations of a CE–ICP–MS interface are countering or minimizing laminar flow through the capillary generated by the operation of the nebulizer[8] and minimizing band broadening for the separation of analytes. There are various strategies in reducing laminar flow through the electrophoretic capillary, and band broadening is minimized through geometry considerations in the design of the CE–ICP–MS interface. These points will be discussed in further detail in this entry.

The nebulizer

A basic understanding of the nebulizer function and the types of nebulizers is necessary to successfully interface CE to the ICP-MS. Nebulization, as previously described, is the process to form an aerosol, i.e., to suspend a liquid sample into a gas in the form of a cloud of droplets. The quality of any nebulizer is based on many different parameters including mean droplet diameter, droplet size distribution, span of droplet size distribution, droplet number density, and droplet mean velocity. There are numerous nebulizers commercially available for the use with ICP-MS systems, and their detailed description can be found elsewhere.[9,10] Pneumatic designs, both concentric and cross flow, are the most popular for CE interfaces with the occasional use of the ultrasonic nebulizer (USN). Fig. 2 shows some typical nebulizers. The pneumatic nebulizer is either a concentric design (Fig. 2A), where both

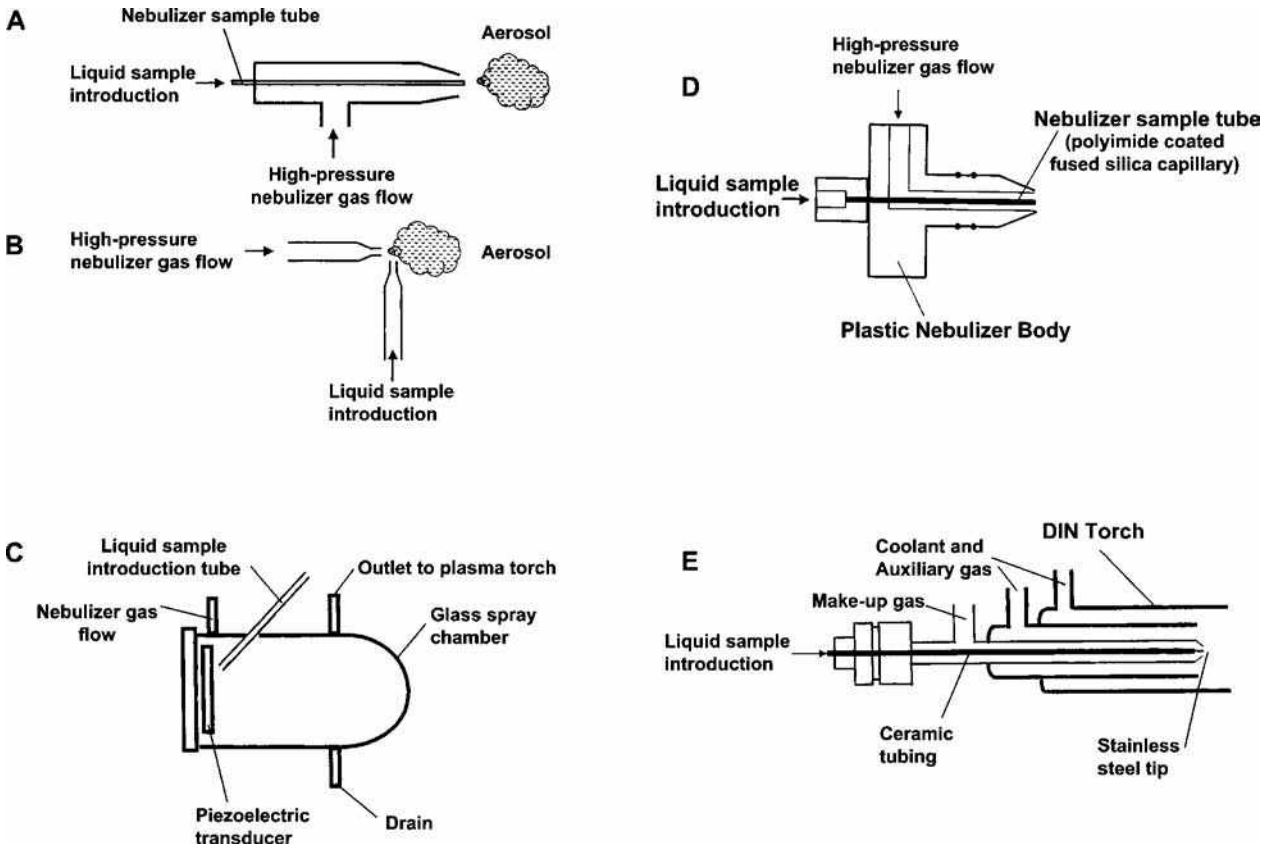

Fig. 2 A, The concentric nebulizer; B, The cross-flow nebulizer; C, The ultrasonic nebulizer (USN); D, The microconcentric nebulizer (MCN) by CETAC. The body of this nebulizer is made of plastic; and E, The direct injection nebulizer (DIN).

the gas stream and the liquid flow in the same direction or the cross-flow design (Fig. 2B), where the gas stream is at a right angle to liquid flow. Gas flowing past the tip of the liquid sample introduction tube generates the aerosol. The ultrasonic nebulizer (Fig. 2C) consists of a piezoelectric transducer and a liquid sample introduction tube. Liquid flow over the transducer plate forms a thin film and is nebulized by the high-frequency mechanical vibrations from the transducer.

There are several concentric-like pneumatic low liquid flow nebulizers commercially available that are often used in the construction of CE–ICP–MS interfaces. The Meinhard high-efficiency nebulizer (HEN) (Meinhard Glass Products, Golden, Colorado) is a variation of the concentric nebulizer that has smaller internal dimensions and is specifically designed to operate at low liquid flow rates. A very similar nebulizer is also commercially available and is known as the MicroMist nebulizer (Glass Expansion Pty. Ltd., Victoria, Australia). Another low-flow commercial nebulizer, the Microconcentric Nebulizer (MCN) (CETAC Technologies, Inc., Omaha, Nebraska, U.S.A.), has been used with liquid flow rates down to 10–30 μl/min. The MCN is also concentric in nature, but it differs from both the Meinhard and MicroMist in having its outer body constructed of plastic instead of glass. Also, the MCN has its inner sample tube made of fused silica capillary tube, not drawn glass (Fig. 2D). All three of these commercial nebulizers have comparable analyte transport efficiencies.

Although there has been limited use with CE interfaces, the direct injection nebulizer (DIN) was first described by Shum et al.[11] and later used by Liu et al.[2] for CE (Fig. 2E). In this design, the nebulizer introduces the sample very near the plasma inside the ICP torch and eliminates the spray chamber assembly. Close to 100% analyte transport efficiency can theoretically be obtained with the DIN, but the nebulizer is restricted to very low-liquid flow rate and thus is well matched to CE interfacing. This design does induce local plasma cooling due the lack of desolvation and detection limits are only slightly improved over other nebulizer designs.[12]

Specific capillary electrophoresis interface designs

The CE–ICP–MS interface based on the sheath-flow (make-up buffer) and pneumatic concentric nebulizers described by Lu et al.[3] is the most widely used CE–ICP–MS interface, and it has also been applied to electrospray MS interfaces.[13] The sheath-flow or make-up buffer acts to complete electrical connection to the exit end of the electrophoretic capillary; grounding is achieved by having a metal tube or metal "tee" near the connection to the

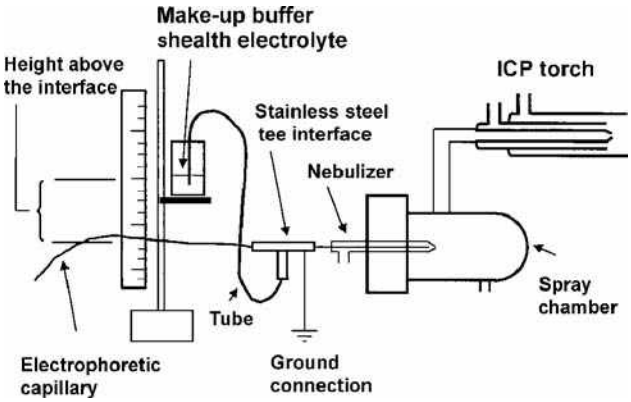

Fig. 3 A typical self-aspirating CE–ICP–MS interface. The make-up buffer/sheath electrolyte reservoir is positioned above the interface to provide the correct pressure and flow of buffer to the pneumatic nebulizer.

nebulizer (Fig. 3) or by coating the capillary with silver[1] (Fig. 4). The second function of the sheath flow is to compensate for the suction effect. Low pressure created near the tip of the pneumatic nebulizer by the flow gas of the operating nebulizer can induce laminar flow through the electrophoretic capillary. This can impair separation of analytes. Sheath flow can be introduced into the nebulizers by either self-aspiration with gravity siphoning control or by a pumping system. These strategies involve the precise addition of a sheath or make-up buffer to the nebulizer to prevent the degradation of the CE separation profile of the analytes. In the self-aspiration designs, the sheath flow is automatic, although adjustments to height of the sheath buffer reservoir (Fig. 3) can be used to optimize flow and separation to the nebulizer–CE interface. When a pumping system is used, the flow rate must be optimized to obtain the desired separation by reducing laminar flow through the capillary.

Silver paint was used to complete the electrical connection. **Source:** From Capillary electrophoresis inductively-coupled plasma spectrometry for rapid elemental speciation, in Anal. Chem.[1]; with permission of the American Chemical Society.

The use of controlled sheath-flow/make-up buffer rates to give equivalent CE/MS and CE–UV electopherograms was reported by Day et al.[14] It has also been reported that the sheath flow should be kept low and just compensate for laminar flow through the electrophoretic capillary.[8] This minimizes dead volume and band broadening of the CE separation. Precise pumping of a make-up buffer was demonstrated by Kinzer et al.[8] and later by Sutton et al.[15] The use of sol–gel frits near the exit tip of the electrophoretic capillary has been reported to reduce laminar flow effects and reduce the sheath flow.[16] Other important design and optimization considerations exit for the sheath-flow/make-up buffer interfaces. The positioning of the electrophoretic capillary into a concentric nebulizer is critical in these designs. Placement of the exit tip of the capillary close to the tip of the nebulizer can increase the "suction effect" and cause greater laminar flow to be generated through the capillary. Placement too far back from the tip of the nebulizer may induce greater band broadening from the extra dead volume. There has been some arguments about dilution effects of the sheath flow; that is, the sheath-flow lowers sensitivity of the MS detector from dilution of the analytes. The use of a sheath flow does not cause a decrease in sensitivity because of dilution, but actually because of a decrease in analyte transport efficiency through the spray chamber to the plasma. Large liquid flow rates generally have less-efficient analyte transport, droplet sizes, and distribution change so that the analyte loss is greater out the spray chamber drain. Generally, the sheath flow rate can be kept low and the low liquid flow nebulizers commercially available have high analyte transport efficiency, making loss of sensitivity minimal. Finally, if the sheath-flow/make-up buffer is different from the run buffer, changes to the separation will obviously occur. Creation of a pH gradient across the electrophoretic capillary or isoelectric focusing from the use of a mismatch of the run and make-up buffer may cause undesirable results with the analyte separation.

Another less often used, but successful, technique to counter laminar flow in pneumatic-based nebulizer CE–ICP-MS interfaces is by the application of negative buffer reservoir pressure. This approach was first demonstrated by Lu et al.[3] and later by Taylor et al.[17] A matching mechanical counterbalance to the pneumatic nebulizer's suction was used in both of these interfaces. The theoretical advantage of non-sheath-flow system is that sensitivity of the CE–ICP–MS system is not reduced by dilution by the make-up buffer. Olesik et al.[1] originally described a sheathless pneumatic interface, but the main flaw in the design was the increased liquid flow through the electrophoretic capillary owing to the suction or Bernoulli effect of the operating nebulizer. The electro-osmotic flow of this CE system was measured at 0.05 μl/min, while the natural aspiration rate of the nebulizer vacuum was measured to be 2 μl/min. Some degradation of the separation of analytes

was noted, but the high plate number of CE and the selective detection capability of MS allowed this to be a useful separation. Another problem encountered in some sheathless interfaces is the loss of electrical connectivity of the electrophoretic capillary.

Finally, other nebulizers have been used in CE–ICP–MS interfaces. In an interface developed by the Barnes research group[18] using the ultrasonic nebulizer, the ground connection was provided by a make-up buffer/sheath-flow electrolyte. The separations obtained with the USN were demonstrated by Barnes' group to be superior to those obtained using a concentric pneumatic nebulizer in their study. Kirlew et al.[19] reported the comparison of a "home-made" ultrasonic nebulizer and a CETAC USN in CE–ICP–MS interfaces. Again, a make-up buffer was used, added to the system via a concentric capillary outside the electrophoretic capillary. In another work by Kirlew and Caruso,[20] an oscillating capillary nebulizer (OCN), which is a variation of the pneumatic concentric nebulizer built from flexible capillary tubes, was used in an interface. The OCN has had little application in CE interfaces, owing to its generally lower sensitivity performance when compared to other pneumatic nebulizers used with ICP–MS detection.[21] The DIN, previously described in "The Nebulizer," was used by Liu et al.[2] in a CE interface. The electrophoretic capillary was directly inserted through the central sample introduction capillary of the DIN. A platinum grounding electrode was positioned into a three-port connector. This connector contained the DIN sample introduction capillary as well as a make-up buffer flow. These alternative nebulizers have been successfully used in CE interfaces, but the pneumatic designs dominate the interface systems reported in the literature.

One last CE–ICP interface worthy of mention that is specific for the determination of elements capable of forming volatile compounds is by the use of a hydride generation system. Hydride generation followed by a gas–liquid separator in CE interfaces has been reviewed.[22] This technique has a drawback, because only arsenic, tin, lead, antimony, bismuth, germanium, selenium, and tellurium are capable of forming gaseous hydrides at room temperature. Hydride generation allows for the introduction of analyte species into the inductively coupled plasma nearly quantitatively; that is, the transport efficiency is nearly 100% percent less some loss by venting in the gas–liquid separator or other inefficiencies within the interface/sampling tube design to the plasma. In theory, detection limits are lower. In practice, hydride generation of the analytes may occur at different rates and the extra complexity and expense of the interface make these systems less useful as compared to the direct sample introduction systems previously described.

APPLICATIONS IN SAMPLE ANALYSIS

As mentioned in the Introduction, the main application of CE–ICP–MS is in the field generally known as elemental speciation analysis. There are a number of good reviews on elemental speciation CE advances including use MS detection; the two most recent were by Kannamkumarath et al.[23] and Timerbaev.[24] Work performed in this relatively young technique is very extensive, and only a few examples will be cited in this entry.

Speciation analysis of arsenic and selenium is very active in the recent literature. The toxicity of arsenic varies widely and is dependent on the specific compound present. Arsenic in its various forms is also widely distributed in the environment and the food that human eats. Speciation of arsenic in human depends both on the form of the arsenic taken in and the metabolism within the body. Inorganic arsenic, in the forms of arsenite (As^{III}) and arsenate (As^{V}), is highly toxic. The common organic forms of arsenic have varying degrees of toxicity. Monomethylarsonic acid [MMA^{v}, $CH_3AsO(OH)_2$] and dimethylarsinic acid [DMA^{v}, $(CH_3)_2AsO(OH)$] exhibit a toxicity factor of 1 in 400 that of the inorganic forms. Arsenobetaine [$(CH_3)_3As^{+}CH_2COO^{-}$] and arsenocholine [$(CH_3)_3As^{+}CH_2CH_2O^{-}$] are commonly found in seafood and are relatively non-toxic. A variety of arsenic compounds are currently used as antifungal agents, herbicides, and pharmaceuticals; they are also used in semiconductor processing and there was an extensive use in pesticides before the invention of the more advanced organophophorus compounds. Thus the literature is filled with arsenic speciation analysis of food, the environment, and biological systems. Selenium has also been widely studied for many of the same reasons. Selenium intake in the human diet is essential, but excess intake can cause toxic reactions. A variety of selenium-containing species are present in the environment, natural foods, and food supplements.

In a previously mentioned work by Kirlew et al.,[19] electrophoretic separations of Se^{IV}, Se^{VI}, As^{III}, As^{V}, and dimethylarsinic acid were performed using various ultrasonic nebulizer (USN) interfaces. Using the optimized CE interface conditions and a borate run buffer at pH 8, a separation was accomplished within 10 min. Electrokinetic injections gave better sensitivities for the analytes as compared to hydrostatic sample injection. In the Kirlew study, arsenate and selenite ions had very similar migration times, but these analytes were easily resolved by the multielement capability of the ICP–MS detector. An electropherogram of this work is shown in Fig. 5. In an application to field samples, Van Holderbeke et al.[25] investigated arsenic speciation in three different sample matrices: drinking water, human urine, and soil leachate. All were run under basic conditions with 20 m*M* borate buffer (pH 9.40) and in the presence of cationic surfactant as the osmotic flow modifier (OFM) supplied by Waters Associates (Milford, Massachusetts, U.S.A.). The separation of As^{v}, monomethylarsonic acid, dimethylarsinic acid, monomethylarsonic acid, arsenite As^{III}, arsenobetaine, and arsenocholine was obtained. Electropherograms from the Van Holderbeke study are shown in Fig. 6.

Capillary electrophoresis has been extensively used to separate biological molecules. Therefore it was only a

natural extension that CE has been used for the analysis of metalloproteins and metal binding with other macromolecules. Also, the use of CE with the ICP–MS detector has been used in many studies reported in the literature. Metallothioneins are involved in metabolism and detoxification of several trace metals; thus the ability to monitor metallothioneins by CE–ICP–MS is of great importance. In a study of standard solutions of metallothionein I and ferritin, B'Hymer et al.[16] used various geometrical configurations of a microconcentric nebulizer to obtain different electropherograms. A run buffer of 15 m*M* Tris (hydroxymethyl) aminomethane adjusted to pH 6.8 by the addition of HCl was used at a potential of 15 kV. An example electropherogram is shown in Fig. 7. The MS detector has the advantage of being capable of simultaneous monitoring of various elements, thus resolving the relative quantities of cadmium, copper, and zinc bound to the metallothionein. Ferritin was clearly resolved from the iron signal.

CONCLUSIONS

The advantages of CE coupled with those of the ICP–MS detector will certainly allow this relatively young hyphenated technique to grow in the areas of elemental speciation and the analysis of environmental and biological samples. It is doubtful that CE will replace HPLC; however, CE will certainly compliment the other more traditional separation techniques owing to its separation being based on a physical rather than chemical partitioning. The ability of CE to use an extensive variety of electrolyte/buffer solutions so that specific chemical species of interest can be maintained during the course of a separation is another advantage.

The improvement in the mass spectrometer will of course lead to better detection limits and capabilities. Again, the low-flow pneumatic nebulizer will probably continue to lead the work performed in building CE–ICP–MS interfaces. Also, the current selection of commercial low-flow nebulizer will aid in the construction and use of interfaces. Finally, two books worthy of further reading are Akbar Montaser's *Inductively Coupled Plasma Mass Spectrometry* (Wiley-VCH, New York, 1998) and Joseph A. Caruso et al.'s *Elemental Speciation—New Approaches for Trace Elemental Analysis*, *Comprehensive Analytical Chemistry XXXIII* (Elsevier Science, Amsterdam, The Netherlands, 2000). Specific chapters were cited in this entry, but both books comprise other chapters containing a wealth of information about capillary electrophoresis–inductively coupled plasma-mass spectrometry.

CEC

Michael P. Henry
Chitra K. Ratnayake
Advanced Technology Center, Beckman Coulter, Inc., Fullerton, California, U.S.A.

INTRODUCTION

Capillary electrochromatography (CEC) is a technique in which a high direct voltage is applied, during analysis, across the ends of a capillary containing a solid stationary phase and a liquid mobile phase. It is thus a blend of high-performance liquid chromatography (HPLC) and capillary electrophoresis (CE).

Typically, fused silica capillaries are used with internal diameters of about 100 μm. Applied voltages of up to 30 kV are common. Mobile phases include low ionic strength aqueous buffer/organic solvent mixtures similar to those used in HPLC. Stationary phases generally consist of the same types of particulate materials as those employed in HPLC, although monolithic packings and surface-modified open tubular columns are gaining in popularity. Stationary phases of any kind usually extend only a portion of the way along the capillary, with particulate materials being held in place with small frits at either end of the packed region. Most CEC columns suffer from a degree of fragility due to the harm caused to the fused silica by the process of installing these two frits. Monolithic and wall-modified open tubular columns do not require frits and so offer an advantage here. Most instrumentation available for CEC is the same as that used for CE. Special capillary columns with a variety of dimensions and packing types are available. All sample classes that can be separated by HPLC can be separated by CEC and a great deal of work has been done to accumulate applications for this technique. There is still some controversy surrounding the immediate future of this technique, since certain technical challenges remain.

The objective of this entry is a clear understanding of the basic concepts, history, instrumentation, applications, and future prospects for CEC.

TECHNIQUE OVERVIEW AND SEPARATION MECHANISMS

The technique and features of CEC are invariably compared to those of HPLC and CE. Krull et al.[1] have published a useful table comparing the three methods, and this is shown in Table 1 with some changes. It can be seen that there are advantages of CEC over, for example, HPLC (efficiency, solvent consumption, and cost per run). On the other hand, HPLC has advantages over CEC (engineering, status of theory, frit integrity), not the least of which is the familiarity of the former and its integration into thousands of validated analyses.

CEC is a technique in which a high direct voltage is applied across the ends of a capillary containing a solid stationary phase and a liquid mobile phase. The mobile phase is driven by the mechanism of electro-osmosis from one buffer vial through the stationary phase, through an unpacked region in the capillary, and finally into a second buffer vial (Fig. 1). A liquid sample is injected from a third vial (sample vial) onto the packed column by means of a brief application of either a lower voltage or pressure. The mobile phase in the buffer vial is again driven through the column at the elution voltage, bringing about the formation of flow-derived zones of separated sample components along the packed bed. Eventually the zones elute from the packed region of the column and pass by a window in the capillary that is adjacent to a detection/data system.

Elution voltages up to 30 kV are normal, and injection voltages from 2 to 5 kV for several seconds are used. Typically, the capillary is made of high electrical resistance fused silica coated with polyimide to improve flexibility. The capillary internal diameter (I.D.) may have values from 5 to 200 μm, and the total length 20–60 cm. The small capillary I.D. is important to minimize Joule heating effects, which depend in part upon the current generated within the mobile phase. The polyimide coating is UV-opaque, and so a short cylindrical piece is removed from the capillary forming a window that is transparent to radiation down to about 190 nm wavelength.

The interior surface of the unmodified capillary is typically negatively charged due to the presence of deprotonated acidic silanol groups. Mobile cations adjacent to this surface are drawn through an electric field towards the cathode and, in the process, drag the mobile phase against the forces of viscosity towards that electrode. This mechanism electro-osmotic flow (EOF) of mobilizing the solution through the capillary results in the generation of an almost flat radial flow velocity profile across the interior, thereby substantially reducing a source of zone broadening.[1a] Sample component zones are therefore generally much narrower in CEC than in HPLC (where flow is generated hydrodynamically) and this leads directly to improved chromatographic resolution of mixture components.

As the mobile phase moves through the capillary containing the sorbent under the effect of this electro-osmotic

Table 1 Features of CEC compared with HPLC and CE.

Feature	CEC	HPLC	CE
Sample types (without additives[a])	Non-polar, polar, ionized	Non-polar, polar, ionized	Ionized
Available theoretical plates	100,000–700,000	<50,000	200,000
Peak capacity	100+	About 50	About 100
Mechanical complexity	Simple	Complex	Simple
Compatibility with MS	Better than CE	Good	Limited
Mass detection limit	Slightly better than HPLC	Good	Often inadequate
Ease of operation	Difficult	Easy	Easy
Solvent consumption	<1% of HPLC	100 L/year	<1% of HPLC
pH operating range	2–11	2–14	2–11
Frits	An experimental problem only with particle-packed columns	Not a problem	Not applicable
Purchase price (US$)	30,000–50,000	20,000–50,000	30,000–50,000
Cost per run (US$, no labor)	0.02	2.00	0.04

[a]Such as surfactants, polymers.

flow, sample components partition between the two phases in sorption and diffusive mechanisms characteristic of -liquid chromatography (LC). Ions in the sample move both under the influence of EOF and by their added attraction towards the oppositely charged electrode (electrophoresis). Uncharged components, on the other hand, move only under the influence of EOF Thus, sample components in general separate by chromatographic and sometimes electrophoretic processes.

Typical mobile phases[1b] are aqueous buffer/organic mixtures, similar to those used in HPLC. Stationary phases[1c] are generally the same as those used in HPLC and are most often particulate in nature, although monolithic (single piece) bonded phases[1d] are also used. In addition, open tubular CEC is possible, in which an adsorptive layer is formed on, or deposited onto, the interior surface of the capillary.[1e] The first generally require end frits, whereas the last do not need frits to maintain column integrity. Actual packed lengths typically range from 10 to 20 cm or in some cases may fill the entire length of the capillary.

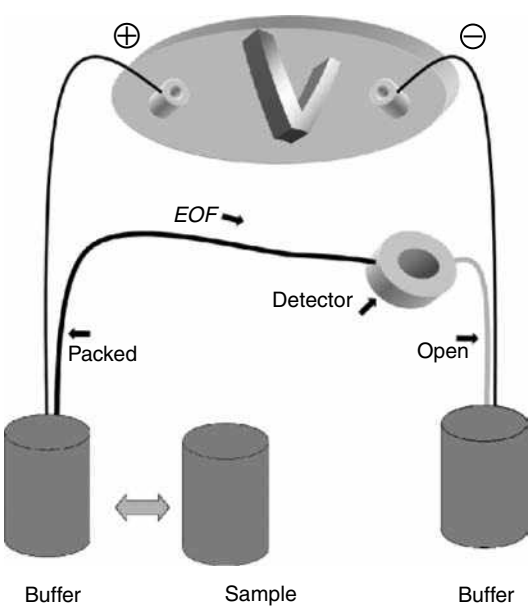

Fig. 1 Schematic illustration of a typical instrument for CEC.

All sample classes that can be separated by HPLC can be separated by CEC (see section on "Applications"). Dipping the capillary inlet into a separate vial containing the sample in solution and applying an injection voltage for a brief time accomplish sampling. The capillary inlet is then moved back to the inlet buffer vial and elution is commenced at the (normally) higher voltage.

Samples are detected by the same techniques as those used in HPLC and CE. The uses of on-column detection with UV-Vis spectrophotometers and lasers and postcolumn detection with mass spectrometers are well established.[1f] Instruments used for CEC are generally the same as those used for CE and consequently have capabilities for full automation of analysis and data processing of the results.

Two books on CEC have been published in the third millennium.[1a–f,2]

HISTORY

Pretorius, Hopkins, and Schieke[3] were among the first investigators to carry out packed column LC in a tangential electric field as a feasible alternative to using pressure. Their 1 mm I.D. quartz columns filled with 75–125 μm silica particles gave reduced plate heights of about 3 by CEC vs. the pressure mode values of about 8.

The advantages of electrochromatography, however, were not to be realized until the technology needed to create narrow capillaries (< 200 μm I.D.), stable frits, and sensitive detection systems had matured. Thus, in 1981, Jorgenson and Lukacs[4] carried out experiments in CEC using an instrument (see schematic in Fig. 1) whose basic design is still used today. Besides acting as a combined injector, separation medium, and flow cell, their column could also be used in the CE, CEC, and micro-LC modes. However, the fused silica capillaries (170 μm I.D.) drawn in their labs, packed with 10 μm particles and operated in neat acetonitrile, gave rather modest improvements in efficiency over standard liquid chromatographic techniques, with reduced plate heights of no less than 1.9. These disappointing results, coupled with an admission of the technical difficulty of using this technique, led these authors to conclude that CEC would only be useful in wider bore (several centimeters) preparative scale processes, a suggestion also made by Pretorius, Hopkins, and Schieke.[3]

Then, in 1991, Knox and Grant,[5] working carefully with 3 and 5 μm particles, showed that it was practical to achieve reduced plate heights of less than 1 in the CEC mode. These results confirmed their strongly optimistic view of the future of this technique, and a few years later, interest in CEC accelerated rapidly.

Over the past decade, CEC has become incorporated into the research and development programs of many universities and industrial organizations.[6] Progress has been made in the areas of column construction, column packing, general instrumentation, mobile phase optimization, applications, and method development.[1a–f] The elucidation of the physicochemical and electrochemical properties of CEC systems and the determination of their influence on the entire analysis is ongoing[7] and adds a fascinating dimension to the study of this technique.

OPERATIONAL LIMITS

Knox and Grant[5] have placed a general maximum limit of 200 μm on the I.D. of capillaries used in CEC in order to avoid problems with excessive internal heating, which harms column efficiency in aqueous/organic solutions. In principle, however, wider bore tubes can be used, provided the current and field strength are kept low, or the thermal conductivity of the system is kept high. Currents in general should be kept below 50 μA and field strengths held below 1000 V/cm. At higher field strengths and currents, outgassing of mobile phases can be a problem. This is often reduced in frequency if both ends of the capillary are pressurized. Most commercially available instruments have this capability. Bubbles are also a problem at higher temperatures; so cooling of the capillary is recommended.

CEC in mobile phases containing organic solvents in any proportion is possible, provided the electrical double layer is formed with appropriate dissolved salts[3] in non-aqueous cases.

The ionic strength of most conventional buffers, such as phosphate, acetate, or borate, needs to be kept within the range 0.002–0.05 *M*, but care needs to be taken with the lower concentration to avoid buffer capacity depletion due to hydrolysis. Zwitterionic buffers such as morpholino ethane sulfonic acid (MES) (whose electrical conductivity is low) can be used in the range 0.01–0.1 *M* without undue heating problems, provided field strength and aqueous content are kept low and the capillary is cooled.

Since there are few or no pressure gradients generated within a CEC column, long packed capillaries containing very small particles are possible, but the longer columns mean slower chromatography and equilibration. Generally, columns in CEC are no longer than 60 cm. Times of analyses may be reduced by increasing flow rates. This is generally accomplished by increasing the applied voltage, while remaining within the limits mentioned above. Alternatively, one may increase the electroosmotic flow rate by increasing pH or decreasing the amount of organic solvent (if any) in the mobile phase. All these changes (in flow rate, voltage, pH, and solvent), however, may cause simultaneous and undesirable shifts in resolution among the peaks of interest.

In some cases, hydrodynamic pressure may be exerted upon the inlet end of the capillary in order to increase the speed of analysis. This generally amounts to just 100 psi, and so improvements are not often seen for conventionally packed columns. However, many types of monolithic and open tubular columns are sufficiently permeable to allow significant increases in flow rates when these low inlet pressures are used.[8] A disadvantage of using applied pressure in this fashion is that efficiency is reduced due to the intrusion of a parabolic radial flow profile into the capillary.

INSTRUMENTATION

Creative solutions to practical problems abound in the evolution of instruments designed to carry out CEC. The graphite electrodes, quartz tubing, glass wool frits, and on-column pressure injection of Pretorius, Hopkins, and Schieke[3] gave way to Jorgenson and Lukacs's[4] fused silica tubing, sintered frits, and electrokinetic injection. Commercially developed automated instruments designed for CE, whose appearance in 1988[9] followed these last authors' breakthrough research, have been used for most applications in CEC. Modern instruments therefore consist of the column, a cooling system, a detector, a voltage controller, an autosampler, and a data processor.

In-capillary optical focusing of UV, visible, and laser radiation has largely solved the problems of detection.[10] In-column (through the packing) detection of appropriate analytes by laser-induced fluorescence has improved

general efficiency by avoiding the deterioration of peak shape that often occurs as the analyte zone passes through the outlet frit.[10] Mass spectrometers are also used for detection and identification in CEC since the low flow rates are compatible with the sampling kinetics required by these instruments.[1]

Columns for modern CEC have been prepared using standard HPLC particles, from 0.5 to 10 μm diameter, bearing C18, phenyl, C8, C6, C4, CN, amino, sulfo, and other functional groups and a variety of chiral polymers such as proteins and polysaccharides.[11] In situ sintered silica-based frits are most often used in these columns,[12] which are generally slurry-packed at high pressures. Several types of so-called monolithic (single piece) columns have been developed,[13,14] which dispense with frits, while generally maintaining high efficiency. Open tubular columns are becoming very popular, and many versions exist.[1]

Companies that have instruments suitable for CEC include Agilent Technologies, Beckman Coulter Inc., Prince Technologies, Unimicro Technologies, Micro-Tech Scientific, and Capital HPLC. More information on commercialized products for CEC can be found in Buyers' Guides to chromatographic instruments and accessories, such as the LC–gas chromatography (GC) North America publication, which is issued yearly in August.

APPLICATIONS

In 1998, Dadoo et al.[10] succeeded in achieving near baseline resolution of five polynuclear aromatic hydrocarbons over a 1 sec interval by CEC (Fig. 2). These high speeds were obtained from a combination of factors including a modest column length (6.5 cm), a high column plate number (13,000 plates) associated with 1.5 μm non-porous C18 particles, and a high voltage (28 kV). Although this separation is one of the fastest achieved in a liquid phase, higher column plate numbers have been obtained. Smith and Evans[15] report values of greater than 8 million plates per meter for the analysis of tricyclic antidepressants on 3 μm sulfopropyl bonded silica. These values are clearly due to a focusing effect within the column, and further work on this phenomenon has been done.[16] Dadoo et al.[10] have produced CEC columns that generate plate numbers of about 700,000 per meter when peaks were detected before they passed through the outlet column frit. These results illustrate how closely practical achievements in CEC have now approached predicted theoretical performance maxima.

Fu et al.[17] have prepared CEC columns from the highly efficient, strong cation exchange material PolySULFOETHYL A for the purpose of separating basic pharmaceuticals in human serum. This is a relatively rare example of the use of an ion exchanger to chromatograph positive organic ions. Fig. 3 shows the high quality of the capillary electrochromatogram achieved.

McKeown, Euerby, and Lomax[18] have made a detailed assessment of silica-based reversed-phase materials for the analysis of basic compounds. Walhagen et al.[19] have

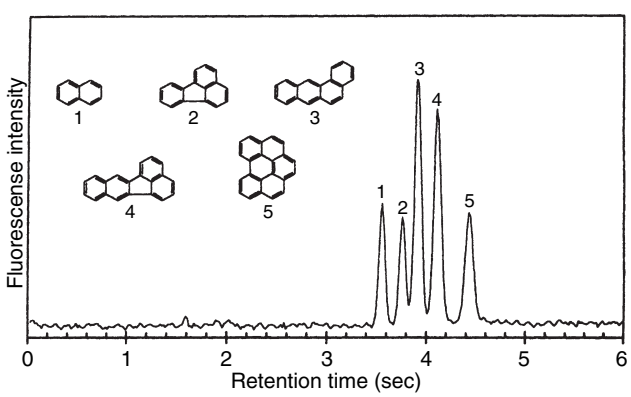

Fig. 2 Electrochromatogram of naphthalene 1, fluoranthene 2, benz[*a*]anthracene 3, benzo[*k*]fluoranthene 4, and benzo [*ghi*]perylene 5, using 1.5 μm non-porous ODS particles. Column dimensions: 100 μm I.D. × 6.5 cm packed length (10 cm total length). Mobile phase: 70% acetonitrile in a 2 m*M* Tris solution. Applied voltage for separation: 28 kV. Injection: electrokinetic at 5 kV for 2 sec.

investigated the nature of the forces controlling the selectivity of peptides. Kang, Wistuba, and Schurig[20] have reviewed progress in chiral separations. A widely applicable cationic/hydrophobic monolithic column has been investigated by Bedair and El Rassi[21] for the high-speed separation of proteins, pesticides, and amino acid derivatives.

Most chemical classes have been separated and analyzed by CEC.[11] These include many classes of pharmaceuticals, environmental chemicals, explosives, natural products, drugs of abuse, polypeptides, oligosaccharides, nucleosides and their bases, and polynucleotides. Applications of CEC, such as the review by Eeltink, Rozing, and Kok in *Electrophoresis*,[22] may be found in other journals such as the *Journal of Chromatography*, *Biomedical Chromatography*, *Chromatographia,* and the *Journal of Separation Science*. Access to the literature of CEC in general is readily achieved through several user-friendly websites.[23–25]

PROBLEMS, ISSUES, AND FUTURE PROSPECTS

Fundamental theory of CEC that will provide a better understanding of mechanisms of separation is being developed. In particular, the work of Rathore and Horváth[7] in elucidating the electrical properties of packed columns is particularly interesting. Technological issues that remain to be addressed include the difficulty of dealing with bubble formation and the fragility of conventional columns due to the aggressive frit-forming methods currently used. Monolithic columns[13,14] and open tubular columns[26] appear to have advantages in this regard.

Majors[6] has compiled the results of his *Perspectives* survey of 14 leading separation scientists with an interest in CEC. As expected, there is a wide divergence in the opinions of these leaders with regard to the current issues and future prospects for CEC. Few, however, underestimate the current technological difficulties in column manufacture, the reproducibility of chromatographic and electroosmotic properties of the packed capillary, and the short-term problems of competing with HPLC or CE. But the majority of scientists interviewed believe that, as with any new technique, these problems will be overcome and that CEC will become a routine method of analysis in time.

On the other hand, the future of CEC may lie with the exciting developments in microfabrication described by Regnier[27] where capillaries here are open channels 1.5 μm wide and 4.5 cm long and can achieve efficiencies of 800,000 plates per meter.

CONCLUSIONS

This entry has been a brief introduction to the technique of CEC. It is a technique in which a high voltage is applied across the ends of a capillary containing a solid stationary phase and a liquid mobile phase. Aspects of the method that were described included a brief overview of the technique, elements of the history of its development, the normal operational limits, aspects of modern instrumentation, a summary of selected applications, and future prospects for the development of CEC.

The future of the technique appears assured,[6] although the progress in moving it from the interesting stage to its use alongside the mature HPLC and CE has been quite slow. Fundamental theory of CEC continues to be developed. Several technological issues remain to be addressed, including the difficulty of dealing with bubble formation and the fragility of conventional columns. Monolithic and open tubular columns appear to have advantages in this regard.

INTRODUCTION

Sedimentation field-flow fractionation (SdFFF) is an efficient, analytical/preparative-scale, cell sorting device, in particular, if coupled with sophisticated cellular characterization techniques, devices, or methods, including flow cytometry (FC). Cell population, by analogy with "polymers," appears very polydisperse and disperses in many dimensions, which may not be essentially biophysical (size, shape, density, and rigidity), but also functional (cell cycle, protein expression, and differentiation stage). Cell sample pretreatment has a unique goal, which is to provide a sterile and viable cell suspension at an appropriate concentration (1–10 million cells/ml). A particular elution mode, made possible in cell purification by exploiting complex hydrodynamic forces, is usually described as a "Hyperlayer." This elution mode exploits slight differences in physical characteristics of the cell (size, shape, density, rigidity, and surface characteristics); trends are opened to their association with complete functional cell characteristics analyses. It is shown that cells can be eluted, in some examples, according to functional parameters (cell cycle and differentiation stage), and that correlations may exist between functional parameters and the physical ones. If a given cell population is considered, considerable information provided by the separation and the complete physical and functional analyses allows one to define, characterize, and produce a new type of cell subpopulation. Such separation/characterization process for cells can be described as "cellulomics," by analogy with what is done for proteins of gene systems, keeping in mind the concept that the cell is the "fundamental and unique" localization and production factory of any gene and protein.

BACKGROUND

The last decades have shown considerable development of a large panel of cell-sorting techniques.[1–5] SdFFF, such as elutriation or centrifugation methods, belongs to the group of "physical methods," comparisons of which have already been assessed.[1] In the present report, we will focus on the specific features of cell elution in FFF and on the necessity of coupling such a physical separation/purification system with detectors of high functional specificity. Cell sorting with FFF emerged in the scientific literature in the early 1980s of the last century. A pioneering report was published in 1984 by Caldwell et al.[6] in which most of the separation rules and methodologies were described. At difference with all other species, cell sorting with FFF success was proved essential by using sedimentation subtechniques that required specific instrumentation and methodological setups. Systematic instrumentation development, allowing separation of living species in sterile conditions for further use, was initiated in the late 1990s in our laboratory.[7,8]

It must be noted here that the main objective of cell separation in FFF is not only analytical, but also preparative. The main goal is strongly linked to the possibility not only to characterize as completely as possible the cell subpopulation, but to provide or produce new living cell subpopulations for any use. It is essential to keep these cells in surviving condition. Therefore considerable attention must be given to characterize a potential subpopulation, and to define and control their survival. However, if non-stable subpopulations are recovered, cinematic studies of their properties must be developed in terms of "time or age"-dependent characteristic modifications. To be clear, cells are eluted at a given stage; they are characterized or used at that stage, in whatever way they can be cultivated, maintained in survival, and evolved to other critical stages (the must be characterized) where they can be functionally used. Such complex receiver-oriented characteristic (ROC) separation/characterization step can de described as "cellulomics."

In this report, specific instrumentation of SdFFF for cell sorting will be described. The interest and potential of the "Steric Hyperlayer"[6,9] elution mode for cell sorting will be discussed, keeping in mind basic rules for physically or functionally oriented separation development. By analogy

with polymers, experimentally driven definitions, descriptions, and characterizations of cell populations will be provided, leading to an information matrix described as "cell population multipolydispersity."[1]

A particular paragraph is devoted to some specific requirements for FFF cell sorting, such as sample preparation or separator poisoning. The battery of cell population or cell subpopulation characterization methods will be described with an FFF-dependent classification: physical methods compared to functional ones. Finally, experimental correlations between functional and physical cell characteristics lead to the isolation of very specific populations, thereby opening the field of "cellulomics." In this report, it is assumed that readers have a basic knowledge of separation sciences, in particular, in chromatography and FFF.

PRINCIPLE OF SdFFF AND INSTRUMENTATION

The FFF family encompasses a broad array of subtechniques; however, FFF techniques have in common the design of a channel, generally parallelepiped and often described as "ribbonlike," in which the critical dimensions are: 1) thickness, usually lower than 300 μm; 2) length, between 20 and 100 cm; and 3) breadth, from 0.5 to 2 cm; with 4) tapered channel ends. An external field acts on the great surface of the ribbon to achieve flow rate-dependent separations (Hyperlayer elution mode for micron-sized species). SdFFF techniques can be divided into two groups. The first uses simple gravity or gravity fractions [i.e., gravitational/subgravitational FFF (GrFFF/GFFF)]; the second uses the multigravity field created by centrifugation generically described as SdFFF. With common associated devices (injection, flow, and detection devices), their instrumental design and setup are completely different. The GFFF separator is very simple to set up and does not require more specific skills than a simple "exploration desire," whereas SdFFF is much more complex to set up and requires long-term know-how in the absence of commercially available devices devoted to cell sorting.

INSTRUMENTATION

Instrumentation for cell sorting can be very simple, using GFFF devices as described by our group,[10–13] or by others.[14–16] A complete technical instrumentation has been also described.[17] The key parameter is the material used to construct the channel walls, which must be as "inert" as possible if considered against the cellular materials or their media (protein clotting). Media or sample-derived wall treatment may occur when changing, considerably, elution conditions. Such goal is empirically well assessed in the biological technology using materials of various "biocompatible" polymers. Therefore it is only necessary to choose as an appropriate material the one compatible with FFF instrumentation (low deformation under sealing pressure). It must be noticed here that some materials can be appropriate for some cell groups and be completely unusable for others, which requires a versatile instrumentation.

In SdFFF, the same strategy is employed with materials tested in GFFF, with the only price that sealing and deformability linked with centrifugation rate must be controlled. However, one particular point must be taken into account in SdFFF; long connection tubings are necessary and they must be chosen to be "biocompatible" and with appropriate inner diameter. This point is highly critical. Diameters that are too narrow may induce shear forces, destroying selective parts of the sample; too large diameters induce non-column band spreading, thereby limiting resolution. Channel dimensions and tubing choices must be chosen in the light of the sample and of the separation goals. Unfortunately, only a few laboratories exert an instrumental effort to define and construct biocompatible SdFFF systems.[18–20]

ELUTION MODE

Cells are in the 3–40 μm diameter range; channel thicknesses ranging from 70 to 250 μm are commonly used, depending on elution selectivity requirements. Therefore cell size cannot be ignored in the light of the channel thickness leading to an experimentally developed elution mode described as "Steric Hyperlayer."[6,9] Again, in the light of the preceding paragraph, a "pure steric elution mode" must be avoided as possibly generating high particle–wall interactions, these being so far determined essentially on an experimental basis. Therefore elution conditions must meet the hypotheses developed in the Hyperlayer condition. As such, model cells are focused on different stream lines by the double and opposite actions of the external field and of forces generated by the cell in motion and described generically under the term of lift forces, driving the cell into an equilibrium position in the channel thickness. The lifting force characteristics are complex, were described for the first time by Ho and Leal,[21] and were developed on a theoretical basis for FFF by Martin and Williams.[22] Experimental proofs were given for cell sorting by Caldwell et al.[6] If little is known about the kinetics of this focusing process using retention ratio analysis, it is simplified in the determination of an average "equilibrium" position in the channel thickness of the cells eluted at a given retention ratio by a position(s) in the channel thickness given by the following equation:

$$R = \frac{3s}{w} \tag{1}$$

where R is the measured retention ratio, s is the distance between the average particle gravity center and the accumulation wall, and w is the channel thickness. The calculated s value does not describe the real distance at equilibrium, but can be considered an accurate evaluation of it, assuming that: 1) in identical experimental conditions, kinematics in the channel thickness of particles of analogous size, shape, and density is analogous; 2) flow injection reduces particle–wall interactions that are negligible; and 3) lifting forces are so intense that no particle–wall retardation effects occur. If s is greater than the cell greater radius, then elution is considered as a Hyperlayer. Therefore it is essential to obtain for cells an average position that is much larger than the cell radius; this ensures that cells have a low probability to interact with channel walls. Such considerations lead to a concept applied by Battu et al.[19,20] for cell sorting—the "safety Hyperlayer" elution mode in which cell recovery is maximum in the case of flow-established injections. Depending on the elution conditions (channel dimensions, external field intensity, and flow rate), it is, so far, possible to state that, for spherical particles of identical density, the elution order is size-dependent, with the larger ones being eluted first. It is also, so far, possible to assess that, at identical sizes, spherical particles are eluted according to their mass, with the least dense being eluted first. More complex situations arise if, as in the case of cells, the population presents independent size and density distributions.

There is a particular injection mode, described often as "stop flow" or primary relaxation step, in FFF. Suspensions are inserted in the channel under an external field, then the flow is stopped for a given time (stop flow time and primary relaxation time) and flow is reestablished for elution. This particular injection procedure is specific for FFF separations[6,23] and increases selectivity considerably, even in the case of the "Hyperlayer" elution mode. Historically, this was set up because of instrumental considerations, where the inlet tubing emerged at the depletion wall.[6,10,23] Simple instrumentation modification involving, in contrast, the accumulation wall made it possible to avoid such procedure driving the species into a geometric location in the channel thickness close to the accumulation wall.[7,8,11–13,18–20] If, experimentally, such modification was successful using a channel of reduced thickness, complex injection hydrodynamics occurs if the channels are thicker than 100 μm. Considerably reducing the "stop flow time," or even avoiding it, is essential if cell sorting strategies are considered. Very little is known in terms of cell–channel interactions (even with biocompatible materials) and the stop flow procedure may be at the origin of (reversible or not) cell sticking, leading either to cell destruction (which may be selective) or cell differentiation by simple contact (stem cells). From injection to injection, the wall structure at the injection zone may be completely altered (modified), leading to analysis or

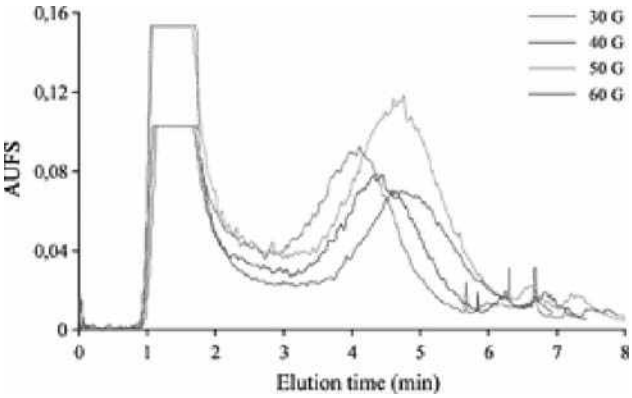

Fig. 1 Cell sorting with FFF.

separation biases. Therefore a price must be paid in terms of separation power to reduce these possible interactions. Limiting separation power by using systematic flow-established injections is essential if cell subpopulation integrity maintenance is required (cell differentiation process); in these conditions, the probability that any cell of the sample will interact with the walls is reduced—a process also limited by the kinetics (whose characteristics are not known) of the Hyperlayer focalization. As collateral consequences of flow injection, separation times are considerably reduced, recovery is enhanced, and channel poisoning is reduced. Fig. 1 shows the fractograms obtained in such conditions in the case of a mixture of ES cells and fibroblasts whose biological properties were analyzed.[7] Low-intensity spikes at the end of every fractogram signifies field stop and a low reversible release of trapped material, which may not necessarily be made of cells only.

Mouse E14 ES cells were routinely grown onto a monolayer of mitomycin-treated primary embryonic mouse fibroblasts as a source of cytokines and growth factors. The medium consisted of DMEM with 15% fetal calf serum (Gibco, Cergy Pontoise, France), 100 U/ml penicillin, 100 μg/ml streptomycin, 1 μM α-mercaptoethanol, and 10^3 U/ml leukemia-inhibitory factor (LIF; Gibco). ES cells were grown at 37°C in a humidified chamber with 10% CO_2. ES cells were recovered with trypsin treatment for SdFFF experiments or subcultures. The SdFFF separation device used in this study includes a separation channel, which consisted of two $870 \times 30 \times 2$ mm polystyrene plates, separated by a Mylar spacer in which the channel ($785 \times 10 \times 0.125$ mm with two V-shaped ends of 70 mm) was carved. Inlet and outlet were 0.254 mm I.D. Peek tubing (Upchurch Scientific, Oak Harbour, Washington, U.S.A.) was directly screwed into the accumulation wall. Then, polystyrene plates and Mylar spacers were sealed onto a centrifuge basket. The channel–rotor axis distance was measured at r (13.8 cm). Cleaning and decontamination procedures have been described in a previous report.[3] The elution signal was recorded at 254 nm.

MULTIPOLYDISPERSITY: PHYSICAL/ FUNCTIONAL AND DETECTION REQUIREMENTS

A First-Order Definition of Multipolydispersity: Example of Mass Distribution

This concept has already been defined for cell sorting.[1] To precisely know the physical characteristics of cell populations, let us imagine a simple bidimensional one where cells are spherical and rigid, and show independent size and density distribution. According to the Steric Hyperlayer mode, with some subpopulations, coelution is possible, generating a need for size or mass detectors. Therefore granulometric or mass measurements appearing at the outlet (online/off-line) are essential in terms of separation developments.

Fig. 2 shows a theoretical bidimentional polydispersity (size and density). The bidimensional Gaussian distribution is shown in Fig. 2a, where (*S*) is the size axis, (*D*) is the density, and *C* represents the number of particles. If such a sample is eluted according to the Hyperlayer elution mode, a broad fractogram is observed, as shown in Fig. 2b. From such a fractogram, every fraction corresponds to particles of different sizes and densities, as qualitatively shown in Fig. 2c. The front of the peak is associated with particles that are very different from the ones at the tail. It is possible to imagine granulometric detection all along the fractogram profile, as shown in Fig. 2d. If the density distribution coinvolved with the size distribution is considered, every fraction is associated with a particular particle size distribution (PSD). It is essential to note that, in the simulation considered here, density distribution is not disperse enough to invert or modify the "size-dependent Hyperlayer elution order," where the biggest and most polydisperse particles elute first. It is now interesting to determine this PSD in the density distributions.

GRANULOMETRIC PATTERNS AND DENSITY DISTRIBUTION

It may be possible to discriminate density vs. size if a single particle mass detector were available for micron-sized species. In the absence of such a detector, only indirect information is affordable, exploring the consequences of the Hyperlayer elution mode. From the above-described bidimentional population (size and density), the Hyperlayer mode allows us to draw iso-density and iso-size retention patterns. Such information coinvolved with the PSD permits the determination of the density distribution envelope of the fractions considered, as shown in Fig. 3. Graph a shows the iso-retention pattern of the population. It is observed that, at

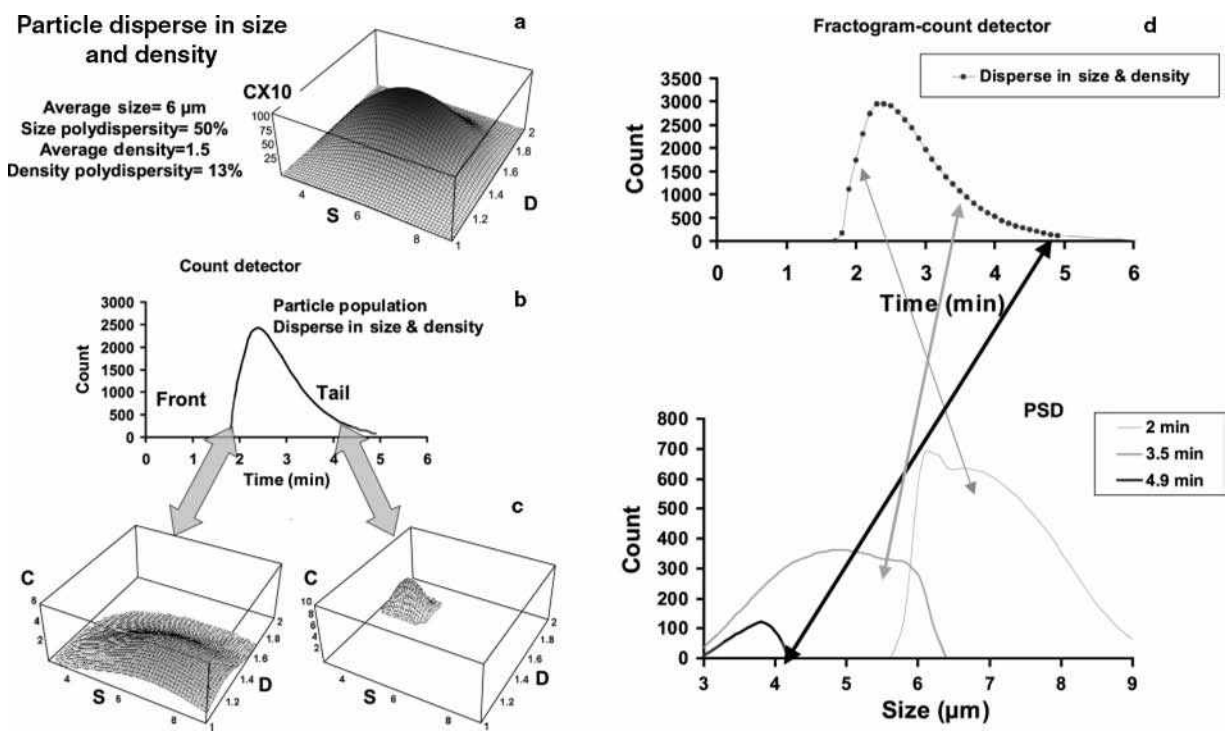

Fig. 2 The multipolydispersity concept: a bidimensional example (size and density distribution). Graph (a) represents the convolution if size and density distribution simulated by a bidimensional Gaussian. Fractogram (b) shows the elution profile obtained in the use of an ideal Steric Hyperlayer elution mode whose channel dimensions, external field, and carrier flow rate are chosen to produce discriminating separations on both size and density. Graph (c) shows bidimensional population pattern composing the fronting and tailing zones of the fractogram. The same fractogram is shown on graph (d), with simulation of fraction collection or granulometric detector time constant with three examples of PSD obtained.

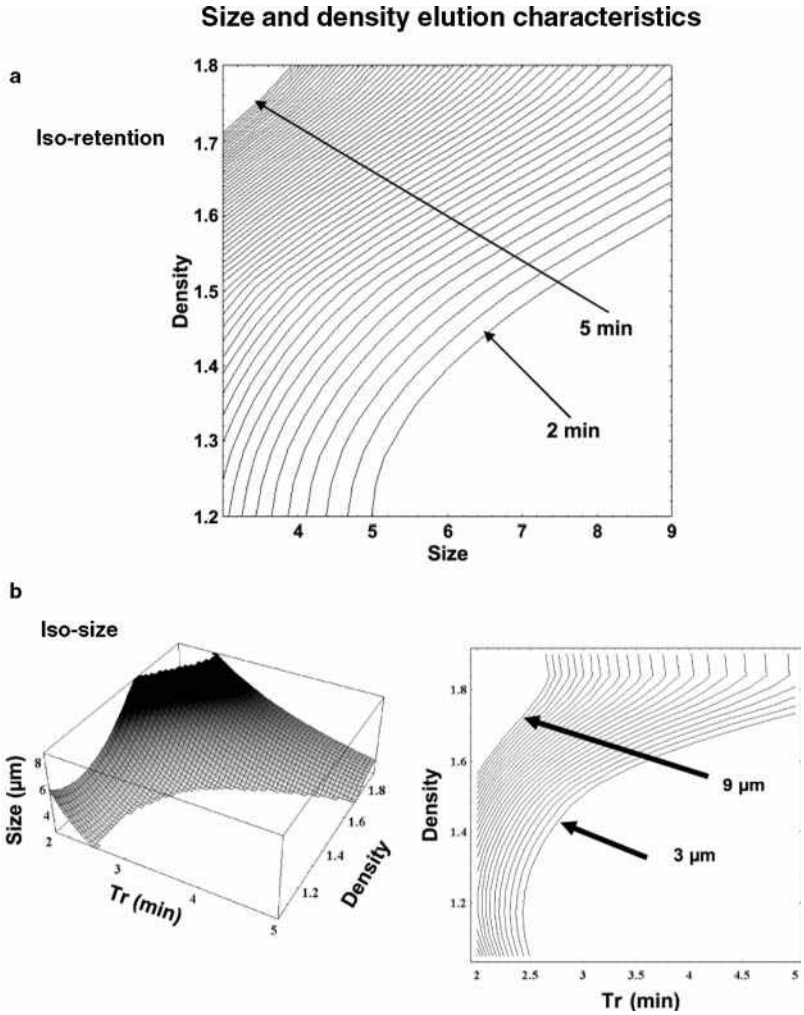

Fig. 3 a, Granulometric pattern and b, density distribution. Particle characteristics are described in Fig. 2.

the peak front, a PSD ranging from 5 to 9 µm is obtained, with light small particles (5 µm, 1.2 density) and heavy big ones (9 µm, 1.6 density). It is tempting to complicate such a chart in three dimensions, as shown in Fig. 3b, to draw an isosize retention chart as a function of density, whose bidimensional projection may be easier to read. Therefore it is observed that 3 µm particles (as well as 9 µm ones) are eluted at very different retention times, depending on their densities. It can be concluded that, in the light of what is known so far from the "Hyperlayer" elution mode, PSD obtained during elution can be linked to other dimensions (density, shape, and rigidity). Therefore it appears that large optimization processes are opened to understand the discriminating effects of channel dimensions, fields, and flow rates on a multipolydisperse population.

HIGHER ORDERS: PHYSICAL AND FUNCTIONAL

If it is relatively easy to adapt offline/online granulometric detectors allowing PSD at every retention time; only very few cell-specific characterization devices are available, with the preferred one being FC.[24] FC's versatility is impressive, allowing particle counting as well as a series of particle characteristics and distribution measurements using light diffusion principles and/or fluorescence.[24] If used in its simplest mode, count histogram vs. diffused light leads to sophisticated information. When a single particle passes in front of a laser beam, the scattered (or emitted fluorescence) light generates a signal proportional to the studied parameter of that particle. If the collected light is at a large angle [90°, side scattering (SS)] from the incident laser beam, the signal is a complex function of the particle refractive index, composition, and surface characteristics.[24,25] If the diffused light is collected at low angles[24–26] [10°, forward scattering (FS)], diffraction predominates and the signal is a function of the particle volume described by the Mie law.[27] Therefore a multidimensional detection allowing population or subpopulation discrimination, whose pattern (fingerprint) can be associated with FFF retention properties, is made possible. Other detection methods can be used with specific functional properties (surface receptors and cell content), as already described by our group.[7,28,29] Every sample or collected fraction (during FFF elution) can be, as a consequence,

described by a battery of information—some being possibly calibrated, and some others looked at only from a qualitative or comparative point of view.

SPECIFIC REQUIREMENTS

Suspension

It is essential to prepare single cell suspensions, which exist naturally in very few cases (cultured cells such as HeLa, Hel, and blood cells). In most critical cases (solid tumors, tissues, and neural cells), a preliminary step is necessary and classically requires transformation of the tissue in suspension. Two methods are used: the first is mechanical,[30] whereas the second requires enzymatic action.[30] It is essential to obtain a monocell suspension, whose characteristics have to be controlled by FC. Once this suspension is obtained, another critical parameter is its concentration; blood cells can be injected in a highly concentrated suspension, whereas neural ones must be inserted into the FFF system highly diluted, requiring large injection volumes. So far, no prediction rules have been established and the technique requires experience-based empirical knowledge.

FFF Device

Channel walls are assumed to be biocompatible, but so is the carrier phase, which can be added with specific surfactants to avoid aggregation during separations: so far, bovine serum albumin (BSA)[11–13] (and, recently, cholic acid) appeared to be more stable and at least as efficient.[31] Such precautions must be associated with systematic recovery measurements—a multidimensional concept associated with the detector pattern, and a comparison of the crude sample with every collected fraction.

Operating Conditions

A flow injection of appropriate cell number sometimes requires adapting the injection volume. In terms of elution, it is essential to observe or follow the safety Hyperlayer requirements that have been already defined. In this order, with the help of the granulometric detector, it is possible to determine the average sizes of cells eluting in the front and the tail of the fractogram, and to calculate, by means of the (S) position, their average position in the channel thickness; by experience, a useful recovery is found if the elution conditions (field and flow) drive to an average position in the channel thickness (s) at, at least, 0.75 times the diameter.

Poisoning/Cleaning

Cell suspensions are often introduced into the SdFFF separator in their cultivation media; these complex solutions encompass proteinaceous hydrophilic compounds as well as hydrophobic ones. It has been also observed that cell recovery may reach 90% in optimized conditions with either a reversible trapping (released at field stopped) or an irreversible one, leading to the release of cellular material that may interact irreversibly with channel walls, thereby leading to surface modifications. Using a biocompatible carrier phase may generate local bacterial growth, either at the channel surface or within the channel; some workers use some toxic cellular killing compounds (e.g., sodium azide).[32] The experimenter must be warned about the toxicity, even at low concentration, of such compounds not only as far as the sample is concerned, but also the experimenter. With experience, it appears that channel poisoning is progressive, with constant recovery reduction, as well as baseline and noise evolution. Therefore there is a need to regularly clean the channel over the life of the separator. This procedure is relatively easy and must be performed in three steps: channel wall regeneration, which destroys sorbed proteins or biological compounds such as membranes or genetic materials; sterilization of the channel by means of an appropriate cocktail involving hypochlorite and ethanol; and rinsing of the separator with sterile mobile phase to completely wash the channel.

The effectiveness of instrument design and setup to reduce cell–accumulation wall interactions was demonstrated, first, by the recovery of cells in the corresponding elution peak (>70%). Second, it was shown by conservation of cell viability, which was, after SdFFF elution, similar to that of the control population. Finally, reduction of interactions was partially demonstrated by a very low cell release peak, which was observed at the end of the fractogram when channel rotation was stopped and the mean gravity was equal to zero (external field applied = 1g; Fig. 4); such procedure is not possible in GFFF. This residual signal corresponded to reversible cell sticking due to weak interactions between cells and the accumulation wall.[7,11–14] Cells or cellular materials can be released from the accumulation wall under the effect of the mobile phase flowing in the absence of channel rotation. However, irreversible cell trapping is due to strong cell–channel interaction and cannot be reversed under these conditions. This phenomenon cannot be observed on the fractogram and leads to channel poisoning, requiring routine channel wall regeneration procedures. For this purpose, cleaning cocktails used in FC or clinical instrumentation appear to be very effective.

These poisonings can be overcome by systematically performed cleaning and decontamination procedures.[19,20,28,29] Some experiments (not published) have shown that the absence of effective and systematic channel cleaning has led to many problems, in particular, an increase in apoptosis of separated cells, even though elution conditions were set up to enhance the "Hyperlayer" mode because the small portion of

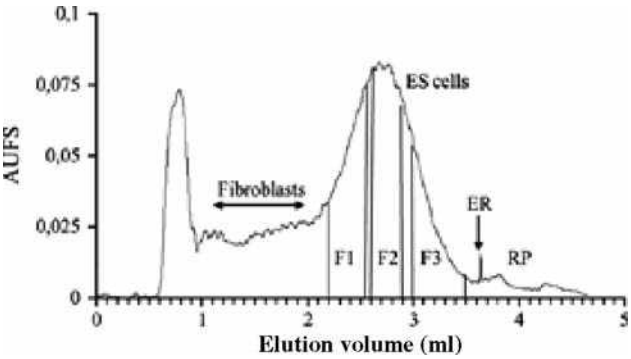

Fig. 4 Optimized SdFFF fractogram of ES Cells. Representative fractogram of ES cell suspensions after SdFFF elution. Elution conditions: Flow injection of 100 μl of ES suspension; flow rate, 0.6 ml/min (sterile PBS, pH 7.4); and external multigravitational field, 40 (0.1 g; spectrophotometric detection at 254 nm). Fractions were collected as follows: PF1, 3 min 40 sec/4 min 15 sec; PF2, 4 min 20 sec/4 min 50 sec; PF3, 5 min 0 sec/5 min 50 sec. ER corresponds to the end of channel rotation. In this case, the mean externally applied field strength was equal to zero gravity; thus RP, a residual signal, corresponds to the release peak of reversible cell accumulation wall sticking.

definitively trapped cell die released apoptotic signals into the separator, which could activate apoptosis in freshly separated cells.

The different steps and instrument setups used for cleaning and decontamination have been extensively described.[19,20,28,29] The cleaning procedure is based on the use of osmotic shock and injection of deproteinizing agent. The use of polystyrene plates and BSA-free mobile phase has simplified the previous steps;[10–13] it is now performed as an end-of-day cleaning–decontamination procedure. First, phosphate-buffered saline (PBS; pH 7.4) was replaced by flushing the entire system with sterile distilled water at a high flow rate. Second, the entire SdFFF device was flushed at 0.8 ml/min for 30 min with a protein cleaning agent (CLENZ; Beckman Coulter, Fullerton, California, U.S.A.). The system was rinsed with sterile distilled water for 1 hr at 0.8 ml/min. Then, the entire SdFFF device was flushed at 0.8 ml/min for 30 min with a 3–4°C sodium hypochlorite solution. The system was rinsed with sterile distilled water for 2 hr at 1 ml/min. The system was then ready to use by replacing the sterile water with sterile PBS. By implementing this cleaning–decontamination procedure, the same channel can be used for analysis of various cell populations without sample cross-contamination and microorganism proliferation.

FROM PHYSICAL/FUNCTIONAL TO BIOLOGICAL, AN EMPIRICAL EXPERIENCE: THE CONCEPT OF "CELLULOMICS"

ES mice embryonic stem cells are an important tool for the generation of transgenic and gene modified mice. We report the effectiveness of an SdFFF cell sorter to provide, from a crude ES cell preparation, a purified ES cell fraction with the highest in vivo developmental potential, to prepare mice chimeras having a high percentage of chimerism.

By taking advantage of biophysical properties (size, density, and shape), SdFFF sorts viable cells without labeling of any kind. SdFFF has a great potential with major biomedical applications, including hematology, neuroscience, cancer research, microorganism analysis, and molecular biology.[8,19,20,30] Embryonic stem cells are used in studies of gene disruption and transgenesis by using their ability to colonize the germline after introduction into blastocysts. Major limitations are the time required to obtain germline transmission, which sometimes required numerous experiments. ES cell suspensions are a mixture of cells at various stages of proliferation; heterogeneity within cells arises during culture with respect to their in vivo developmental potential. We tested the effectiveness of SdFFF to provide, from crude ES cells, an enriched cell fraction with the highest in vivo developmental potential, to prepare chimeras having a high percentage of chimerism,[7] as shown in Fig. 5.

E14 ES cell cultures and the SdFFF device were used as previously described.[7,33] The optimal elution conditions (Hyperlayer mode[34]) were: flow injection 1.5×10^5 cells/0.1 ml, flow rate 0.6 ml/min, mobile phase PBS pH 7.4, external multigravitational field strength 40.0 ± 0.1 g, and spectrophotometric detection $\lambda = 254$ nm. Three cell fractions were collected as shown in Fig. 4: F_1: 3 min 40 sec/4 min 15 sec; F_2: 4 min 20 sec/4 min 50 sec; F_3: 5 min/5 min 50 sec. Fractionated ES cells were stained with propidium iodide and analyzed for DNA cell status using an XL.2 flow cytometer (Beckman Coulter). The percentage of G_0/G_1 cells was higher in F_3 as compared with F_1 and F_2. The percentage of $Ki67^+$ cells (a protein expressed in all phases of the cell cycle, except G_0 and early G_1)[5] confirmed results with propidium iodide. Thus because F_2 and F_3 cells had the highest and lowest in vitro clonogenicity, respectively, 10 cells from these fractions were injected into C57 Bl/6 blastocysts to derive somatic chimeras. The frequency of chimeras obtained was similar (9 of 37 injected blastocysts). In contrast, a higher degree ($p < 0.02$, Mann–Whitney U-test) of color coat chimerism was obtained with F_3 ($87 \pm 5\%$) compared to F_2 ($63 \pm 9\%$). A germline transmission was obtained for all four F_3 males within 3 months as compared with one of four F_2 males after 6 months.

These results clearly show that SdFFF can sort, in a few minutes, the most convenient ES cell population to generate chimeras having the highest ability to colonize the germline. This result is, in particular, based on its newly described capacity to sort cells by their position in the cell cycle. In conclusion, SdFFF is of great interest to improve transgenesis and might also have further interesting applications for human gene therapy.

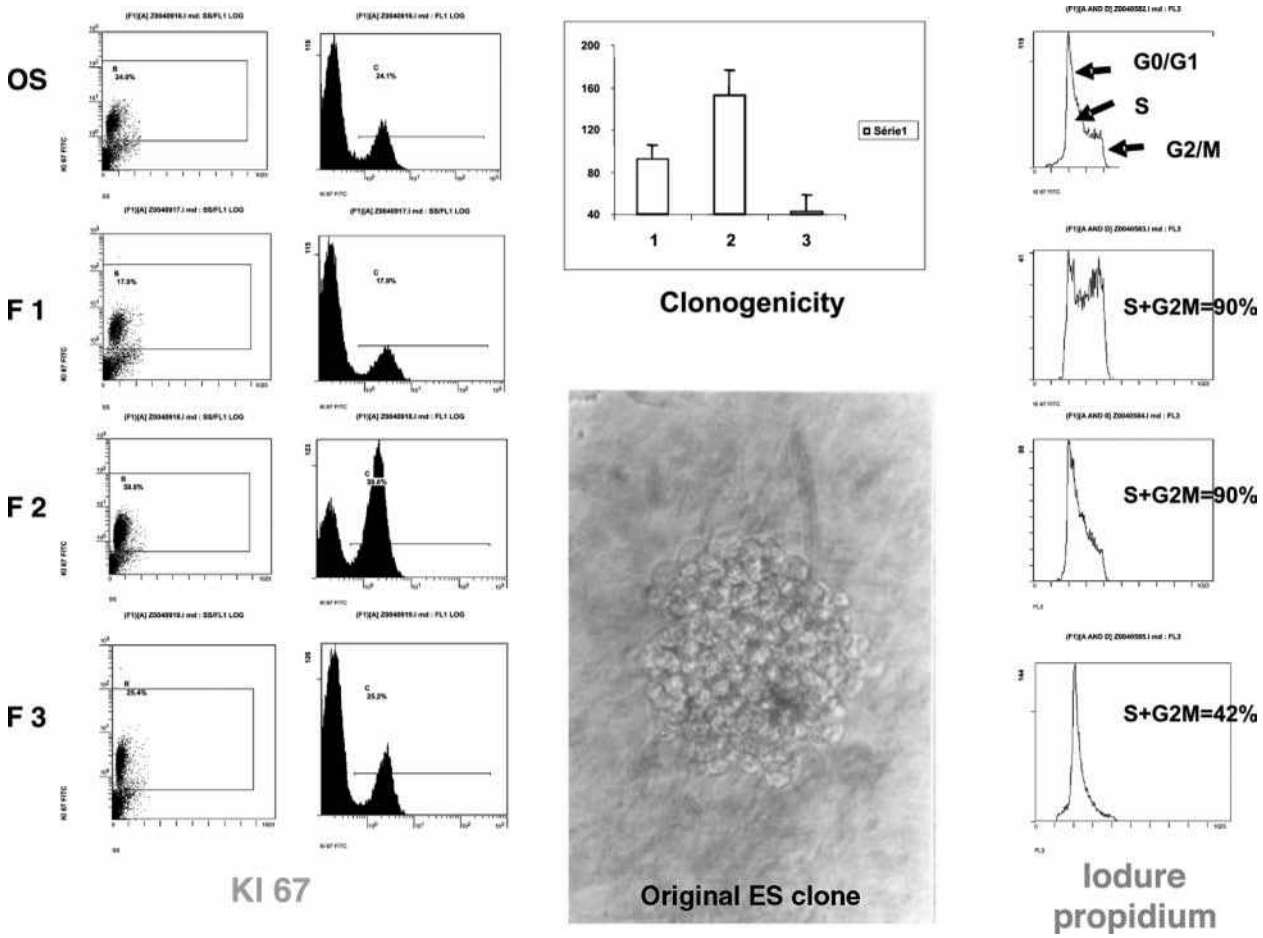

Fig. 5 ES cells, eluted as shown in Fig. 4, are characterized according to functional parameters described in the text: Bidimensional cytometric map of FS and fluorescence (Ki67). Right: Monodimensional propidium iodine fluorescence. Top center: Clonogenicity activities of the three collected fractions of Fig. 4. Bottom center: Microscopic image of ES cell clone.

CONCLUSIONS

The major difficulty in the development of FFF methodologies and instrumentations is linked to the complexity of correlating elution mode hypotheses (Hyperlayer) with experimental proofs, which depends essentially upon physical properties of the cellular material, such as size, density, shape, rigidity, and cellular viscosity, which are of greatest interest if the "physical point of view" is considered. This point of view is historical and is linked to the wide experience of FFF practitioners with latex or silica, micron-sized species, or starch granules, or others. There are some examples dealing with cellular materials (e.g., red blood cells[10] or yeast[35]) where elution is correlated with the above-described physical properties; in these cases, "cellulomics" concepts are relatively simple.

More delicate are the situations where experimentally obtained functional properties, such as specific receptor presence or cell-dependent cycle elution, are the essential ROC and define the goal or the results of the separations. There is, as a consequence, a considerable task in understanding the very different origins of such links, where physics meets or generates biological results of interest, leading to the wide domain of "cellulomics."

The main general consideration that can be stated so far is: 1) the smoothness of the separations; 2) the absence of cell prelabeling; and 3) the development of biocompatible instrumentation, which allows subpopulation lineage to be produced, which are not only usable for fundamental studies such as differentiation pathways or apoptosis studies, but also for transplantation or genetic engineering. One must have in mind that the cell is definitively the place, home, and native localization of genes and proteins. The possibility of rapid, non-destructive separation, purification, and characterization of cells (cellulomics) opens fabulous dimensions for proteomics and genomics.

Cells: Affinity Chromatography

Terry M. Phillips
Ultramicro Analytical Immunochemistry Resource (UAIR), DBEPS, ORS, OD, National Institutes of Health, Bethesda, Maryland, U.S.A.

INTRODUCTION

Affinity cell separation techniques are based on similar principles to those described in procedures for the isolation of molecules and are used to quickly and efficiently isolate specific cell types from heterogeneous cellular suspensions. The procedure (Fig. 1) involves making a single cell suspension and passing it through a column packed with a support to which a selective molecule (ligand) has been immobilized. As the cells pass over the immobilized ligand-coated support (Fig. 1a), the ligand interacts with specific molecules on the cell surface, thus capturing the cell of interest (Fig. 1b). This cell is retained by the ligand-coated support, while non-reactive cells are washed through the column. Finally, the captured cell is released (Fig. 1c) by disrupting the bond between the ligand and its selected molecule, allowing a homogeneous population of cells to be harvested.

METHODOLOGY

Although affinity chromatography of cells is essentially performed in a manner similar to other affinity techniques, it is commonly used for both negative and positive selection. Negative selection removes specific cell types from the sample population, whereas positive selection isolates a single cell type from the sample. In the latter situation, the selected cells are recovered by elution from the immobilized ligand, thus yielding an enriched population. However, unlike molecules, cells are often quite delicate, and care must be exercised when choosing the chromatographic support and the method of retrieval. The support matrix must exhibit minimal non-specific cell adhesion but be sufficiently porous to allow cells to pass through without physically trapping them or creating undue sheer forces likely to cause cell injury or death. Usually the support matrices of choice are loosely packed fibers, large pore cross-linked dextrans or agarose and large plastic or glass beads. Immunologists have long used the relatively non-specific affinity of charged nylon wool to fractionate lymphocytes into different subpopulations. Such separations are achieved because certain subpopulations of lymphocytes express an affinity for the charged fibers while others do not. This negative selection process has been used to prepare pure suspensions of T-lymphocytes for many years, but has recently been replaced by the more selective antibody-mediated or immunoaffinity procedures. The use of immobilized ligands on magnetic beads has gained popularity, especially when employing immobilized lectins or antibodies as the capture ligand.[1,2]

AFFINITY LIGANDS

Plant lectins are some of the most popular ligands for affinity cell separations. These molecules express selective

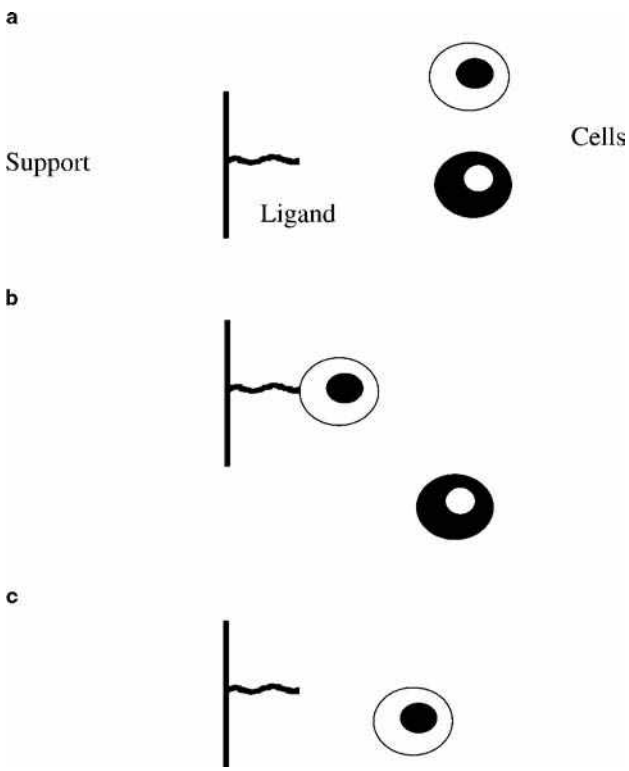

Fig. 1 Affinity isolation of specific cells. (a) A cell suspension containing the cell of interest (clear cytoplasm) and another cell type (dark cytoplasm) are passed over the support bearing a selective ligand immobilized to its surface. (b) The ligand interacts, with the surface molecules on the cell of interest, thus capturing it. The other cell type is not bound and passes through the column. (c) The bound cell is released by the addition of an elution agent to the running buffer of the column. This agent competes or disrupts the interaction between the ligand and the cell thus releasing the cell. The free cell is now washed through the column and harvested.

Table 1 Lectins and their reactive sugar moieties.

Common name	Latin name	Reactive sugar residues
Castor bean RCA_{120}	*Ricinus communis*	β-D-Galactosyl
Fava bean	*Vicia faba*	D-Mannose D-Glucose
Gorse UEA I UEA II	*Ulex europaeus*	α-L-Fucose *N*,*N*′-Diacetylchitobiose
Jacalin	*Artocarpus integrifolia*	α-D-Galactosyl β-(1,3)-*n*-Acetyl galactosamine
Concanavalin A	*Canavalia ensiformis*	α-D-Mannosyl α-D-Glucosyl
Jequirity bean	*Abrus precatorius*	α-D-Galactose
Lentil	*Lens culinaris*	α-D-Mannosyl α-D-Glucosyl
Mistletoe	*Viscum album*	β-D-Galactosyl
Mung bean	*Vigna radiata*	α-D-Galactosyl
Osage orange	*Maclura pomifera*	α-D-Galactosyl *N*-Acetyl-D-galactosaminyl
Pea	*Pisum sativum*	α-D-Glucosyl α-D-Mannosyl
Peanut	*Arachis hypogaea*	β-D-Galactosyl
Pokeweed	*Phytolacca americana*	*N*-Acetyl-β-D-glucosamine oligomers
Snowdrop	*Galanthus nivalis*	Non-reducing terminal end of α-D-mannosyl
Soybean	*Glycine max*	*N*-Acetyl-D-galactosamine
Wheat germ	*Triticum vulgaris*	*N*-Acetyl-β-D-glucosaminyl *N*-Acetyl-β-D-glucosamine oligomers

affinities for certain sugar moieties often present on cell surfaces (Table 1), different lectins being used as selective agents for specific sugars. Whitehurst, Day, and Gengozian[3] found that the lectin *Pisum sativum* agglutinin could bind feline B-lymphocytes much more readily than T-lymphocytes and used lectin-coated supports to obtain pure subpopulations of T-lymphocytes by negative selection. Additionally, the retained cells were recovered by elution from the immobilized lectin with a suitable sugar. Lectins are efficient ligands for cell selection, but in many cases, their interaction with the selected cell surface molecule is highly stable and efficient, requiring mechanical agitation of the packing before recovery of the cells can be achieved. Pereira and Kabat[4] have reported the use of lectins immobilized to Sephadex or Sepharose beads for the isolation of erythrocytes.

Another useful ligand is protein A, which is a protein derived from the wall of certain *Staphylococcus* species of bacteria. This reagent binds selected classes of IgG immunoglobulin via their Fc or tail portion, making it an excellent ligand for binding immunoglobulins attached to cell surfaces, making it an ideal general-purpose reagent. Ghetie, Mota, and Sjoquist[5] demonstrated that protein A-coated Sepharose beads were useful for cell separation following initial incubation of the cells with IgG antibodies directed against specific cell surface markers. Surface IgG-bearing mouse spleen cells were pretreated with rabbit antibodies to mouse IgG prior to passage over the protein A-coated support. The cells of interest were then isolated by positive selection chromatography.

In addition to bacterial proteins, other binding proteins such as chicken egg white avidin have become popular reagents for affinity chromatography. These supports work on the principle that immobilized avidin binds biotin, which can be chemically attached to a variety of ligands including antibodies. Tassi et al.[6] used a column with an avidin-coated polyacrylamide support to bind and retain cells marked with biotinylated antibodies. Human bone marrow samples were incubated with monoclonal mouse antibodies directed against the surface marker CD34, followed by a second incubation with biotinylated goat anti-mouse immunoglobulins. Binding of the biotin to the avidin support effectively isolated the antibody-coated cells.

A wide variety of immobilized antigens, chemicals, and receptor molecules have been used effectively for affinity cell chromatography. Sepharose beads coated

with thyroglobulin have been used to separate thyroid follicular and parafollicular cells, while immobilized insulin on Sepharose beads has been used to isolate adipocytes by affinity chromatography. Dvorak, Gipps, and Kidson[7] reported the successful retrieval of a 95% pure fraction of chick embryonic neuronal cells using an affinity chromatography approach utilizing α-bungarotoxin immobilized to Sepharose beads.

Tlaskalova-Hogenova et al.[8] demonstrated the usefulness of affinity cell chromatography to isolate T- and B-lymphocytes from human tissues. These authors describe comparative studies on three popular approaches to the isolation of lymphocyte subpopulations, namely nylon wool columns, immunoaffinity cell panning (a batch technique using antibodies immobilized to the bottom of culture dishes), and immunoaffinity using anti-human immunoglobulins attached to Sephron (hydroxyethylmethacrylate) or Sepharose supports. These studies clearly indicate that the selectiveness of immobilized antibodies was superior for isolating defined subpopulations of cells.

Immobilized antibody ligands or immunoaffinity chromatography is now the approach of choice for cell separation procedures. Kondorosi, Nagy, and Denes[9] prepared columns packed with a support coated with non-immune rat immunoglobulin and used these columns to isolate cells expressing surface Fc or immunoglobulin receptors, while van Overveld et al.[10] used anti-human IgE-coated Sepharose beads as an immunoaffinity chromatography step when fractionating human mast cells from lung tissue.

ELUTION TECHNIQUES

The elution agent used to recover affinity-selected cells must be carefully chosen. It must be able to either disrupt the binding of the ligand to the cell surface molecule or compete with the cell molecule for ligand binding. In many cases, such as lectin affinity chromatography, the elution agent is easy to select—it is usually a higher concentration of the sugar to which the ligand binds. Elution agents for other techniques such as immunoaffinity are harder to select. Harsh acid or alkaline conditions, although efficient at breaking antibody–antigen binding, are usually detrimental to cell membranes. Elution in these cases is often achieved using mild acids or mild chaotropic ion elution (Table 2).

Table 2 Elution buffers suitable for cell affinity chromatography.

Acids
0.33 *M* Citric acid
0.15 *M* Formic acid
Chaotropic ions
1–3.0 *M* Sodium and potassium thiocyanate
0.9 *M* Sodium chloride
0.5–1.5 *M* Iodine
Competition agents
Various sugars as competition agents for lectin binding (see Table 1)
Antigens for competition binding in immunoaffinity matrices

Centrifugal Precipitation Chromatography

Yoichiro Ito
National Heart, Lung, and Blood Institute (NHLBI), National Institutes of Health (NIH), Bethesda, Maryland, U.S.A.

Abstract
Centrifugal precipitation chromatogram performs purification of proteins and other macromolecules according to their solubility in suitable precipitants such as ammonium sulfate (AS) and ethanol. It has been successfully applied to separation of a variety of macromolecules including human serum albumin (HSA), γ-globulin, recombinant ketosteroid isomerase (rKSI), carotenoid cleavage enzymes, RNA, plasmid DNA, and polysaccharides. The method can single out a target compound by ligand-affinity or immunoaffinity separation. It has been demonstrated that the sample size can be increased up to 100 mg using a separation column consisting of convoluted tubing with a dialysis tubing insert.

INTRODUCTION

For many years, proteins have been fractionated with ammonium sulfate (AS) by stepwise precipitation. In this conventional procedure, an increasing amount of AS is added to the protein solution and the precipitates are removed by centrifugation in each step. Recently, "centrifugal precipitation chromatography"[1–3] has been developed to replace the tedious manual procedure. This novel chromatographic system is capable of internally generating a concentration gradient of AS through a long separation channel under a centrifugal force field. Proteins introduced into the channel are exposed to a gradually increasing AS concentration and finally precipitated at different locations according to their solubility in the AS solution. Then, the AS concentration in the upper channel is gradually reduced so that the AS concentration gradient in the lower channel is proportionally decreased. This manipulation causes the precipitated proteins to be redissolved and eluted out by repeating precipitation and dissolution along the channel. As in liquid chromatography (LC), the effluent is continuously monitored with a UV monitor and fractionated in test tubes using a fraction collector.

PRINCIPLE AND DESIGN OF THE APPARATUS

The principle and unique design of the separation column is shown in Fig. 1 and Figs. 2 and 3, respectively. In Fig. 1, a pair of separation channels is partitioned by a dialysis membrane. A concentrated (C) AS solution is introduced through the upper channel at a high flow rate (V) from the right, whereas water is fed into the lower channel from the left at a much lower rate (v). This countercurrent flow of the two liquids through the channels results in AS transfer from the upper channel to the lower channel at every point, as shown by arrows across the membrane. Because the AS transfer rate through the membrane is proportional to the difference in AS concentration between the two channels, an exponential gradient of AS concentration (c) is formed through the lower channel. The system allows manipulation of the AS concentration in this gradient by modifying the AS concentration in the upper channel as described earlier. The separation column is fabricated from a pair of plastic disks (high-density polyethylene, 13.5 cm in diameter and 1.5 cm thick) equipped with mutually mirror-imaged spiral grooves (1.5 mm wide, 2 mm deep, and ~200 cm long), as shown in Fig. 2a. On both sides of the spiral groove in the lower disk (right), a pair of circular grooves is made to set O-rings to provide a perfect seal. A regenerated cellulose membrane with desirable pore size (MWCO 6000–8000 or 12,000–14,000) is cut in a doughnut shape as shown in Fig. 2a bottom and placed over the spiral groove between the two O-rings. Then the two disks are put together and tightly pressed between two metal plates with a number of screws (Fig. 2b). The capacity of each channel is about 5 ml. This column assembly is mounted on a seal-less continuous flow centrifuge, which allows continuous elution through the rotating column without the use of a conventional rotary seal device. Fig. 2c schematically illustrates the entire elution system of the present chromatographic system. Two sets of pumps are used, one (upper right) for pumping AS solution at a high rate, and the other (upper left) for eluting buffer solution and protein samples at a lower rate. The total of four flow tubes leading from these two pumps are bundled together and clamped at the top of the seal-less continuous flow centrifuge to reach the column assembly as illustrated. As mentioned above, these flow lines are twist free as the column rotates around the central axis of the centrifuge. Consequently, the system eliminates various complications such as leakage, clogging, and cross-contamination, which often arise from the use of the conventional rotary seal device for multiple flow lines. Fig. 3 shows a cross-sectional view through the central axis of the centrifuge.

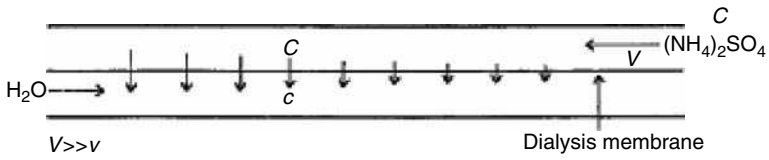

Fig. 1 Principle of the present method.

BASIC STUDIES

A series of experiments was conducted to study the AS transfer rate through the dialysis membrane by pumping a concentrated AS solution into the upper channel at 1 ml/min and water into the lower channel at varied flow rates ranging from 1 to 0.1 ml/min without sample injection. In these experiments, the AS input concentration into the upper channel and the AS output concentration from the lower channel were compared. The rate of AS transfer rose, as expected, with decrease of flow rate through the water channel, and at a flow rate of 0.1 ml/min the AS concentration collected through the lower channel reached nearly 100% that of the AS input in the upper channel. While AS diffuses from the upper channel toward the lower channel, water in the lower channel is absorbed into the upper channel. This water transfer rate is estimated by comparing input and output flow rates through the water channel. At an input rate of 0.1 ml/min, the outlet flow was decreased to one-fourth of the input rate, indicating that the separated fractions would be eluted in a highly concentrated state. Generating an AS concentration gradient and concentrating fractions are the two unique capabilities of the

present system, which can be effectively utilized for the fractionation of proteins.

APPLICATIONS

Separation of Serum Proteins

Fig. 4 illustrates serum protein separation by centrifugal precipitation chromatography: the chromatographic tracing of the elution curve in Fig. 4A and sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) analysis of separated fractions in Fig. 4B. In this example, 100 μl of normal human serum (pooled) was diluted to 1 ml and introduced into the separation channel. The experiment was initiated by filling both upper and lower channels with 75% AS solution followed by sample charge into the lower channel through the sample loop. After the separation column assembly was rotated at 2000 rpm, the upper channel was eluted with 75% AS solution at a flow rate of 1 ml/min,

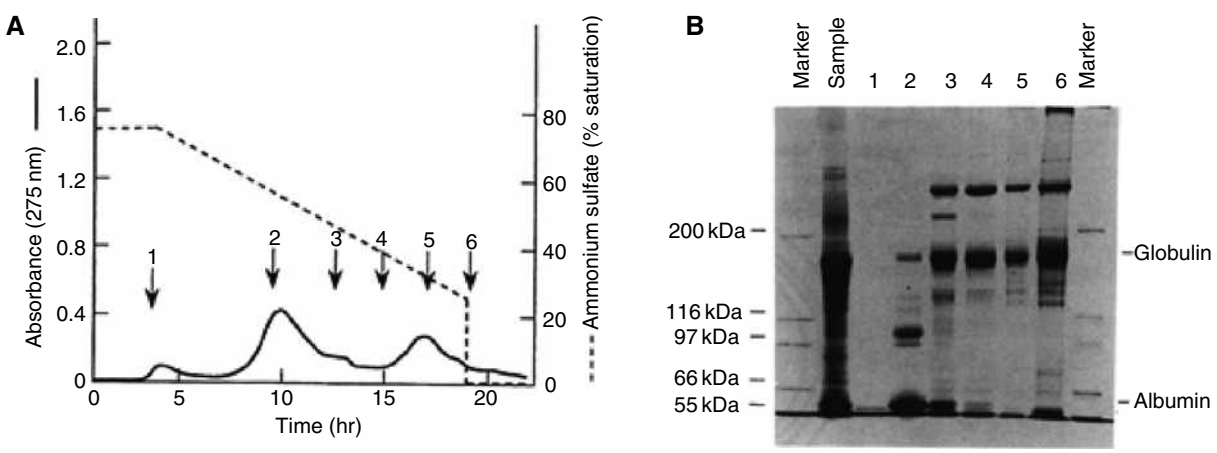

Fig. 4 Separation of human serum proteins by centrifugal precipitation chromatography. A, Elution curve; B, SDS–PAGE analysis of separated fractions.

while the lower channel was eluted with 50 m*M* potassium phosphate at 0.06 ml/min. After 4 hr of elution, the AS concentration in the upper channel was linearly decreased down to 25%, as indicated in the chromatogram. The effluent from the lower channel was continuously monitored with a UV monitor (LKB Uvicord S) at 275 nm and fractionated into test tubes using a fraction collector (LKB Ultrorac), while the AS solution eluted from the upper channel was discarded. The chromatogram (Fig. 4A) produced two major peaks, one at AS saturation at 60–50% and the other at 35–30%. The SDS–PAGE analysis of peak fractions (Fig. 4B) revealed that the first peak represents albumin (MW 68,000) and the second peak, γ-globulin (MW 160,000).

Separation of Antimast Cell Antibody

The present method was applied to purification of monoclonal antibody against human mast cells from the supernatant of culture media (hybridoma). The sample solution was prepared from 45 ml of hybridoma culture supernatant by adding AS at 60% saturation followed by centrifugation to precipitate the target protein, and the concentrated suspension (2 ml) was injected into the separation column. Fig. 5 illustrates the precipitation chromatogram, which shows three peaks, the first peak corresponding to calf serum albumin initially added to the culture medium, the second peak to IgM, and the third peak to γ-globulin. Using the fluorescent labeling technique with secondary antibodies, strong activity was found in the IgM fraction that produced a high activity of over 10 times that in the original supernatant, as indicated in the diagram. Monoclonal antibodies (IgG) present in ascitic fluids were similarly separated by the present method.

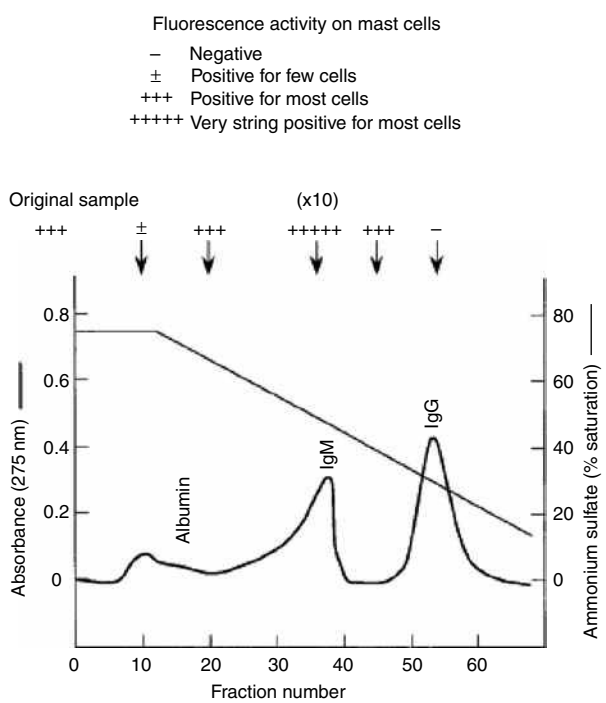

Fig. 5 Purification of monoclonal antibody from cell culture supernatant by centrifugal precipitation chromatography.

Separation of Recombinant Ketosteroid Isomerase Using Affinity Ligand

Crude *Escherichia coli* lysate containing a recombinant ketosteroid isomerase (rKSI) was fractionated with and without an affinity ligand estradiol-PEG5000. Fig. 6a and b show the results without the ligand. The chromatogram shows the first peak mostly consisting of a mixture of low-molecular-weight compounds and the second peak consisting of a mixture of proteins including the target rKSI, as shown in SDS–PAGE analysis of fractions in Fig. 6b. Fig. 6c and d show the results obtained by adding the affinity ligand to the sample solution under otherwise identical conditions. The addition of the ligand in the sample solution produced a remarkable change in the chromatogram. The second peak become smaller and a new small peak appeared later, which was followed by a large peak of the affinity ligand. The SDS–PAGE analysis revealed that the third small peak (fraction 7) mainly consisted of rKSI forming dimers and tetramers due to its high concentration, while no protein band was detected in the fourth peak (fraction 8). Although the rKSI fractions thus obtained also contain high-molecular-weight compounds, they can be eliminated by pretreating the sample solution by adding AS at 40% followed by centrifugation. The supernatant is then used as the sample solution after adding the ligand. The present method also works well to detect a minute amount of KSI present in *E. coli* mutant strain.

Immunoaffinity Separation of Human Serum albumin

This method uses an antibody to purify an antigen by precipitating the complex followed by dissociating the antigen with a releasing reagent.[4] The antibody is added to the sample solution to form an antigen-antibody complex that is precipitated at a low AS concentration of 35% saturation in the column. After most of the other proteins are eluted out from the column, a releasing agent is added to the AS channel to dissociate the antigen from the complexes which is then harvested from the column. The antibody still remaining in the column is recovered by elution with water through AS channel. Fig. 7 illustrates an example of the present method using a rabbit polyclonal antibody to purify human serum albumin (HSA).

In addition to the above examples, the present system has been successfully applied to the fractionation of various samples, including minor protein components (less than 1% of total proteins) from a crude rabbit reticulocyte lysate containing a large amount of

Sample: human blood plasma 20 μl mixed with 2 mg of rabbit anti-HSA polyclonal antibody (Sigma). The releasing solution: 0.5 *M* glycine in 50% saturated AS at pH 10 and after HSA was harvested, the antibody was recovered by pumping water at 1 ml/min through AS channel. Water channel flow rate: 0.03 ml/min throughout; rotation: 2000 rpm: Gel: precasted tris-glycine gel (invitrogen). M: marker; Ab: antibody; Ag: antigen; Pl: plasma.

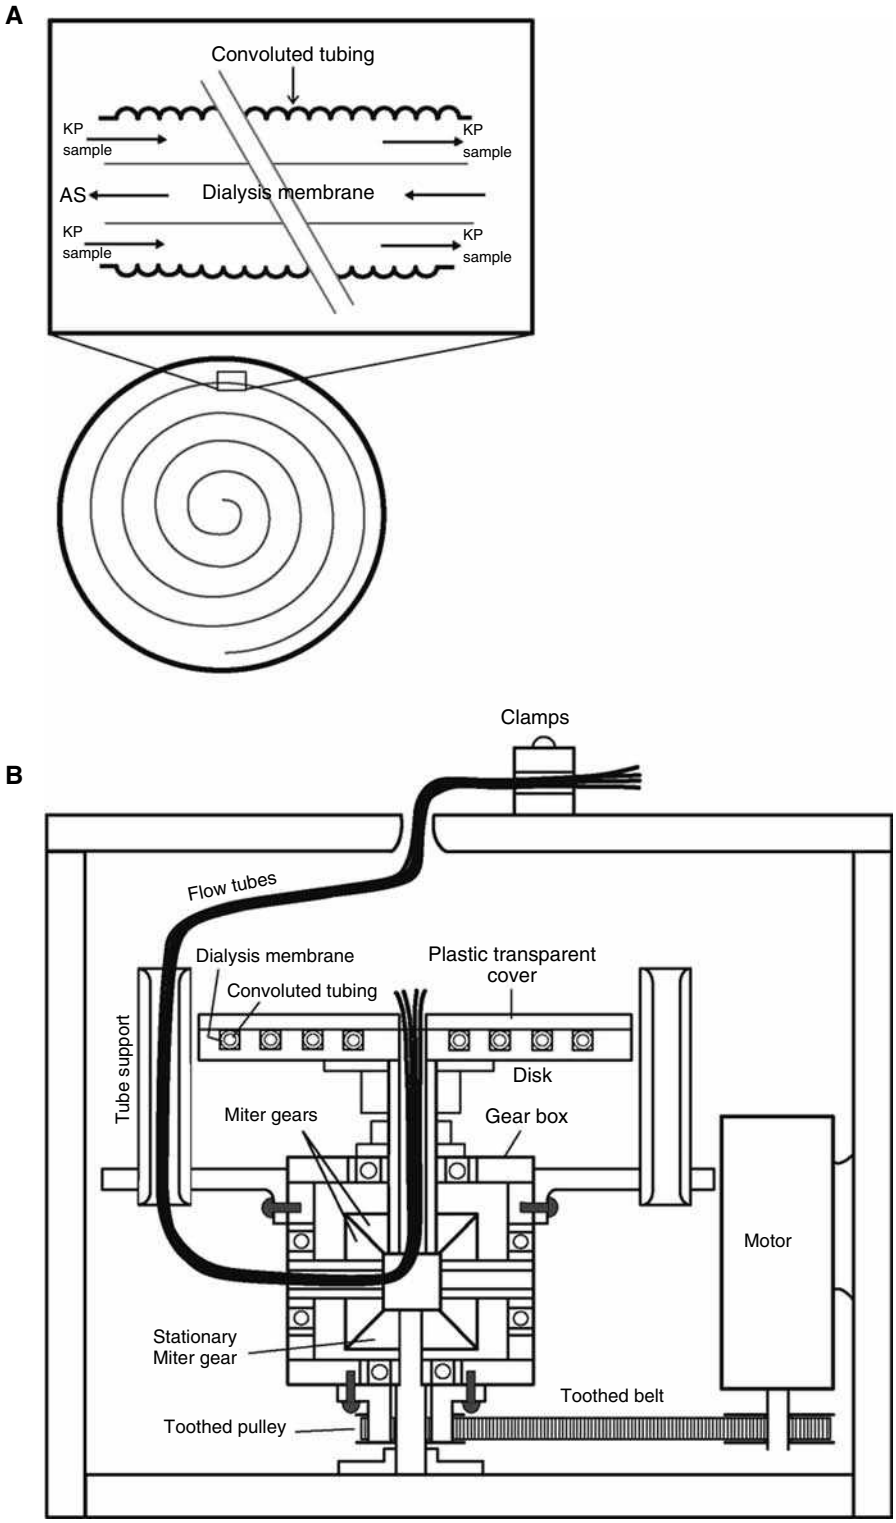

Fig. 8 Preparative centrifugal precipitation chromatograph. A, Column design: a dialysis tubing (3 mm I.D.) is inserted into convoluted tubing (5.7 mm I.D. and 2.2 m length). B, Cross-sectional view through the apparatus. The convoluted tubing is accommodated in a spiral groove of the centrifuge head.

Centrifugal precipitation chromatography can produce highly purified protein fractions because the proteins are refined by repetitive precipitation and dissolution. The method has the following advantages over the conventional manual procedure: The method is programmed and automated; the fractions are almost free of small molecules, which are dialyzed through the membrane or otherwise quickly eluted out from the channel; non-charged macromolecules such as polysaccharides are washed out while charged biopolymers

such as DNA and RNA may also be separated according to their solubility in AS solution; the method may be amenable for micro-scale to large-scale fractionation by designing the separation column in suitable dimensions.

PREPARATIVE SCHEME

Recently, the sample loading capacity of the method was improved by a new column design, which uses dialysis membrane inserted into convoluted Teflon tubing (Fig. 8A).[10] The column is snugly accommodated in a spiral groove of the rotary plate of the centrifuge (Fig. 8B). The AS solution is introduced through the dialysis tubing (membrane channel), while the phosphate buffer is eluted through the outside of the dialysis membrane (tubing channel) in the opposite direction. In this way, precipitated protein molecules can be retained more stably on the inner wall of the convolution tubing. A sample mixture containing 50 mg each of HSA and γ-globulin was separated by either stepwise or linear gradient elution of AS solution through the membrane channel.

Channeling and Column Voids

Eileen Kennedy
Novartis Crop Protection, Inc., Greensboro, North Carolina, U.S.A.

INTRODUCTION

Channeling can occur when voids that are created in the packing material of a column cause the mobile phase and accompanying solutes to move more rapidly than the average flow velocity. The most common result of channeling is band broadening and, occasionally, elution of peak doublets.

DISCUSSION

Column voids can develop in a poorly packed column from settling of the packing material or by erosion of the packed bed. In a properly packed column, voids can develop gradually over time or suddenly as the result of pressure surges. A void that forms in the inlet of a column may lead to poor peak shape, including severe band tailing, band fronting, or even peak doubling for every peak in the chromatogram. Filling the column inlet with the same or equivalent column packing can sometimes reduce voids. For this type of repair, the column should be held in a vertical position while the inlet frit is removed. The void will be evident as either settling of the packing material or as holes in the column surface. The new packing should be slurried with an appropriate mobile phase and packed into the column void with a flat spatula. Once the top of the new packing is level with the column end, a new inlet frit can be added and the end fitting reinstalled. The column should then be reconnected to the liquid chromatography (LC) system and conditioned with the mobile phase at a fairly high flow rate to help settle the new column bed. After filling the void, the packing bed will generally be more stable if the repaired column is operated with the direction of flow reversed from the original direction. This repair procedure can be used to extend column life; however, it should be noted that the plate number of the repaired column would be, at best, only 80–90% of the original column. Columns that develop voids over time are often near the end of their useful life spans and in some cases it may be more cost efficient to discard such a column rather than to repair it.

Chemical Warfare Agent Degradation Products: HPLC/MS Analysis

Clayton B'Hymer
Kenneth L. Cheever
National Institute for Occupational Safety and Health, Centers for Disease Control and Prevention, U.S. Department of Health and Human Services, Cincinnati, Ohio, U.S.A.

Abstract
High-performance liquid chromatography–mass spectrometry (HPLC–MS) has become a commonly used analytical technique for the analysis of chemical warfare agent (CWA) degradation products. This area of research has gained greater importance in recent years. Most CWAs are not persistent and degrade in the open environment. The degradation products are usually polar or ionic; thus, HPLC is considered an ideal separation technique. MS detection offers a sensitive and specific means for quantitative analysis for these compounds. Some of the common designs and strategies of HPLC–MS are discussed as well as the common analytical challenges. Also, specific examples of HPLC–MS applications involving screening procedures are reviewed and described. These procedures utilized both reversed-phase and ion-pair reversed-phase HPLC to separate several alkyl methylphosphonic acids, which are the degradation products of nerve agents.

INTRODUCTION

Many chemical warfare agents (CWAs) are not persistent, that is, they readily degrade or hydrolyze in the general environment with the only exceptions being some of the mustard agents. This has led to a need to analytically detect and quantitate the levels of CWA degradation products in soil, surface waters, or contaminated surfaces. Many CWAs, as well as some of their degradation products, have low polarity or are volatile; thus, much of the past analysis methodology was based on gas chromatography (GC). However, the majority of CWA degradation products are polar and non-volatile. High-performance liquid chromatography (HPLC) allows for the analysis of a broader range of compounds from low polarity to ionic. Also, HPLC techniques require only the solubility of the target analyte, whereas GC requires volatility and thermal stability of the analyte or chemical derivative of an analyte. The main limitation with HPLC analysis has been in applicable detection systems. The majority of important CWA degradation products are without chromophores or fluorophores, which makes their detection by ultraviolet absorbance or fluorescence impossible. Although many other types of HPLC detectors have been used for CWA degradation products, mass spectrometry (MS) has offered the greatest potential owing to its inherent advantages of high sensitivity and analyte specificity. Specificity, or the lack of interferences, is very important because of the general complexity of sample matrices encountered from environmental samples. HPLC–MS analysis of CWA degradation products has experienced significant growth in recent years and has seen numerous applications reported in the literature. This entry will report and summarize the current literature and discuss a few applications of HPLC–MS analysis of CWA degradation products.

BACKGROUND AND DEGRADATION PRODUCTS

Increases in terrorist activity around the world during the twenty-first century, as well as increases in the development and use of CWAs by third world nations, have led to a high demand for improved methods for the analysis of the active agents and their degradation products. The sophistication of weapons used by terrorists as well as the frequency of terrorist attacks has dramatically risen in recent years. The 1995 release of the nerve agent sarin in the Tokyo subway resulted in the death of 12 people; approximately 5000 were injured or exposed.[1,2] The 2001 use of anthrax in the U.S. Postal system resulted in six deaths from respiratory anthrax infections. Also, the need for better methodology was spurred by the convention of the prohibition of the development, production, stockpiling, and use of chemical weapons and on their destruction.[3] This convention came into force in 1997 and analytical methods were needed in verification of its fulfillment. Most nations in the world, with the exceptions of some Mideastern countries and North Korea, have agreed to the convention which eliminates the use and stockpiling of CWAs.

Most CWAs are not persistent in the environment; they generally undergo a variety of abiotic and biotic

degradation mechanisms. Munro et al.[4] have described the degradation pathways and reviewed the general toxicity of the major CWA degradation products. Most CWAs have the characteristic of being highly reactive to nucleophiles, particularly with water present in the environment. The analysis of biological or environmental residues for hydrolysis degradation products is, therefore, an important part of CWA analysis. Handheld or field-deployable detectors are useful in many settings for CWA or degradation product analysis, but most portable instruments lack both sensitivity and specificity of laboratory-based instrumental techniques.[5] The most frequently used technique for the analysis of CWAs or their degradation products is GC–MS.[6] However, GC–MS is not suitable for the direct analysis of the polar and non-volatile CWA hydrolysis products. Many of these compounds require sample derivatization before introducing them into a GC, and they frequently require a significant sample preparation scheme.[6] These reasons, as well as those mentioned in the introduction, make HPLC–MS the preferred methodology for the analysis of CWA degradation products.

The main exception to low persistence of CWAs is sulfur mustard, which maintains a high degree of stability. Most of this discussion will refer to the chemical agent bis(2-chloroethyl) sulfide (HD) (Table 1), which is the pure form. Older munitions and the older manufacturing process of mustard gas contain up to 40% bis[2-(2-chloroethylthio)ethyl] ether (HT) and a variety of contaminants and impurities. Although volatilization in an open environment is significant for HD, the primary fate mechanism of stored or buried sulfur mustard is hydrolysis.[4] HD is more stable in seawater than in freshwater owing to the high concentration of chloride in seawater.[7] The final hydrolysis product is thiodiglycol (TDG), which may occur by either of the two degradation routes depending on the availability of water. Fortunately, TDG has relatively low toxicity, and it has been easily analyzed by HPLC–MS.[8]

The nitrogen mustards belong to the same vesicant or blister agents like sulfur mustard. Nitrogen mustards were developed in the 1930s[9] and were never stockpiled on a large scale in the U.S. chemical warfare inventory. The three nitrogen mustards are bis(2-chloroethyl)ethylamine (HN1), bis(2-chloroethyl)methylamine (HN2), and tris (2-chloroethyl)amine (HN3) (Table 1). On the basis of susceptibility to hydrolysis and volatility, HN3 is environmentally persistent, whereas HN1 and HN2 are considered moderately persistent. The primary degradation fate process in either water or soil is hydrolysis; weakly alkaline conditions enhance the hydrolysis of the nitrogen mustards. The major degradation products of HN1 are diethanolamine (DEA) and *N*-ethyldiethanolamine (EDEA). Correspondingly, the major degradation product of HN2 is methyldiethanolamine (MDEA) and triethanolamine (TEA) for HN3. These compounds have been analyzed by HPLC–MS;[10] however, they represent more of an analytical challenge. DEA and TEA are frequently used in common consumer and industrial products including soaps, detergents, cosmetics, and textiles. DEA is also used as liquid detergent for emulsion paints, a dispersing

Table 1 Structures of the mustard agents and their major degradation products.

CW compound	Abbreviation	CW structure	Major degradation product(s)	Degradation product abbreviation	Degradation product structure
Sulfur mustard					
bis(2-Chloroethyl) sulfide	HD		Thiodiglycol	TDG	Nitrogen mustards					
bis(2-Chloroethyl) ethylamine	HN1		Ethyldiethanolamine	EDEA				Diethanolamine	DEA	bis(2-Chloroethyl) methyl amine	HN2		Methyldiethanolamine	MDEA	tris (2-Chloroethyl) amine	HN3		Triethanolamine	TEA	
agent, and is often found as a component in metal-cutting fluids. EDEA is also used in detergents and MDEA is used as a catalyst for polyurethane foams and as a pH control agent in various formulations. These rather innocuous uses of ethanolamines can lead to false positives for nitrogen mustard agent degradation products from environmentally collected samples.

The nerve agents represent the most toxic and probably the most feared CWAs. Chemically, the nerve agents are alkyl phosphonic acid esters which elicit toxicity by the specific irreversible inhibition of the enzyme cholinesterase resulting in the accumulation of acetylcholine. The accumulation of acetylcholine results in continuous stimulation of the nervous system and eventual failure of the vital autonomic body functions after a lethal exposure level to the nerve agent. The nerve agents are subdivided into two classes, the V agents and the G agents (Table 2). *O*-ethyl-*S*-[2-(diethylamino)ethyl] methylphosphonothioate (VX) is among the most lethal substances ever produced by man and is a persistent nerve agent on surfaces as well as possessing the slowest hydrolysis rate. *O*-isobutyl-*S*-[2-(diethylamino)] methylphosphonothioate (Russian VX or RVX) is chemically very similar. The G agents include ethyl phosphorodimethylamidocyanidate (tabun, GA); isopropyl methylphosphonofluoridate (sarin, GB); pinacolyl methylphosphonofluoridate (soman, GD); and cyclohexyl methylphosphonofluoridate (cyclosarin, GF). The G agents are volatile and present a vapor hazard, but in turn, dissipate more quickly in the open environment. The G agents are also more susceptible to hydrolysis than the V agents. All the nerve agents can act by dermal, oral, or inhalation routes of exposure. The anticholinesterase mechanism of action of these organophosphonic acids is due to the oxo group (=O) and is influenced by the presence of alkyl substituents in the molecular structure. Thus, many of the initial degradation products of these compounds may retain some anticholinesterase activity and toxicity, but hydrolysis of one or more alkyl ester bonds results in the generally non-toxic alkyl methylphosphonic acids. The final degradation product of GB, GD, and GF is methylphosphonic acid (MPA), although isopropyl methylphosphonic acid (iPrMPA) is an intermediate degradation product of GB; pinacolyl methylphosphonic acid (PinMPA) is an intermediate degradation product of GD; and cyclohexyl methylphosphonic acid (CHMPA) is the corresponding intermediate product of GF. MPA is, however, fairly stable in the environment. GA hydrolyzes to ethylphosphoryl cyanidate and dimethylamine under acidic conditions; GA hydrolyzes ultimately to phosphoric acid, cyanide, and dimethylamine at neutral or basic pH conditions with *O*-ethyl *N,N*-dimethylamidophosphoric acid (EDMAPA) as an intermediate. VX also has two hydrolysis pathways. At pH values of less than 6 and greater than 10, the main signature degradation product is ethyl methylphosphonic acid (EMPA). EMPA can continue to degrade to MPA. At a pH range between 7 and 10, VX will degrade to *S*-(2-diisopropylaminoethyl) methyl phosphonothioate (EA 2192). EA 2192 is highly soluble in water and is not readily found in soil, but remains toxic and is relatively stable in water. RVX initially degrades to isobutyl methylphosphonic acid (iBuMPA) and finally to MPA. MPA is, therefore, a common degradation product for GB, GD, VX, and RVX, and it is a common target analyte for most HPLC–MS methods.

Other CWAs and their degradation products have been actively analyzed, reported, and reviewed in the literature,[1,2,4] but will not be described in further detail. Additional vesicants include the chlorovinylarsines (Lewisites) which are complex mixtures of several related compounds. The third class of CWAs, the blood agents, interferes with the oxygen transport capability of blood and thus causes death by suffocation. The primary blood agent used during World War I was hydrogen cyanide. Finally, a fourth class of CWAs, incapacitating agents, has generally non-lethal physiological effects such as vomiting or mental disorientation. The compound 3-quinuclidinyl benzilate (BZ) is an example of a modern incapacitant which causes mental disorientation. This discussion will remain focused on the analysis of degradation products of the nerve and mustard agents.

HPLC–MS

General Advantages

The general advantages of HPLC for use as a separation technique for chemical warfare degradation products have been mentioned. Since the degradation products are generally water-soluble and polar, HPLC can be used directly unlike GC which would require a more complicated derivatization procedure to make the analytes volatile for chromatographic analysis. Generally, reversed-phase HPLC has been used for CW degradation product analysis although some ion-pair reversed-phase HPLC procedures have been applied. Some of these applications will be discussed in detail later. MS has much strength for use with HPLC; MS possesses high sensitivity and adds a higher degree of specificity, the ability of a technique to accurately measure the analyte in the presence of all potential sample matrix components without interference. Since the CW degradation products would be tested in environmental samples, test method specificity is a very important analytical trait. Also, as in the case of the MPAs, the lack of UV absorbance and fluorescence makes direct MS detection the preferred technique. Earlier HPLC methods using derivatization with *b*-bromophenacyl bromide to provide a UV chromophore have been reported,[11] but the use of MS detection eliminates a derivatization step to the analysis procedure. Another added benefit in avoiding chemical derivatization is that preliminary interpretation of

fragmentation, in the case of unknowns, is much simpler with the underivatized analytes.

The Mass Spectrometer and Its Various Designs

The various designs of the mass spectrometers have been described in detail in the literature,[12–14] and its basic function is to measure the mass-to-charge ratios (*m*/*z* ratio) of analyte ions. The HPLC–MS system has four main components, consisting of a sample introduction system or inlet, an ion source, a mass analyzer, and an ion detector. The sample introduction system vaporizes the HPLC column effluent. This can be simple as a nebulizer, which have been described in the literature.[14] The other three components of the mass spectrometer will be described in further detail.

The ion source creates analyte ions from the neutral species in the vapor phase. Several designs of ion sources have been used for CWA degradation product analysis in recent years including thermospray ionization (TSP),[15] atmospheric pressure chemical ionization (APCI),[16,17] and electrospray ionization (ESI).[18] These "soft" ionization techniques generally produce $[M–H]^-$ or $[M+H]^+$ fragments for the alkyl phosphonic acids and some other CWA degradation products. The inductively coupled plasma (ICP) is a "hard" ionization source and has been described in the literature.[19] HPLC–ICP–MS has been reported for the detection of alkyl phosphonic acids.[20] In recent years, ESI has become the most common ion source in HPLC–MS analysis in general with the APCI source a close second. The thermospray source has fallen out of favor in HPLC–MS systems since the introduction of ESI.

ESI is commonly used as an ion source for HPLC–MS. The ESI technique was invented by Nobel Prize winner John Fenn in 1992. ESI has rapidly displaced the older TSP and continuous flow fast atom bombardment (FAB) sources for most commercial HPLC–MS systems. In ESI, the HPLC effluent is passed through a small capillary jet or nebulizer held at a high electrical potential (2000–5000 V) along with a nitrogen flow. This results in electrostatic nebulization of the liquid. During desolvation of the aerosol droplets, the electric field increases strength at the diminishing droplet surface under vacuum; this process leads to the ejection of charged analyte ions upon final evaporation. The ESI source is a "soft" ionization technique and does not cause as significant thermal degradation when compared to the other ion sources. ESI also has a high level of ionization efficiency which leads to high MS sensitivity for the analyte ion, which is an advantage for the detection of trace levels of CWA degradation products.

In APCI, the HPLC effluent is heated and sprayed with a high flow of nitrogen from a nebulizer, which generates an aerosol. This aerosol is subjected to a corona discharge to form ions of the sample analytes. In APCI, the ionization occurs in the gas phase, unlike ESI which occurs in the liquid phase. The APCI source allows for improved analysis of non-polar and medium-polar analyte compounds as compared to the ESI source.

In ICP, the plasma is formed from a flow of gas, usually argon, through a quartz torch. The quartz plasma torch is typically constructed of concentric tubes and is surrounded by a copper load coil. The load coil is connected to the radio frequency generator and power (~1000–1500 W) is directed into the coil. This induces an oscillating magnetic field near the end of the torch and a plasma is formed while a spark is applied to the flowing gas stream. Sample introduction is by means of a carrier argon gas flow through the central tube in the quartz torch. Liquid samples are nebulized into an aerosol before being carried into the plasma torch; a function performed by a nebulizer. Once a sample analyte is exposed to the 8000 K plasma, vaporization, atomization, and ionization of the analyte occurs almost simultaneously. The ICP source is known as a "hard" ionization source, that is, the analytes are reduced to atomic ions. Until recently, the specific analysis of phosphorus from alkyl phosphonic acids by ICP–MS was limited because of its high first ionization potential (10.5 eV) and polyatomic interferences produced by the ICP technique.[21] Recent developments in collision/reaction cell technology with ICP–MS have allowed for the analysis of phosphorus and other elements prone to isobaric and polyatomic interferences through removal by collisional dissociation.[22] The only chromatographic limitation of the ICP is that methanol is the preferred organic modifier. Acetonitrile-based mobile phases will cause sooting of the MS sampler cone and should be avoided.[19]

The third component of a mass spectrometer, the mass analyzer, separates the formed ions according to their *m*/*z* ratios. The most widely used analyzer design is the quadrupole (or multipole) analyzer, used as either a single stage or a triple quadrupole (TQ) combined with a soft ionization technique. In the TQ design, with additional soft ionization such as a collision gas, tandem MS can be accomplished. A quadrupole consists of four parallel rods, which utilize an oscillating electric field to select ions passing through a radio frequency field generated by the quadrupole. Many modern instruments actually use hexapoles or octapoles; they have a more compact geometry using more rods, but operate under the same principle as the "quadrupole" described previously. Many of these multipoles are referred to as a quadrupole. In tandem MS, a TQ mass spectrometer consists of three sets of quadrupoles that transmit ions or function as a mass filter. The middle quadrupole of the TQ serves as a collision cell and produces daughter ions to be filtered by the last quadrupole. Other mass analyzer types, such as the time of flight (TOF), have been coupled to HPLC. The ion trap is another commonly used design in HPLC–MS, since the "trap" can be used to accumulate, fragment, and then eject selected ions. All of these common mass analyzers have been described in detail elsewhere in the literature.[12,13]

The last component of the MS is the ion detector, which is necessary to record the separated ions. Multipliers are the most frequently used detectors for commercial HPLC–MS instruments and ion detectors have been described in detail in the literature.[12,13]

COMMON STRATEGIES OF HPLC–MS IN CWA DEGRADATION PRODUCT ANALYSIS

The accurate determination of CWA degradation products from surface water, soil, or wipe samples from various surfaces creates an interesting challenge for the analytical chemist. Although there is a common perception that the use of HPLC–MS, and especially HPLC–MS/MS, practically guarantees method specificity, in practice this may not be the actual case. Common problems include ion suppression caused by the sample matrix effects and interference from other components encountered from environmental sampling. Several strategies are generally incorporated into HPLC–MS method design and development to counter matrix problems. Stable isotope-labeled internal standards (isotope dilution), such as deuterated or carbon-13 analogues, can be used to counter matrix effects. The importance of initial sample cleanup and good chromatographic separation cannot be overstated. Removal of inorganic salts from a sample matrix can reduce ion suppression of the ESI source. Liquid–liquid extraction (LLE) or solid-phase extraction (SPE) can be used for sample cleanup of environmental samples. The use of chromatographic gradients to increase the separation of sample analytes or components can reduce the probability of possible interferences.

Strategies to optimize chromatographic conditions to the MS ion source employed must be considered. Black and Read[23] noted that a considerable improvement in sensitivity was obtained by using formic acid instead of trifluoroacetic acid (TFA) in the mobile phase of a reversed-phase HPLC system when using ESI as the ionization source for the analysis of alkyl phosphonic acids. Zhou and Hamburger[24] reported that formic acid enhances the formation of $[M+H]^+$ ions for a range of compounds when using ESI–MS and have given a detailed discussion of the factors involved. As with all HPLC–MS, only volatile buffers and acids are compatible with the MS detector.

APPLICATIONS OF HPLC–MS IN CWA DEGRADATION PRODUCT ANALYSIS

Black's research[6,16,23,25] has included extensive work in the analysis of CWA degradation products. In one study, the separation of the major alkyl phosphonic acids was accomplished using gradient reversed-phase HPLC.[23]

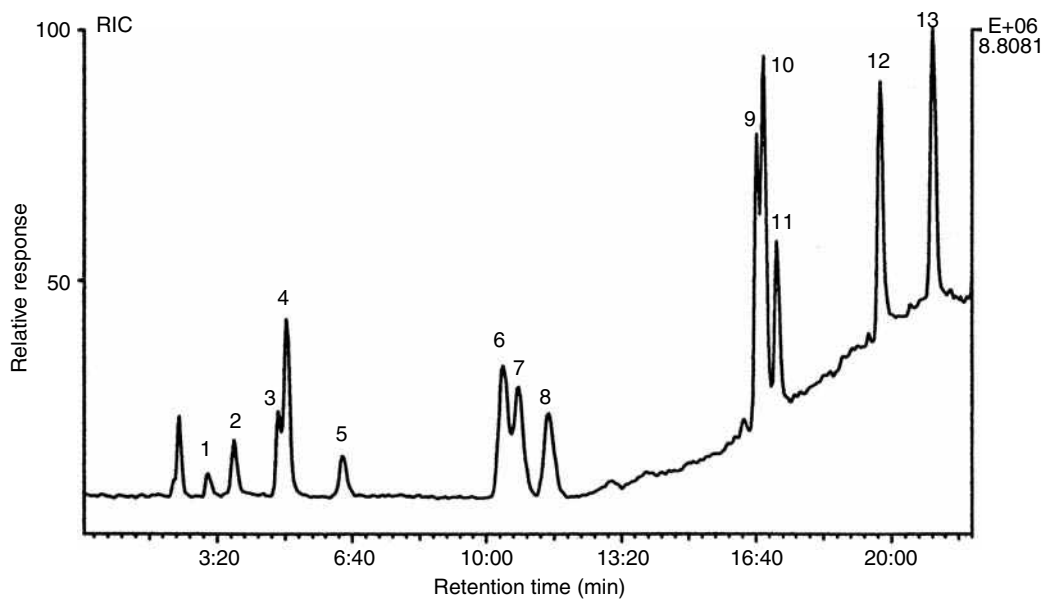

Fig. 1 HPLC–ESP–MS reconstructed (total) ion chromatogram from a standard mixture of alkyl phosphonic acids at a concentration of 1 μg/ml each: 1) methylphosphonic acid (MPA); 2) ethylphosphonic acid (EPA); 3) methyl ethylphosphonic acid (MEPA); 4) ethyl methylphosphonic acid (EMPA); 5) *n*-propylphosphonic acid (*n*PrPA); 6) ethyl ethylphosphonic acid (EEAP); 7) isopropyl methylphosphonic acid (iPrMPA); 8) *n*-propyl methylphosphonic acid (*n*PrMPA); 9) isopropyl ethylphosphonic acid (iPrEPA); 10) *n*-propyl ethylphosphonic acid (*n*PrEPA); 11) isobutyl methylphosphonic acid (iBuMPA); 12) cyclohexyl methylphosphonic acid (CHMPA); 13) pinacolyl methylphosphonic acid (PinMPA).
Source: From Analysis of degradation products of organophosphorus chemical warfare agents and related compounds by liquid chromatography–mass spectrometry using electrospray and atmospheric pressure chemical ionisation, in J. Chromatogr. A.[23]

An example reconstructed (total) ion chromatogram from this study which demonstrates the separation of alkyl phosphonic acids is shown in Fig. 1. The chromatographic conditions included the use of a 5 μm particle C_8/C_{18} mixed-phase column (Hichrom, Theale, U.K.) with dimensions of 150 × 2.1 mm. Optimum ESI sensitivity was obtained with 0.1% formic acid in water (mobile phase A) and 0.1% formic acid in methanol (mobile phase B). The elution gradient was 5% B (0–5 min), 5–80% B (5–15 min), and hold 80% B at a flow rate of 0.2 ml/min. Injection volume was 5 μl. Ions *m/z* 97, 111, 125, 139, 153, 181, and 179 were monitored (Finnigan TSQ700 MS, Thermo Electron Corporation, San Jose California, U.S.A.) for the various target alkyl phosphonic acid analytes (see compounds listed in Fig. 1 caption). This method was essentially designed as a rapid screening procedure of aqueous samples or extracts and avoided extensive sample pretreatment or concentration. Black and Read[23] noted that the avoidance of derivatization not only made a simpler sample preparation scheme, but also made preliminary interpretation of fragmentation, in the case of unknowns, much less complicated than with derivatized analytes. Other interesting results were reported from this study. ESI was compared to APCI and found to be approximately twice as sensitive for the alkyl phosphonic acids. Formic acid was found to improve sensitivity when using ESI by nearly an order of magnitude over a similar mobile phase using TFA as the acid modifier. This study indicated that HPLC–MS could not completely displace GC–MS with respect to the hydrolysis products for the nerve agents since some GC-based methods have superior sensitivity and limits of detection.[23]

In a study by Richardson, Baki, and Caruso,[20] reversed-phase ion-pairing HPLC was used in conjunction with the ICP–MS to separate and detect EMPA, iPrMPA, and MPA. Phosphorus-31 was monitored for the ICP–MS detector and a collision cell was used to minimize interference from nitrogen polyatomic species formed in the plasma. ICP–MS is generally noted in its ability to obtain high sensitivity and very low detection limits. A chromatogram showing the separation of MPA, EMPA, and iPrMPA, respectively, using reversed-phase ion-pair HPLC is shown in Fig. 2. Chromatographic conditions included the use of a 5 μm C_8 column (Alltima C8, Alltech Associates, Deerfield, Illinois, U.S.A.) with dimensions of 150 × 3.2 mm. The isocratic mobile phase consisted of 2/98 (v/v) methanol/water made 50 m*M* in ammonium acetate (apparent pH 4.85) and 5 m*M* myristyl trimethylammonium bromide as the ion-pair reagent. The flow rate was 0.5 ml/min and the injection volume was 100 μl. Isotope $^{31}P^+$ and polyatomic $^{47}PO^+$ were monitored by the MS (Agilent 7500ce, Agilent Technologies, Tokyo, Japan), and the He collision cell was optimized before each experiment. This study also included an investigation into the use of complex samples; river water, tap water, topsoil, and potting soil were spiked with the three target analytes.

Chromatographic separation methods for various CWA degradation products have been devised and used within this laboratory. As part of a current study, an HPLC–MS/MS method employing ESI as the source was developed to allow for the trace analysis of environmental water samples or surface wipe samples for specific degradation products of organophosphate (OP) nerve agents. Specifically, the target analytes were MPA, EMPA, EDMAPA (a short-lived intermediate degradation product of GA), iPrMPA, PinMPA, and diisopropyl methylphosphonic acid (DiPrMPA, an impurity of production grade GB). Two gradient reversed-phase systems were employed; one utilized formic acid as the acid modifier and the other was an ion-pair system using heptafluorobutyric acid (HFBA). Example chromatograms of these two systems are displayed in Figs. 3 and 4. For the formic acid system, an Atlantis dC18 125A column with dimensions of 150 × 3.0 mm I.D. (Waters Corporation, Milford, Massachusetts, U.S.A.) was used. The mobile-phase composition consisted of 0.1% (v/v) formic acid in water (mobile phase A) and 0.1% (v/v) formic acid in acetonitrile (mobile phase B). The gradient elution program was 100% mobile phase A for 4 min followed by a linear ramp of 0–95% mobile phase B in 7 min and then a hold at 95% mobile phase B. The flow rate was constant at 0.3 ml/min with a sample injection volume of 5 μl. The Atlantis column is noted for its ability to run 100% aqueous initially for gradients, and a reasonable retention of MPA was obtained as is shown in Fig. 3. For the second ion-pair

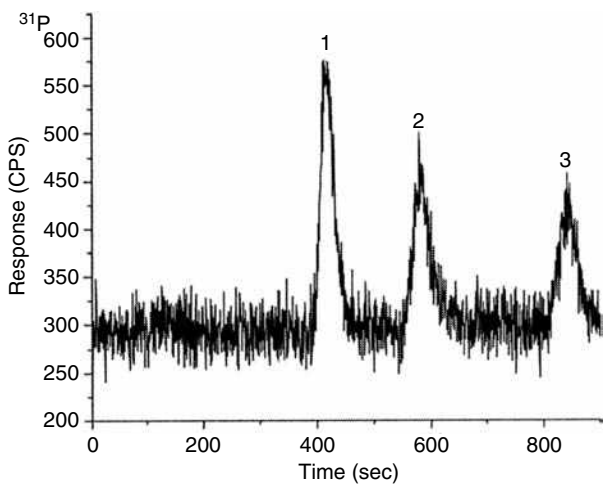

Fig. 2 HPLC–ICP–MS single ion monitoring (SIM) from a standard mixture of three alkyl phosphonic acids at a concentration of 100 ng/ml each: 1) methylphosphonic acid (MPA); 2) ethyl methylphosphonic acid (EMPA); 3) isopropyl methylphosphonic acid (iPrMPA).
Source: From Reversed phase ion-pairing HPLC–ICP–MS for analysis of organophosphorus chemical warfare agent degradation products, in J. Anal. At. Spectrom.[20]

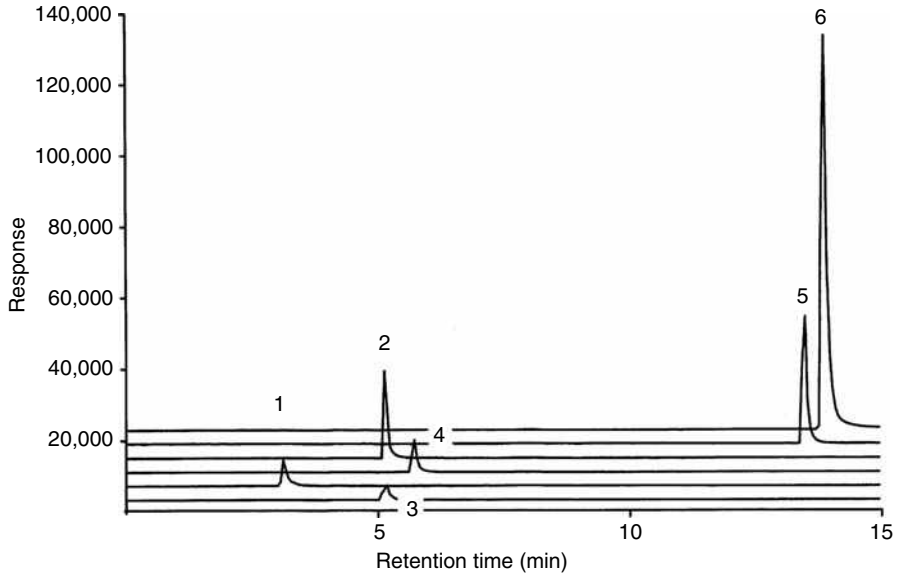

Fig. 3 Reversed-phase HPLC–MS/MS chromatogram using formic acid in the mobile phase and an Atlantis dC18 column. The standard mixture of alkyl phosphonic acids with a concentration of 10 μg/ml each was detected using multiple reaction monitoring (MRM): 1) methylphosphonic acid (MPA, *m/z* 96.8→78.7); 2) ethyl methylphosphonic acid (EMPA, *m/z* 125→96.8); 3) *O*-ethyl *N,N*-dimethylamidophosphoric acid (EDMAPA, *m/z* 154.2→126); 4) isopropyl methylphosphonic acid (iPrMPA, *m/z* 139.1→96.8); 5) pinacolyl methylphosphonic acid (PinMPA, *m/z* 181.3→96.8); 6) diisopropyl methylphosphonic acid (DiPrMPA, *m/z* 181.3→139.1). See the text for further chromatographic details and the MS/MS conditions used.

chromatographic system, a Zorbax SB-Aq 3.5 μm column (Agilent Technologies, Palo Alto, California, U.S.A.) with dimensions of 150 × 3 mm I.D. was used. The mobile-phase composition consisted of 0.1% (v/v) HFBA in water (mobile phase A) and 0.1% (v/v) in acetonitrile (mobile phase B). The gradient elution program was 100% mobile phase A for 3 min followed by a linear ramp of 0–95% mobile phase B in 6 min and then a hold at 95% mobile phase B. The flow rate was constant at 0.3 ml/min with a sample injection volume of 5 μl. Both chromatographic systems used an Agilent Model 6410A Triple Quad MS/MS detector equipped with an ESI interface operated in positive mode using multiple reaction monitoring (MRM); the ions monitored are listed in the captions of Figs. 3 and 4. Both systems can be used for quantitative measurements using isotopically labeled analogues of the analytes which are not shown in the chromatograms displayed.

This study showed some interesting results. Formic acid appeared to have slightly better sensitivity over HFBA; the response of DiPrMPA was roughly double in the formic acid system over the ion-pair system. This result is similar to what Black and Read[23] noted during their comparison of formic acid and TFA mobile phases for the analysis of nerve agent degradation products. MPA and some of the other analytes were not as suppressed by HFBA using the ESI interface, but generally all the analytes had lower responses. Also, the Atlantis dC18 column produced more symmetrical peaks than the ion-pair system and showed less peak tailing (Figs. 3 and 4). Both chromatographic systems could be used for a general screening

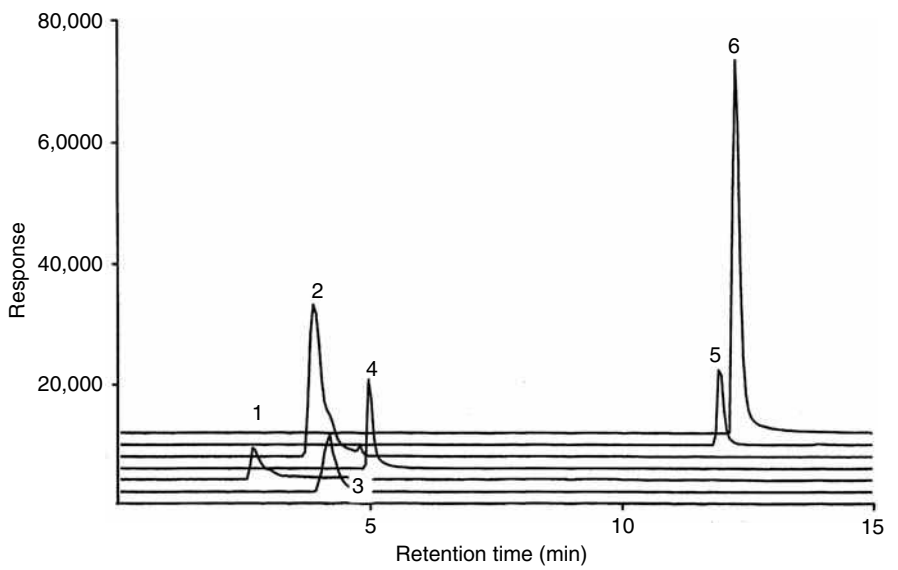

Fig. 4 Ion-pair reversed-phase HPLC–MS/MS chromatogram using heptafluorobutyric acid (HFBA) as the ion-pair reagent in the mobile phase and a Zorbax SB-Aq column. The standard mixture of alkyl phosphonic acids with a concentration of 10 μg/ml each was detected using MRM: 1) MPA (*m/z* 96.8→78.7); 2) EMPA (*m/z* 125→96.8); 3) EDMAPA (*m/z* 154.2→126); 4) iPrMPA (*m/z* 139.1→96.8); 5) PinMPA (*m/z* 181.3→96.8); 6) DiPrMPA (*m/z* 181.3→139.1). See the text for further chromatographic details and the MS/MS conditions used.

procedure for a variety of nerve agent degradation products as well as other CWAs. For example, *N*-ethyl diethanolamine (EDEA, *m/z* 134→116) from the agent HN1 had a retention time of 4 min and TDG (*m/z* 123→105) from the agent HD had a retention time of 5 min using the described formic acid HPLC conditions; thus, this methodology can easily be applied to general screening analysis for a variety of CWA degradation products and has greater versatility than just for the analysis of alkyl methylphosphonic acids.

CONCLUSIONS

HPLC–MS CWA degradation product analysis is a vital technique for use in general enforcement of the chemical warfare treaty and the continued threat of sophisticated world terrorism of the twenty-first century. The inherent advantages of the mass spectrometer with analyte specificity, high sensitivity, and a wide dynamic range of detection, combined with HPLC, makes HPLC–MS a valuable analytical tool for use in CWA degradation product analysis methods for many years to come. HPLC–MS has been demonstrated by various researchers to be useful in rapid screening for the degradation products of OP agents, as well as other agents, particularly when minimum sample pretreatment and preliminary interpretation of fragmentation, in the case of unknowns, is simplified over derivatized analytes.

ACKNOWLEDGMENTS

The authors would like to acknowledge the support of the U.S. Environmental Protection Agency for providing one of the HPLC columns and some of the reagents used in this work. The authors would also like to thank Dennis Lynch, Galye DeBord, Anne Vonderheide, Jeanette Krause, and Nathan Coker for their help in reviewing, editing, and correcting this manuscript.

DISCLAIMERS

The findings and conclusions in this report are those of the authors and do not necessarily represent the views of the National Institute for Occupational Safety and Health (NIOSH) or the Centers for Disease Control and Prevention (CDC). Chemical Warfare Agents: GC Analysis

Stanisław Popiel
Institute of Chemistry, Military University of Technology, Warsaw, Poland

Zygfryd Witkiewicz
Institute of Chemistry, Jan Kochanowski University, Kielce, Poland

INTRODUCTION

Chemical warfare agents (CWA) are still an element of equipment of some countries' military forces.[1] Thus, their usage in military conflicts and for acts of terror cannot be excluded, despite the existence of the Convention on the prohibition of the development, production, stockpiling, and use of chemical weapons and their destruction.[2] The Convention provides measures for checking compliance of their provisions. Those measures include (among others): CWA, substrates for their production, and degradation products analysis. Chemical warfare agents analyses performed by inspectors of the Organisation for Prohibition of Chemical Weapons in CWA stockpiles and places of their destruction are presently the most important. Necessity for CWA analysis in the battlefield or following their use by terrorists cannot be, however, excluded.

Chemical warfare agents are mainly organic compounds and, as is the case with many other organic compounds, chromatography is the best method for their analysis. Gas chromatography (GC) is mainly used for the CWA analysis, although liquid column and thin-layer chromatography are also used for this purpose.[3,4] GC is characterized by high detectability and speed and possibility of continuous operation even in field conditions. It is possible to identify CWAs in complex mixtures, even at very low quantities—e.g., picograms and lower.

The particular CWAs differ considerably in their physicochemical properties—e.g., polarity and boiling point, which are important in chromatographic analysis. The formulae and basic physicochemical properties of CWAs are provided in Table 1.

COLLECTION AND SAMPLE PREPARATION FOR CWA ANALYSIS

The collected samples should have the qualitative and quantitative composition representative of the original analyzed material. This should be observed both during the isolation of analytes from their matrix and during their preparation.

Chemical warfare agents samples from the atmosphere are taken mainly through adsorption or absorption. The absorption method consists of passing the polluted air through a solvent or mixture in which the chemical agents dissolve or through the solution of a reagent with which the chemical agents form derivatives. Solvent cooling fosters common dissolution. Samples collected this way may often be analyzed without additional concentration. If concentration is required, solvent evaporation or extraction with a solvent other than that used for absorption is applied. Other extraction methods, including solvent-free techniques (often utilized for liquid samples), may also be used.

Adsorption is an important means of collecting CWA samples from the atmosphere. Adsorption tubes filled, among others, with activated carbon, silica gel, and porous polymers are used for this purpose. A properly selected adsorbent allows for selective analyte adsorption. A chemical agent adsorbed onto a small quantity of adsorbent in a large gas volume (e.g., 50 L) becomes concentrated. In order to transfer it into a solution, analyte desorption is performed with use of a solvent or by direct heating in a thermal desorber, constituting an integral part of a GC.

In cases where chemical agent concentrations in the atmosphere are sufficiently high for direct analysis, they are collected into Tedlar sampling bags. Metal or glass containers usage is not recommended due to the possibility of irreversible chemical agents adsorption to their walls.

Aerosols are collected with filters made of glass fibres, with pores up to 5 μm, and next dissolved in a proper solvent or solvent mixture. Chemical warfare agents or their degradation products, which are dissolved in water or other solvents, are extracted by liquid–liquid extraction (LLE), solid-phase extraction (SPE), solid-phase microextraction (SPME), and stirr bar sorptive extraction (SBSE) methods. Head space (HS) analysis is also employed. In the case of the SPE method, XAD-4 and XAD-2 resins are frequently used.

For analysis of some CWA and their degradation products, it is favorable to transform them into their derivatives.[5] An interesting concept of combining extraction and derivatization was realized using XAD-2 resin impregnated with pentafluorobenzyl bromide. This method may be useful in the analysis of degradation products of organophosphorus warfare agents contained in water.[6]

Table 1 Nomenclature and physicochemical characteristics of selected chemical warfare agents (CWA).

Chemical name [CAS number]	Common name/ Chemical formula	Abbreviation	Class schedule no.	Structure	Molecular weight	m.p.,°C/ b.p.,°C
Isopropyl methylphosphonofluoridate [107-44-8]	Sarin $C_4H_{10}FO_2P$	GB	Nerve agent 1.A.1		140.1	–54/151.5
Pinacolyl methylphosphonofluoridate [96-64-0]	Soman $C_7H_{16}FO_2P$	GD	Nerve agent 1.A.1		182.1	–80/167
Cyclohexyl methylphosphonofluoridate [74192-15-7]	Cyclosarin $C_7H_{14}FO_2P$	GF	Nerve agent 1.A.1		180.2	–30/239
Ethyl *N*,*N*′-dimethylphosphoroamidocyanidate [77-81-6]	Tabun $C_5H_{11}N_2O_2P$	GA	Nerve agent 1.A.2		162.1	–50/230
O-ethyl, S-2-diisopropylaminoethyl methylphosphonothiolate [50782-69-9]	VX $C_7H_{18}NO_2PS$	VX	Nerve agent 1.A.3		267.3	–30/>300
Diisopropyl phosphorofluoridate [55-91-4]	DFP $C_6H_{14}FO_3P$	PF-3	Nerve agent —		184.2	–82/183
Bis-(2-chloroethyl)sulfide [505-60-2]	Sulfur mustard; Yperite $C_4H_8Cl_2S$	H, HD	Vesicant 1.A.4		159.1	14.5/217
1,2-Bis-(2-chloroethylthio)ethane [3563-36-8]	Sesquimustard $C_6H_{12}Cl_2S_2$	Q	Vesicant 1.A.4		219.2	56.6/140 (2 *Torr*)
Bis-(2-chloroethylthioethyl)ether [63918-89-8]	O-mustard $C_8H_{16}Cl_2OS_2$	T	Vesicant 1.A.4		263.3	10/120 (0.2 *Torr*)

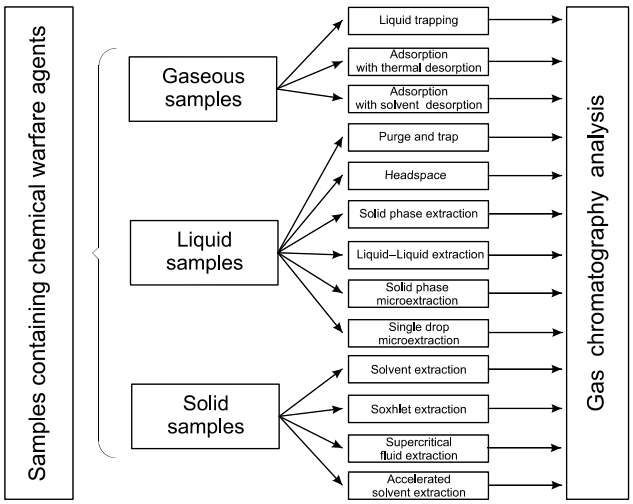

Fig. 1 Methods of sampling and sample preparation for GC analysis of CWAs.

In order to enrich samples containing trace amounts of the CWAs, lyophilization is sometimes applied. In a different procedure, an organic solvent is added to the water and, after freezing out ice, the organic phase is physically removed.

Most methods of collecting and preparing samples of contaminated soil are rather complex. They are predominantly useful only with respect to chemically stable CWA that are resistant to degradation reactions occurring in the environment. The common method of isolating CWAs to be analyzed from soil is their extraction with organic solvents, preceded by wetting of the soil with water. The volatile and medium volatile substances may be isolated from soil by evaporation. The evaporated CWAs are introduced to a chromatographic column directly or after their concentration.

Supercritical fluid extraction may be useful for extraction CWAs or products of their destruction—e.g., for alkyl alkylphosphonofluoridates and dialkyl alkylphosphonates from painted surfaces.[7]

Chemical warfare agents are usually isolated from vegetable materials by the homogenization and extraction of the toxic substances in a Soxhlet apparatus with a mixture of organic solvents.

The contamination of humans and animals is usually determined by analyzing body fluids, such as urine, plasma, or blood. The isolation of CWAs or their metabolites is usually performed by LLE, SPE, or SPME. If tissues are to be analyzed, the CWAs are extracted after homogenization with water.

Examples of sampling and sample preparation procedures for GC analysis of materials contaminated with CWA are shown in Fig. 1.

GENERAL PROBLEMS OF CWA ANALYSIS BY GAS CHROMATOGRAPHY

Gas chromatography is a proper method for analysis of CWAs whose vapor pressures are high enough or if they can be transferred into the gaseous state without decomposition. The properties of only a few CWAs, mainly arsenic containing substances, are not proper for direct GC analysis. Such chemical agents, especially the products of their decomposition and metabolites, including organophosphorus agents and vesicants, are analyzed after their derivatization.[5]

Packed and capillary columns are suitable for chemical agent analysis. Chemical warfare agents are mostly polar, so in packed columns, silanized supports are most often used—mainly Chromosorbs W and G and Gas-Chrom Q and P. The majority of analyses are performed using capillary columns, especially the fused silica types.

Stationary phases SE-52 and OV-1 are considered to be among the best for CWA analysis. They do not react with chemical agents and have high thermal stability. SE-54, DB-1, DB-5, and FFAP are also recommended, especially for use in the analysis of organophosphorus compounds, vesicants, and irritants. OV-1701 may be used for analyzing DFP and SE-54 for hydrogen cyanide (HCN), cyanogen chloride, and phosgene.

A good way to introduce CWA samples into a chromatographic column is to inject a sample into the column directly. By applying direct injection, the thermal decomposition of some compounds, e.g., VX, is avoided. When using a glass injector, it is important to note that during the analysis of some agents, e.g., soman, adsorption onto the active surface of the glass injector may occur. Strongly adsorbed phosgene and HCN may undergo decomposition, so the use of deactivated injection systems is essential.

DETECTORS FOR CWA ANALYSIS

Many detectors have been used in the analysis of CWA. Among them, selective detectors are especially recommended because they facilitate, considerably, the identification of chemical agents. They are useful for detecting agents that contain elements to which the molecules of these detectors are particularly sensitive. The following detectors can be employed for analysis of the following chemical agents: electron capture detector (ECD) for agents containing halogens; flame-photometric detector (FPD) for agents containing sulphur and phosphorus; nitrogen-phosphorus detector (NPD) for agents containing nitrogen and phosphorus; and alkali flame-ionization detector-AFID (alkali thermionic detector-ATD) for organophosphorus agents.

The flame-ionization detector (FID) and thermal conductivity detector (TCD) are rarely used in CWA analyses due to their relatively low sensitivity and selectivity. Sometimes, combining two detectors may be useful—e.g., FID–AFID, FID–ECD, FID–FPD, and ECD–AFID. Such combinations facilitate the identification of agents separated in one or two chromatographic columns.

Currently, instruments consisting of a GC and a spectrometer are very often employed. Mass spectrometry (MS), atomic emission spectrometry (AES), and infrared spectrometry with Fourier transformation (FTIR) are commonly used in this case.[8,9]

The most often used apparatus for CWA analysis is GC–MS.[4,10] Such a device is very useful for rapid analysis of trace amounts of chemical agents present in a complex mixture. The mass spectra recorded for the components of the mixture are compared with those contained in a computer database, and on this basis, the particular substances are reliably identified. The detectability of these instruments is very good. It is possible to detect organophosphorus agents at the level of 10^{-12}–10^{-13} g and even lower.

In some cases, the identification of chemical agents with GC–MS may be difficult. In those cases, analysis with GC–AED (atomic emission detector) may be of assistance. This device makes elemental analysis of chemical agents separated in the chromatographic column possible. The quantitative assay of elements in a given chemical compound allows determination of its molecular formula. Analysis of the same samples with GC–MS and GC–AED allows much more certain identification of chemical agents than the utilization of any of those instruments separately.

Using ordinary detectors (e.g., FID, TCD, ECD, NPD), the identification of particular chemical agents is usually performed by comparing the retention indices of the substances being identified and the standard agent measured on at least two columns containing stationary phases of different polarities. Under isothermal conditions, the Kovats indices are applied and, under temperature programing, the equation of Van den Dool and Kratz is applied.[11–13]

THE SPECIFICITY OF ANALYSIS OF PARTICULAR GROUPS OF CHEMICAL AGENTS

Due to the high toxicity of organophosphorus chemical agents, their detection requires detectors characterized by high detectability. The presence of phosphorus in molecules of those chemical agents enables satisfactory detectability with FPD, ATD, and AED. Analysis of organophosphorus chemical agents is not difficult, but an analysis of polar products of their degradation is not easy and is frequently performed following their derivatization, consisting of the conversion of hydroxyl groups to their methyl esters using diazomethane or to trimethylsilyl (TMS) esters using *N*,*O*-bis (trimethylsilyl) trifluoroacetamide (BSTFA) or BSTFA +1% trimethylsilyl chloride (TMSCl).[5]

Organophosphorus chemical agents are often mixtures of isomers. It is possible to separate, chromatographically, four stereoisomers of soman and enantiomers of sarin and tabun using short capillary columns packed with chiral stationary phases. They may also be separated in columns packed with Triton X-305 and DC-550 phases. The analysis of isomers is particularly important when studying organophosphorus chemical agents' transformations in living organisms.

Among vesicants, the majority of analyses apply to sulfur mustard (yperite), and much less to lewisite. After yperite was used in the Iraq–Iran war, this agent was analyzed in the munition, water, soil, and body fluids of contaminated soldiers. Numerous products of yperite's decomposition were also analyzed. In a lump of sulphur mustard taken from the sea approximately 50 years after it sank, approximately 40 other chemical compounds have were detected.[9,14] Those been probably impurities of the yperite and products of its degradation. GC–MS is frequently used for analysis of those chemical agents, but FPD and ECD may also be used.

Lewisite may be analyzed indirectly. In the course of action of sodium hydroxide on lewisite present in water, acetylene is released, which is easy to chromatographically analyze. This method allows detection of lewisite in water at concentration levels down to $10^{-8\%}$. The derivatization of lewisite with thiol reagent makes it possible to detect it using the FPD.[5]

Irritants are used as vapors or aerosols. The most important irritants are chloroacetophenone (CN), chloropicrin (PS), *O*-chlorobenzylidenemalonodinitrile (CS), camite (CA), dibenzo[bf]-1-4-oxazepine (CR), and adamsite (DM). Because of the presence of halogens in the molecules of these chemical agents, the ECD is commonly used for their detection. This detector allows detection of tear agents at the nanogram and subnanogram levels. Nitrogen-phosphorus detector is also suitable for the analysis of agents containing nitrogen in their molecules.

GC–MS instruments allow the rapid analysis of irritant agents with good detectability and reliable identification. Using such instruments, it is possible to determine CN, CS, and CR at concentrations lower than 1 ng/ml.

Chloropicrin is often analyzed by GC–MS and GC with ECD, as it is used as a component of plant protection agents and as a monitoring substance for testing filtration equipment. Analysis of PS in water by headspace analysis or extraction with *n*-heptane is often applied.

Chloroacetophenone and CS may be analyzed using Carbowax 20 *M* and other polar stationary phases. Packed columns filled with squalane or silicone phases, or capillary columns containing DB-5, OV-1, SE-30, or OV-17 phases are used for PS assay.

As with other organic arsenical chemical agents, DM analysis is difficult. Their detectability is not good[15] and derivatization may facilitate their analysis.[16] Adamsite degradation products may be analyzed with capillary columns containing SE-52 or OV-1 phases.

At present, HCN, cyanogen chloride, and phosgene are of less importance as CWAs, but the agents were used in battle in the past. Presently, they are of industrial

significance (especially phosgene), and, in case of a tank or a reactor breakdown, they may cause intoxication, including fatal results.

Glass and metal containers are not recommended for collection of HCN samples; this is due to adsorption of the compound onto the walls of such containers. Good results are achieved when HCN is adsorbed onto porous materials, from which it can be desorbed with a solvent or by using thermal methods. For HCN detection in biological samples (e.g., in blood), a HS analysis method may be applied. Hydrogen cyanide detectability with a thermionic nitrogen detector may reach 1 pg in a sample.

In the analysis of HCN in mixtures of inorganic gases, medium polarity and polar stationary phases in packed and capillary columns (SE-52, SE-54), as well as Porapaks (e.g., QS) and Chromosorb 104, may be used.

After derivatization of HCN with chlorinating agents—e.g., chloramine T—cyanogen chloride is obtained. Following dissolution of cyanogen chloride in ethylacetate, toluene, or hexane, it can be determined by GC with ECD. This method was used for the determination of HCN in tobacco smoke. The amount of HCN in one cigarette was found to exceed 50 ng.[3]

The GC analysis of phosgene is difficult due to its high reactivity. At low concentration, it decomposes completely, even on contact with active surfaces. This is the reason that some parts of a GC should be made of inert materials (e.g., polytetrafluoroethylene or glass). Using ECD, phosgene may be determined at the 1–2 ppb level. Derivatization of phosgene with nucleophilic regents, e.g., amines, is the recommended solution.[17]

Liquid stationary phases (e.g., didecyl phthalate, E-301) are mainly used for phosgene analyses, but adsorbents may be used, as well. An example of a CWA chromatogram is given in Fig. 2.

CONCLUSION

Thanks to GC, it is possible to rapidly analyze CWA in complex mixtures with good detectability and sensitivity in air, water, soil, plants, and animal organisms. There are instruments which may be used in automatic air control systems. In the military, instruments consisting of GC and MS are applied for CWA analysis in air and water under field conditions. Portable and pocket chromatographs are also known.[18]

Abstract
In this entry, advances in thin-layer chromatography (TLC) of chemical warfare agents (CWA) are reviewed. Procedures for the separation and identification of CWA occurring alone or in the presence of related compounds, such as nerve agents in organophosphorous pesticides, are described. Analysis of blister agents (vesicants) and their differentiation, irritants (CS, CN, and CA), and mixtures of irritants and nerve agents are discussed. Solvents for running the TLC plates, reagents, and conditions for development of the plates are described in detail. Two-dimensional overpressured TLC (OPLC) used for the separation and identification of nerve agents in the presence of organophosphorous pesticides proved to be an adequate technique for detecting very low concentrations of these compounds.

INTRODUCTION

Chemical warfare agents (CWA), commonly used during World War I, were also produced for possible use during World War II; however, they were not used in the battlefield during the latter war. Only hydrogen cyanide was used for killing prisoners held in German death camps, e.g., in Auschwitz. Despite existing proof that a war was fought without the use of CWA, these agents were industrially produced after World War II. Those were used on a local scale, and still remain in the stores of some armies. Therefore, use of CWA cannot be ruled out in local armed conflicts. Also, there have been instances of CWA use by terrorists.[1]

The international community revoked the development, production, storage, and usage of CWA with a Chemical Weapons Convention (CWC), which came into force in 1997. One of the basic tasks foreseen by the Convention is the destruction of CWA stocks owned by member states of the Convention. Inspectors of the Organization for the Prohibition of Chemical Weapons (OPCW), monitoring observance of provisions of the Convention, perform analyses of chemical substances that could potentially be CWA. Analyses of various substances are also performed in places where the use of chemical warfare is suspected. One of the analytical methods used for the detection and determination of precursors for the production of CWA, CWA themselves, and their decomposition products is thin-layer chromatography (TLC).

Currently, gas chromatography (GC), including GC–mass spectrometry (GC–MS), is the main method used for CWA analysis.[2,3,4] High-performance liquid chromatography with MS (HPLC–MS) is another popular method frequently used for that purpose. These analytical methods are very efficient but are expensive and require some complex apparatuses.

TLC is a relatively simple and cheap analytical method, although increasingly elaborate devices are used in it, and it is a fully instrumental method. High selectivity, good detectability of analytes, and reliability of the analysis, even if a relatively simple equipment is used, make the method applicable not only for stationary laboratories, but also for mobile field laboratories.

GENERAL CHARACTERISTICS OF TLC AS A CWA ANALYSIS METHOD

A TLC analysis can be performed right at the site of occurrence of suspicious chemicals, checking, for example, 34–40 samples in 4–5 hr. The analysis provides information on the presence or absence of the chemicals of interest, and dubious samples can be further analyzed using other chromatographic techniques, such as GC–MS. Analysis using TLC is particularly recommended if numerous samples of unknown origin have to be analyzed. Therefore, in some armies, including the Polish army, TLC apparatuses and procedures have been and are still used for CWA analysis in field laboratories.

For TLC analyses, the samples should be in the form of a solution. If the analyzed material is located on a chemical

reactor wall, the surface of a contaminated equipment, or the remains of a missile, the surface is wiped with cloth or polyester and the chemical substance is extracted with a proper solvent, e.g., dichloromethane, hexane, or acetone. Also samples of soil and water are extracted with solvents. These extracts can be concentrated, if necessary.

Extracts thus obtained are applied onto a chromatographic plate covered by a thin layer of adsorbent (volume 1–5 μl). Silica gel is most frequently used as an adsorbent, and aluminum oxide is used less frequently. Components of the sample mixture are separated by developing a chromatogram using a single or mixed mobile phase characterized by appropriate polarity and elution force. After development of a chromatogram, colorless components are transformed into colored chemicals by spraying the chromatographic plate with the solution of an appropriate reactant. Positive color reactions can occur immediately, after some time (depending on the quantity of analyte), or only after the plate is heated up. Detectability limit of TLC is usually between 10^{-6} and 10^{-9} g per spot, and of HPTLC, between 10^{-9} and 10^{-12} g.

Sample components on the plate are identified by comparing the obtained colors with a specific standard. To increase the reliability of identification, several reactants can be used, which yield products of various colors characteristic of a given CWA.

Apart from the color of the analyte, the delay factor of a given spot with respect to the front end of the mobile phase (R_F) can also form the basis for identification. Value of the measured delay factor is then compared to the corresponding value of this factor for a standard.

In cases where a toxic substance occurs alone, without any admixtures, it can be detected on a chromatographic plate without developing a chromatogram. A drop analysis is performed using one or more reactants that provide colored products with the detected (identified) substance.

Besides the visualization of components on a chromatogram realized by their transition to colored chemicals, other visualization methods also are used, e.g., irradiation with UV light. After irradiation of a developed chromatogram, spots invisible in visible light can become fluorescent, or the background fluorescence of the plate surface can get extinguished. Components of a single sample can be detected and identified on a single plate using various methods.

TLC is used for qualitative, semiquantitative, and quantitative analyses. Precise, accurate and repeatable results of quantitative analysis are achieved using densitometers. In this method, spot chromatograms can be transformed into peak chromatograms and absorption spectra of the analytes can be registered. These spectra are used for the identification of analyzed substances. Detailed description of TLC as an analytical method is presented, among others, in a monograph edited by Nyiredy.[5]

Some examples of the analysis of individual groups of CWA using TLC are provided below.

ANALYSIS OF ORGANOPHOSPHOROUS COMPOUNDS

Combination of mixture components separation using HPTLC with enzymatic visualization is a very good method for the analysis of organic phosphorous compounds. This method is characterized by low detectability thresholds. Organic phosphorous compounds are inhibitors of the enzymes cholinesterase or acetylcholinesterase.[6,7] Therefore, their detection on a plate is limited to finding those places on a chromatogram, where the enzyme was applied. For example, analysis of sarin, soman, tabun, and VN_1 is performed using a plate covered by a layer of silica gel and diatomaceous earth, and a mobile phase containing hexane, pyridine, and dioxane (7:2:1). After the plate is dried, it is sprayed with aqueous solution of an enzyme (cholinesterase), and after 5 min, with a mixture of β-naphthol acetate and diazo-*o*-dianisidine in aqueous alcohol solution. White spots contrasting on an intense violet gel appear in those places where organic phosphorous toxic compounds are located. This visualization method allows the detection of 10 ng of an organic phosphorous compound per spot. Under the conditions described above, VN_1 appeared as two spots of isomers: thiolic and thionic.

Enzymatic reaction can be used for the analysis of not only organic phosphorous chemical agents, but also organic phosphorous pesticides and carbamates, as these compounds also inhibit cholinesterase, and can occur together with CWA in field conditions. Therefore, methods have been developed for differentiating cholinesterase-blocking pesticides and organic phosphorous CWA.[8] Ten insecticides and soman and VX were separated on a plate with silica gel. A mixture of dichloroethane and ethyl acetate (9:1) was used as the mobile phase. Analyzed chemicals were identified with selective reactions. Total time of the analysis did not exceed 30 min.

Enzymatic visualization of organic phosphorous warfare agents (sarin, soman, tabun, and VX) and organic phosphorous pesticides (diazinon, dichlorvos, chlorfenvinphos, fenitrothion, and phosalone) uses 4-methylumbelliferone esters as reagents. The performance of the enzymatic reaction on a chromatographic plate was estimated by the measurement of fluorescence of the reaction product 4-methylubelliferone. The results of this reaction were compared with those of another reaction where indoxyl acetate was used. Using this procedure it was possible to determine sarin, soman, and tabun at the level of a dozen picograms per spot and VX as well as pesticides from the individual nanograms to their dozens per spot.[9]

Two-dimensional overpressured TLC (OPLC) has been used for the separation and quantitative densitometric

analysis of organophosphorous warfare agents in the presence of 22 pesticides.[10] The CWA were tabun, sarin, soman, DFP, and VX, and the pesticides belonged to the groups of organochlorine (5), organophosphorus (13), carbamate (2), and carbamide (2) compounds. The optimum composition of the mixed eluents was established using the PRISMA model. The chromatograms were developed to a distance of 6 cm in the first direction with diisopropyl ether/benzene/tetrahydrofuran/*n*-hexane (10:7:5:11, v/v) and to a distance of 6 cm in the second direction with tetrahydrofuran/*n*-hexane (2:3, v/v). Three spray reagents were used for visualization of the analyzed compounds: Reagent A was a solution of cholinoesterase in borate buffer; reagent B was a solution of butyrylthiocholine iodide and Michler's hydrol; and reagent C was a saturated solution of cobaltic chloride in acetone. After evaporation of the mobile phase, the plate was sprayed with reagent A, placed in an oven at 37°C for up to 15 min, and then sprayed successively with reagents B and C. The presence of the analytes was revealed as blue spots on a white background. The detectability was 1.3 pg for tabun and 48 ng for VX, and it was possible to determine the organophosphorous warfare agents quantitatively in the range of 15 pg to 100 ng (JPC 4).

It was found that the presence of metal ions in the enzymatic visual reagent leads to a decrease in the detection limit of organophosphorous compounds to the level of 10^{-12} g per spot. The best results were obtained for Co^{2+}; the results were slightly worse for Mg^{2+} ions.[11,12]

DFP can be determined using a highly sensitive nonenzymatic method, after its visualization in a reaction with 2,4-dinitrophenol (DNP) and 2,4,6-trinitrophenol (TNP).[13] Spots—brown (DNP) or orange (TNP)—disappeared within several minutes. Restaining could be achieved by spraying the plate with NaOH solution. Determinability of DFP was between 1 and 2 nmol per spot.

ANALYSIS OF BLISTER AGENTS (VESICANTS)

This group of CA includes mustards and arsenic compounds, especially lewisites. Various reagents were used for the visualization of sulfur and nitrogen mustards. A group reagent for sulfur and nitrogen mustards can be 4,4′-nitrobenzylpyridine, which forms blue-colored products with mustards. Sulfur mustards can be differentiated from nitrogen mustards by spraying the plates with Cu-3,3′-dimethoxybenzidine. These reagents allow the detection of mustards at a level of micrograms per spot.[14] Also, a biochemical method was used for the development of thin-layer chromatograms of compounds having cytotoxic activity. This method allowed determination of sulfur mustards at the level of a single microgram.

Munawalli and Pannel[15] analyzed sulfur mustard and its metabolites in biological fluids using TLC. Very good separation of these substances was achieved using a two-component mixture of chloroform and methanol (10:1) and chloroform and acetylnitrile (5:1) for the development of chromatograms. Visualization of the chromatograms was achieved using 1% $KMnO_4$ solution in 6% Na_2CO_3 and 7% 4,4′-*p*-nitrobenzylpyridine solution in acetone. Heating of the plate for 15 min at 70°C and exposure to ammonia vapors caused the formation of blue stains in places where sulfur mustard was present. This method allowed the detection of less than 0.05 μg of yperite per spot.

A significant amount of CWA, mostly sulfur mustard, was sunk in the Baltic Sea after World War II.[16,17] The analysis of a yperite block retrieved from the Baltic Sea in 1997 was performed using HPTLC and OPLC.[18] Using of two-dimensional elution, it was possible to detect from 13 to 22 different compounds in the samples from the block. The detected compounds were identified by GC–MS. Sulfur mustard was found to be the major component of the yperite block. It was determined at a limit of detection of 20 ng per spot. The maximum quantity of sulfur mustard in the analyzed samples did not exceed 26%. Plates with silica gel were used for analysis. The following mobile phases were used: for development in one direction toluene/dichloromethane/*n*-propanol/*n*-hexane (25:25:1:50, v/v) and for development in the second direction diisopropyl ether/chloroform/*n*-hexane (1:1:3, v/v). The chromatograms were visualized by spraying with a reagent containing 4,4′-bis(diethylamino)benzophenone and mercury(II)chloride in ethanol. Better separation results for the components of a mixture and in shorter time were achieved using OPLC, as compared to HPTLC. It is interesting to note that even after staying for approximately 50 years in marine water, the block contained significant amounts of yperite.

The group of necrosis-inducing CWA also includes primary, secondary, and tertiary arsines. These chemical compounds were also analyzed using TLC. Separation of mixtures of these arsines is not difficult, and they can be visualized using Michler's thioketone, iodine, dithizone, and a metacresol purple dye. Using the last reagent it is possible to detect lewisite at the level of 0.05 μg per spot.[19]

ANALYSIS OF IRRITANTS

Chemicals belonging to this group differ in polarity, which requires an appropriate mobile phase on the one hand, and favors their separation on the other. Good separation of a mixture of CS, CA, and CN can be achieved using 5% chloroform in benzene as a mobile phase. Developing the chromatogram with quinone solution yields a yellow CA spot and a blue CS spot. Following additional spraying with 5% NaOH solution, a brown CN spot appears.

DM and diphenylcyanoarsine can be separated using 20% acetone in chloroform and visualized with a solution of 3,3′-dimethoxybenzidine, copper acetate, and 50% H_2SO_4, which yields an orange spot.

CA, CS, and CN present in a single sample become separated when a chromatogram is developed using a mixture of toluene and dichloroethane (1:1). After a plate is sprayed with thiourea and 3,3′-dimethoxybenzidine solution, yellow CA, beige CS, and brown-violet CN spots are obtained. Detectability of these substances is approximately 1 μg per spot.

A mixture of CA, CS, and CN can be using chloroform as a mobile phase. Dragendorff reagent or $KMnO_4$ solution can be used for development. Separation takes place according to the following order of increasing R_F values: CA < CN < CS.

ANALYSIS OF MIXTURES CONTAINING CWA BELONGING TO PARTICULAR GROUPS

In the analysis of a blend of 12 organic phosphorous compounds, necrosis-inducing compounds, and irritants using an enzymatic reaction, besides the spots corresponding to organic phosphorous compounds, spots corresponding to lacrimators CS and CN also appear. Spots of these agents overlap the spots of sarin and soman, and therefore analysis of such a blend should be carried out in two chromatographic systems. In the first one a mixture of *n*-hexane, dioxane, and pyridine (1:1:2) can be used as a mobile phase. Developing the chromatogram using an enzymatic reaction leads to the appearance of GB, GA, GD, VN_1, CS, and CN spots, and spraying the chromatogram with Tollens' reagent leads to the appearance of mustard, CA, CS, CN, and DM spots. In a second system, using dichloroethane and ethyl acetate (7:3) as a mobile phase, separation of CS, CN, DM, and GB as well as GA can be achieved. In this system, R_F values for lacrimators and organic phosphorous toxic agents were clearly different. Chromatogram can be visualized using an enzymatic reaction. Preliminary spraying of the plate with I_2 solution in chloroform increases the sharpness of the silhouettes of spots and makes the visualization of adamsite possible.

Analysis of sulfur mustard can be performed when the compound is contained in a blend of organic phosphorous and/or organic chlorine insecticides.[20] Identification of sulfur mustard was possible by the application of a mobile phase that ensured its good separation from pesticides. For yperite R_F value was high, and for the other components of the blend it was low. Mustard spot was visualized using a selective reagent, e.g., an iodineplatinate ion $[PtJ_6]^{2-}$. This allowed the detection of yperite at the submicrogram level.

CONCLUSIONS

Presented data concerning CWA analysis using TLC method indicate that there are numerous procedures for the separation, identification, and determination of CWA. Analysis using TLC is possible even when CWA are present in mixtures, containing other substances, that can be present in environmental samples. Analyses can be carried out in the mobile laboratories many armies are equipped with.

Although no new methods of CWA analysis have been published recently, analysis methods for chemical compounds similar to CWA by using TLC are being developed. A procedure intended for the analysis of organic phosphorous pesticides described by Hamada and Wintersteiger could be used for the analysis of organic phosphorous toxic agents.[21]

For the analysis of organic phosphorous compounds in human serum after acute poisoning, the procedure proposed by Futagami et al.[22] may be used. They applied HPTLC for the detection of 25 commonly used organic phosphorous insecticides in human serum. These organophosphates were separated on plates with three different separating systems within 6–18 min and detected by means of UV radiation and coloring reactions.

Not only common TLC, but also some of the more advanced techniques can be used for CWA analysis. For example, a combination of TLC with flame ionization detection was suggested for the analysis of phosphorous and sulfur compounds.[23]

Chromatographic plates used for typical TLC analysis of CWA can be used for preliminary, rapid detection of CWA. Chromatograms are not developed in that case, but tested samples in the form of a solution are applied over a layer of adsorbent and then wetted with solutions of appropriate reagents. Appearance of characteristic green spots indicates the presence of a toxic agent in the tested sample.[24]

Chemometrics

Tibor Cserháti
Esther Forgács
Institute of Chemistry, Chemical Research Center, Hungarian Academy of Sciences, Budapest, Hungary

INTRODUCTION

During the last few decades, one of the major advances in chromatography has been the development and commercialization of automated chromatographic instruments. The output of retention data per unit of time has been considerably increased, and the evaluation of large data matrices, containing large amounts of chromatographic information (i.e., retention parameters of a homologous or non-homologous series of solutes, measured on various stationary and mobile phases), is no longer possible without the application of high-speed computers and a wide variety of chemometric techniques. These methods allow the simultaneous evaluation of an almost unlimited amount of data, highly facilitating the clarification of both practical and theoretical problems. These chemometric procedures have been extensively employed in chromatography for the identification of the basic factors influencing retention and separation; for the comparison of various stationary and mobile phases; for the assessment of the relationship between molecular structure and retention behavior [quantitative structure–retention relationship, (QSRR)]; for the elucidation of correlations between retention behavior and biological activity; etc. As each chemometric procedure generally highlights only one, or only a few features of the chromatographic problem under analysis, the concurrent application of more than one technique is rather a rule than an exception.

The objectives of this entry are the enumeration, brief description, and critical evaluation of the recent results obtained in the application of various chemometric techniques in chromatography, and the comparison of the efficacy of various methods for the quantitative description of a wide variety of chromatographic processes. Fundamentals of chemometrics are discussed to an extent to facilitate the understanding of the principles at the application level.[1]

CHEMOMETRIC METHODS IN CHROMATOGRAPHY

Linear Regression Analyses

Linear and various multiple linear regression analysis techniques have been developed for the elucidation of the relationship between one dependent and one or more independent variables.[2] Because of their simplicity and excellent predictive power, they have been successfully applied in various fields of chromatography, such as gas–liquid chromatography (GLC), thin-layer chromatography (TLC), and high-performance liquid chromatography (HPLC).

Linear regression analysis with one independent variable

This simple technique can be employed in the case when the dependence of one parameter (dependent variable, Y) on another parameter (independent variable, X) has to be verified:

$$Y = a + bX \tag{1}$$

The result contains the intercept (a) values, an indicator of the amount of Y when X is equal to zero; slope (b) values measuring the change of Y at unit change of X; and the regression coefficient (r), an indicator of the extent of fit of equation to the experimental data, which serves for the determination of the significance level of the correlation and for the calculation of the variance of Y explained by X. Because of the restricted number of independent variables, the method found is only limited in applications in chromatography. It has been employed for the calculation of the dependence of the retention of one solute and the temperature of a column in GLC, and the concentration of one component in the mobile phase in TLC and HPLC. Furthermore, it can be used for the comparison of the separation characteristics of two (and no more) chromatographic systems. The log k'_o values of commercial pesticides, measured on alumina and on octadecyl-coated alumina columns, have been compared with this technique. They have been used for the calculation of the dependence of retention on the number of ethylenoxide groups of oligomeric non-ionic surfactants on a porous graphitized carbon column; for the study of the effect of salt and pH on the hydrophobicity parameters of surfactant; for the assessment of the relationship between the retention and the hydrophobic surface area of nonylphenyl ethylene oxide oligomers on a polyethylene-coated zirconia HPLC column; for the determination of congenericity of a set of 2,4-dihydroxythiobenzanilide derivatives by reversed-phase (RP) HPLC; etc.

Linear regression analysis with more than one independent variable (multiple linear regression analysis)

When the relationship between one dependent variable and more than one independent variables has to be calculated, Eq. 1 must be modified accordingly:

$$Y = a + b_1X_1 \ldots + b_iX_i \ldots + b_kX_k \quad (2)$$

In this instance, the r value is suitable only for the calculation of the variance of Y, explained by the X values; consequently, for the establishment of the significance level of the correlation, the F value has to be calculated and compared with the tabulated data. The path coefficients (normalized slope values) indicate the relative impact of the individual X values independent of their original dimensions. Because of the possibility to include more variables in the equation, the application field of multiple linear regression is more extended than that of simple linear regression analysis. Thus, it has been recently employed for the investigation of the molecular mechanism of separation, for the classification of modern stationary phases, for structure–retention relationship study in HPLC and in GLC, for the elucidation of the correlation between retention and biological activity, and for the study of the retention mechanism in adsorption and RP TLC. The method found further applications in the study of the effect of cyclodextrins and cyclodextrin derivatives on the retention characteristics of a wide variety of bioactive compounds such as steroidal drugs, in the prediction of chromatographic properties of organophosphorous insecticides, and those of polychlorinated biphenyls in GLC.

Stepwise Regression Analysis

Stepwise regression analysis can be also used when the relationship between one dependent variable and more than one independent variables has to be assessed. In the common multiple linear regression analysis, the presence of independent variables exerting no significant influence on the change of dependent variable considerably decreases the significance level of the equation. Stepwise regression analysis automatically eliminates from the selected equation the dependent variables having no significant impact on the dependent variable, thereby increasing the reliability of calculation. The final form of the results of stepwise regression analysis is similar to Eqs. 1 or 2, depending on the number of independent variables selected by the method. Because of its versatility and simplicity, the method has been frequently used in chromatography. It has found application in the study of the retention behavior of ethylene oxide surfactants and dansylated amino acids in adsorption and RP TLC, in the elucidation of the relative impact of various molecular parameters on the retention in adsorption and RP HPLC and GLC, in the determination of the molecular parameters significantly influencing the interaction of antibiotics with sodium dodecyl sulfate measured by TLC, in the evaluation of the stability of pigments of paprika (*Capsicum annuum*) measured by HPLC, and in the determination of the relative impact of HPLC conditions on the retention behavior.

Partial Least Squares (PLS) Regression

When the independent variables are highly interrelated, the application of traditional methods for the calculation of linear regressions may cause biased and unreliable results. PLS has been developed for the prevention of errors originating from such intercorrelations. PLS has not been frequently employed in the analysis of chromatographic retention data; it has been only used in GLC for the study of the retention behavior of oxo compounds, in HPLC for the QSRR of chalcones, and in RP HPLC for the QSRR study of antimicrobial hydrazides.

Free–Wilson and Fujita–Ban Analysis

These special cases of multiple linear regression analysis have been developed for the determination of the impact of individual molecular substructures (independent variables) on one dependent variable. Both techniques are similar; yet, the Free–Wilson method considers the retention of the unsubstituted analyte as base, while Fujita–Ban analysis uses the less substituted molecule as reference. These procedures have not been frequently employed in chromatography; only their application in QSRR studies in RP TLC and HPLC have been reported.

Canonical Correlation Analysis (CCA)

CCA can be considered as a special case of multiple linear regression analysis, when the relationship between minimally more than one dependent variable (matrix I) and minimally more than one independent variable (matrix II) has to be elucidated. CCA acalculates the relationships between matrices I and II by extracting theoretical factors which explain the maximum of variance of the matrix with the lower number of variables. However, it can be employed only in the instances when the number of dependent variables is lower than that of independent variables. The maximal number of equations selected by CCA is equal to the number of columns in the smaller set of data. The results consist of the standard and weighted canonical coefficients (they are similar to the b values and path coefficients of Eq. 2), of the r values related to the ratio of variance explained by the equations, and of the X (Greek Chi) value, indicating the fitness of equation to the experimental data. Despite its evident benefits, the technique has not been frequently employed for the analysis of chromatographic data. It has been applied for the elucidation of the relationship between the retention parameters of ring-substituted aniline derivatives determined on

various HPLC columns (smaller matrix) and their calculated physicochemical parameters (larger matrix), for the study of the relationship between the physicochemical parameters of steroidal drugs and their retention characteristics in HPLC, and for the assessment of the correlation between the physicochemical parameters of tetrazolium salts and their retention behavior in various TLC systems.

Multivariate Mathematical–Statistical Methods

The prerequisite of the application of the regression analytical methods discussed above is that one or more chromatographic parameters have to be considered as being the dependent variables. However, when the simultaneous relationships among more retention parameters, or more retention parameters and more physicochemical parameters of a given set of analytes have to be elucidated, the linear regression methods cannot be employed. A considerable number of multivariate methods have been developed to overcome the disadvantages of regression analyses.[3] Various multivariate mathematical–statistical methods have been successfully employed for the elucidation of the relationship between the retention parameters and the structural descriptors of solutes for the comparison of more than two stationary phases, for the prediction of solute retention, for the assessment of the correlation between retention characteristics and biological activity, etc. As the information content of the mathematical–statistical methods considerably depends on the mode of calculation, the character of the problem to be elucidated limits, to some extent, the choice of the method.

Principal Component Analysis (PCA)

PCA can be used when the inherent relationships between the columns and rows of a data matrix have to be determined without one (stepwise regression analysis) or more (CCA) being the selected dependent variables. PCA is a versatile and easy-to-use multivariate mathemathical–statistical method. It has been developed to contribute to the extraction of maximal information from large data matrices containing numerous columns and rows. PCA makes possible the elucidation of the relationship between the columns and rows of any data matrix without being one the dependent variable. PCA is a so-called projection method representing the original data in smaller dimensions. It calculates the correlations between the columns of the data matrix and classifies the variables according to the coefficients of correlation. The results of PCA generally contain the so-called eigenvalues which are related to the relative importance of the principal components calculated by PCA, the variance explained by the individual PCs, and the contributions (impacts) of the columns and rows of the original matrix to the principal component loadings and variables, respectively. Unfortunately, PCA does not define the principal components as concrete physical or physicochemical entities; it only indicates its mathematical possibility. Calculating linear regression between the principal component loadings and the chromatographic parameters and physicochemical characteristics may help the determination of the concrete constitution of principal components. Stepwise regression analysis is especially adequate to carry out such types of calculations.

Because of its simplicity, PCA has been frequently used in many fields of up-to-date chromatographic research. Thus, PCA has been employed for the evaluation of molecular lipophilicity, for QSRR studies, for the testing of the authenticity of edible oils, for the determination of the botanical origin of cinnamon, for the differentiation of Spanish white wines, for the characterization of RP supports, for the assessment of the relationship between molecular structure and retention behavior, etc. The method has found further applications in the classification of chili powders according to the distribution of pigments separated by TLC, in the determination of the molecular parameters of peptides and barbituric acid derivatives showing a significant impact on their retention on porous graphitized carbon column, in QSRR study of pesticide retention on polyethylene-coated silica column, in the study of the retention characteristics of titanium dioxide and polyethylene-coated titanium dioxide stationary phases, in the comparison of alumina stationary phases in TLC and HPLC, in the elucidation of the relationship between the retention of environmental pollutants on an alumina HPLC column and their physicochemical parameters, and in the study of the energy of interaction between commercial pesticides and a non-ionic surfactant by GLC.

Spectral Mapping (SPM) Technique

The calculation methods discussed above classify the chromatographic systems (stationary and mobile phases) or solute molecules while simultaneously taking into consideration the retention strength and retention selectivity; thus, it cannot be applied when the separation of the strength and selectivity of the effect is required. SPM, another multivariate mathematical–statistical method, overcomes this difficulty.[4]

The SPM divides the information into two matrices using the logarithm of the data in the original matrix. The first one is a vector containing so-called potency values proportional to the overall effect; that is, it is a quantitative measure of the effect. The second matrix (selectivity map) contains the information related to the spectrum of activity, i.e., the qualitative characteristics of the effect. SPM first calculates the logarithm of the members of the original data matrix, facilitating the evaluation of the final plots in terms of log ratios. Subsequently, SPM subtracts the corresponding column-mean and row-mean from each logarithmic element of the matrix calculating potency values. The source of variation remaining in the centered data set can be evaluated graphically (selectivity map). This elegant and versatile calculation method has been used in chromatography for

the characterization of stationary phases in TLC and HPLC, for the separation of the solvent strength and selectivity on a cyclodextrin-coated HPLC column using monoamine oxidase inhibitory drugs as solutes, for the investigation of the complex interaction between anticancer drugs and cyclodextrin derivatives, for the determination of the influence of storage conditions on pigments analyzed by HPLC, for the comparison of polymer-coated HPLC columns, and for the optimization of the microwave-assisted extraction of pigments for HPLC analysis.

Cluster Analysis (CA) and Non-linear Mapping (NLM) Technique

Although both the PCA and the SPM techniques reduce the number of variables, the resulting matrices of PC loadings and variables and the spectral map are still multidimensional. The plot of PC loadings in the first vs. the second principal component has been frequently used for the evaluation of the similarities and differences among the observations. This method takes into consideration only the variance explained in the first two principal components and entirely ignores the impact of variances explained by the other principal components on the distribution of the matrix elements. The use of this approximation is only justified when the first two principal components explain the overwhelming majority of variance, which is not probable in the case of large original data matrices. As the evaluation of the distribution of data points in the multidimensional space is extremely difficult, calculation methods were developed for the reduction of the dimensionality of the matrices to one (CA) or to two (NLM). These methods can also be employed for the reduction of the dimensionality of the original data matrices before any other mathematical–statistical evaluation. CA has been employed for the elucidation of the retention behavior of anti-hypoxia drugs in adsorption TLC, that of barbituric acid derivatives and anti-inflammatory drugs in HPLC, for the classification of pharmaceutical substances according to their retention data, for the prediction of retention of phoshoramidate derivatives, etc.

However, both CA and NLM take into consideration the positive and negative sign of the coefficient of correlation and carry out the calculation accordingly. Therefore, the highly but negatively correlated points are far away on the maps and on the cluster dendograms in the same manner as the points that are not correlated. This procedure leads to correct assumptions in the case when the scientist is interested only in the positive correlations among variables and observations. To evaluate precisely the relationships between the points without taking into consideration the positive or negative character of the correlation, it is advisable to carry out the calculations with the absolute values of PC loadings and variables. The validity of this experimental approximation has been proven in the evaluation of the interaction of non-steroidal anti-inflammatory drugs with a model protein studied by HPLC, and the parallel application of the original PC loadings and their absolute values in the data reduction techniques has been proposed. This procedure has been successfully used for the study of the effect of carboxymethyl-β-cyclodextrin on the hydrophobicity parameters of steroidal drugs measured by TLC, and for the assessment of the binding characteristics of environmental pollutants to the wheat protein, gliadin, investigated by HPLC.

The distances between the elements on the cluster dendograms and NL maps are a quantitative measure of similarity: Smaller distances indicate greater similarity. However, the fact that the differences among the elements are significant or not cannot be established on the traditional NL map or on the cluster dendogram. A graphical approximation has been developed for the inclusion of standard deviation in the NL maps and cluster dendograms. The data matrix for PCA has been composed from the main values of the matrix elements, the mean values minus twice their standard deviation, and the mean values plus twice their standard deviation. PCA has been carried out, and the cluster dendograms and NL maps have been calculated. A circle can be formed from the mean values and the mean value $\pm$ two standard deviations on the NL map, the center of the circle being the mean, and the radius of the circle being represented by the mean $\pm$ two standard deviations. It was assumed that the differences between the elements on the map are significant at the 95% significance level when the circles do not overlap. It was further assumed that the mean value and mean value $\pm$ two standard deviations of the matrix elements are close to each other (form a triad) on the cluster dendogram when they significantly differ from the others. The method has been employed for the classification of paprika (*C. annuum*) powders according to their pigment composition as determined by HPLC and for the comparison of HPLC and TLC systems.

Miscellaneous Multivariate Methods

The chemometric methods discussed above have found widespread applications in chromatography, and many theoretical and practical chromatographers have become familiar with these techniques and have applied them successfully. However, other less well-known methods have also found applicability in the analysis of chromatographic retention data. Thus, canonical variate analysis has been applied in pyrolysis GC/MS,[5] artificial neural network for the prediction of GLC retention indices, and factor analysis for the study of the retention behavior of *N*-benzylideneaniline derivatives.[6]

CONCLUSIONS

The examples enumerated above prove conclusively that chemometric techniques can be effectively employed for the elucidation of a large number of problems in

chromatography, connected with the accurate and precise evaluation of large data matrices.

These methods allow not only the classification and clustering of any set of chromatographic systems but also exact determination of the relationship between the characteristics (physicochemical parameters or molecular substructures) of solutes and their retention behavior. It can be further concluded that chemometry considerably promotes a more profound understanding of the basic processes underlying chromatographic separations, increasing, in this manner, the efficiency (reliability, rapidity, etc.) of the methods.

Chiral CCC

Ying Ma
Yoichiro Ito
National Heart, Lung, and Blood Institute (NHLBI), National Institutes of Health (NIH), Bethesda, Maryland, U.S.A.

INTRODUCTION

Countercurrent chromatography (CCC) can be used for the separation of a variety of enantiomers by adding a chiral selector to the liquid stationary phase.[1,2] The method is free of complications arising from the use of a solid support and also eliminates the procedure of chemically bonding the chiral selector to a solid support as in conventional chiral chromatography.

In the past, various CCC systems, such as droplet CCC, rotation locular CCC (RLCCC), and centrifugal partition chromatography (CPC), have been used for the separation of chiral compounds. None of those techniques, however, is considered satisfactory for preparative purposes in terms of sample size, resolution, and/or separation time. In the early 1980s, the high-speed CCC (HSCCC) technique improved both the partition efficiency and separation time and has been successfully applied to the separation of racemates using a Pirkle-type chiral selector. Both analytical (milligram) and preparative (gram) separations can be performed simply by adjusting the amount of chiral selector in the liquid stationary phase in the standard separation column. A large-scale separation of enantiomers can also be performed by pH-zone-refining CCC, a recently developed preparative CCC technique for the separation of ionized compounds.[3] One of the important advantages of the CCC technique over the conventional chiral chromatography is that the method allows computation of the formation constant of the chiral-selector complex, one of the most important parameters for studies of the mechanism of enantioselectivity.[4]

STANDARD HIGH-SPEED CCC TECHNIQUE IN CHIRAL SEPARATION

The separations are performed using a commercial high-speed CCC centrifuge equipped with a multilayer coil separation column(s). The column is first entirely filled with the stationary phase that contains the desired amount of chiral selector (CS). In order to prevent the contamination of CS in the eluted fractions, some amount of the CS-free stationary phase should be left at the end of the column, typically at about 10% of the total column capacity. After the sample solution is injected through the sample port, the mobile phase is pumped into the column while the column is rotated. Separation can be carried out by the successive injection of samples without renewing the stationary phase containing the chiral selector in the column.

Figure 1 shows the separation of four pairs of DNB–amino acid enantiomers by the standard CCC technique using a two phase solvent system composed of hexane–ethyl acetate–methanol–10 m*M* HCl and *N*-dodecanoyl-L-3,5-dimethylanilide as a CS which is almost entirely partitioned into the organic stationary phase ($K > 100$) due to its high hydrophobicity. All analytes are well resolved in 1–3 hr. The CS used in this separation is similar to the chiral stationary phase which has been introduced by Pirkle et al. for the high-performance liquid chromatography (HPLC) separation of racemic DNB–amino acid *t*-butylamide. A hydrophobic *N*-dodecanoyl group is connected to the CS molecule for retaining the CS in the organic stationary phase.

The effect of CS concentration in the stationary phase was investigated.[1] As the CS concentration is increased, the separation factor and peak resolution are also increased.[5] The result clearly indicates an important technical strategy: The best peak resolution is attained by saturating the CS in the stationary phase in a given column, where the resolution is further improved by using a longer and/or wider-bore coiled column, which can hold greater amounts of CS in the stationary phase.

The preparative capability of the present system is demonstrated in the separation of DNB–leucine enantiomers by varying the CS concentration in the stationary phase. The sample loading capacity is found to be determined mainly by the CS concentration or total amount of CS in the stationary phase; that is, the higher the CS concentration in the stationary phase, the greater the peak resolution and sample loading capacity. Consequently, the standard HSCCC column can be used for both analytical and preparative separations simply by adjusting the amount of CS in the stationary phase.

pH-ZONE-REFINING CCC FOR CHIRAL SEPARATION

pH-Zone-refining CCC is a powerful preparative technique that yields a succession of highly concentrated

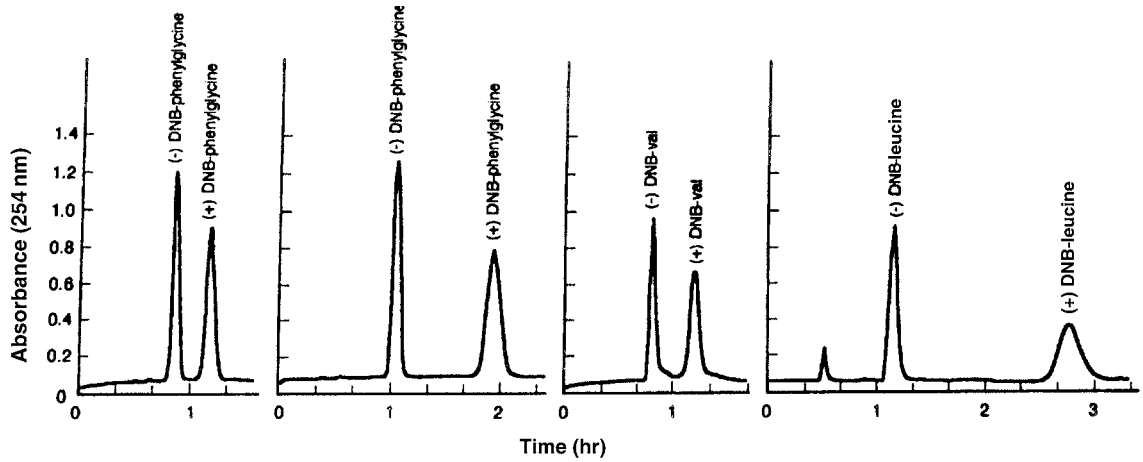

Fig. 1 Separation of four pairs of (±)-DNB–amino acids by the standard analytical HSCCC technique with a CS (*N*-dodecanoyl-L-proline-3,5-dimethylanilide) in the stationary phase.

rectangular solute peaks with minimum overlap where impurities are concentrated at the peak boundaries (see *pH-Peak-Focusing pH-Zone-Refining CCC*, p. 1808). This technique was applied to the resolution of DNB–amino acid racemates using a binary two-phase solvent system composed of methyl *t*-butyl ether–water where trifluoroacetic acid (retainer) and CS were added to the organic stationary phase and ammonia (eluter) to the aqueous mobile phase. Figure 2 shows a typical chromatogram obtained by pH-zone-refining CCC. The pH of the fraction (dotted line) revealed that the peak was evenly divided into two pH zones, each corresponding to a pure enantiomeric species with a sharp transition. Compared with the standard CCC technique, the pH-zone-refining CCC technique allows separation of large amounts in a shorter elution time.

In both techniques, leakage of the chiral selector into the elute can be completely eliminated by filling the outlet of the column with a proper amount of the CS-free stationary phase so as to absorb the chiral selector leaking into the flowing mobile phase.

ADVANTAGES

Countercurrent chromatography can be applied to the separation of enantiomers by adding a suitable chiral selector to the liquid stationary phase by analogy to binding the

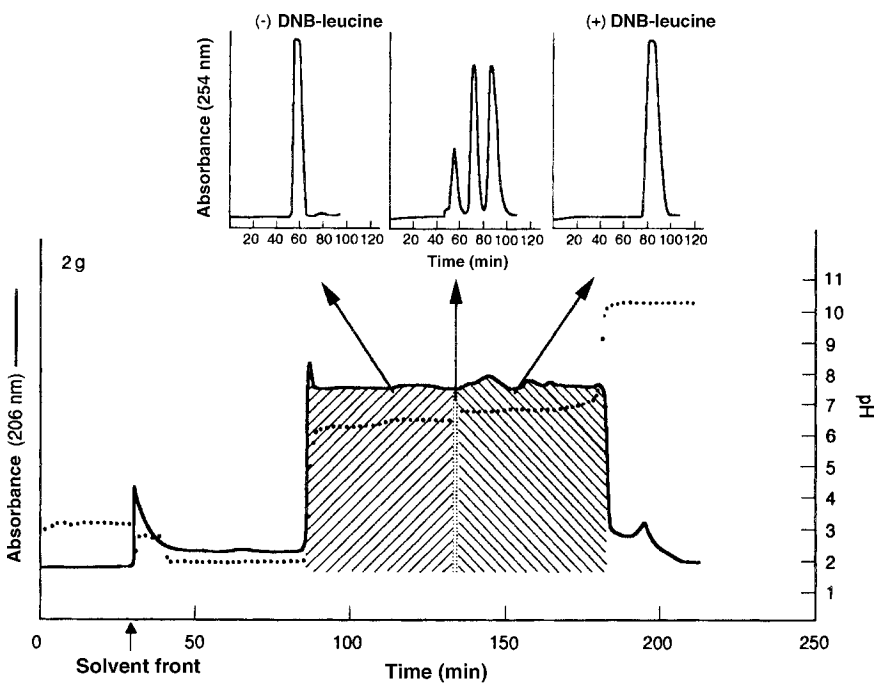

Fig. 2 pH-Zone-refining CCC separation of 2 g (±) DNB–leucine using the same HSCCC centrifuge with a CS (*N*-dodecanoyl-L-proline-3,5-dimethylanilide) in the stationary phase.

CS to the solid support in conventional chiral chromatography. The HSCCC technique has the following advantages over the conventional chromatography technique:

1. The method permits repetitive use of the same column for a variety of chiral separations by choosing appropriate CSs.
2. Both analytical and preparative separations can be performed with a standard CCC column by adjusting the amount of CS in the liquid stationary phase, and the method is cost-effective, especially for large-scale preparative separations.
3. The separation factor and peak resolution can be improved simply by increasing the concentration of CS in the stationary phase.
4. The method is very useful for the investigation of the enantioselectivity of CS including determination of the formation constant and separation factor.
5. pH-Zone-refining CCC can be applied for gram-quantity separation in a short elution time.

Chiral Chromatography by Subcritical and SFC

Gerald J. Terfloth
Research and Development Division, SmithKline Beecham Pharmaceuticals, King of Prussia, Pennsylvania, U.S.A.

INTRODUCTION

The intrinsic physical properties of supercritical fluids—increased diffusivity and reduced viscosity—when compared to "normal" liquid phases make sub-/supercritical fluid chromatography a very attractive technology when short cycle times are required. Chiral sub-/supercritical fluid chromatography typically is carried out using packed columns (pSFC) that frequently are identical in mechanical construction to the ones used in traditional high-performance liquid chromatography (HPLC). It should be noted, though, that capillary columns coated or packed with a chiral stationary phase (CSP) have been used for the separation of racemic mixtures. The direct separation of racemic mixtures by chromatographic means can be effected by using a CSP or chiral mobile phase additives. Both techniques have been used successfully in HPLC and pSFC. The use of chiral pSFC is not limited to analytical applications. The relative ease of solvent removal and recycling, typically carbon dioxide modified with a polar organic solvent such as methanol, makes pSFC a very attractive tool for preparative separations. Equipment for laboratory- and industrial-scale pSFC in traditional discontinuous batch-chromatography mode as well as continuous simulated moving bed (SMB) mode has been developed and is commercially available. pSFC can be used as an orthogonal method when techniques such as reversed-phase HPLC, capillary electrophoresis, or capillary electrochromatography provide insufficient or ambiguous results.

CHARACTERISTICS AND ADVANTAGES OF SUBCRITICAL AND SUPERCRITICAL FLUIDS

The advantages of using supercritical mobile phases in chromatography were recognized in the 1950s by Klesper et al.,[1] among others.[2] Carbon dioxide is the most frequently used supercritical mobile phase due to its moderate critical temperature and pressure, almost complete chemical inertness, safety, and low cost. Virtually all chiral pSFC separations published have used carbon dioxide as the primary mobile phase component. Compared to most commonly used organic solvents, it is environmentally friendly. The reduced viscosity of carbon dioxide-based mobile phases, typically one order of magnitude less than that of water (0.93 cP at 20°C), allows for efficient chromatography at higher flow rates. In addition, diffusion coefficients of compounds dissolved in supercritical mobile phases are about one order of magnitude larger than in traditional aqueous and organic mobile phases [D_M(naphthalene): 0.97×10^{-4} cm^2/sec in CO_2 at 25°C, 171 bar, 0.90 g/cm]. This directly translates to higher efficiency of the separation due to improved mass transfer.

The first chiral separation using pSFC was published by Caude and colleagues[3] in 1985. pSFC resembles HPLC. Selectivity in a chromatographic system stems from different interactions of the components of a mixture with mobile phase and stationary phase.[4] Characteristics and choice of the stationary phase are described in the "Method Development" section. In pSFC, the composition of the mobile phase, especially for chiral separations, is almost always more important than its density for controlling retention and selectivity. Chiral separations are often carried out at $T < T_c$ using liquid modified carbon dioxide. However, high linear velocity and low pressure drop typically associated with supercritical fluids are retained with near critical liquids. Adjusting pressure and temperature can control the density of the sub-/supercritical mobile phase. Binary or ternary mobile phases are commonly used.[5] Modifiers, such as alcohols, and additives, such as acids and bases, extend the polarity range available to the practitioner.

A typical pSFC instrument, at first glance, is designed like an HPLC system. The major differences are encountered at the pump, the column oven, and downstream of the column. pSFC is best carried out using pumps in a flow-control mode. A regulator mounted downstream of the column and ultraviolet (UV)/visible detector controls the pressure drop in the chromatographic system. Detection is not limited to UV. If pure carbon dioxide is used as the mobile phase, an easy-to-use, sensitive, and stable universal detector such as the FID can be employed. Other detection techniques are FTIR and evaporative light scattering detection (ELSD), or hyphenated techniques such as pSFC/MS and pSFC/NMR. Temperature control of mobile phase and column is achieved by a column oven allowing for operation under cryogenic conditions and/or from ambient temperature to 150°C. Capillary column supercritical fluid chromatography (cSFC), though, resembles gas chromatography (GC) at high pressures, with the pressure (density) programming

taking the place of temperature programming in GC. Typical operating temperatures are up to 100°C.

METHOD DEVELOPMENT

Mechanistic considerations, e.g., the extensive work published on brush-type phases, or the practitioner's experience might help to select a CSP for initial work.[6] Scouting for the best CSP/mobile phase combination can be automated by using automated solvent and column switching. More than 100 different CSPs have been reported in the literature to date. Stationary phases for chiral pSFC have been prepared from the chiral pool by modifying small molecules like amino acids or alkaloids, by the derivatization of polymers such as carbohydrates, or by bonding of macrocycles. Also, synthetic selectors such as the brush-type ("Pirkle") phases, helical poly(meth)acrylates, polysiloxanes and polysiloxane copolymers, and chiral selectors physically coated on graphite surfaces have been used as stationary phases.

Generally accepted starting conditions are summarized in Table 1. Typically, alkanol-modified carbon dioxide is used as the mobile phase. Depending on the nature of the analyte, acids or bases can be added to the modifier for controlling ionization of stationary phase and analyte. If partial selectivity is observed after the first injection, it is advisable to first adjust the modifier concentration. If the peak shape is not satisfactory, then the addition of 0.1% trifluoroacetic acid or acetic acid for acidic compounds or 0.1% diethylamine or triethylamine for basic compounds to the modifier can bring about an improvement. In case the selectivity cannot be improved by the previous measures, decreasing the operating temperature can result in the desired separation. Although many chiral separations improve as the temperature is reduced, this does not occur in all cases. The temperature dependence of the selectivity does not necessarily follow the van't Hoff equation ($\ln \alpha \propto 1/T$), as one might expect based on experience with other chromatographic techniques. Stringham and Blackwell,[7] who have reported several examples of entropically driven separations, studied the effects of temperature in detail. In the temperature range between –10, 70 (T_{iso}), and 190°C, a reversal of elution order for the enantiomers of a chlorophenylamide was observed on an (*S*,*S*) -Whelk-O 1 CSP using 10% ethanol in carbon dioxide at a pressure of 300 bar. The potential for reversing the elution order can be valuable if just one enantiomer of the CSP affecting the separation is available. If all of the above adjustments should fail, a different CSP should be investigated. Due to the low viscosity of carbon dioxide-based mobile phases, multiple columns can be coupled. This provides the opportunity to increase chemical selectivity for the analysis of complex samples by coupling an initial achiral column with a chiral column.[8] Also, the successful coupling of multiple different chiral columns has been reported.

Table 1 Initial conditions for chiral method development using modified carbon dioxide as the mobile phase.

Parameter	Unit	Value
Flow rate	ml/min	2.0
Pressure	bar	200
Temperature	°C	30
Methanol	%	5
Gradient	%/min	5
Gradient time	min	10
Injection volume	μl	5
Sample concentration	mg/ml	1
Detection	Diode array detector, 190–320 nm	

CONCLUSIONS

Analytical applications of chiral pSFC in chemical and pharmaceutical research, development, and manufacturing comprise screening of combinatorial libraries, monitoring chemical and biological transformations from the laboratory to the process scale, following stereochemical preferences of drug metabolism and pharmacokinetics, and assessing toxicology and stability of drug substance and dosage form. Preparative applications are of considerable interest because of the relative ease with which the mobile phase can be removed and recycled. This is of particular interest in the pharmaceutical environment since a small amount of the desired product can be obtained almost free of solvent quite rapidly. Recent advances in automation and separation technology now allow for a predictable scale-up of the separation from a laboratory to a production scale.

Chiral Compounds: Separation by CE and MEKC with Cyclodextrins

Bezhan Chankvetadze
Department of Physical and Analytical Chemistry and Molecular Recognition and Separation Science Laboratory, School of Exact and Natural Sciences, Tbilisi State University, Tbilisi, Georgia

Abstract
This entry summarizes the application of cyclodextrins (CDs) for separation of enantiomers by using capillary electrophoresis (CE) [capillary electrokinetic chromatography (CEKC) and micellar electrokinetic chromatography (MEKC)]. Together with major properties of cyclodextrins as very useful chiral selectors, some mechanistic aspects of enantioseperations by using CE techniques are also emphasized.

INTRODUCTION

Cyclodextrins (CDs) and their derivatives represent a unique group of chiral selectors applicable for enantioseparations in almost all instrumental separation techniques such as gas chromatography (GC), high-performance liquid chromatography (HPLC), super/subcritical fluid chromatography (SFC), and capillary electrophoresis (CE). CDs are non-reducing, cyclic oligosaccharides produced enzymatically from starch. The most widely applied native α-, β-, and γ-CDs are constructed from six, seven, and eight glucose units bonded through 1, 4-α linkages, respectively. The inner cavity of the CDs, which is lined with hydrogen atoms and glycoside oxygen bridges is hydrophobic, which favors hydrophobic interactions between a guest and the CD host in aqueous medium. The outer CD rims are formed by the secondary 2- and 3- and the primary 6-hydroxyl groups. The location of the polar hydroxyl groups on the outer rim determines the solubility of the CDs in aqueous solutions as well as hydrogen bonding, and other polar interactions preferably in non-aqueous medium. The intramolecular hydrogen bonding between the secondary C(2) and C(3) hydroxyl groups of adjacent D-glucopyranosyl residues stabilizes the structure of the CD macrocycle.

DISCUSSION

The ability of CDs to form intermolecular complexes with other molecules was already known in the early twentieth century. These complexes are mostly of inclusion type but might also be of "external" type. Another important property of CDs is that each glucose molecule in this macrocycle contains five chiral carbon atoms, which results in a chiral recognition ability in complex formation. This property of CDs was first evidenced by Cramer in 1952.[1] Relatively easy availability from regenerable natural sources, existence in various sizes, stable structure, localized hydrophobic and hydrophilic areas, solubility in the hydrophilic solvents, ability of intermolecular complex formation, and chiral recognition ability together with their non-toxicity, transparency for UV-light, and feasibility of their modification contributed greatly to the establishment of CDs as major chiral selectors in CE and CD-modified micellar electrokinectic chromatography (CD–MEKC) separation of enantiomers.

The first applications of CDs as chiral selectors in CE were reported in capillary isotachophoresis (CITP)[2] and capillary gel electrophoresis (CGE).[3] Soon after, Fanali described the application of CDs as chiral selectors in the so-called free-solution CE[4] and Terabe used the charged CD for enantioseparations in the capillary electrokinetic chromatography (CEKC) method.[5] It seems important to note that although the experiments in CITP, CGE, CE, and CEKC are different from one another, the enantiomers in all of these techniques are mainly resolved based on the same (chromatographic) principle, i.e., a stereoselective distribution of enantiomers between two (pseudo)phases with different mobilities. Thus, enantioseparations in CE are commonly based on an electrophoretic migration principle and on a chromatographic separation principle.[6] Exceptions from this mechanism are also possible as is shown below.[6,7]

Separation of enantiomers in CE significantly differs from true electrophoretic separations that are based on the difference in charge-to-mass (size) ratio between the analyte molecules. These peculiarities need to be considered when looking at the differences between enantioseparations with uncharged and charged chiral selectors

respectively, and between enantiomer separations in capillary zone electrophoresis (CZE) and MEKC, for the evaluation of the role of the electro-osmotic flow (EOF) in enantiomer separations in CE, and so forth.

The separation of enantiomers in CE means that they reach a detection window at different periods of time after their simultaneous injection at the capillary inlet. Thus, to be separated by CE, the enantiomers must migrate with different velocities along the longitudinal axis of a separation capillary. For species possessing different charge-to-mass (size) ratios, this occurs automatically after a voltage is applied between the ends of the separation capillary. However, enantiomers do not differ from each other in terms of their effective charge-to-mass ratio in an achiral medium. Therefore, in order to achieve enantioseparations, the addition of chiral substances—the so-called chiral selectors—to the background electrolyte (BGE) is required. If a chiral selector interacts stereoselectively with enantiomers of an analyte, this secondary equilibrium can generate a velocity or mobility difference between the enantiomers of a chiral analyte ($\Delta\mu$) that can be calculated using the following equation:[8]

$$\Delta\mu = \mu_R - \mu_S = \frac{\mu_f + \mu_{cR}K_R[C]}{1 + K_R[C]} - \frac{\mu_f + \mu_{cS}K_S[C]}{1 + K_S[C]} \quad (1)$$

where μ_R and μ_S are the observed mobilities of R and S enantiomers, respectively, μ_f is the mobility of the analyte enantiomers in the non-complexed form, K_R and K_S are the complexation equilibrium constants of the R and S enantiomers with the chiral selector, μ_{cR} and μ_{cS} are the mobilities of the respective temporary diastereomeric complexes between the chiral selector and the R and S enantiomers, respectively, and [C] is the concentration of the chiral selector. As mentioned above, the mobilities of the free enantiomers in an achiral medium are equal. For many years it was assumed that the mobilities of the temporary diastereomeric associates also do not differ significantly ($\mu_{cR} = \mu_{cS}$), while the association constants of R and S enantiomers with the chiral selector may be different ($K_R \neq K_S$).

This enabled the simplification of Eq. 1 to the following equation:[8,9]

$$\Delta\mu = \frac{(\mu_f - \mu_c)(K_S - K_R)[C]}{1 + (K_R + K_S)[C] + K_R K_S[C]^2} \quad (2)$$

This simplified equation was widely used in enantiomer separations in CE and favored the establishment of the idea that no enantioseparation is possible in CE without a difference between the association constants of the two enantiomers with the chiral selector. In addition, Eq. 2 was also used to calculate the concentration of the chiral selector that will induce the maximal mobility difference between the enantiomers.[10,11]

Contrary to above-mentioned assumption, a few earlier studies indicated that the mobilities of the diastereomeric associates of two enantiomers with the chiral selector are not always equal to each other.[12,13] In 1997, a theoretical assumption was made that two enantiomers can be resolved in CE even when their association constants with the chiral selector are equal to each other ($K_R = K_S = K$).[6] The prerequisite for enantiomer separation in this particular case is the non-zero difference between the mobilities of temporary diastereomeric associates ($\mu_{cR} \neq \mu_{cS}$). Under these conditions Eq. 1 transforms to Eq. 3.[7,14]

$$\Delta\mu = \frac{K[C](\mu_{cR} - \mu_{cS})}{1 + K[C]} \quad (3)$$

The theoretical possibility of enantiomer separation even in the case of equal affinity of the enantiomers to a chiral selector is a conceptual difference between chromatographic techniques and CE.[6,7,14,15]

As shown in Eq. 2, in separations based on the difference between the affinities of the enantiomers to the chiral selector ($K_R \neq K_S$), the other necessary requirement for enantioseparation is a mobility difference between the free and the complexed analyte ($\mu_f - \mu_c \neq 0$). Otherwise, it will be impossible to generate a chiral separation based on chiral recognition. This prerequisite is not met when neutral analytes are analyzed with uncharged chiral selectors. Therefore, enantiomers of neutral chiral analytes cannot be resolved with uncharged chiral selectors in CE. However, in this particular case, an additional charged component can be added to the BGE which can assist in generating a difference between the mobilities of the analyte in its free and complexed forms. This is achieved by an achiral micellar phase in CD-modified micellar electrokinetic chromatography.[16] However, a charged CD[17] or a charged chiral micellar phase can combine both of the above-mentioned functions (chiral recognition and the mobility difference between free and complexed analyte) of a neutral CD and a micellar phase.

Depending on the experimental conditions, the EOF may contribute significantly to the mobility of analytes in CE. The EOF is considered to be a non-selective mobility and this is true but only for those separations that are based on the mobility difference of diastereomeric associates (described by Eq. 3). However, for enantioseparations based on different affinities of the enantiomers to the chiral selector, both the EOF and the electrophoretic mobility of the analyte are inherently non-enantioselective. The enantioselective analyte–selector interactions may turn both of

these mobilities into a selective transport mechanism with equal success. This is the principal difference between the roles of the EOF in true electrophoretic separations and in chiral CE separations.

The principal mechanism for separation of enantiomers in CE is enantioselective selector–analyte interactions. The enantioselectivity might be reflected in the binding constants, in the mobilities of diastereomeric associates, or in both simultaneously.

One of the important technical advantages of CE as compared to other instrumental enantioseparation techniques, apart from its extremely high peak efficiency, miniaturized size, low costs, and less environmental problems, is its high flexibility. Separation in different modes can be performed using the same instrumental setup, and it takes just a few minutes to change from one chiral selector to another, to combine two or more chiral selectors, or to vary the concentration of a chiral selector. These variations are impossible or very time-consuming in chromatographic techniques.

The number of variables available for adjustment of separations is higher in CE compared with chromatographic techniques, and these include the type and concentration of the chiral selector, pH of the BGE, concentration and type of the buffer, achiral buffer additives, capillary dimensions and nature of its inner surface, EOF, temperature, and so forth.

Owing to high theoretical plate numbers, CE makes it possible to observe even very weak (enantio) selective effects in intermolecular interactions that are not detectable using other techniques. This important advantage of CE is not yet effectively exploited for studies of noncovalent intermolecular interactions.

CDs are commercially available in various sizes (α, β, γ), carrying different functionalities, with different substitution pattern, different electric charge, and so forth. At present, β-CD and its neutral and ionic derivatives are considered to be the most suitable chiral selectors in CE. However, α- and γ-CD sometimes offer complementary chiral recognition ability to that of β-CD.[7,9,19] Among the native CDs, β-CD is characterized with the lowest solubility in aqueous solutions. Therefore, the neutral derivatives carrying alkyl and hydroxyalkyl substituents that possess a higher solubility in aqueous buffers and sometimes offer complementary chiral recognition properties are widely used as chiral selectors in CE. Among the neutral CD derivatives, single-component heptakis-(2,6-di-*O*-methyl)-β-CD, heptakis-(2,3-diacetyl)-β-CD, and heptakis-(2,3-6-tri-*O*-methyl)-β-CD generate special interest. Many

Table 1 Enantiomer affinity pattern of selected chiral analytes to native and selectively methylated CDs.

	Chiral selector and the first-migrating enantiomer		
Analyte	**β-CD**	**DM-β-CD**	**TM-β-CD**
Aminoglutethimide	S	S	R
Brompheniramine	(−)	No separation	(+)
Chlorpheniramine	(−)	(+)	(+)
Dimethindene	S	R	R
Ephedrine	(+)	(−)	(−)
Ketoprofen	R	No separation	(S)
Metaraminol	(+)	(−)	(+)
Tetramisole	R	R	S
Verapamil	(−)	(−)	(+)

chiral compounds exhibit the opposite affinity pattern toward the last two derivatives as compared with native β-CD (Fig. 1 and Table 1). This is of practical importance when the adjustment of enantiomer migration order is desired based on the analytical challenge.[9] In addition, the elucidation of the molecular mechanisms of this phenomenon can markedly contribute to a better understanding of the nature of forces determining the binding of the chiral analytes to CDs and their enantioselective recognition.

Ionic derivatives of CDs represent another group of effective chiral selectors in CE.[6,9,17] They offer the following advantages for enantioseparations: 1) enhanced solubility in aqueous buffers; 2) self-electrophoretic mobility enabling their application also for enantioseparation of neutral analytes; 3) presence of additional functional groups for alternative and more intense intermolecular interactions; 4) their use as chiral carriers; 5) higher separation power toward enantiomers of chiral analytes carrying the opposite electric charge, which is not only due to more tight electrostatic interaction but also due to the countercurrent mobility of an analyte and a selector; 6) easier online coupling of chiral CE with mass spectrometry (MS); and so forth.

Charged CD derivatives are commercially available with cationic and anionic groups. Among cationic CDs, randomly substituted 2-hydroxypropylammonium salt of β-CD and 6-monoamino-6-monodeoxy-β-CD have been intensively studied as chiral selectors in CE.[9] Cationic CD derivatives tend to be adsorbed to the negatively charged inner surface of a fused-silica capillary and reverse the direction of EOF from the cathode to the anode. Therefore, these derivatives need to be used with capillaries having neutral or positive inner-wall coatings. The number of randomly substituted and well-characterized single-component cationic CD derivatives has increased in the last few years. Despite this, anionic derivatives of CDs are still more widely used as charged chiral selectors in CE.

Among the anionic CDs, randomly substituted carboxyalkyl, sulfoalkyl, and sulfate derivatives became commercially available earlier and played an important role in the development of chiral CE.[6,9,18] However, all randomly substituted uncharged and charged derivatives of CDs suffer from the disadvantages of being a multicomponent mixture. The individual components of these mixtures may exhibit different enantiomer-resolving properties. In rare cases, even the opposite migration order of the enantiomers has been reported depending on the degree of substitution of the charged CDs. Thus, it is extremely difficult to optimize and validate a chiral CE separation using randomly substituted derivatives of CDs. Therefore, after the introduction of various single-component sulfated CD derivatives by Vigh's group[17] these became the predominantly used anionic chiral selectors in CE.[19] These derivatives are of significance not only for the development of reproducible, validated methods in chiral CE, but also for mechanistic studies.[19]

Another important advantage of charged CD derivatives is their use as chiral carriers.[5,6,9,7,20] This enables one to mobilize a neutral analyte even in the absence of EOF and a charged analyte in the opposite direction to its electrophoretic mobility, and to suppress the mobility of an analyte in the uncomplexed form. The last offers an important advantage for the improvement of the separation factor.

Two unique advantages of chiral CE using the selector in a double function, first for the separation of enantiomers and in addition for transport of the resolved enantiomers, are illustrated in Fig. 2. The chiral compounds are the well-known former sedative drug thalidomide (TD) and its metabolites detected in the body of humans after TD administration. TD had been withdrawn from clinical practice in the 1960s due to severe toxic effects probably residing in one enantiomer, but the drug has been reapproved in 1998 as a result of its potential antileprosy, anti-HIV, anti-inflammatory, and

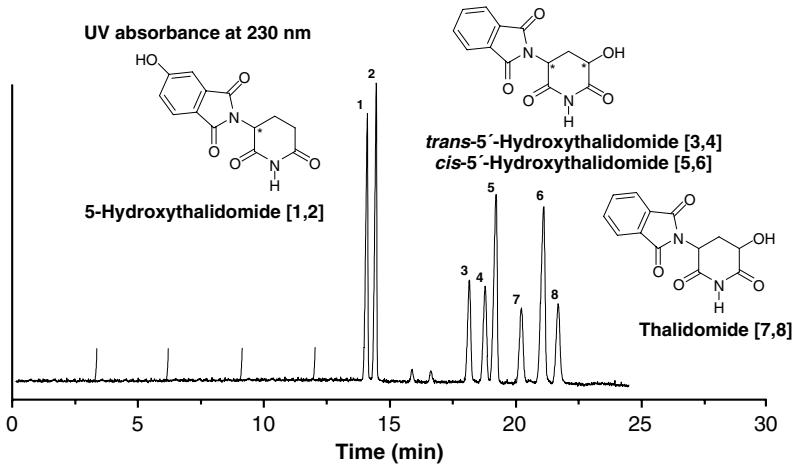

Fig. 2 Simultaneous separation and enantioseparation of thalidomide, 5-hydroxythalidomide, and 5′-hydroxythalidomide in CE using polyacrylamide-coated capillary and a mixture of 15 mg/ml sulfobutyl (4.0)-β-CD and 10 mg/ml β-CD as the chiral carrier.

antirheumatoid activity. The compounds to be separated in this particular case are uncharged and lack electrophoretic mobility. This makes separation difficult. In the separation system described in Fig. 2, the analytes are stereoselectively accelerated with one of the CDs (sulfobutyl-β-CD) and also stereoselectively but decelerated by another CD (β-CD). This, in combination with an easy variation of the CD concentration, allows one to optimize this complex separation to achieve simultaneous baseline separation and enantioseparation of all components. This example also illustrates the application of enantioselective CE separations for solving of practical biomedical problems. This seems to be one of the major application areas of chiral CE.[9]

It seems important to notice that CDs can be used for separation of enantiomers of chiral compounds by CE not only in aqueous buffers but also in non-aqueous media.[21] Contrary to the assumption that inclusion complex formation with CDs may not be favored in non-aqueous buffers, our recent studies indicate that CDs may form inclusion complexes also in non-aqueous buffers. In addition, non-inclusion type complexes of CDs are also enantioselectively formed with chiral analytes, which may lead to separation of enantiomers in CE.

CONCLUSION

CDs and their uncharged and charged derivatives are clearly established as the major chiral selectors in CE, CEKC, and MEKC (in combination with achiral surfactants). In the near future, together with the applications for solving analytical problems in chemical, agrochemical, food, environmental, and, mainly, in pharmaceutical and biomedical fields, CDs shall be used to an increasing extent for understanding the fine mechanisms of non-covalent (enantioselective) intermolecular interactions.

ACKNOWLEDGMENT

I would like to thank the Georgia National Science Foundation (GNSF) for financial support of my research in the field of microseparation techniques.

Chiral Separations by GC

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

In gas chromatography (GC), chiral selectivity is controlled solely by the choice of the stationary phase and the operating temperature. Thermodynamically, it is achieved by introducing an additional entropic component to the standard free energy of distribution. This is accomplished by employing a chiral stationary phase which will have unique spatially oriented groups or atoms that allow one enantiomer to interact more closely with the molecules of the stationary phase than the other. The enantiomer that can approach more closely to the stationary phase molecules will interact more strongly (the dispersive or polar charges being nearer) and, thus, the standard enthalpy of distribution of the two enantiomers will also differ. Consequently, the Van't Hoff curves will have different slopes and intersect at a particular temperature (see *Thermodynamics of Retention in GC*, p. 2307 and *van't Hoff Curves*, p. 2406). At this temperature, the two enantiomers will coelute and, hence, temperature is an important variable that must be used to control chiral selectivity. The farther the operating temperature of the column is away from the temperature of coelution, the greater the separation ratio and the easier will be the separation (less theoretical plates, shorter column, faster analysis).

HISTORICAL BACKGROUND

The first effective chiral stationary phases for GC were the derivatized amino acids,[1] which, however, had very limited temperature stability. The first reliable GC stationary phase was introduced by Bayer and coworkers,[2] who synthesized a thermally stable, low-volatility polymer by attaching l-valine-tbutylamide to the carboxyl group of dimethylsiloxane or (2-carboxypropyl)-methylsiloxane with an amide linkage. This stationary phase was eventually made available commercially as Chirasil-Val and could be used over the temperature range of 30°C to 230°C. OV-225 (a well-established polar GC stationary phase) has also been used for the synthesis of chiral polysiloxanes, which, in this case, possess more polar characteristics than the (2-carboxypropyl)-methylsiloxane derivatives.

Although the polysiloxane phases carrying chiral peptides are still used in contemporary chiral GC, the presently popular phases are based on cyclodextrins. These materials are formed by the partial degradation of starch followed by the enzymatic coupling of the glucose units into crystalline, homogeneous, toroidal structures of different molecular sizes. The best known are the α-, β-, and γ-cyclodextrins which contain six (cyclohexamylose), seven (cycloheptamylose), and eight (cyclooctamylose) glucose units, respectively. The cyclodextrins are torus shaped macromolecules which incorporate the D(+)-glucose residues joined by α-(1-4)glycosidic linkages. The opening at the top of the torus-shaped cyclodextrin molecule has a larger circumference than that at the base. The primary hydroxyl groups are situated at the base of the torus, attached to the C_6 atoms. As they are free to rotate, they partly hinder the entrance to the base opening. The cavity size becomes larger as the number of glucose units increases. The secondary hydroxyl groups can also be derivatized to insert different interactive groups into the stationary phase. Due to the many chiral centers the cyclodextrins contain (e.g., β-cyclodextrin has 35 stereogenic centers), they exhibit high chiral selectivity and, as a consequence, are probably the most effective GC chiral stationary phases presently available.

DISCUSSION

The α-, β-, or γ-cyclodextrins that have been permethylated do not coat well onto the walls of quartz capillaries and must be dissolved in appropriate polysiloxane mixtures for stable films to be produced. In contrast, underivatized cyclodextrins can be coated directly onto the walls of the column with the usual techniques. The thermal stability of a mixed stationary phase can be improved by including some phenylpolysiloxane in the coating material. Phenylpolysiloxane also significantly inhibits any oxidation that might take place at elevated temperatures. However, unless some methylsiloxane is present the cyclodextrin may not be sufficiently soluble in the polymer matrix for successful coating.

The inherent chiral activity of the cyclodextrins can be strengthened by bonding other chirally active groups to the secondary hydroxyl groups of the cyclodextrin. Certain derivatized cyclodextrins are susceptible to degradation, on contact with water or water vapor. Consequently, all carrier gases must be completely dry and all samples that are placed on the column must also be dry.

Derivatized cyclodextrins can interact with chiral substances in a number of different ways. If, the positions 2 and 6 are alkylated (pentylated), very dispersive (hydrophobic)

centers are introduced that can strongly interact with any alkyl chains contained by the solutes. After pentylation of the 2 and 6 positions has been accomplished, the 3-position hydroxyl group can then be trifluoroacetylated. This stationary phase is widely used and it has been found that the derivatized γ-cyclodextrin is more chirally selective than the β material. It has been successfully used for the separation of both very small and very large chiral molecules. The cyclodextrin hydroxyl groups can also be made to react with pure "S" hydroxypropyl groups and then permethylated. As a result, the size selectivity of the stationary phase is reduced, but its interactive character is made more polar (hydrophilic). In general, the α or γ phases have less chiral selectivity than the β material. There are a considerable number of cyclodextrin based chiral stationary phases commercially available and, without doubt, there will be many more introduced in the future.

Chiral Separations by HPLC

Nelu Grinberg
Richard Thompson
Analytical Research Department, Merck Research Laboratories, Rahway, New Jersey, U.S.A.

INTRODUCTION

Chirality arises in many molecules from the presence of a tetrahedral carbon with four different substituents. However, the presence of such atoms in a molecule is not a necessary condition for chirality. An object is said to be chiral if it is not superposable with its mirror image and achiral when the object and its mirror image are superposable. A chiral pair can be distinguished through their interaction with other chiral molecules to form either long-lived or transient diastereomers. Diastereomers are molecules containing two or more stereogenic (chiral) centers and having the same chemical composition and bond connectivity. They differ in stereochemistry about one or more of the chiral centers.

LONG-LIVED DIASTEREOMERS

Long-lived diastereomers are generated by chemical derivatization of the enantiomers with a chiral reagent. They may be separated subsequently by achiral means. Their formation energies have no relevance to their chromatographic separation; it is, rather, due to the difference in their solvation energies. Differences in their shape, size, or polarity will affect the energy needed to displace solvent molecules from the stationary phase.[1]

There are several characteristics of diastereomeric chiral separations (also known as indirect enantiomeric separations) that are worth mentioning. Achiral phases that are cheaper, more rugged, and widely commercially available are used. The elution order can be controlled by choice of the chirality of the derivatizing agent. This feature is useful for the analysis of trace levels of enantiomers. The separation can be designed such that the minor enantiomer is eluted first, allowing for more accurate quantitation.

Derivatization requires that the species of interest must contain a functional group that can be chemically modified. There should be no enantioselectivity of the rate of the derivatization.[2] There are several disadvantages to an indirect chromatographic chiral separation. The derivatization procedure may be complex and time-consuming and there is always a possibility of racemization during the derivatization procedure. In the case of preparative chromatography of the diastereomeric species, they have to be chemically reversed to the initial enantiomers. Fig. 1 shows the main types of derivatives formed from amines, carboxylic acids, and alcohols in reaction with chiral reagents.[3]

There are several structural considerations to achieving a diastereomeric separation. The diastereomers should possess a degree of conformational rigidity in order to maximize their physical differences. Large size differences between the groups attached to the chiral center enhance the separation in most cases. The distance between the asymmetric centers should be minimal and ideally less than three bonds. The presence of polar or polarizable groups can enhance hydrogen-bonding interactions with the stationary phase, resulting in increased resolution.

TRANSIENT DIASTEREOMERS

Objects that can distinguish between enantiomers are chiral receptors. Nature gives us plenty of examples of chiral receptors, such as enzymes and nucleic acids. There are also man-made chiral receptors such as chiral phases (CP) used in gas chromatography high-performance liquid chromatography (GC HPLC), supercritical fluid chromatography (SFC), and capillary electrophoresis (CE). The operation of a CP involves the formation of transient diastereomeric complexes between the enantiomer (selectand) and the CP (selector). They must be energetically nondegenerate in order to effect a separation. Because of their transient nature, it is usually not possible to isolate them.

There are specific criteria for the interaction between the selectand and the selector which leads to separation on a particular column:[4]

1. Strong interactions, such as p–p interactions, coordinative bonds, and hydrogen bonds between the selector and selectand
2. Close proximity of the transient bonds to the respective asymmetric carbons
3. Inhibition of free rotation of the transient bonds
4. Minimal non-contributing associative forms that do not bring the respective asymmetric centers to proximity

The diastereomeric associate between selectand and selector is formed through bonds between one or more

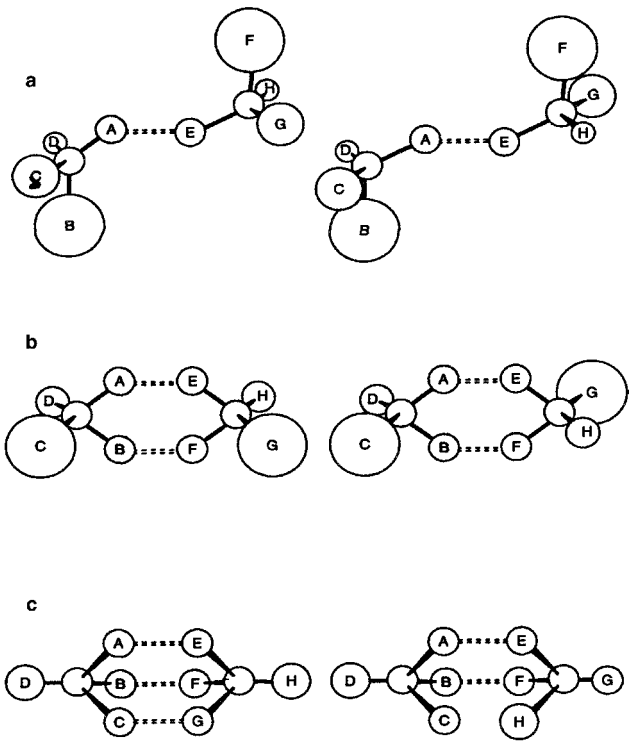

Fig. 2 Schematic representation of selectand–selector association. A dotted line represents a leading interaction between the two molecules. (a) The selectand forms a bond that involves only one substituent of its asymmetric carbon; (b) the selectand binds through two of its substituents; (c) the selectand binds through three substituents. **Source:** From Chiral separation of enantiomers via selector/selectand hydrogen bondings, in Chirality.[1]

substituents of the asymmetric carbon. These bonds are the leading selectand–selector interactions. Only when the leading bonds are formed and the asymmetric moieties of the two molecules are brought to close proximity do the secondary interactions (e.g., van der Waals, steric hindrance, dipole–dipole) become effectively involved (Fig. 2). The secondary interactions can affect the conformation and the formation energy of the diastereomeric associates. In Fig. 2a, the size, shape and polarity of the unbounded B, C, and D substituents of the selectand and their positions to the groups F, G, and H of the selector will determine the enantioselectivity of the system. One particular enantiomer of the selectands will interact more strongly with a particular selector. When the selective associate is formed through interactions A–E and B–F (Fig. 2b), enantioselectivity and elution order are determined by the effective size of unbounded groups C and D their relative positions, syn or anti, to groups G and H of the selector. In most of the cases that include hydrogen-bonding or ligand–metal complexes, the enantiomer with the larger non-bonded groups positioned syn to the selector's larger non-bonded group will elute last from the chiral column. When the selective association is formed through three leading interactions (Fig. 2c), the enantioselectivity is determined by the stereochemistry of the two enantiomers. One enantiomer in one configuration will establish three leading bonds (H bonds or a combination of H bonds and π–π interactions), whereas the other one will not.[1]

In chromatographic systems, the selectors are either added to the mobile phase [chiral mobile phases (CMP)] or are bonded to a stationary phase (e.g., silica gel) as chiral stationary phases (CSP).

CHIRAL MOBILE PHASES

In this mode of separation, active compounds that form ion pairs, metal complexes, inclusion complexes, or affinity complexes are added to the mobile phase to induce enantioselectivity to an achiral column. The addition of an active compound into the mobile phase contributes to a specific secondary chemical equilibrium with the target analyte. This affects the overall distribution of the analyte between the stationary and the mobile phases, affecting its

Antibiotics	Rifamycin	Amino acids	CE	[14]

retention and separation at the same time. The chiral mobile phase approach utilizes achiral stationary phases for the separation. Table 1 lists several common chiral additives and applications.

CHIRAL STATIONARY PHASES

Compared to CMP, the mechanism of separation on a chiral stationary phase is easier to predict, due to a much simpler system. Because the ligand is immobilized to a matrix and is not constantly pumped through the system, the detection limits for the enantiomers are much lower. Depending on the ligand immobilized to the matrix, one can have different types of interactions between the selectand and selector: metal complexes, hydrogen-bonding, inclusion, π–π interactions, and dipole interactions, as well as a combination thereof.

CHIRAL SEPARATION WHERE THE LEADING INTERACTION IS ESTABLISHED THROUGH METAL COMPLEXES (LIGAND EXCHANGE)

Chiral separation using ligand-exchange chromatography involves the reversible complexation of metal ions and chiral complexing agents. The central ion, usually Cu^{2+} or Ni^{2+} forms a bis complex with bidentates ligands. If one of the chelating ligands is anchored to a support, the CSP can form diastereomeric adsorbates with the bidentate selectand. The metal ion is held by the stationary phase through coordination to the bound ligand. If the coordination sphere of the metal is unsaturated or is occupied by weakly bound solvent molecules, it can reversibly attach different solute ligands from the mobile phase. The solute ligands are then resolved according to differences in their binding constants. Ligand exchange is possible only in systems where the interaction of the mobile ligand with the stationary phase is reversible. The coordination bonds must be kinetically labile. If the chelating ligands are amino acids and the metal is copper (II), the amine and carboxylate groups of the ligands are arranged around the metal ion in a trans configuration, forming a square planar complex. A third interaction should take place to ensure enantioselectivity. The third interaction may arise through steric hindrance or attractive or repulsive interactions between the selector and the selectand.[15,16]

CHIRAL SEPARATION WHERE THE LEADING INTERACTION IS ESTABLISHED THROUGH HYDROGEN BONDING

A hydrogen bond is formed by the interaction between the partners R–X–H and :Y–R′ according to

$$R-X-H\,1:Y-R9 \rightarrow R-X-H^{\cdots}Y-R'$$

R–X–H is the proton donor and :Y–R′ makes an electron pair available for the bridging bond. X and Y are atoms of higher electronegativity than hydrogen (e.g., C, N, P, O, S, F, Cl, Br, I). Hydrogen-bonding acceptors are the oxygen atoms in alcohols, ethers, and carbonyl compounds, as well as nitrogen atoms in amines and Nheterocycles. Hydrogen-bonding donors are hydroxy, carboxyl, and amide protons. Interactions can be modified by changing the elution conditions. The more non-polar the elution conditions, the stronger the H-bond interactions. Enantioselectivity is determined by the strength of the hydrogen bonds, which is, in turn, affected by secondary interactions such as steric hindrance or attractive or repulsive interactions between the selector and the selectand.

CHIRAL SEPARATION THROUGH CHARGE TRANSFER

Complexes formed by weak interactions of electron donors with electron-acceptor compounds are known as charge-transfer complexes. The necessary condition for the formation of a charge transfer complex is the presence of an occupied molecular orbital of sufficiently high energy in the electron-donor molecule, and the presence of a sufficiently low unoccupied orbital in the electron-acceptor molecule. Small unsaturated hydrocarbons are usually weak donors or weak acceptors. Polynuclear aromatic

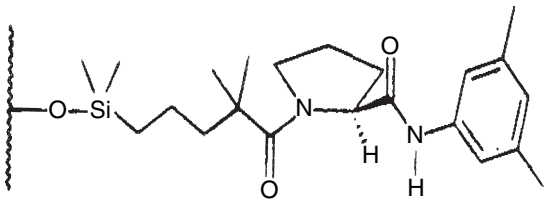

Fig. 3 The structure of the (*S*)-proline derivative chiral stationary phase.
Source: From Chiral recognition studies: Intra and intermolecular 1H{1H}-nuclear overhauser effects as effective tools in the study of bimolecular complexes, in J. Org. Chem.[18]

hydrocarbons are efficient π-donor molecules. Replacement of a hydrogen atom in the parent molecule with an electron-releasing substituent such as alkyl, alkoxy, or amino, increases the capability of the molecule to donate π-electrons. Aromatic molecules containing groups such as NO_2, Cl, C N are efficient electron acceptors. Carbonyl compounds are acceptors to aromatic hydrocarbons but are donors to bromine.

The overlapping and the orientation of the molecules in the crystal correspond to parallel planes if the bonding occurs only through π orbitals. π-donor–π-donor interactions do not occur in the same fashion because of repulsion between the π clouds. This repulsion leads to edge-to-face interactions, where weakly positive H atoms at the edge of the molecule point toward negatively charged C atoms on the faces of adjacent molecule. The dihedral ring planes are often close to perpendicular. Aromatic rings can act as hydrogenbond acceptors for the amidic proton.[17]

In general, the stability of a charge-transfer complex increases with the increase in the polarity of the solvent. To establish the enantiomeric separation under such conditions, secondary interactions must occur: namely the charge-transfer interactions have to be accompanied by hydrogen bonds and/or steric hindrance. Under these conditions, the mobile-phase conditions should be adjusted such that these interactions are achieved. Fig. 3 presents an example of a chiral stationary phase designed by Pirkle's group. This CSP allows for charge-transfer interaction with secondary interactions such as hydrogen-bonding and steric hindrance.[18]

CHIRAL SEPARATION THROUGH HOST–GUEST COMPLEXATION

Cyclodextrins and crown ethers are the main classes of compounds able to undergo host–guest complexes with a particular pair of enantiomers. Cyclodextrins (CD) are natural macrocyclic polymers of glucose that contain 6–12 D-(+)-glucopyranose units which are bound through α-1,4-glucopyranose linkages. The number of glucose

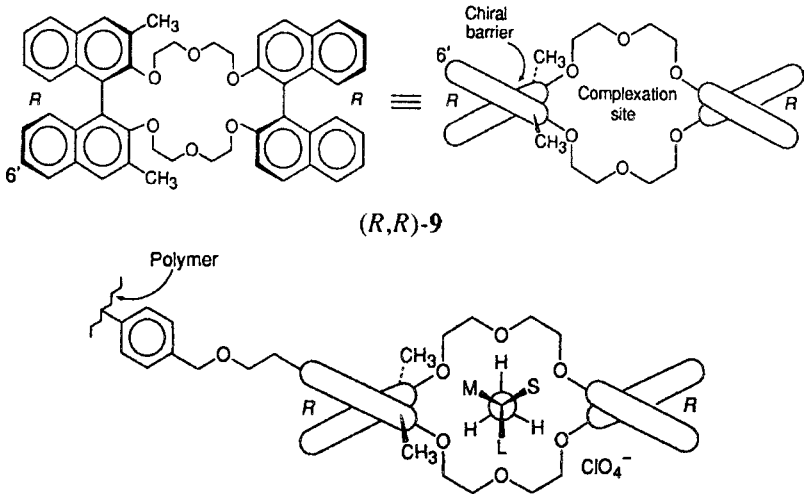

Fig. 5 Structure of the crown ether and the most stable complex.
Source: From *Container Molecules and Their Guests.*[21]

units per CD is denoted by a Greek letter: α for six, β for seven, and γ for eight (Fig. 4).[19] The inherent chirality of the CD renders them useful for chromatographic enantioseparations. In most cases, an inclusion complex is formed between the solute and the cyclodextrin cavity. The host–guest complexation is dependent on the polarity, hydrophobicity, size, and geometry of the guest, as well as the size of the internal cavity of the CD. Enantioselectivity is then determined by the fit in the cavity and by the interactions between substituents attached to or near the chiral center of the analyte and the unidirectional secondary hydroxyl groups at the mouth of the cavity. The temperature, pH, and the composition of the mobile phase influence the complexation.

Under reversed-phase conditions (RP), the presence of an organic modifier affects the binding of the guest molecule in the CD's cavity. The inclusion complex is usually strongest in water and decreases upon addition of organic modifiers. The modifier competes with the guest analyte for the cavity. Under normal-phase conditions, apolar solvents such as hexane and chloroform occupy the CD's cavity and cannot be easily displaced by the solute molecules. In these circumstances, the solute is usually restricted to interactions with the exterior of the CD. Chemical modifications of CD has opened new possibilities for enantiorecognition, widening the range of compounds that can be separated into enantiomers.[20]

Crown ethers, especially 18-crown-6 ethers, can complex not only inorganic cations but also alkylammonium compounds. The primary interactions occur between the hydrogens of the ammonium group and the oxygens of the crown ether. The introduction of bulky groups such as binaphtyl onto the exterior of the crown ether provides steric barriers and induces enantioselective interactions with the guest molecule.

The rigid binaphthyl units occupy planes that are perpendicular to the plane of the cyclic ether. One of the naphthalene rings forms a wall that extends along the sides and outward from the other face of the cyclic ether. The substituents attached at the 3-position of the naphthalene rings extend along the side or over the face of the cyclic ether. In the presence of a chiral primary amine, it forms a triple hydrogen bond with the primary ammonium cation. The same complex is formed whether the guest approaches from the top or from the bottom of the crown ether, as the crown ether has a C_2 axis of symmetry. In the complex, the large (L), medium (M), and small (S) groups attached to the asymmetric carbon of the guest must adjust themselves into two identical cavities. The L is placed in one cavity and the M and S into the other cavity. M will reside in the pocket with S against the wall for the more stable diastereomeric complex (Fig. 5).[21]

CHIRAL SEPARATION THROUGH COMBINATION OF INTERACTIONS

Included in this category are stationary phases such as biopolymers (e.g., celluloses and cellulose derivatives, proteins),[22,23] as well as macrocyclic antibiotics.[24] These stationary phases exhibit interactions with a particular enantiomer through hydrogen-bonding, charge transfer, and inclusion interactions. They proved to be very effective in resolving a wide class of racemates encompassing a variety of structures. Describing the mechanism of such separation is very challenging due to the complexity of these stationary phases. Such stationary phases can be operated under RP conditions (protein phases, cellulose phases, and macrocyclic antibiotics), as well as in the normal-phase conditions (cellulose phases and macrocyclic antibiotics). Conformational changes of biopolymers under the temperature and mobile-phase conditions can occur and they should be controlled such that the separation can be maximized.[25,26]

Chiral Separations by MEKC with Chiral Micelles

Koji Otsuka
Shigeru Terabe
Department of Material Science, Himeji Institute of Technology, Hyogo, Japan

INTRODUCTION

Since micellar electrokinetic chromatography (MEKC) was first introduced in 1984, it has become one of major separation modes in capillary electrophoresis (CE), especially owing to its applicability to the separation of neutral compounds as well as charged ones. Chiral separation is one of the major objectives of CE, as well as MEKC, and a number of successful reports on enantiomer separations by CE and MEKC has been published. In chiral separations by MEKC, the following two modes are normally employed: (a) MEKC using chiral micelles and (b) cyclodextrin (CD)-modified MEKC (CD/MEKC).

MEKC USING CHIRAL MICELLES

An ionic chiral micelle is used as a pseudo-stationary phase; it works as a chiral selector. When a pair of enantiomers is injected to the MEKC system, each enantiomer is incorporated into the chiral micelle at a certain extent determined by the micellar solubilization equilibrium. The equilibrium constant for each enantiomer is expected to be different more or less among the enantiomeric pair; that is, the degree of solubilization of each enantiomer into the chiral micelle would be different for each. Thus, the difference in the retention factor would be obtained and different migration times would occur.

CD/MEKC

An ionic achiral micelle [e.g., sodium dodecyl sulfate (SDS)] and a neutral CD are typically used as a pseudo-stationary phase and a chiral selector, respectively. When a pair of enantiomers is injected into this system, two major distribution equilibria can be considered for the solutes or enantiomers: (a) the equilibrium between the aqueous phase and the micelle (i.e., micellar solubilization) and (b) the equilibrium between the aqueous phase and CD (i.e., inclusion complex formation). Each enantiomer may have a different equilibrium constant for the inclusion complex formation among the enantiomeric pairs due to the enantioselectivity of the CD. As a result, each enantiomer exists in the aqueous phase at a different time among the enantiomeric pairs; hence, the time spent in the micelle would be varied.

In some cases, an ionic chiral micelle (e.g., a bile salt) is also used as a chiral pseudo-stationary phase with a CD. Moreover, cyclodextrin electrokinetic chromatography (CDEKC), where a CD derivative having an ionizable group is used as a chiral pseudo-stationary phase, has become popular recently since several commercially available ionic CD derivatives have appeared. Although the CDEKC technique is actually beyond the field of MEKC, it is an important method for enantiomer separation by CE.

In this section, chiral separation by MEKC with chiral micelles is mainly treated. The development of novel chiral surfactants adaptable to pseudo-stationary phases in MEKC for enantiomer separation is continuously progressing. It seems somewhat difficult for a researcher to find an appropriate mode of CE when one wants to achieve a specific enantioseparation. However, nowadays, various method development kits for chiral separation have been commercially available and some literature on the topic is also available, so that helpful information may be obtained without difficulty.

MEKC USING NATURAL CHIRAL SURFACTANTS

Bile Salts

Bile salts are natural and chiral anionic surfactants which form helical micelles of reversed micelle conformation. The first report on enantiomer separation by MEKC using bile salts was the enantioseparation of dansylated DL-amino acids (Dns-D,L-AAs) and, since then, numerous papers have been available. Nonconjugated bile salts, such as sodium cholate (SC) and sodium deoxycholate (SDC), can be used at pH > 5, whereas taurine-conjugated forms, such as sodium taurocholate (STC) and sodium taurodeoxycholate (STDC), can be used under more acidic conditions (i.e., pH > 3). Several enantiomers, such as diltiazem hydrochloride and related compounds, carboline derivatives, trimetoquinol and related compounds, binaphthyl derivatives, Dns-DL-AAs, mephenytoin and its metabolites, and 3-hydroxy-1,4-benzodiazepins have been successfully separated by MEKC with bile salts. In general, STDC is considered as the the most effective chiral selector among the bile salts used in MEKC.

The use of CDs with bile salt micelles has been also successful for enantiomer separations. For example, Dns-DL-AAs, baclofen and its analogs, mephenytoin and fenoldopam, naphthalene-2,3-dicarboxaldehyde derivatized DL-AAs (CBI-DL-AAs), diclofensine, ephedrine, nadolol, and other β-blockers, and binaphthyl-related compounds were enantioseparated by CD/MEKC with bile salts.

Digitonin and Saponins

Digitonin, which is a glycoside of digitogenin and used for the determination of cholesterol, is a naturally occurring chiral surfactant. By using digitonin with ionic micelles, such as SDS or STDC as pseudo-stationary phases, some phenylthiohydantoin-DL-AAs (PTH-DL-AAs) were enantioseparated.

On the other hand, glycyrrhizic acid (GRA) and β-escin can be employed as chiral pseudo-stationary phases in MEKC. Chiral separations of some Dns-DL-AAs and PTH-DL-AAs were achieved.

MEKC USING SYNTHETIC CHIRAL SURFACTANTS

N-Alkanoyl-L-Amino Acids

Various *N*-alkanoyl-L-amino acids, such as sodium *N*-dodecanoyl-L-valinate (SDVal), sodium *N*-dodecanoyl-L-alaninate (SDAla), sodium *N*-dodecanoyl-L-glutamate (SDGlu), *N*-dodecanoyl-L-serine (DSer), *N*-dodecanoyl-L-aspartic acid (DAsp), sodium *N*-tetradecanoyl-L-glutamate (STGlu), and sodium *N*-dodecanoyl-L-threoninate (SDThr) have been employed as synthetic chiral micelles in MEKC; several enantiomers have been successfully separated (Fig. 1). In each case, the addition of SDS, urea, and organic modifiers such as methanol or 2-propanol were essential to obtain improved peak shapes and enhanced enantioselectivity.

N-Dodecoxycarbonyl-Amino Acids

Chiral surfactants of amino acid derivatives, such as (*S*)- and (*R*)-*N*-dodecoxycarbonylvaline (DDCV) and *N*-dodecoxycarbonylproline (DDCP) are available for enantiomer separation by MEKC: Several pharmaceutical amines, benzoylated amino acid methyl ester derivatives, piperidine-2,6-dione enantiomers, and aldose enantiomers were successfully resolved. Because both enantiomeric forms of DDCV or (*S*)- and (*R*)-forms are available, we can expect that the migration order of an enantiomeric pair would be reversed.

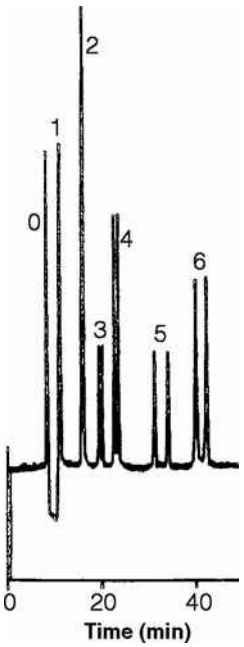

Fig. 1 Chiral separation of six PTH-DL-AAs by MEKC with SDVal. Corresponding AAs: (1) Ser, (2) Aba, (3) Nva, (4) Val, (5) Trp, (6) Nle; (0) acetonitrile. Micellar solution: 50 m*M* SDVal–30 m*M* SDS–0.5 *M* urea (pH 9.0) containing 10% (v/v) methanol; separation column: 50 μm inner diameter × 65 cm, 50 cm effective; applied voltage, 20 kV; current, 17 μA; detection wavelength, 260 nm; temperature, ambient.
Source: From Chiral separations by micellar electrokinetic chromatography with sodium *N*-dodecanoyl-valinate, in J. Chromatogr. A.[6]

Alkylglucoside Chiral Surfactants

Anionic alkylglucoside chiral surfactants, such as dodecyl β-D-glucopyranoside monophosphate and monosulfate, and sodium hexadecyl D-glucopyranoside 6-hydrogen sulfate, were used as chiral pseudostationary phases in MEKC, where several enantiomers (e.g., PTH-DL-AAs and binaphthol) were resolved.

Several neutral alkylglucoside surfactants, such as heptyl-, octyl-, nonyl-, and decyl-β-D-glucopyranosides and octylmaltopyranoside, were also employed for the enantiomer separation of phenoxy acid herbicides, Dns-DL-AAs, 1,1′-bi-2-naphthyl-2,2′-diyl hydrogen phosphate (BNP), warfarin, bupivacaine, and so forth.

Tartaric Acid-Based Surfactants

A synthesized chiral surfactant based on (*R*,*R*)-tartaric acid was used for the enantiomer separation in MEKC, where enantiomers having fused polyaromatic rings were separated easier than those having only a single aryl group.

Some PTH-DL-AAs and drug enantiomers were successfully resolved by using tartaric acid-based chiral surfactants.

Steroidal Glucoside Surfactants

Neutral steroidal glucoside surfactants, such as *N*,*N*-bis-(3-D-gluconamidopropyl)-cholamide (Big CHAP) and *N*,*N*-bis-(3-D-gluconamidopropyl)-deoxycholamide (Deoxy Big CHAP), which contain a cholic or deoxycholic acid moiety, respectively, have been introduced for use as chiral pseudo-stationary phases in MEKC. By using a borate buffer under basic conditions, these surfactant micelles could be charged via borate complexation. Some binaphthyl enantiomers, Tröger's base, phenoxy acid herbicide, and Dns-DL-AAs were enantioseparated.

MEKC USING HIGH-MOLECULAR-MASS SURFACTANTS

The use of a high-molecular-mass surfactant (HMMS) or polymerized surfactant has been recently investigated as a pseudo-stationary phase in MEKC. Because a HMMS forms a micelle with one molecule, enhanced stability and rigidity of the micelle can be obtained. Also, it is expected that the micellar size is controlled easier than with a conventional low-molecular-mass surfactant (LMMS). The first report on enantiomer separation by MEKC using a chiral HMMS appeared in 1994, where poly(sodium *N*-undecylenyl-L-valinate) [poly(L-SUV)] was used as a chiral micelle and binaphthol and laudanosine were enantioseparated. The optical resolution of 3,5-dinitrobenzoylated amino acid isopropyl esters by MEKC with poly(sodium (10-undecenoyl)-L-valinate) as well as with SDVal, SDAla, and SDThr was also reported.

As for the use of monomeric and polymeric chiral surfactants as pseudo-stationary phases for enantiomer separations in MEKC, a review article has been available.

The use of an achiral HMMS butyl acrylate/butyl methacrylate/methacrylic acid copolymer (BBMA) sodium salt was also investigated for enantiomer separations with CDs or as a CD/MEKC mode. A better enantiomeric resolution of Dns-DL-AAs was obtained by a β-CD/BBMA/MEKC system than an β-CD/SDS/MEKC system.

Polymerized dipeptide surfactants, which are derived from sodium *N*-undecylenyl-L-valine-L-leucine (L-SUVL), sodium *N*-undecylenyl-L-leucine-L-valine (L-SULV), sodium *N*-undecylenyl-L-leucine-L-leucine (L-SULL), and sodium *N*-undecylenyl-L-valine-L-valine (L-SUVV), were employed. Among these dipeptides, poly(L-SULV) showed the best enantioselectivity for the separation of 1,1′-bi-2-naphthol (BN).

Chlorinated Fatty Acids: Trace Analysis

Wenshan Zhuang
Taro Pharmaceuticals, Inc., Brampton, Ontario, Canada

INTRODUCTION

Many fatty acids, especially the so-called essential fatty acids, are of great nutrient importance; their chlorinated derivatives seem to have little usage in human life. Nevertheless, naturally occurring chlorinated fatty acids were found in marine animals,[1,2] though little is known about their biological functions. On the other hand, most chlorinated fatty acids found in the environment are of anthropogenic origin; they are generated as unwanted byproducts by industrial processes involving the use of chlorine-based reagents.[1,2] Their discharge into the aquatic environment and their presence in certain food products[1,2] have caused an increasing concern, because they are highly bioaccumulative and persistent in the food chain.[3] Not only do these compounds tend to be passively stored in the depot lipids of exposed animals,[1,2] but also they are actively built into cell membrane lipids.[4] Strikingly, chlorinated fatty acids were found to account for a major portion of extractable organochlorine in marine fish,[1,2] freshwater fish,[5] bivalves,[1,2] and lobster[6] that had been exposed to the waters in which chlorine bleaching effluents or municipal sewage are gathered. Although the toxicology of chlorinated fatty acids was not studied as much as that of those commonly known organochlorine compounds, e.g., chlorinated pesticides, polychlorinated biphenyls, and chlorinated dioxins, some effects on the biological properties of animal tissues and the functions of cell membranes were reported in recent years.[3,7,8]

A major difficulty with analysis of chlorinated fatty acids has been that they are usually present at levels undetectable by most chromatographic detectors. In this entry, chromatographic techniques including enrichment methods that were successfully developed and used in the analysis of these compounds in the past, mostly in the last decade, are summarized.

GAS CHROMATOGRAPHIC ANALYSIS WITHOUT PRIOR ENRICHMENT

As chlorinated fatty acids in lipid extracts cannot be separated from non-chlorinated matrix by routine cleanup techniques, because of the similarity in their chemical and physicochemical properties, chromatographic elution is often the sole effective means of separation for identification and quantitation of chlorinated fatty acids. As chlorinated fatty acids are present in biota extracts at trace levels, it is critical to have a detector that is highly specific for organochlorine. There are a range of detection techniques and specialized detectors that can be specific for chlorine or halogen: the electron capture detector (ECD); the atomic emission detector (AED); a mass spectrometer with negative ion chemical ionization (NICIMS); the selective ion monitoring (SIM) technique employed in mass spectrometry with commonly used ionization sources such as electron impact ionization, positive and negative ion chemical ionizations, and with other ionization sources such as the dissociative electron attachment (DEA) and the chemical reaction interface mass spectrometer (CRIMS); the Hall electrolytic conductivity detector (ELCD); and the halogen-specific detector (XSD^{TM}). Among these detectors, only the ELCD and XSD have been successfully used in gas chromatography (GC) for identification and quantitation of trace chlorinated fatty acid methyl esters (FAMEs) in transesterified fish lipids without resorting to prior enrichment of the analytes.[5,9–11] This is particularly desirable for quantitative analysis of trace chlorinated fatty acids in complex matrices, as enrichment processes often cause certain amount of sample loss.

Gas Chromatography/Hall Electrolytic Conductivity Detector

The ELCD can detect selectively halogen (X), nitrogen (N), or sulfur (S), depending on the instrument setup. In the X mode, GC eluate undergoes hydrogenolysis in a pyrolysis reactor, where X-containing compounds are converted to HX. This strong electrolytic species is carried into a conductivity cell and ionized in 1-propanol whose conductivity is monitored. An increase in conductivity owing to the presence of halide is translated to the response of the detector. A postreactor chemical scrubber is needed to remove HX and H_2S for ELCD operating in the N mode; otherwise the detector response to NH_3, a weak electrolyte resulting from hydrogenolysis of N-containing compounds, would be severely interfered if there is any X- or S-containing compound present in the eluate. In the S mode, air (oxygen) is used as the reaction gas, yielding an oxidative environment in the reactor in which S-containing compounds are pyrolyzed to SO_2, and a specific scrubber is employed to remove HX. Both S and N modes need a more polar solvent than does the X mode in the conductivity cell, usually methanol (capable of ionizing SO_2) for the S mode and aqueous *tert*-butyl alcohol (in which NH_3 is ionizable) for the N mode. The X-mode ELCD exhibits a very high selectivity for chlorine; one of its manufacturers proclaims that Cl/HC $> 10^6$, Cl/N $> 10^5$,

and Cl/S $> 10^5$.[12] The detection limit of ELCD, defined as the analyte amount that yields a detection response twice the noise, is about 0.25 ng of methyl dichlorooctadecanoate or 50 pg of chlorine.[9] For this compound, the reported linear range of ELCD is up to 500 ng/μl with a correlation coefficient of 0.999.[13]

Using GC/ELCD with coinjection of the synthesized reference standard, Wesén et al.[9] identified methyl 9,10-dichlorooctadecanoate in transesterified eel lipids containing 1200 ppm of Cl and quantitatively determined that the concentration of the analyte is 600 ppm.[9] In comparison, when the same sample was analyzed with GC/ECD, the detector was incapable of overcoming the interference from non-chlorinated FAMEs that were dominant components in the sample and generated a useless chromatogram.[9] In a subsequent study,[10] based on linear relationship obtained from plotting the linear retention indices vs. the carbon chain lengths of a homologous series of reference standards and of chlorinated unknowns in the eel sample with tentatively assigned carbon numbers, these researchers identified six major peaks in the GC/ELCD chromatogram as being *threo*- and *erythro*-diastereomers of methyl dichlorooctadecanoate, dichlorohexadecanoate, and dichlorotetradecanoate.

Gas Chromatography/Halogen-Specific Detector

The XSD manufactured by the OI Analytical is a GC detector that is dedicated to the selective detection of halogen-containing compounds. The detector consists of an alkali glass ceramic rod, a cathodic platinum bead attached to the bottom of the rod, an anodic platinum coil wound around the rod above the bead, and a reactor core which maintains a high temperature for the detector and serves as an auxiliary anode (Fig. 1). The working principle of the XSD roots in thermal electron emission, and negative and positive surface ionizations, whereby free electrons, anions, and cations are produced to form the emission current.[14] The detector is operated at 800–1100°C; therefore the background current is attributed largely to the thermal electron emission of the cathode. The GC effluent flowing into the heated reactor tube with the added reaction gas (air or oxygen at 20–40 ml/min) is pyrolyzed at high temperature. Halogenated compounds in the effluent are oxidized to CO_2, H_2O, and halogen atoms, which are subsequently absorbed onto the potassium-sensitized cathode surface. Negative surface ionization occurs, as the electron affinities of halogens (e.g., 3.61 eV for Cl) are higher than the work function of the sensitized cathode (2.29 eV). Detector response is noted by a sharp increase in thermal electron emission owing to a decrease of the surface's work function by halogen adsorption and also because of an increase in the local surface temperature caused by excess energy released from negative surface ionization. Potassium atoms on the cathode surface or K^+ ions arriving from the anode may react with halogen atoms or anions by impinging on them; this exothermic reaction also contributes to a rise in the local temperature. Halogen species

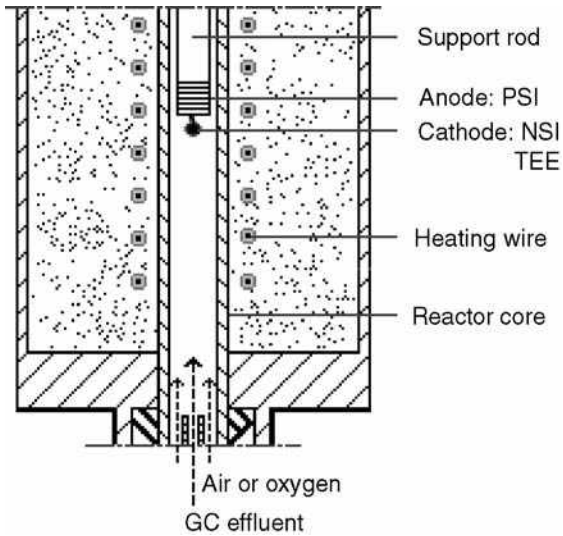

Fig. 1 A cutaway view of the core portion of XSD. PSI, positive surface ionization; NSI, negative surface ionization; TEE, thermal electron emission.[14]

(X^- and KX) are subsequently desorbed from the cathode surface into the gaseous flow moving toward the anode. The cathode surface is replenished by K^+ ions migrating from the anode in the external electric field. These cations are derived from positive surface ionization of potassium atoms on the surface of the anode, which is in contact with the potassium source (the alkali glass ceramic). It is possible that some of KX molecules desorbed from the cathode surface subsequently strike the anode surface. When this happens, KX incident on the hot surface could dissociate into K and X atoms, the former thus being recycled. The high selectivity of XSD lies in the fact that, among common elements of organic compounds such as C, H, O, N, S, and X, only halogens, formed in the heated oxidative environment, possess sufficient high electron affinities to cause significant increase in thermal electron emission. Indeed, in an evaluation of XSD for analysis of trace chlorinated FAMEs in a matrix composed of non-chlorinated FAMEs, the selectivity of Cl over C is estimated to be 10^5:1,[14] which agrees with the manufacturer's claim that Cl/HC $\geq 10^4$.[15] In addition, it was shown that under optimal conditions XSD has a detectivity, defined as being twice the peak-to-peak noise level divided by the response factor, of about 0.5 pg Cl/sec for dichloro FAMEs or detection limit of about 10 pg of methyl dichlorooctadecanoate (equivalent to 2 pg Cl), and a linearity range of up to 50-ng injection for methyl dichlorooctadecanoate (equivalent to 10 ng Cl) with an R^2 of 0.999.[14] These values are in agreement with the manufacturer's performance specifications.[15]

The XSD has found increasing use in the analysis of chlorinated compounds in biological samples.[5,11,16–18] Using GC/XSD, Zhuang et al.[5,11] identified and quantitated methyl esters of *threo*-5,6-dichlorotetradecanoic, *threo*-7,8-dichlorohexadecanoic, and *threo*-9,10-dichlorooctadecanoic

acids in transesterified lipids of filets, gonad, intestinal fat, and carcass of freshwater fish (white sucker) with the chlorine content ranging from 22 to 124 ppm. Identification was accomplished by matching the retention times of sample peaks with those of synthesized authentic reference standards and by comparing the elution behavior of configurational and positional isomers of dichloro FAMEs.[11] The work presented for the first time the unambiguous determination of chlorine positions in dichlorohexadecanoic and dichlorotetradecanoic acids present in fish lipids, thus providing analytical evidence to support the hypothesis of β-oxidative metabolism of dichlorooctadecanoic acid in fish. Quantitative analysis was based on internal standard calibration using methyl esters of *threo*-10,11-dichloroundecanoic and *threo*-10,11-dichlorononadecanoic acids as internal standards, which eluted before and after all analytes, respectively, and for which there was no chromatographic interference from samples.[5] Gustafson-Svärd et al.[16] used GC/XSD to study the incorporation, metabolism, and secretion of chlorinated fatty acids following the incubation of two human cell lines with 9,10-dichloro-octodecanoic acid.[16] The GC/XSD was also a useful tool in the enrichment of chlorinated fatty acids.[17,18]

CONFIRMATION WITH THE SECOND CHROMATOGRAPHIC COLUMN

After a chlorinated fatty acid or derivative has been identified chromatographically with the aid of the authentic reference standard, a simple approach of confirming the identification is to run the sample on a second chromatographic column, which has a very different polarity or elution mechanism. The second column of such selection greatly reduces the chance of false identification because the coelution is not likely to occur again when an unknown which is not the same compound as the reference standard does happen to coelute on the first column. Zhuang et al.[11] identified three metabolism-related dichloro FAMEs by GC/XSD with an HP-5 column (5% phenyl and 95% methyl polysiloxane), which is basically a non-polar GC column, and subsequently confirmed the identification using a DB-WAX column (polyethylene glycol), a typically polar GC column.

ENRICHMENT

Structural analysis of traces of chlorinated fatty acids in biota often requires prior enrichment or cleanup. Analysis of chlorinated pesticides and polychlorinated biphenyls can be facilitated by a simple cleanup procedure such as the sulfuric acid treatment or gel permeation chromatography with a single cutoff point to eliminate high molecular weight lipids. Owing to the similarity in chemical and physicochemical properties between analytes (chlorinated fatty acids) and matrix compounds (non-chlorinated fatty acids), conventional cleanup procedures are not applicable for the enrichment of chlorinated fatty acids that are present in complex biological matrices such as fish lipids. To deal with chlorinated fatty acids in biota samples, several successful enrichment techniques were developed.[6,10,17–21] The goal of enrichment is to maximize the degree of removal of non-chlorinated matrix compounds while minimizing the loss of chlorinated analytes.

COMPLEXATION

One of the enrichment techniques is based on complexing mechanisms, which involves the treatment of lipid sample solutions separately or consecutively with ethanol–water (1:1)-containing 25% (w/v) silver nitrate and with urea moistened with methanol.[10] Silver ions tend to interact strongly with polyunsaturated hydrocarbon chains of FAMEs to form complexes which are favorably partitioned into the polar EtOH–H_2O phase; uncomplexed FAMEs remain in the nonpolar phase (e.g., isooctane) in which the whole lipid sample was initially dissolved. Chlorinated FAMEs that do not possess polyunsaturated acyl chains are thus concentrated in the enriched samples. Urea has an interesting property: when it crystallizes in the presence of certain long-chain aliphatic molecules, it forms hexagonal prisms in such a way that a channel is created, in which the long straight carbon chain of the molecule is trapped and together forms a complex known as the urea inclusion complex. Uncomplexed lipid components can be extracted with effort by appropriate organic solvents from the urea slurry. It is known that branched, cyclic, and polyunsaturated FAMEs are too bulky to be contained in urea channels. It was assumed that the presence of bulky chlorine atoms in dichloro FAMEs would also inhibit the molecules from fitting into urea channels.[10]

In a study of transesterified eel lipids containing 1200 ppm Cl, Mu et al.[10] observed significant enrichment from each of the silver nitrate and urea treatments and also from the consecutive treatments (silver nitrate followed by urea), the latter resulting in a 30-fold increase in the ELCD response and by the appearance of new chlorinated peaks which had been undetectable prior to enrichment. Based on linear GC retention indices, column difference values, and response ratios of ELCD vs. the flame ionization detector (FID) and GC/mass spectrometry (MS), they identified additional chlorinated FAMEs in the enriched sample of the previously studied eel lipids: isomers of methyl dichlorooctadecenoate, dichlorohexadecenoate, and dichlorotetradecenoate, and isomers of methyl tetrachlorooctadecanoate and tetrachlorotetradecanoate.[19] Identification of *erythro*, *erythro*- and *threo*, *threo*-tetrachlorooctadecanoates, each present in two diastereomeric forms, was established by coinjection of the synthesized reference standards.[19] Mu et al.[10] also successfully applied the consecutive treatments to fish samples containing only 30–60 ppm Cl.

However, the effectiveness of the complexing methods depends on the fatty acid composition of the sample and thus the type and source of the sample. For instance, neither of the

above treatments was effective in enrichment of chlorinated components in transesterified lipids obtained from freshwater fish (white sucker).[17] The silver nitrate treatment was found to be unsatisfactory for enrichment of chlorinated species in transesterified lipids from the lobster digestive gland.[6]

GC with Cryogenic Trapping of Selected Eluate

A straightforward approach for enriching chlorinated fatty acids is the repeated collection of the selected narrow GC fractions corresponding to chromatographic peaks which are recorded by a halogen selective detector, such as ELCD or XSD. To maximize the degree of enrichment, GC conditions should be optimized so that there are no major non-chlorinated components (as indicated by FID) coeluting with the ELCD or XSD peaks. Using glass splitters, the GC outlet can be connected to a halogen-specific detector and to a number of separate coils of capillary tubing which are ended with shut-off valves.[20] By opening a valve, about a half of the eluate was diverted into the respective coil. The coils are cooled by dry ice and the diverted eluate is thus condensed and collected. By applying this technique to the transesterified eel lipids that contained 1200 ppm Cl, Wesén et al.[20] successfully obtained several GC fractions for GC/MS studies, in which two diastereomeric forms of methyl tetrachlorooctadecanoate were identified and the previously identified methyl *threo*-dichlorooctadecanoate was confirmed.

Thin-Layer Chromatography

One of the first techniques that have been utilized for enrichment of chlorinated fatty acids in biota lipids is thin-layer chromatography (TLC). White and Hager[21] used preparative TLC (20 cm × 20 cm plates precoated with silica gel F-254, 2.5 mm thick) to enrich chlorinated components in jellyfish lipids that contained 4.8 mg Cl/g lipid. After chromatography of the transesterified lipids with hexane–diethyl ether–acetic acid (90:10:1), 30% of the chlorine was recovered in a fraction having a R_f value of 0.22–0.38. When eel filet lipids containing 1.2 mg Cl/g lipid is studied, Mu et al.[10] used silica gel TLC with a solvent system of cyclohexane–diethyl ether (96:4) to enrich chlorinated FAMEs following consecutive treatment with silver ions and urea. A band with R_f 0.14–0.18 was found to contain the major portion of chlorinated species, among which were methyl dichlorooctadecanoate, dichlorohexadecanoate, and dichlorotetradecanoate.[10]

Florisil Column Chromatography

The presence of a hydroxyl group in FAMEs has the same effect on the GC elution time as does the incorporation of a chlorine atom into the FAMEs.[11] Thus, dichloro FAMEs were unseparated from chlorohydroxy analogs on the GC column; the same was true for the tetrachloro FAMEs and trichlorohydroxy analogs.[11,22] Heikes[22] used an absorption column that contained 60–100 mesh Florisil (magnesia–silica gel) that had been activated at 650°C, to separate chloro FAMEs from chlorohydroxy FAMEs. The former was eluted from the column by 12% ethyl ether in petroleum ether, and the latter by 20% ethyl ether in petroleum ether.

Gel Permeation Chromatography

The solute molecules according to their hydrodynamic volumes using gel permeation chromatography (GPC). Milley et al.[7] reported a reinforced enrichment process, in which transesterified lipids of lobster digestive glands containing about 50 ppm Cl were enriched for chlorinated FAMEs first by the urea treatment and then further by GPC fractionation (Sephadex LH-20). One of the GPC fractions contained a high concentration of methyl dichlorotetradecanoate and was thus identified and confirmed by GC/MS.

High-Performance Liquid Chromatography

High-performance liquid chromatography (HPLC) has been widely used for analytical separations by virtue of its high-resolution capability. This type of chromatography is characterized by wide selections of stationary and mobile phases. Although preparative HPLC columns are commercially available, enrichment can also be made with an analytical column by repeated runs from which the same HPLC fractions are pooled. Small quantities of enriched samples are usually sufficient for GC/MS studies. As chlorinated FAMEs are usually analyzed by GC, the advantage of using HPLC for enrichment is that enrichment chromatography and analysis chromatography are based on different elution mechanisms. Thus when matrix compounds coeluted with chlorinated FAME in HPLC are collected together in an HPLC fraction, the chance for a second coelution is greatly reduced in the subsequent GC analysis.[17]

After carrying out preconcentration with three sequential TLC systems, Song et al.[23] further enriched hatching factors in barnacle lipids by normal-phase HPLC fractionation on an S5w column using hexane–isopropanol–acetic acid (97:3:0.1) as the mobile phase. Each fraction was tested for hatching factor activity, and one of the most active fractions was subsequently subjected to GC/MS. Several major components were identified as being hydroxylated fatty acids, two of which happened to be chlorodihydroxy fatty acids.[23]

However, in general cases, such as analysis of chlorinated fatty acids in food and environmental samples, it is difficult to determine in which of HPLC fractions trace chlorinated components are present, because none of LC detectors are specific for chlorine. Zhuang et al.[17] devised a new enrichment approach of utilizing reversed-phase RP-HPLC for its high separation power and XSD for its high selectivity for organochlorine. In a study of white sucker lipids, to maximize the degree of enrichment of traces of chlorinated FAMEs, a gradient elution using water, methanol, acetonitrile, and cyclohexane–isopropanol (1:1) as mobile phases

was optimized so that chlorinated analytes were present in the valleys of the elution profile of matrix materials.[23] Owing to their presence at trace levels with coeluting matrix compounds, chlorinated analytes were invisible in chromatograms recorded by the photodiode-array detector (215 nm) employed in HPLC fractionation; the determination of optimal demarcation for fractionation was assisted by GC/XSD, which is capable of detecting these otherwise undetectable chlorinated analytes. As a result, the bulk of non-chlorinated matrix was removed by RP-HPLC fractionation using an ODS2 column, and target-chlorinated analytes were selectively enriched. As assessed by a universal detector (FID), on a transesterified fish lipids containing only 15 ppm Cl, chlorinated FAMEs were completely nondetectable prior to HPLC fractionation, but were present as moderate or small yet discernible peaks after the HPLC enrichment.[17] This enrichment method is efficient with good selectivity, reproducibility, and predictability.

Solid-Phase Extraction

Solid-phase extraction (SPE) offers an alternative way for enrichment of chlorinated fatty acids. Akesson-Nilsson[18] presented an aminopropyl-based SPE technique for enrichment of chlorinated FAMEs in a cell-culture medium and for previously silver nitrate and urea treated eel lipids. In this application, a 500-mg aminopropyl column was connected to a vacuum manifold and conditioned with 2 ml of hexane. After transesterified lipid samples in 0.2 ml of hexane were loaded, the column was first eluted with 6 ml of hexane and then with 4 ml of a solvent mixture made of hexane–diethyl ether–dichloromethane (89:1:10).[18] In this way, the majority of non-chlorinated FAMEs were removed in the first elution and chlorinated FAMEs enriched in the later elution.

IDENTIFICATION AND CONFIRMATION BY GC/MS FOLLOWING ENRICHMENT

Mass spectrometry coupled with chromatography is commonly used for identification and confirmation of unknowns. Mass spectrometry can offer more structural information needed for identification and confirmation, but it is less selective and less sensitive than those detectors designed specifically for organohalogen such as ELCD and XSD. Therefore, GC/MS studies often require prior enrichment of chlorinated analytes. The sensitivity of MS for trace analytes can often be enhanced dramatically by SIM and, in the case of MS/MS, by selected-reaction monitoring (SRM). Several ionization modes and reagent gases were reported for GC/MS analysis of chlorinated FAMEs in the presence of non-chlorinated matrix compounds. The objective in choosing ionization conditions is to increase sensitivity through achieving high ionization efficiency, especially for chlorinated analytes, and low degrees of fragmentation.

GC/EIMS Analysis of Methyl Esters

Electron impact (EI) is the most common ionization mode used in MS. Generally EIMS is not favored for trace analysis because of its high degree of fragmentation. Nevertheless, when enriched samples contain adequate concentrations of analytes, GC/EIMS is a convenient tool for identification.

By using GC/EIMS (70 eV) with known synthetic compounds, White and Hager[21] identified several isomers of chlorohydroxyhexadecanoic and chlorohydroxyoctadecanoic acids in a TLC-enriched jellyfish lipid sample. Song et al.[23] used GC/EIMS operated at a low electron acceleration potential (25 eV) to analyze methyl ester trimethylsilyl ether derivatives of an HPLC fraction that exhibited strong hatching factor activity. In addition to a number of trihydroxy fatty acids that were determined, two unknown GC peaks which had almost identical mass spectra were tentatively identified as being 9-chloro- and/or 11-chloro-8,12-dihydroxyeicosatetraenoic acids. GC/EIMS was also used for tentative identification of chlorinated fatty acids in transesterified fish lipids following enrichment.[10,19,20]

GC/PICIMS Analysis of Methyl Esters

Ions generated by soft ionization such as positive ion chemical ionization (PICI) are much less fragmented; thus, those characteristic ions are generally produced with sufficient intensities, which are desirable for trace analysis, especially when SIM is utilized. An additional advantage of using soft ionization is that molecular ions are usually observable. Note that only a limited number of reagent gases were found to be suitable for analysis of trace chlorinated FAMEs. In analysis of chlorinated fatty acid in food items derived from bleached flours, Heikes[24] reported the formation of significant protonated molecular ion adducts through the use of ethylene oxide (oxiran) as the reagent gas in GC/MS with PICI operated at 200°C and 45 eV. The identification of 9,10-dichloro-12-octadecenoic acid along with several other chlorinated fatty acids in these flour-containing food samples was established by matching GC retention indices and mass spectra between the test samples and the synthesized reference standards. Shortly thereafter, Sundin et al.[25] reported that PICI using ammonia as the reagent gas results in abundant ammonium adduct molecular ions $[M + NH_4]^+$ in the mass spectrum of monochloro and dichloro FAMEs. Gas chromatography equipped with ammonia-induced PICIMS was later used by them as an important tool for identification and confirmation of chlorinated FAMEs in transesterified fish lipids.[4,10,19,20] To assist the trace analysis, SIM[4,20] and high-resolution SIM[19] were also utilized.

GC/DEA–NICIMS Analysis of Methyl Esters

Negative ion chemical ionization is an attractive ionization method for analysis of trace chlorinated compounds,

because chloride ions generated can be conveniently used for detecting chlorinated unknowns in the chromatographic elution profiles of complex samples.

Curtis and Boyd[26] utilized this feature to the full by optimizing NICI conditions for achieving "hard" ionization, viz., DEA, by which chloride ions are predominantly produced from chlorinated compounds and detected by SIM at *m/z* 35 and 37. Operated in this way, NICIMS is effectively turned into a chlorine-specific GC detector with selectivity and sensitivity comparable to those of the ELCD. By using this technique, Milley et al.[6] successfully identified dichlorotetradecanoic acid in a GPC-enriched sample from lobster digestive gland lipids (but with the chlorine position remaining undetermined). The identification of this compound was supported by the mass spectrum obtained with "soft" NICI optimized for molecular anions, which resembled that of a synthesized 9,10-dichlorotetradecanoic acid.

GC/NICIMS Analysis of Pentafluorobenzyl Esters

Fatty acids and their methyl esters are ineffective in ionization under normal (soft) ionization conditions. On the other hand, the ionization efficiency can be enhanced significantly by using an appropriate derivative. Zhuang et al.[27] demonstrated striking difference between NICIMS response to pentafluorobenzyl esters and that to methyl esters or underivatized fatty acids. An additional desirable feature of NICIMS of pentafluorobenzyl esters of chlorinated fatty acids is their extreme low degrees of fragmentation: the most abundant ion (the base peak) shown in the mass spectrum is usually the quasi-molecular ion, i.e., the carboxylate anion generated upon the loss of the pentafluorobenzyl moiety from the pentafluorobenzyl ester having captured a thermal electron. Based on this feature, Zhuang et al.[27] presented a GC/NICIMS technique that is particularly useful for detecting and identifying trace chlorinated unknowns. The method consists of the following sequential steps:

1. Enriching chlorinated analytes by HPLC fractionation or other effective enrichment techniques.
2. Performing GC/NICIMS following pentafluorobenzyl esterification.
3. Locating chlorinated analytes: when available reference standards do not match in retention time with unknown chlorinated compounds, chloride ion chromatograms extracted at *m/z* 35 and 37 from full scans can utilized for locating traces of chlorinated unknowns in a total ion chromatogram (TIC) that is complicated by the presence of ions derived from non-chlorinated matrix compounds.
4. Retrieving the mass spectrum: once the location of a chlorinated unknown has been determined, the mass spectrum scanned in a narrow range of its retention time can be readily retrieved.
5. Analyzing the mass spectrum: the origins of significant ions displayed in the retrieved mass spectrum can be evaluated using ion chromatograms extracted at the *m/z* of these ions; the chromatographic peaks of those ions derived from the chlorinated unknown are expected to center at the retention time determined by chloride ion chromatograms, whereas those originating from matrix compounds are not. Furthermore, the isotopic patterns of chlorinated ions can be examined against their theoretical relative abundances.
6. Analyzing the background-subtracted mass spectrum: once matrix ions have been identified, they can be subtracted from the spectrum. The resulting spectrum provides information on the molecular identity of the chlorinated unknown; for instance, the molecular weight and the number of chlorine can be readily obtained from the quasi-molecular ions. The comparison of the background-subtracted spectrum with the spectrum of the synthesized reference standard, if available, that matches in retention time with the chlorinated unknown will establish the identification of the unknown analyte.

STRUCTURAL ANALYSIS WITH GC/EIMS FOLLOWING DMOX DERIVATIZATION

A traditional method to determine halogen positions in unknown halogenated fatty acids is dehalogenation which may be followed by ozonation, with the subsequent GC analysis of dehalogenated or ozonated products, from which the double bond position(s) and thus the chlorine position(s) can be deduced.[28] Recently, Zhuang et al.[29] presented a GC/MS technique to locate the chlorine in fatty acids containing vicinal dichloro atoms. In this method, lipid samples including chlorinated components are transformed to 4,4-dimethyloxazoline (DMOX) derivatives, which are then subjected to EIMS. It was found that DMOX derivatives of dichloro fatty acids display some distinctive EIMS features, which are characteristic of positional isomers, and fragmentation mechanisms responsible for important fragment ions and patterns are inherently related to the position of the vicinal dichloro group on the acyl chain. Furthermore, a "$144 + 14x$" rule, which facilitates mass spectral interpretation was identified: the first ion in a homologous series of characteristic chlorodienyl ions, notable by their sizeable intensity and chlorine isotope pattern, has a *m/z* equal to "$144 + 14x$," where x is a number corresponding to the location of the first of the vicinal chlorine atoms on the acyl chain.

CONCLUSIONS

A difficulty with analysis of chlorinated fatty acids has been that they are often present at levels undetectable by most chromatographic detectors. In this entry, the approaches such as gas chromatographic analysis without prior enrichment, GC/ELCD, GC/XSD, enrichment, complexation, GC with cryogenic trapping of selected eluate, TLC, florisil

column chromatography, GPC, HPLC, SPE, identification and confirmation by GC/MS following enrichment, and GC/EIMS analysis of methyl esters have been described.

Chromatographic Peaks: Causes of Fronting

Ioannis N. Papadoyannis
Anastasia Zotou
Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece

INTRODUCTION

Peaks with strange shapes represent one of the most vexing problems that can arise in a chromatographic laboratory. Fronting of peaks is a condition in which the front of a peak is less steep than the rear relative to the baseline. This condition results from non-ideal equilibria in the chromatographic process.

DISCUSSION

Fronting peaks, as well as tailing or other misshaped peaks, can be hard to quantitate. Some data systems have difficulty in measuring peak size accurately. As a result, the precision and/or reliability of assay methods involving fronting or other misshaped peaks is often poor when compared to good chromatography. There are a number of different causes of peak fronting, and discovering why peaks are thus misshaped and then fixing the problem can be a difficult undertaking. Fortunately, there is a systematic approach based on logical analysis plus practical fixes that have now been documented in numerous laboratories. Fronting peaks are less commonly encountered in liquid chromatography (LC), but they are readily distinguished from other peak-shape problems. Fronting peaks are the opposite of tailing peaks. Whereas tailing peaks suggest that sample retention decreases with increasing sample size or concentration, fronting peaks suggest the opposite: retention increases with larger samples. In both cases, a decrease in sample size may eliminate peak distortion. However, this is often not practical, because some minimum sample size is required for good detectability. In the case of tailing peaks, it is believed that peak distortion often arises because large samples use up some part of the stationary phase. However, the cause of fronting peaks is seldom fully understood.

Ion-pair chromatography (IPC) is more susceptible to peak fronting than other modes in LC. *Column temperature* problems can cause fronting peaks in IPC. Fig. 1 shows the separation of an antibiotic amine at ambient temperature. Repeating the separation at 45°C eliminated the fronting problem. Some studies have shown peak fronting in IPC that can be corrected by operating at a higher column temperature, whereas some other separations are best carried out at lower temperatures. The reason for this peculiar peak-shape behavior is unclear, but it may be related to the presence of reagent micelles in the mobile phase for some experimental IPC conditions. Generally, it is good practice to run ion-pair separations under thermostatted conditions, because relative retention tends to vary with temperature in IPC. Usually, narrower bands and better separation results when temperatures of 40–50°C are used for IPC.

The use of a *sample solvent other than the mobile phase* is another cause of fronting peaks in IPC. In this case, the sample should only be injected as a solution in the mobile

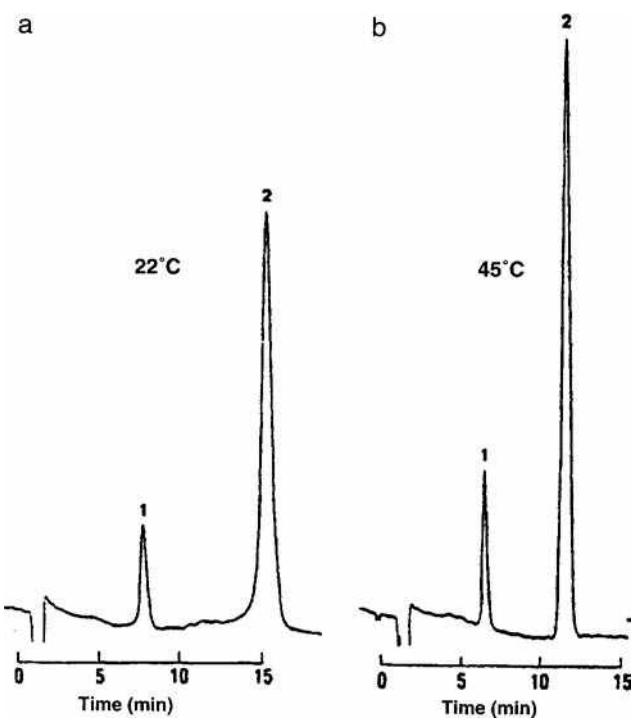

Fig. 1 Peak fronting in IPC as a function of separation temperature. Column: Zorbax C_8 mobile phase: 10 m*M* sodium dodecyl sulfate and 150 m*M* ammonium phosphate in 33% acetonitrile; pH: 6.0; flow rate: 2.0 ml/min; temperature: (a) = 22°C and (b) = 45°C. Peaks: 1 = lincomycin B; 2 = lincomycin A.

phase. No more than 25–50 μl of sample should be injected, if possible.

Silanol effects can adversely alter peak shape in IPC, just as in reversed-phase separations. Therefore, when separating basic (cationic) compounds, the column and mobile phase should be chosen bearing this in mind. When ion-pair reagents are used, however, silanol effects are often less important. The reason is that an anionic (acidic) reagent confers an additional negative charge on the column packing and this reduces the relative importance of sample retention by ion exchange with silanol groups. Similarly, cationic (basic) reagents are quite effective at blocking silanols because of the strong interaction between reagent and ionized silanol groups.

Still another cause of peak fronting is for the case of *anionic (acidic) sample molecules separated with higher-pH mobile phases*. For silica-based packings, the packing has an increasingly negative charge as the pH increases, and this results in the repulsion of anionic sample molecules from the pores of the packing. With larger sample sizes, however, this effect is overcome by the corresponding increase in ionic strength, caused by the sample. A remedy for this problem is to increase the ionic strength of the mobile phase, by increasing the mobile-phase buffer concentration to the range of 25–100 m*M*. It should be mentioned here that ionic or ionizable samples should never be separated with unbuffered mobile phases.

Finally, *column voids* and *blocked frits* can also cause peak fronting.

Circular and Anti-Circular TLC

C. Marutoiu
Department of Chemistry, Lucian Blaga University of Sibiu, Sibiu, Romania

M.L. Soran
National Institute of Research and Development for Isotopic and Molecular Technology, Cluj-Napoca, Romania

INTRODUCTION

Thin-layer chromatography (TLC) has developed recently because of the theoretical and practical optimization of the chromatographic technique. The introduction of the commercial chromatographic plates, covered with stationary phases that have particles with controlled size and tight distribution of particle sizes (5–15 μm), was one of the reference points in modern TLC development. These new plates have given a higher efficiency and a shorter time of analysis, compared with conventional plates, when the optimum sample quantity was applied onto the stationary phase. Initially, only silica gel plates were commercially available but, in the last years, various normal and chemically modified stationary phases, including alumina, cellulose, reverse phases containing ethyl-, octyl-, octadecyl-, and diphenylsilyl radicals bonded onto silica gel have appeared. The most recent stationary phases contain a chiral layer for enantiomer separations.[1]

At the same time, with diversification of the stationary phases, various new apparatuses, like the apparatus for automatic application of spots, the chromatographic chambers for circular and anti-circular development, automatic multiple development, or development at high pressure, chambers with gradients, equipment for registering "in situ" chromatograms have appeared.[2]

The mobile phase used in TLC can migrate along the stationary phase by capillarity or by applying another external force. Depending on the movement mode of the mobile phase, various development techniques have appeared: ascending, horizontal, continuous, multiple, bidimensional, circular, and anti-circular development. The last two techniques have experienced a continuous development, especially in recent times, because of their employment in preparative applications for the separation of bioactive substances from plants.[3]

CIRCULAR AND ANTI-CIRCULAR DEVELOPMENT

Circular TLC

In circular chromatography (radial chromatography), the sample for separation is spotted in the center of a plate as a circular spot. The mobile phase is introduced in the center of the circular chromatographic plate (Fig. 1). This technique can be used with normal chromatographic plates too, but cannot be used with multi-channel plates.

The movement of the mobile phase is radial, from the center to the periphery (Fig. 1), owing to capillarity and the centrifugal force induced by rotation of the plate. The retention factor (R_F) for circular development is given by Eq. 1, which is valid only when the start position coincides with the solvent entry position, i.e., the geometrical center of the chromatographic plate:

$$R_{F(lin)} = (R_{Fcirc})^2 \tag{1}$$

In the case when the entrance of the solvent and the start positions are different (Fig. 2), the circular retention factor can be calculated with the following equation:[4]

$$R_{Fcirc} = \sqrt{\frac{z_s^2 + R_{Flin}\,(z_f^2 - z_s^2)}{z_f - z_s}} - z_s \tag{2}$$

This equation was obtained from Kaiser's equation:[5]

$$R_{Flin} = \frac{z_c^2 - z_s^2}{z_f^2 - z_s^2} \tag{3}$$

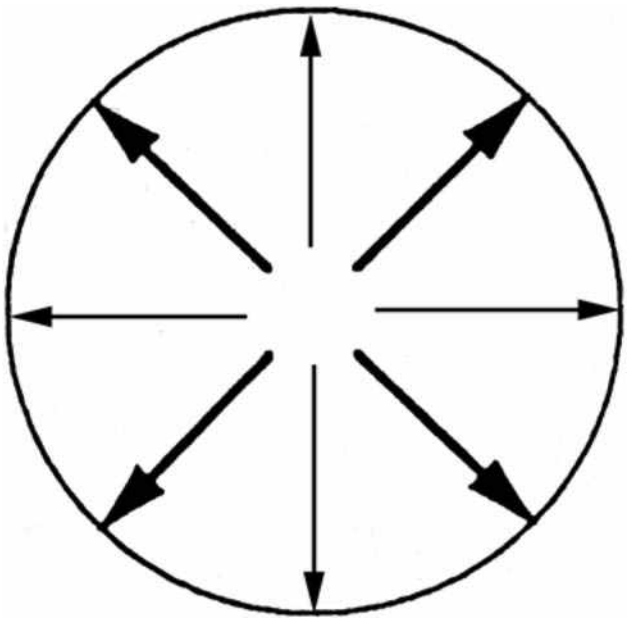

Fig. 1 Circular development.

The advantage of this technique is the improvement of resolution for compounds with low R_F, compared with linear chromatography.

One can achieve a better resolution, however, with increasing development time by modification of the circular chromatographic chamber. This modification consists of apertures made in the external part of the lid of the chamber, which leads to a continuous evaporation of the solvent. Sometimes, the solvent is continuously evaporated by heating.

By successive operations of development-drying applied to the chromatographic plate, a circular multiple development is achieved. Thus, the solvent front is multiply displaced through the chromatogram zones, achieving a concentration and deformation of the chromatographic spots. This results, in some cases, in elliptical spots or straight bands. Usually, this approach leads to an increase in resolution for compounds with R_F less than 0.5. The circular multiple development can be performed using one eluent or different eluents with various polarities, and on various lengths of development.

Anti-Circular TLC

In the case of the anti-circular technique, the chromatographic plate is placed horizontally, the sample is spotted as circles at the periphery of the plate, and the elution is performed from exterior to interior of the plate (Fig. 3).

The relationship between the retention factors in linear chromatography and anti-circular chromatography is given by the equation:

$$R_{\text{Flin}} = (R_{\text{Fanticirc}})^{0.5} \tag{4}$$

This method is advantageous for the separation of compounds with high R_F values.

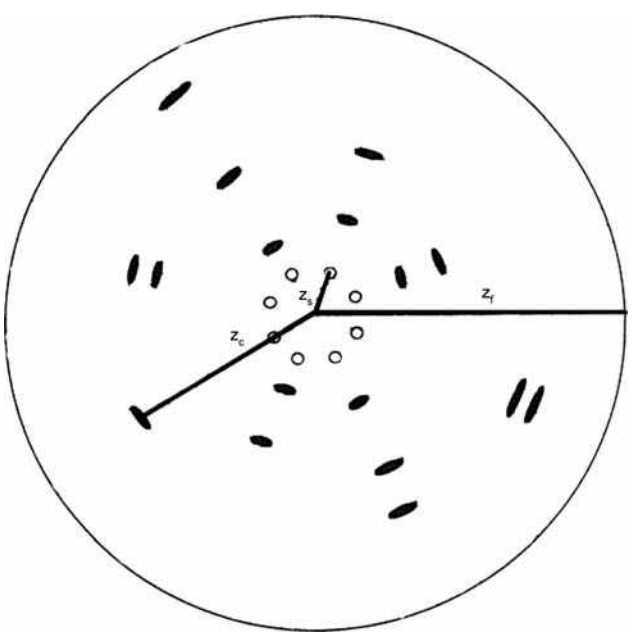

Fig. 2 Densitogram of a circular development.

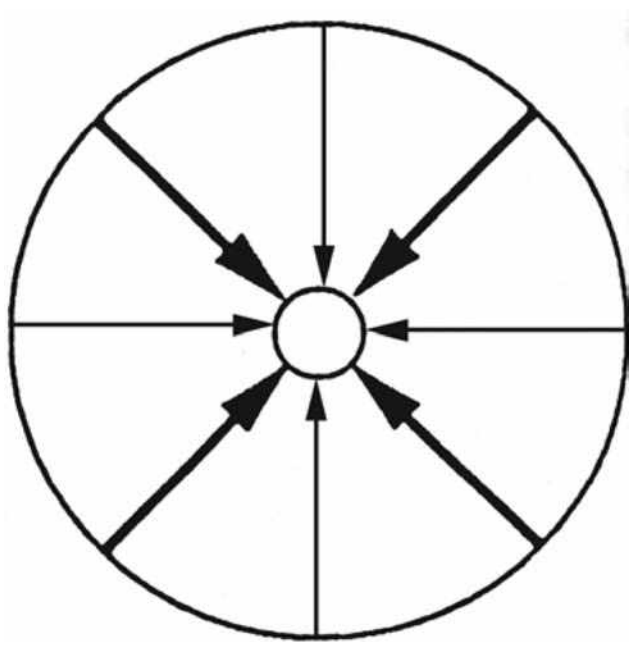

Fig. 3 Anti-circular development.

Equipment Used in Circular and Anti-Circular Chromatography

The first researchers in TLC, Ismailov and Schraiber, did not use a chamber; a vertical pipet supplied the solvent to the center of an applied sample spot. The simplest equipment for development of circular or anti-circular chromatograms in a closed system is a Petri dish containing the mobile phase and an appropriate means of transfer of mobile phase by capillary action to the chromatographic plate.[3]

The rotational circular chambers in an open system (Fig. 4) comprise a motor that rotates the chromatographic plate and a system for supplying the mobile phase, which is positioned perpendicularly to the chromatographic plate's center.

Rotation planar chromatography (RPC) uses a centrifugal force for mobile phase migration, in addition to the capillary action. The size of the vapor space above the chromatographic plate is an essential criterion in RPC methods and, based on this, the methods are classified into four basic techniques, namely normal chamber RPC (N-RPC), microchamber RPC (M-RPC), ultra-microchamber RPC (U-RPC), and column RPC (C-RPC).

Sequential RPC (S-RPC) is a special technique in which circular and anti-circular development modes are carried out sequentially in a normal chamber.

In N-RPC, the layer rotates in a stationary chromatographic chamber, whereas in M-RPC, a co-rotating chromatographic chamber is used and the vapor space is reduced. When using U-RPC, a quartz glass cover plate is placed directly on top of the layer, which almost completely eliminates the vapor space.

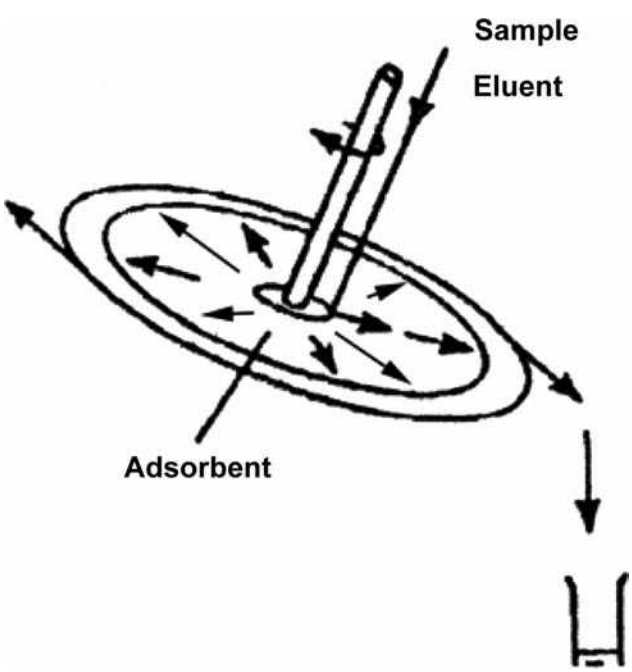

Fig. 4 Rotational chromatographic plate.

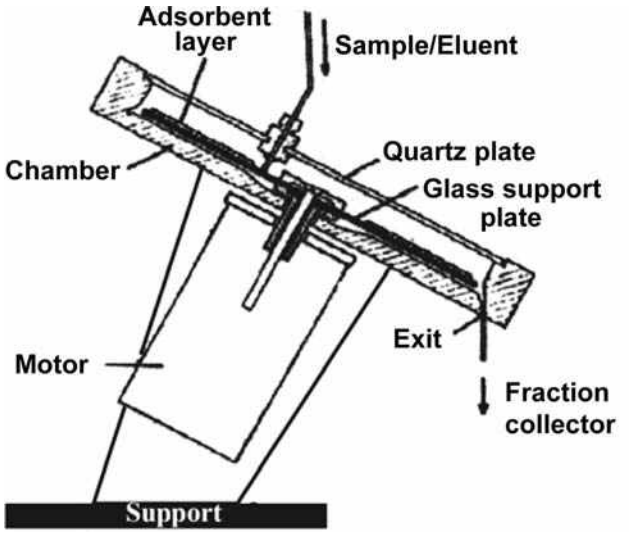

Fig. 5 Rotationally circular chromatographic chamber.

C-RPC differs from the previous three methods in that the stationary phase is placed in a closed circular chamber (planar column) and, hence, there is no vapor space. Owing to the special geometric design of the column, the volume of the stationary phase remains constant along the entire separation distance and the flow is accelerated linearly as in column chromatography.[6] The primary advantage of this design is the elimination of the extreme band broadening normally observed in all circular development techniques. As a result of its operating principle, C-RPC is only used for preparative separations.

Generally, these chambers comprise a support with a motor that rotates the circular chromatographic chamber and the chromatographic plate (Fig. 5).

The chamber is covered with a quartz glass and the mobile phase and the sample are introduced by a slide placed in the lid center of the chromatographic chamber. The mobile phase and the separated compounds are collected in a fraction collector after development.

The automatic apparatuses used for rotational circular chromatographic separations are called Chromatotron, Rotachrom, Cyclograph, and Extrachrom.

Applications of Circular Planar Chromatography

Circular planar chromatography is suitable for analytical purposes and preparative separations as well. Coumarine

from *Peucedanum polustre* (L.), iridoid glycosides, (+) catechin, and (−) epicatechin were isolated, separated, and identified by this technique for analytical purposes.[7] Circular planar chromatography was applied by Nyiredy and coworkers,[6] with success, for preparative separation of various classes of natural compounds, e.g., for peridin and β-carotene separation from *Gonyaulax polyedro* seaweed.[8]

CONCLUSIONS

The circular TLC is used for resolution increase in compounds with low R_F; the circular multiple developments are frequently used for separation of compounds with R_F less than 0.5. The anti-circular TLC is advantageous for the separation of compounds with high R_F values. The circular TLC can be performed in a closed system, on Petri dish, or in an open system, rotational circular chamber. Circular TLC was used with success for separation of bioactive compounds from plants.

Clinical Diagnosis by CE

Cheng-Ming Liu
Department of Medical Technology, Institute of Biomedical Technology, Taipei Medical University, Taipei, Taiwan

INTRODUCTION

The capillary electrophoresis (CE) technique has been developing since the late 1970s and early 1980s by Jorgenson and Lukacs[1] and some other investigators. This technique provides a rapid and accurate separation without the limitation of molecular size. Many instrument companies started to build a relatively sophisticated instrument for meeting the demand in the late 1980s. The first commercialized CE instrument was introduced into the market in 1989. At that time, major diagnostic reagent companies were interested in developing CE methods and reagents by using those instruments for clinical uses. So far, some routine clinical analyses, such as serum protein, myeloma protein, urinary Bence Jones protein, and hemoglobin (Hb) by CE are widely accepted by consumers. Some other specialized clinical analyses, such as nucleic acid and drug analyses, are still restricted in some clinical laboratories because of the lack of test kits and suitable software.

CLINICAL ANALYSIS

The Advanced Development Department of Beckman Instruments, Inc. (Beckman Coulter Inc., Fullerton, California, U.S.A.) began researching serum protein, myeloma protein, urinary protein, and Hb variants analysis by CE. The reason to start with those proteins as the analytes were because of their high concentrations existing either in serum or in blood. Because ultraviolet (UV) absorption has been used for protein quantitative analysis, so the concentration becomes a limitation and key factor. The results were published in Clinical Chemistry.[2] They compared the results from CE to results from the conventional methods (by gel electrophoresis) and found that they are highly similar. In serum protein analysis, the CE peaks were comparable with the results from conventional agarose gel electrophoresis in all five classical bands: albumin, alpha-1, alpha-2, beta, and gamma regions. However, CE analysis has prevailed over gel electrophoresis in terms of running time. Each run in CE, including conditioning, washing, and rinsing, required less than 10 min, as opposed to 2 hr in gel electrophoresis. High-resolution CE serum analysis was developed by the Beckman Advanced Research group in 1991.[3] Ten major serum proteins were separated, as shown in Fig. 1. Some proteins, which could not be separated by gel electrophoresis (such as C3 complement, beta lipoprotein, alpha-2 macroglobulin, alpha-1 acid glycoprotein, and prealbumin), were able to be separated by high-resolution CE analysis. These ten major proteins can give clinicians more information regarding disease status. A sharp, narrowed, outstanding peak in the gamma region usually represents myeloma protein in the serum. This "church spire-like" peak is very easy to find in the gamma region. However, the peak does not distinguish between classes and subtypes of M protein. To solve this problem, the investigators used antibodies against IgG, IgM, IgA, kappa, and lambda, each labeled with a solid phase column, separately. The patient sera were passed through the column individually, and the eluted sera were subjected to CE. The attenuated or absent peak thus reflected the class or subtype of M protein.[4] Fig. 2 is a panel of electropherograms, which represents an example of an IgGλ myeloma protein serum sample. The upper-left panel represents the whole electropherogram of patient serum. The upper-right is an overlap of two electropherograms, one before passing through the column with anti-IgG solid phase, and the other after passing through the column. Focusing on the region of immunoglobulin, the IgG peak of the second run is seen to attenuate substantially. A similar pattern is found in the antilambda column, while the remainder of the electropherograms generally overlap between the two runs. These results may indicate that the M-protein belongs to the IgG class and lambda type. Some myeloma patients may produce light-chain immunoglobulin. These proteins may be filtered through the kidney and ultimately appear in their urine (Bence Jones protein). The detection of either serum proteins or M-protein, using UV absorption (λ = 214 nm), was attempted when a small amount of undiluted urine was injected into the capillary to allow for normal spikes. The results showed a multipeaked electropherogram, with smaller protein peaks hiding among some other peaks. This renders identification of specific proteins difficult. To remove these non-protein peaks, a permeated polyacrylamide bead column was used. Large protein molecules passed through the column, while small molecules were bound by the beads. The eluted urine from the column was subjected to CE analysis, and the resulting electropherogram showed that all non-protein small molecules were retained in the column and only protein peaks

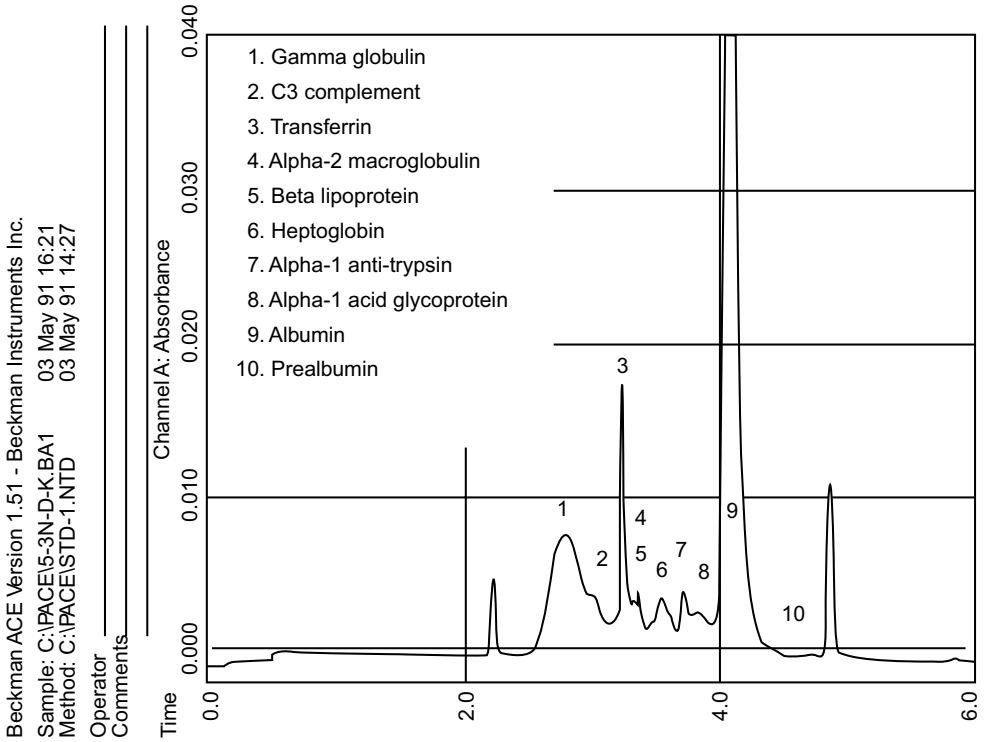

Fig. 1 The electropherogram from normal serum sample by CE. Running conditions: Fused silica capillary, 25 μm I.D. × 27 cm; detection at 214 nm; applied potential, 10 kV with Beckman Coulter proprietary running buffer. appeared, as if it was spiked or as it originally existed.[5] The first automated clinical CE instrument, Paragon CZE (capillary zone electrophoresis) 2000 (Beckman Coulter) was commercialized in the late 1990s. This automated CZE, with seven capillaries, provides reproducible and rapid serum electrophoresis. It is particularly useful in clinical laboratories that have a relatively large daily workload.

Hb is another analyte, which is easily amenable to CE analysis. This is because of its high clinical concentrations as well as its homogeneity. UV detection (absorption of 415 nm visible light) of Hb is more accurate than the dye-staining technique for protein quantitation. Hb variants such as HbS, HbC, and HbA (normal control) were subjected to CE analysis. With an optimized running buffer, the three species of Hbs were separated as three distinct peaks in the electropherogram (Fig. 3a); these results are comparable to conventional gel electrophoresis (Fig. 3b).[2]

Another clinical utility for Hb is in quantitation of HbA1c. HbA1c results from glucose binding with Hb via a non-enzymatic reaction (the Amadori rearrangement), to form a stable, glycated Hb. HbA1c is one of the best indicators for monitoring the status of diabetes control, and its clinical measurement has been recommended, by the American Diabetes Association, for patients. Glucose itself is a small, low-molecular-weight molecule, and when it is bound to Hb, the change of mobility within CE is not significantly noticeable. To solve this problem, the same group of investigators used high ionic strength running buffer, with high pH, for HbA1c analysis.[6] Fig. 4 shows that the glycated Hb was separated from non-glycated normal Hb in both a non-diabetic subject (upper panel) and in a diabetic patient (lower panel). A group of investigators in Belgium (Analis)[7] used a proprietary malic acid buffer, pH 4.5, in a preconditioned capillary tube, which was rinsed with an initiator solution and followed by a polyanion for HbA1c analysis. They found a high resolution for the HbA1c peak and some other Hb variant peaks such as HbS and HbC in the resulting electropherogram. This high-resolution Hb analytical method is very reproducible and well suited for clinical diagnostic requirements.

Single-wavelength detection is the standard method for analyte quantitative analysis. Because of the limitation of its sensitivity, a new method to overcome this problem uses a laser-induced fluorescence (LIF) approach. LIF offers high-sensitivity detection for some trace amounts of proteins or drugs in body fluids such as hormones, acute phase reactants, and drugs. The basic principle of LIF involves labeling a specific fluorochrome on either an antibody or antigen (analyte), which depends on the direct or competitive immunoassay.[8] When an analyte is bound to antibody to form a complex, the sizes and/or charges of the

molecules will be changed, and the migration time will also most likely be changed. The complex peak then can be identified by its fluorescence on the antibody moiety and excited by laser; the emission light is collected and transformed to a signal by a photomultiplier tube (PMT).

Another major application of clinical CE is for DNA analysis. It includes DNA fragments analysis and DNA sequence analysis. The separation mechanism of DNA involves employing polyacrylamide-filled or agarose-filled capillaries; the different sizes of DNA fragments migrate through the pores of the gel. Hjerten[9] used 150 μm internal diameter (I.D.) gel-filled capillaries for both large- and small-molecule separations with high resolving power. Cohen, Najarian, and Karger[10] demonstrated an extremely high-resolution separation by using polyacrylamide gel, which contained sodium dodecyl sulfate; they obtained even higher resolution. The DNA fragment was amplified by using polymerase chain reaction (PCR) with fluorescent dye-labeled nucleotides. Applied Biosystems (ABI) offers the commercialized instrument, Genetic Analyzer (ABI Prism 310), which is an automated single-capillary genetic analyzer designed for a wide range of sequencing and fragment analysis applications.[11] It is very useful for rapid mapping of genetic traits leading to gene discovery and eventual diagnostic testing. Some genetic disease and neoplastic disorders[12,13] can be detected with this instrument.

In addition to aforementioned macromolecules, another area of interest is small-molecule analyses or some endogenous or exogenous compounds in biofluids and tissues, which are important for clinical diagnosis. Two capillary electrophoretic modes for small molecules analysis are CZE and micellar electrokinetic capillary chromatography (MEKC). As UV absorption detection has been used in most of cases, sample preparation is generally required. Samples are commonly from blood, serum, or urine, which may contain some macromolecules that may interfere with the UV absorption. These macromolecules such as proteins

have to be removed by either precipitation or extraction. The detection wavelength may depend upon the analyte compound's absorption maximum. Shihabi[14] used two volumes of acetonitrile mixed with one volume of serum to remove most proteins; this allows a large volume of sample to be injected into the capillary. They found some advantages of CE in drug analysis, compared with traditional high performance liquid chromatography or gas chromatography. Advantages include simplicity of sample preparation and instrumental setup, speed of analysis, high plate number of the separation, more modes for selection, and lower cost. There are two major areas for drug analysis. One is for therapeutic drug monitoring (TDM) and the other is for detection of drugs of abuse. TDM is one of the largest areas in clinical laboratory medicine, because of many drugs with narrow therapeutic windows; the other is continuous discovery of new drugs. TDM deals with the quantitation of drugs present in the serum as it relates to patient treatment and management. Many drugs such as antiepileptic drugs, immunosuppressive drugs, antiasthmatic drugs, analgesics, and antidepressants possess narrow therapeutic windows. In this regard, the precision quantitative drug analysis in serum becomes very critical. The other area for drug analysis is to detect some drugs such as cocaine, heroin, methamphetamine, lysergic acid diethylamide (LSD), and phencyclidine (PCP) that are elicited in body fluids such as urine or serum. A simple quantitative method uses CE with liquid cooling to analyze commonly seized illicit substances. Comparisons of CE quantitations with results from other laboratory techniques demonstrate the reliable adaptation of CE to the forensic laboratory.

CONCLUSIONS

Although CE is a mature analytical method in the research arena, in the clinical laboratory, it is still in its kindergarten stage. In 2001, only 13 out of 739 clinical laboratories in the U.S.A. subscribed to CAP proficiency testing for serum protein electrophoresis. To broaden the acceptance of CE in the mainstream of the clinical laboratory, the instrument companies need to develop chemical reagent kits and suitable software, with the instrument for the end user in the clinical laboratory. Because CE is still perceived as requiring a high technical expertise, precluding its use in a laboratory in which personnel are less technically adept. How to educate the laboratory personnel to convince them to understand the friendly operational procedure and efficient separation will be the future task.

Coil Planet Centrifuges

Yoichiro Ito
National Heart, Lung, and Blood Institute (NHLBI), National Institutes of Health (NIH), Bethesda, Maryland, U.S.A.

INTRODUCTION

We have defined "coil planet centrifuge" (CPC) as a term that designates all centrifuge devices in which the coiled separation column undergoes a planetary motion, i.e., the column rotates about its own axis while revolving around the central axis of the centrifuge. Except for the original CPC, all existing CPCs are equipped with a flow-through system so that the liquid can pass through the rotating coiled column. In most of these flow-through CPCs, the use of a conventional rotary seal device is eliminated. These sealless systems are classified into two categories according to their modes of planetary motion, i.e., synchronous and non-synchronous (see *CCC: Instrumentation,* p. 327, Fig. 3). In the synchronous CPC, the coiled column rotates about its own axis during one revolution cycle, whereas in the non-synchronous CPC, the rates of rotation and revolution of the coiled column are freely adjustable. Among several different types of CPCs, the following four instruments are described below in terms of their best applications: the original CPC, the type-J CPC, the cross-axis CPC, and the non-synchronous CPC.

ORIGINAL CPC

This first CPC model was devised in an effort to improve the efficiency of lymphocyte separation which was conventionally performed in a short centrifuge tube. If a long tubing is wound into a coil and rotated in a centrifugal field, the particles present in the tube would travel through the tube from one end to the other at a rate depending on their size and density. This idea was implemented in the designs of the first device named the "CPC."[1]

Principle

Physical analysis of the motion of a particle in the rotating helical tube of a CPC has been carried out by means of a simple model is as follows.[1]

(A) We consider a tube filled with a fluid of density ρ_0 coiled into a helix of radius R, with its axis horizontal. If a spherical particle of radius a, density ρ, is placed in the tube, we can determine motion of the particle when the helix undergoes uniform rotation about its axis with angular velocity ω. As a first approximation, we neglect the lateral motion in the tube and assume that in a given turn of the coil, the particle moves on a vertical circle of radius R. The position of the particle can then be specified by the angle θ, as indicated in Fig. 1. With this approximation, the particle is acted on by only two forces, the Stokes drag

$$F_s = -6\pi a\eta R(d\theta/dt - \omega)$$

where η is the viscosity of the fluid, and the net gravitational force g tangent to the circular path

$$F_g = -(4\pi/3)a^3(\rho - \rho_0)g\sin\theta$$

The equation of motion is therefore

$$(4\pi/3)a^3\rho R(d^2\theta/dt^2) = F_s + F_g$$

and on introducing the total angle of rotation of the helix, $x = \omega t$, this can be written in the convenient form

$$d^2\theta/dx^2 + (1/\omega\tau)\{d\theta/dx - 1 + (\omega_e/\omega)\sin\theta\} = 0 \quad (1)$$

where τ is the relaxation time

$$\tau = 2\rho a^2/9\eta \quad (2)$$

and ω_e is the critical angular velocity

$$\omega_e = (2/9)\{(\rho - \rho_0)ga^2\}/\eta R = V_e/R \quad (3)$$

where V_e is the equilibrium Stokes velocity. We consider separately the motion for

$$\omega_e/\omega > 1 \quad \text{and} \quad \omega_e/\omega < 1$$

(B) $\omega_e/\omega > 1$. In this case, Eq. 1 has a singular point at $\omega_e/\omega \sin\theta = 1$, i.e., at $\theta = \theta_2 = \sin^{-1}(\omega/\omega_e)$, $0 \le \theta \le \frac{\pi}{2}$, and at $\theta = \pi - \theta_e$. The terms θ_e and $\pi - \theta_e$ are the angles at which the drag of the liquid is just balanced by the gravitational force so that the particle is at equilibrium when at rest. It is readily seen from physical considerations that the equilibrium at θ_e is stable while that at $\pi - \theta_e$ is unstable. More precisely, an analysis in the neighborhood of the singular points shows that $\pi - \theta_e$ is an unstable saddle point, while θ_e is

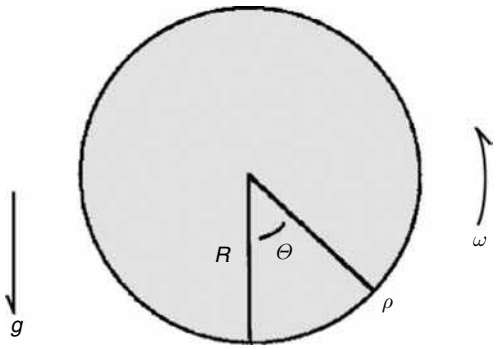

Fig. 1 The coil unit for mathematical analysis of the motion of a particle.
Adapted from The coil planet centrifuge, in Nature.[1]

a stable node if $\omega\tau \leq 1/4 \tan \theta_e$ and a stable spiral point if $\omega\tau > 1/4 \tan \theta_e$. Consequently, after a time of the order of τ, the particle will remain fixed at θ_e. Its angular velocity relative to the tube will then be

$$\omega_{rel} = \omega\{d\theta/dx - 1\} = -\omega \quad (4)$$

That is, it will spiral down the helix at a rate independent of its size and density.

(C) $\omega_e/\omega < 1$, $\omega\tau < 1$. When $\omega_e/\omega < 1$, Eq. 1 has no singular points. The character of the motion, however, depends to some extent on the size of $\omega\tau$, and we shall consider in detail only the physically interesting case $\omega\tau < 1$. It can readily be shown that within this limit, after a time of the order of τ, angular velocity of the particle adjusts itself in such a way that the inertial term, $\omega\tau\, d^2\theta/dx^2$, becomes negligible, so that Eq. 1 reduces to

$$d\theta/dx = 1 - \omega_e/\omega \ \sin \theta \quad (5)$$

The particle then always rotates in the same direction as the tube, but more slowly than the tube when $0 < \theta < \pi$ and more rapidly when $\pi < \theta < 2\pi$. The two effects, however, do not quite cancel out, and the net effect is that, again, the particle spirals down the tube in a direction opposite to that of the tube rotation.

To determine the mean angular velocity of this spiraling motion, we first calculate the time required for the particle to traverse one turn of the coil. We have from Eq. 5

$$X(2\pi) - X(0) = \int_0^{2\pi} d\theta/\{1 - (\omega_e/\omega) \sin \theta\} = 2\pi/\{1 - [(1 - \omega_e/\omega)^2]\}^{1/2}$$

The mean angular velocity of the particle relative to the tube is therefore

$$\omega_{rel} = \omega\{2\pi/[X(2\pi) - X(0)] - 1\} = -\omega\{1 - [1 - (\omega_e/\omega)^2]^{1/2}\} \quad (6)$$

which joins continuously on to the value at $\omega_e/\omega = 1$ of Eq. 4.

When ω is close to ω_e, ω_{rel} is rather insensitive to the size and density of the particle. When $\omega_e/\omega < 1$, however, Eq. 6 becomes

$$\omega_{rel} = -\omega_e^2/2\omega \quad (7)$$

so that the rate of motion down the tube is proportional to a^4 and $(\rho - \rho_0)$. Thus, when $\omega_e < \omega < 1/\tau$, the method should be quite effective in segregating particles of different size and density.

In order to apply (A)–(C) to the CPC, the value of g should be replaced by that of the centrifugal force acting on the axis of the rotating helical tube.

Design of the Original CPC

Fig. 2 shows the first commercial model of the CPC manufactured by Sanki Engineering, Ltd. (Kyoto, Japan).[1,3] The main body of the apparatus consists of three parts, each capable to rotation as a unit: coil holder (6) and interchangeable

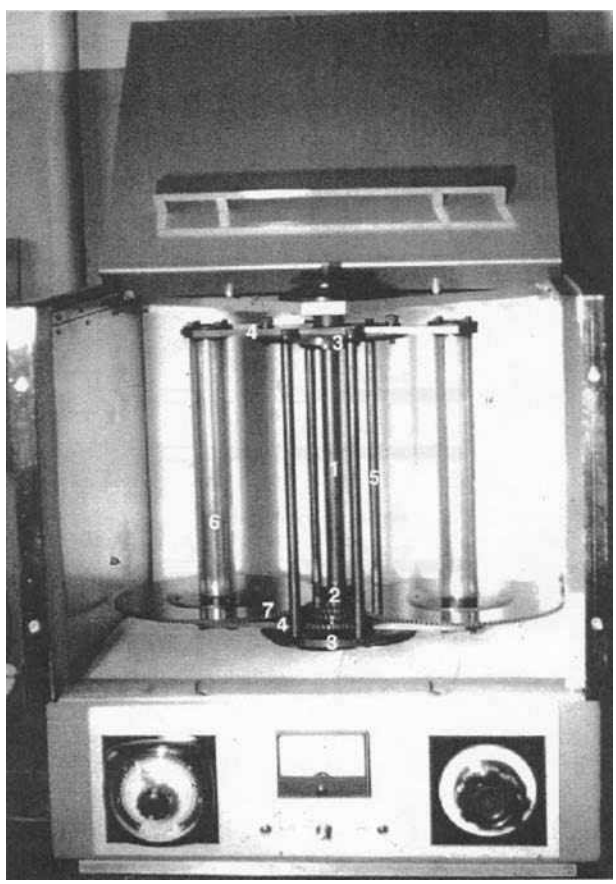

Fig. 2 The coil planet centrifuge fabricated by Sanki Engineering Ltd., Kyoto, Japan.
Source: From The coil planet centrifuge, in Nature.[1]

gear (7) (part I); frame or a pair of arms (4) and discs (3) bridged with links (5) (part II); and central shaft (1) and gear 2 which interlocks to gear 7 of part I. Simultaneous rotation of parts II and III at different angular velocities results in revolution and rotation of part I as a planet. The rotation of part I is determined by the difference in angular velocity between parts II and III and by the gear ratio between 2 and 7.

The apparatus can produce $1000 \times g$ force where the ratio between the coil rotation and revolution can be adjustable to 1/100, 1/300, or 1/500 by interchanging the planetary gears (7) at the bottom of the column holder (6). Each coil holder is equipped with six straight grooves at its periphery to accommodate six coiled tubes that are covered by a transparent vinyl sheath protector tightly fitted to the outside of the holder. Each coil is made by winding either polyethylene or Teflon tubing (typically 0.3 mm I.D.) onto a glass core (15 cm long and 6 mm diameter). After the liquid and sample are introduced into the tube, both ends of the coil are closed before loading onto the holder.

Three Different Modes of Operation

Preliminary experiments with the CPC revealed some interesting features of the apparatus. The results are summarized in Fig. 3.[1]

(I) Single medium: When the tube is filled with a single medium and a particle mixture is introduced at one end, centrifugation separates the particles according to Fig. 3. The difference in size and relative density. The method was effectively demonstrated by a model experiment using polyacrylic resin particles.[1]

(II) Two mutually miscible media (gradient method): When the tube is filled with two mutually miscible media, the heavier in one half and the lighter in the other half, centrifugation produces a density gradient. After centrifugation for some time, the gradient reaches a fairly stable state. In practice, such a stable gradient between water and isotonic saline solution can be introduced into the coil to measure osmotic fragility of erythrocytes. Erythrocytes introduced into the saline side of the coil are forced to travel through the gradient down to the point where hemolysis occurs, the distribution of hemoglobin thus formed, indicating the osmotic fragility of the sample.[2]

(III) Two mutually immiscible media CC. When two mutually immiscible media are used similarly, centrifugation forces these two media to undergo countercurrent motion, and, in the final stage, each turn of the coil is occupied by the two media nearly half and half as illustrated in Fig. 3-III. Consequently, a small amount of a sample injected beforehand at the interface of the two media, i.e., the middle portion of the tube, is distributed along the tube according to its partition coefficient. This CC method is applicable to microgram amounts of chemicals with a high efficiency that may be equivalent to near 1000 units of a Craig countercurrent distribution apparatus.

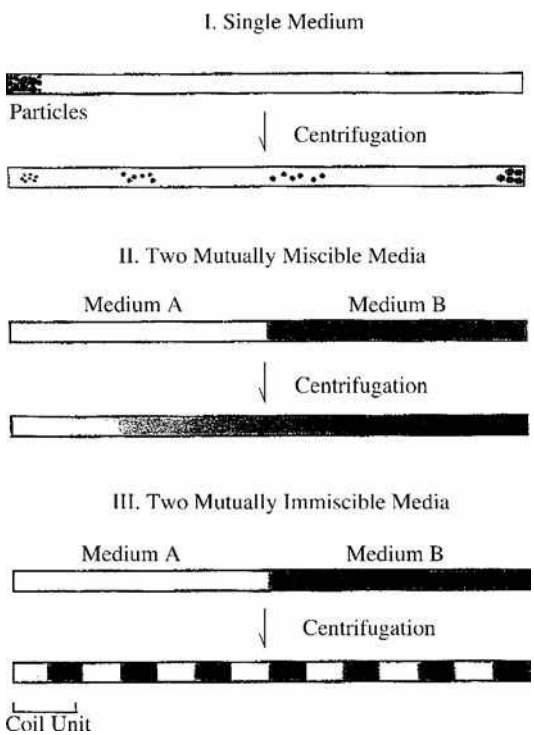

Fig. 3 The principle of three different applications of the coil planet centrifuge. All tubes are shown uncoiled before and after centrifugation.
Source: From The coil planet centrifuge, in Nature.[1]

Applications to CC

Capability of the apparatus for performing microscale CC has been demonstrated using three different samples, i.e., a mixture of dyes, agal proteins, and mammalian erythrocytes.[3]

Separation of dyes

Fig. 4a shows CC separation of four basic dyes, i.e., methyl green (MG), methylene blue (MB), neutral red (NR), and basic fuchsin using a two-phase solvent system composed of isoamylalcohol–ethanol–acetic acid-distilled water (4:2:1:5, v/v). The first coil displays the separation of the mixture, and the other coils show distribution of individual dyes to demonstrate the reproducibility of the method. The separation was performed with 6 m of 0.35 mm I.D. tubing (~300 helical turns) at relative coil rotation of 0.25 rpm at $300 \times g$ for 10 hr.

Separation of algal proteins

Phycoerythrin and phycocyanin were extracted from dried Asakusa-nori (*Porphyra tenera*) and subjected to partition with an aqueous polymer phase system (Table 1) using the above standard countercurrent method. Fig. 4b shows the results of separation, where two components are well resolved.

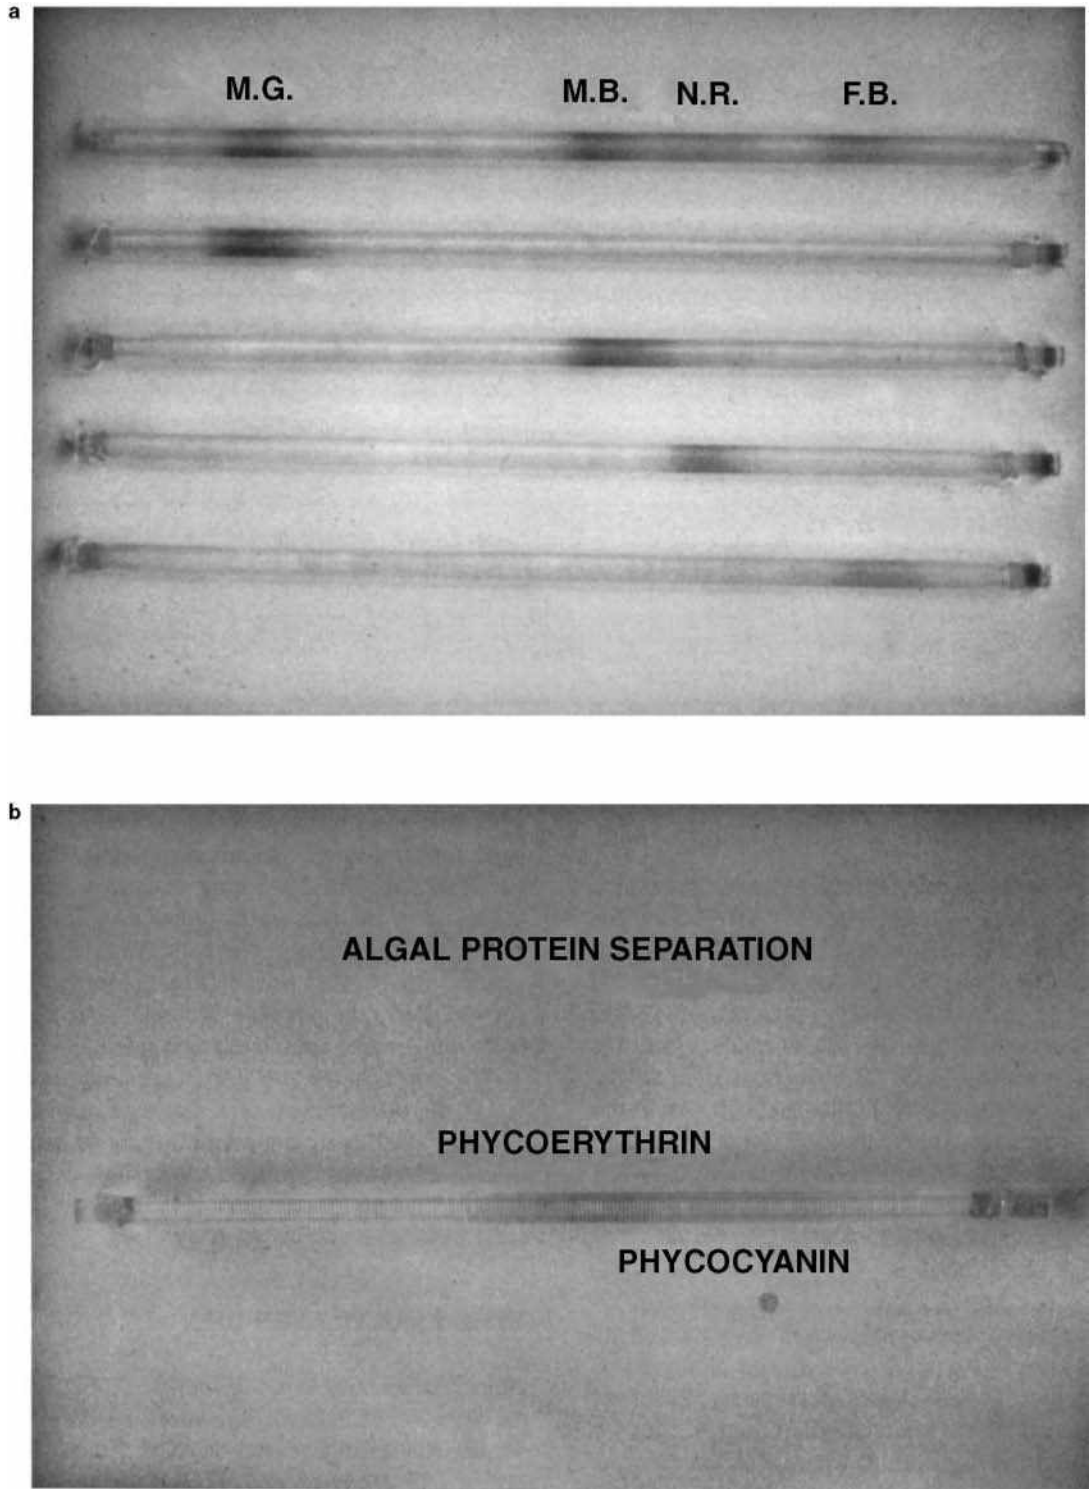

Fig. 4 Countercurrent separation of various samples by the coil planet centrifuge. a, Separation of basic dyes with an organic/aqueous two-phase solvent system. Erythrocyte separation

The separation of human and rabbit erythrocytes was performed with a modified method using a gradient between a pair of polymer phase systems A and B (Table 2), where the upper phase of A and the lower phase of B were used for separation. Before charging with sample, the coil was rotated at 1500 rpm at a relative rotation of 1/100 (15 rpm) for 30 min, which produced a gradient between the two phases along the coil. Then the sample cell mixture was loaded followed by centrifugation for 1 hr. Fig. 4c shows the partition of human and rabbit erythrocytes which were completely separated along the coil.

The results of the above studies using the original CPC led to the development of a series of new CPC devices equipped with a flow-through system that permits continuous elution through the column as in other chromatographic systems.

TYPE-J MULTILAYER CPC

Among all existing types of seal-free flow-through CPCs, the type-J CPC affords the most efficient and speedy separations or "high-speed CCC," and it has been extensively used for preparative separations of natural and synthetic products.

Mathematical Analysis of Planetary Motion

The type-J synchronous planetary motion of the coil holder is shown in Fig. 5a (see also *CCC: Instrumentation,* p. 327, Fig. 3), where the holder rotates about its own axis and simultaneously revolves around the axis of the centrifuge at the same angular velocity but in the opposite direction. Simple mathematical analysis[4] is performed using a coordinate system shown in Fig. 5b, where the center of the revolution coincides with the center of the coordinate system (point O). For convenience of analysis, the center of rotation and an arbitrary point are initially located on the *x*-axis. After the lapse of time t, the holder circles around point O by $\theta = \omega t$, while the arbitrary point circles around the axis of rotation by 2θ to reach $P(x, y)$ where

$$x = R \cos \theta + r \cos 2\theta \tag{8}$$

$$y = R \sin \theta + r \sin 2\theta \tag{9}$$

The acceleration produced by the planetary motion is then obtained from the second derivatives of Eqs. 8 and 9,

$$d^2x/dt^2 = -R\omega^2(\cos\theta + 4\beta\cos 2\theta) \quad (10)$$

$$d^2y/dt^2 = -R\omega^2(\sin\theta + 4\beta\sin 2\theta) \quad (11)$$

where $\beta = r/R$.

From Eqs. 10 and 11, two centrifugal force components, i.e., Fr (radical component) and Ft (tangential component), are computed using the following formula:

$$\mathrm{Fr} = R\omega^2(\cos\theta + 4\beta) \quad (12)$$

$$\mathrm{Ft} = R\omega^2(\sin\theta) \quad (13)$$

Fig. 5c shows the distributions of force vectors computed from Eqs. 12 and 13 at various locations on the column holder. All vectors confined in a plane perpendicular to the holder axis. As the holder rotates, both the direction and the net strength of the force vector fluctuate in such a way that the vector becomes longest at the point remote from the centrifuge axis and shortest at the point close to the central axis of the centrifuge. In most locations, the vectors are directed outwardly from the circle except for $\beta < 0.25$, where its direction is reversed at the vicinity of the center of revolution. This fluctuating centrifugal force field creates unique hydrodynamic effects on the two solvent phases in the coiled tube.

Stroboscopic Observation of Hydrodynamic Motion of Solvent Phases

Fig. 6 schematically illustrates motion of the two solvent phases in a spiral column, which is subjected to the type-J synchronous planetary motion. The upper diagram shows distribution of two solvent phases in the column observed under stroboscopic illumination. About one-fourth of the area near the center of revolution (point O) shows vigorous mixing of the two phases (mixing zone), whereas in the rest of the area, the two phases are separated by a strong centrifugal force in such a way that the lighter phase occupies the inner portion and the heavier phase occupies the outer portion of the tube. Four stretched tubes in the lower diagram illustrate the traveling pattern of the mixing zone through the spiral tube in one revolution cycle. In analogy to the motion of a wave advancing over water, the mixing zone travels one spiral turn for each revolution. This indicates that the solutes are subjected to an efficient partition process of repeating mixing and settling at a high rate of 13 times per second at 800 rpm of revolution. This accounts for the high partition efficiency of the present system, and we have called it "high-speed CCC."[4]

Design of the Apparatus

Fig. 7 shows a photograph of the most advanced model of the multilayer CPC, which holds a set of three multilayer coil separation columns symmetrically around the rotary frame.[5,6] All columns are connected in series with flow tubes which are supported by counterrotating pipes placed between the column holders. The type-J synchronous planetary motion of the holder is provided by engaging a planetary gear on the column holder with an identical stationary sun gear mounted around the central stationary shaft of the centrifuge. The counterrotation of the tube holder is effected by interlocking a pair of identical gears, one mounted on the holder and the other on the tube holder. Flow tubes from each end of the column assembly are passed through the central rotary shaft to exit the centrifuge on each side, where they are tightly affixed with a pair of clamps.

The multilayer coil separation column is prepared by winding a single piece of Teflon or Tefzel tubing around a spool-shaped column holder making multiple coiled layers between a pair of flanges. Currently, three different sets of multilayer coils are commercially available: the large preparative scale (2.6 mm I.D., ~1000 ml total capacity); the standard preparative column (1.6 mm I.D., ~320 ml total capacity); and the analytical scale (0.85 mm I.D., ~120 ml

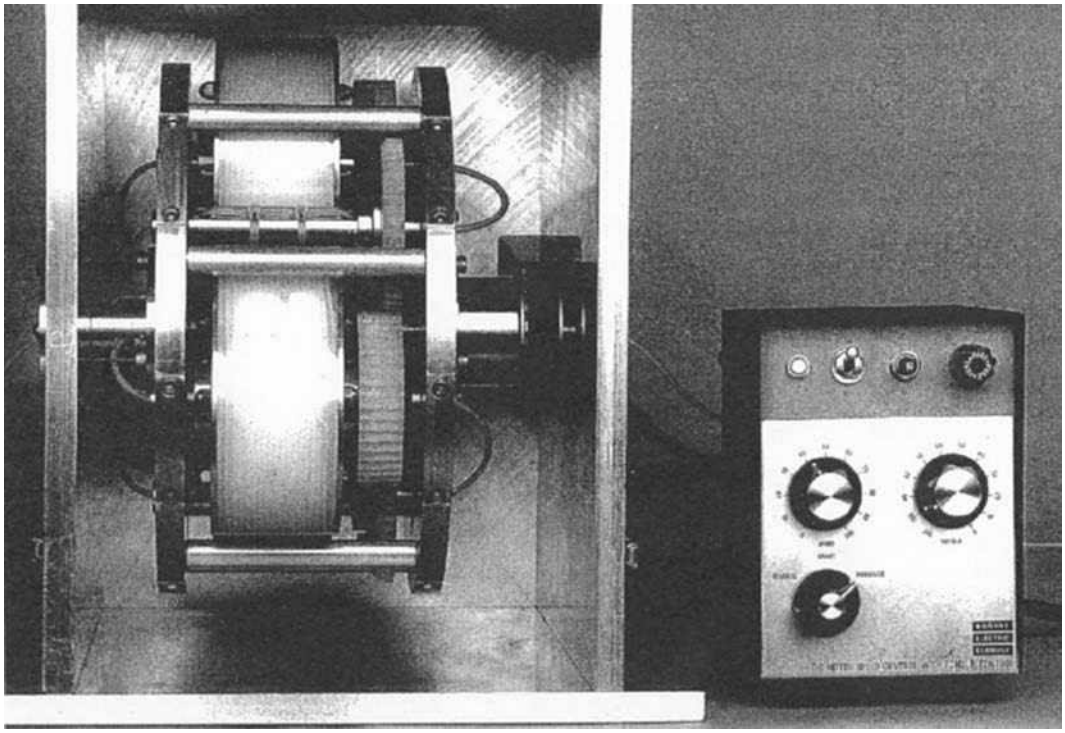

Fig. 7 Improved high-speed CCC centrifuge equipped with three column holders.

capacity). The optimal revolution speed of the apparatus ranges from 800 to 1200 rpm.

Applications

Because of its rapid and high separation efficiency, the multilayer coil CPC has been extensively used for separation and purification of variety of compounds using suitable organic/aqueous solvent systems. The application also covers special CCC techniques such as peak-focusing CCC and pH-zone-refining CCC[7] (see *pH-Peak-Focusing and pH-Zone-Refining CCC*, p. 1808); chiral and affinity CCC (see *Chiral CCC*, p. 413); foam CCC[8] (see *Foam CCC*, p. 905), liquid–liquid dual CCC;[9] and CCC/MS (see *CCC/MS*, p. 323).

The method, however, fails to retain viscous, low interfacial tension polymer phase systems such as polyethylene glycol (PEG)–dextran systems[10] due to its intensive mixing effect which tends to produce emulsification, resulting in carryover of the stationary phase. This problem is largely eliminated by the cross-axis CPC described below.

CROSS-AXIS CPC

The cross-axis CPC has a specific feature in that it permits the universal use of two-phase solvent systems including aqueous–aqueous polymer phase systems which are useful for partitioning macromolecules and cell particles.[10]

Acceleration Field

The design of the cross-axis CPC is based on the hybrid between type-L and type-X planetary motions, which results in an extremely complex centrifugal force field with a three-dimensional fluctuation of force vectors during each revolution cycle of the holder. The pattern of this centrifugal force field produced by the cross-axis CPC somewhat resembles that produced by the type-J planetary motion (Fig. 5c), but it is superimposed by a force component acting in parallel to the axis of the coil holder. This additional force component acts to improve the retention of the stationary phase. This beneficial effect is greatest in type-L planetary motion and becomes smallest in the type-X planetary motion. A detailed mathematical analysis on this planetary motion is described elsewhere.[11]

Design of the Apparatus

Fig. 8 shows the general principle of various cross-axis CPCs. The geometrical parameter of the system is shown in Fig. 8a, where the orientation and planetary motion are indicated relative to the axis of the apparatus. The vertical axis of the

apparatus and the horizontal axis of the coil are always kept perpendicular to each other at a fixed distance. The cylindrical column revolves at the central axis at the same rotational speed with which it rotates about its own axis. Three parameters displayed in Fig. 8a explain various versions of the cross-axis prototypes: r is the radius of the column holder, R is the distance between the two axis, and L is the measure of the lateral shift of the column holder along its axis. The name of a cross-axis device is based on the ratio L/R, when $R \neq 0$. Types *X* and *L* represent the limits for the column positions; type *X* involves no shifting of the column holder, while type L corresponds to an infinite shifting. Some examples of prototypes fabricated at the machine shop in the National Institutes of Health, Bethesda, MD, are shown in Fig. 8b.

The two different column designs are schematically shown in Fig. 9: The first column (multilayer coil) is used for preparative scale separations, while the second column (eccentric coil) is for analytical scale separations. The multilayer coil is prepared by winding a large Teflon tubing (2.6 mm I.D.) directly onto the holder hub in such a way that after completing each coiled layer, the tubing is directly returned to the starting point to wind the second layer over this connecting tube segment, and so on. This results in multiple coiled layers of the same handedness that are connected in series with short-tube segments as shown in Fig. 9a. The eccentric coil is prepared by winding a piece of Teflon tubing (typically 0.85 mm I.D.) onto a set of multiple short cores (~6 mm O.D.), which is arranged around the periphery of the holder hub as shown in Fig. 9b.

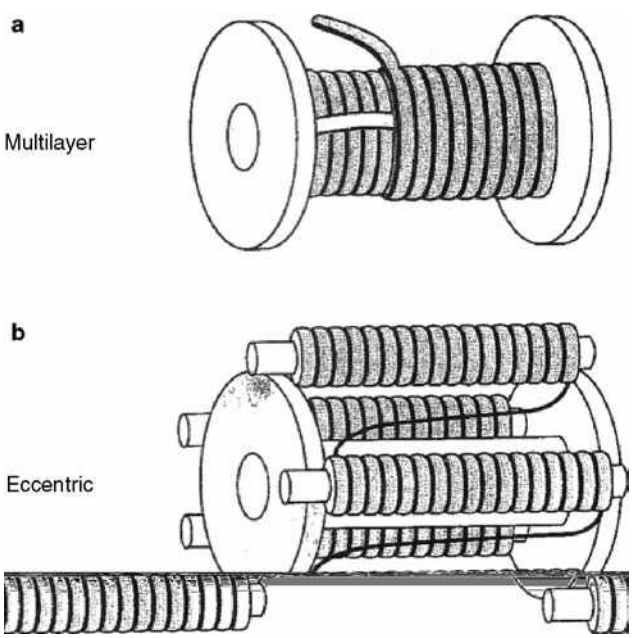

Fig. 9 Two different types of coiled columns for cross-axis CPC. Multilayer coil is for large-scale separations and eccentric coil assembly for small-scale separations.

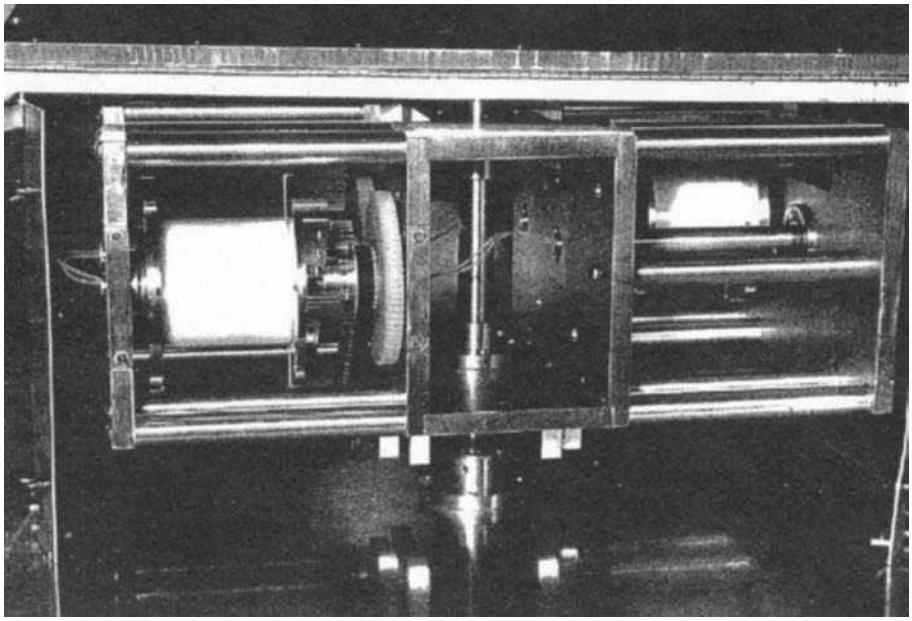

Fig. 10 Photograph of *X*-1.5 *L* and *L* prototypes. The rotary frame of the apparatus is driven by a motor (back of the apparatus) by coupling a pair of toothed pulleys one on the motor shaft and the other on the central shaft with a belt. Two cylindrical holders are mounted in the *X*-1.5 *L* or off-center position. The inlet and the outlet Teflon tubes go through the upper plate of the apparatus inside the hollow part of the central vertical axis. A circular metallic plate around the rotary frame decreases the torque by an average of 30%.

Fig. 10 shows a photograph of a recently designed cross-axis CPC equipped with a pair of multilayer coil separation columns.[12] The column can be mounted on the rotary frame in two positions, *X*-1.5 *L* (off-center position) and *L* (central position). The off-center position is used for both organic/aqu-eous and aqueous PEG—potassium phosphate systems, while the central position is used for viscous, low interfacial tension PEG–dextran systems.

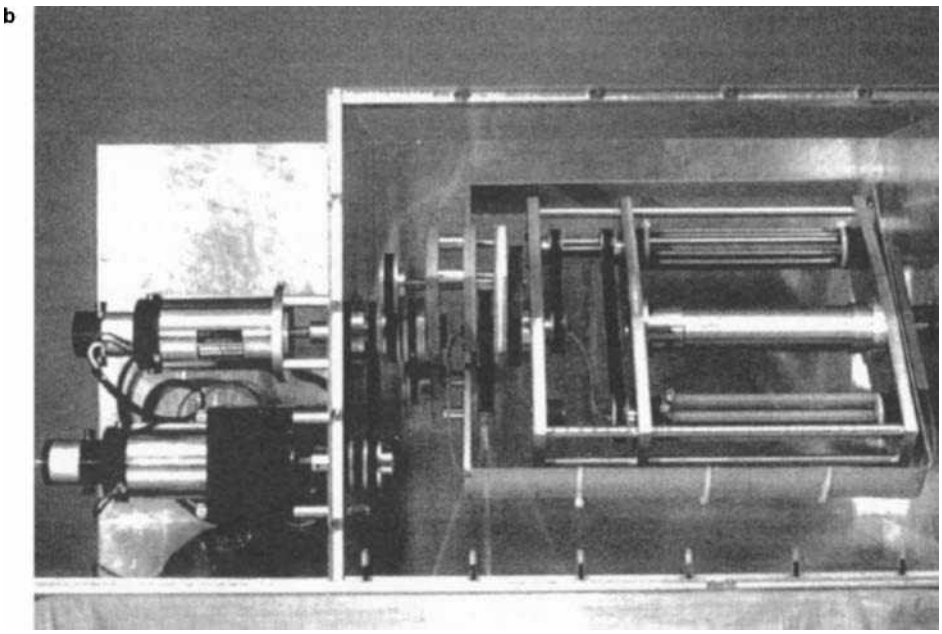

Fig. 11 (*Continued*)

Applications

Although cross-axis CPCs yield less efficient separations than the type-J multilayer CPC, they provide more stable retention of the stationary phase and are therefore useful for large-scale preparative separations with polar solvent systems. These are especially useful for the purification of proteins with aqueous–aqueous polymer phase systems composed of PEG and potassium phosphate. The cross-axis CPC has been used for the purification of various enzymes including choline esterase, ketosteroid isomerase, purine nucleoside phosphorylase, lactic acid dehydrogenase, uridine phosphorylase (see *Proteins: Cross-Axis Coil Planet Centrifuge Separation*, p. 1935).

NON-SYNCHRONOUS CPC

The non-synchronous flow-through CPC is a particular type of planetary centrifuge which allows adjustment of the rotational rate of the coiled separation column at a given revolution speed. The first prototype was equipped with a dual rotary seal for continuous elution.[13] Later, an improved model[14] was designed to eliminate the rotary seal which had become a source of complications such as leakage, contamination, and clogging.

Design Principle of the Seal-Free Non-synchronous CPC

Fig. 11a shows a cross-sectional view through the central axis of the apparatus. The rotor consists of two major rotary structures, i.e., frames I and II, which are coaxially bridged together with the center piece (dark shade).

Frame I consists of three plates rigidly linked together and directly driven by motor I. It holds three rotary elements, namely, the centerpiece (center), countershaft I (bottom), and countershaft II (top), all employing ball bearings. A pair of long arms extending symmetrically and perpendicularly from the middle plate forms the tube-supporting frame, which clears over frame II to reach the central shaft on the right side of frame II.

Frame II (light shade) consists of three pairs of arms linked together to rotate around the central shaft. It supports a pair of rotary shafts, one holding a coil holder assembly and the other the counterweight.

There are two motors, i.e., motors I and II, to drive the rotor. When motor I drives frame I, the stationary pulley 1 introduces counterrotation of pulley II through a toothed belt; therefore, countershaft I rotates at $-\omega_I$ with respect to rotating frame I. This motion is further conveyed to the centerpiece by 1:1 gearing between gears 1 and 2. Thus, the centerpiece rotates at $2\omega_I$ or at ω_I with respect to the rotating frame I. The motion of frame I also depends upon the motion of motor II.

If motor II is at rest, pulley 5 becomes stationary same with pulley 1 so that countershaft II counterrotates at ω_I as does countershaft I. This motion is similarly conveyed to the rotary arms of frame II by 1:1 gearing between gears 3 and 4, resulting in rotation of frame II at $2\omega_I$ or the same angular velocity as that of the centerpiece. Consequently, coupling of pulleys 6 to 7 and 8 to 9 with toothed belts produces no additional motion to the rotary shaft, which simply revolves with frame II at $2\omega_I$ around the central axis of the apparatus.

When motor II rotates at ω_{II}, idler pulley 4 coupled to pulley 3 on the motor shaft rotates at the same rate, which, in turn, modifies the rotational rate of pulley 5 on countershaft II. Thus, countershaft II now counter-rotates at $\omega_I - \omega_{II}$ on frame I. This motion further alters the rotational rate of frame II through 1:1 gear coupling between gears 3 and 4. Subsequently, frame II rotates at $2\omega_I - \omega_{II}$ with respect to the earth or at $-\omega_{II}$ relative to the centerpiece which always rotates at $2\omega_I$. The difference in rotational rate between frame II and the center piece is conveyed to the rotary shafts through coupling of pulleys 6 to 7 and 8 to 9. Consequently, both rotary shafts rotates at ω_{II} about their own axes while revolving around the central axis of the apparatus at $2\omega_I - \omega_{II}$. This gives the rotation/revolution ratio of the rotary shaft

$$r/R = \omega_{II}/(2\omega_I - \omega_{II}) \quad (14)$$

Therefore, any combination of revolutional and rotational speeds of the coil holder assembly can be achieved by selecting the proper values of ω_I and ω_{II}.

Coiled Column and Flow Tubes

Two different column configurations are used: a multilayer coil and an eccentric coil assembly. The multilayer coil column is prepared by winding a piece of Teflon tubing, typically 1.6 mm I.D., directly onto the holder hub ($\sim$ 2.5 cm O.D.), making multiple coiled layers as those for the type-J high-speed CCC. The eccentric coil assembly was made by winding a piece of Teflon tubing, typically 1 mm I.D., onto a set of six units of 0.68 cm O.D. stainless steel pipe in series. These coil units are arranged around the holder with their axis in parallel to the holder axis (see "Eccentric coil assembly" in Fig. 9, lower diagram). A pair of flow tubes from each end of the coiled column is first led through the hole of the rotary shaft and then pass through the opening of the centerpiece to exit at the middle portion of frame I. The flow tubes are then led along from the tube support to clear frame II and then reach the side hole of the central shaft near the right wall of the centrifuge where they are tightly held by the stationary tube supporter.

Fig. 11b shows the overall photograph of the apparatus equipped with an eccentric coil assembly. The revolution speed of the coil holder assembly is continuously adjustable up to 1000 rpm combined with any given rotational rate between 0 and 50 rpm in either direction.

Applications

The non-synchronous CPC is a most versatile centrifuge which can be applied to a variety of samples including cells, macromolecules, and small molecular weight compounds. Cell separations may be performed with a single phase such as physiological solution or culture medium[14,15] and also with PEG–dextran polymer two-phase systems.[16] DNA and RNA are partitioned with a PEG–dextran system by optimizing the pH.[14]

CONCLUSIONS

The CPC, which was originally developed for separating blood lymphocytes, has evolved into several useful instruments for separations of cells, macromolecules, and small molecular weight compounds. Among those, the type-J multilayer CPC is most extensively utilized for high-speed CCC separations of natural and synthetic products. The utility of the type-J CPC may be extended to the polymer phase separation of macromolecules and cell particles with a spiral disk assembly currently being developed in our laboratory.

Collagen: HPLC and Capillary Electromigration

Ivan Miksík
Institute of Physiology, Academy of Sciences of the Czech Republic, Prague, Czech Republic

INTRODUCTION

The term collagen covers a broad group of proteins. It is a family of extracellular matrix proteins possessing typical features—they consist of three polypeptide chains (called α-chains) and contain at least one domain composed of a repeating tripeptide sequence: -Gly-X-Y-. The protein chains are coiled together into a left-handed helix and are then wound around a common axis to form a triple helix with a shallow right-handed superhelical pitch; so, the overall structure is a rope-like rod. The typical presence of glycine at every third position is essential for this packing to a coiled-coil structure and is one of the ways to determine the presence of collagen in a tissue sample. Any amino acid other than glycine can be present in the X and Y positions, but proline is often found in the X position and 4-hydroxyproline in the Y position. 4-Hydroxyproline plays particularly an important role, because these residues are essential for the stability of the triple helix. All collagens also have non-collagenous domains.

Collagens are the most abundant proteins in the human body, constituting approximately 30% of its protein mass. At present, there are at least 28 known collagen types in vertebrates, containing a total of 42 distinct α-chains, and more than 20 additional proteins have collagen-like domains. Besides α-chains, there are also β-chains (dimers of α-chains) and γ-chains (trimers of α-chains).

The most common types of collagens occur in fibers and networks. These proteins are poorly soluble (if at all), are found in many tissues such as connective tissue, and have a slow metabolic turnover. This is the reason why they are more susceptible to some enzymatic or non-enzymatic posttranslational modifications.

Polymerized fibril-forming collagens (whether polymerized physiologically or non-physiologically) are insoluble and their solubilization is routinely performed either by mild pepsinization, in which short terminal regions containing the polymerization sites (crosslinks) are cleaved off, or by cyanogen bromide (CNBr) cleavage, which results in a limited fragmentation of the parent α-chains, as mentioned previously. Tissue collagenases split the triple-helical structure two-thirds of the way from its N-terminus; bacterial collagenases (from *Clostridium histolyticum*) are far less specific, they cleave the sequence into small fragments (mostly tripeptides) and are, therefore, of little use in structural studies.

Investigations of these proteins can either focus on their intact α-polypeptide chains or on their fragments (after cleavage). The most traditional methods for the analysis of collagens are slab gel electrophoresis (HPLC), low-pressure and high-performance liquid chromatography (HPLC), but recently capillary electromigration methods have also begun to be used.

STANDARD (LOW-PRESSURE) LIQUID CHROMATOGRAPHIC SEPARATION PROCEDURES

The application of classical (low-pressure) chromatography for the isolation of fibril-forming collagens from tissues has a long tradition and involves a large number of methods. Practically all types of chromatographic operational modes have been utilized for this purpose [for a review, see, e.g., Deyl and Adam (1989)] and frequently strategic combinations of them are used, exploiting, e.g., the presence or absence of S–S bonds in the terminal region (or along the whole molecule as is the case with collagen type III), charge, molecular size, the presence of glycosidic residues, or differences in the physicochemical properties of individual collagen species in their native and denatured forms.

The most common methods for the preparation of collagens are various extractions and precipitations or the release of protein by enzymatic hydrolysis. These methods mainly include extraction with an NaCl–phosphate buffer, acetate buffer, or acetic acid, and precipitation using various concentrations of NaCl (their usage depends on the tissue and type of collagen).

The most useful low-pressure chromatographic method for the purification of collagens is diethylaminoethyl (DEAE)-cellulose chromatography for removing co-extracted proteoglycans. Typical conditions for this form of chromatography can be as follows: the sample of collagen is dissolved in 0.2 mol/L NaCl with 0.05 mol/L Tris–HCl at pH 7.5 and fed into a DEAE-cellulose column (e.g., Whatman DE-52) which was equilibrated with the same buffer. After that, collagens are eluted with additional buffer, and proteoglycans are eluted by an increasing concentration of NaCl (1 mol/L).

Other chromatographic methods should also be mentioned: gel-permeation methods (molecular sieving), carboxymethyl (CM) cellulose chromatography, bioaffinity

chromatography (Concanavalin A, thiol-activated Sepharose, Heparin Sepharose) or zone precipitation chromatography. Cation-exchange chromatography and phosphocellulose chromatography are very popular methods (elution is carried out with an NaCl gradient).

The separation steps are most often monitored by SDS-PAGE.

HPLC AND CAPILLARY ELECTROPHORETIC METHODS

Separations of collagens must contend with the problems of achieving high resolution among poorly soluble high molecular mass proteins or a complex mixture of peptides with similar structures (glycine at every 3rd position). This task makes high demands on advanced high-performance separation methods—HPLC and capillary electrophoresis (CE).

Parent Chains

HPLC

The analysis of collagenous chains is a difficult task due to the poor solubility (hydrophobicity) of these proteins. HPLC methods are not frequently used for the separation/characterization of individual chains of a collagen type.

The reversed-phase HPLC method is a traditional method for the analysis of peptides and proteins. A good choice for the stationary phase could be a short-alkyl reversed-phase (e.g., C_4) with wide pores (30 nm). It has been shown that large pore supports give distorted peaks with small collagens and triple helical peptides, resulting in poor resolution. The formation of broad peaks has been ascribed to conformational instability of the separated solutes and slow *cis–trans* isomerization of the peptide bonds. The best sorbents of those examined were diphenyl or non-porous C_{18} reversed-phases; standard water–acetonitrile gradients were recommended as mobile phases.

For example, reversed-phase chromatography on a C_8 phase using an acetonitrile gradient in 0.1% trifluoroacetic acid was described as a suitable method for the separation of α-chains of collagen types V and XI.

Cyanopropyl bonded packing has been described as suitable for the separations of human type I–III collagens. Other stationary phases should also be mentioned: LiChrosorb Diol, TSK-SW gels and Separon HEMA 1000 Glc (a copolymer of 2-hydroxyethyl methacrylate and ethylene dimethacrylate covalently bonded with glucose). The first two phases are widely used for the separation of a number of proteins, but the use of the last phase (HEMA) is mainly used for the separation of collagens. The elution is performed by isocratic conditions with 0.2 *M* NaCl–2 *M* urea–0.05 *M* Tris/HCl (pH 7.5) as the mobile phase. This enabled the separation of α-, β-, and γ-chains of collagen type I and this method also enables the separation of a number of collagens and collagenous chains (the related molecular mass of the eluted proteins decreases with prolonged migration time).

Capillary electrophoresis

Collagen chains can be analyzed by capillary zone electrophoresis in very dilute buffers (typically 2.5 m*M* sodium borate, pH 9.2) or acidic buffers (pH∼2.5, about 25 m*M* buffer). Separation in an alkaline buffer is sensitive to overloading; the recommended buffer is sodium tetraborate. The reason for this sensitivity is probably due to the adsorption of protein onto the capillary wall.

The separation of groups of α, β, and γ can also be achieved in a phosphate buffer (at the same pH), but the resolution of individual chains (α_1 from α_2, etc.) was lost. A similar effect was observed if the background electrolyte contained a submicellar concentration of sodium dodecyl sulphate (SDS), when only the peaks of α, β, and γ fractions could be seen. At higher (supramicellar) concentrations of the negatively charged surfactant, all fractions migrated as a single broad zone. The separation of collagen chains under acidic conditions (100 m*M* phosphate buffer, pH 2.5) is possible, but again without separating tri-, di-, and monomers.

Another possibility is to use a capillary gel electrophoretic method that is nowadays a routinely and commercially available method for the determination of the molecular mass of proteins/polypeptides. This method can also be used for the separation of collagen chains and their polymers. For example, this procedure is described in the literature for the separation of collagen type I α-chains and chain polymers β (dimers), and γ (trimers), and also chain polymers of related molecular mass 300,000 and higher (typically in the study of the formation of cross-links). Besides commercially available kits, another option is to use fused-silica or polyvinylalcohol-coated capillaries filled with non-cross-linked polyacrylamide or hydroxylpropylmethylcellulose in a 50 m*M* Tris–glycine buffer (pH 8.8) or phosphate buffer (50 m*M*, pH 2.5) (Table 1).

CNBr Fragments

Analyses of the structure and modifications of the collagen molecule/chain require solubilization and fragmentation of the protein to smaller peptides. In principle, two methods can be used—non-enzymatic (chemical) or enzymatic treatment. The chemical method is cleavage by CNBr. Cyanogen bromide splits the protein molecule at specific locations—at the methionines (in this case toward the C-terminal end). In the collagen molecule, methionine is a relatively rare amino acid (some 10–20 amino acids per collagen molecule). The small number of methionine residues leads to a rather limited number of cleavage products (CNBr peptides). The profile of CNBr peptides is typical,

Table 1 Capillary electromigration methods for separation of collagens.

Collagen types	Conditions
α, β-chains (types I, II, V, IX, XI)	2.5 m*M* Sodium tetraborate buffer, pH 9.2
α, β, γ-chains (type I)	4% Non-cross-linked polyacrylamide; 50 m*M* Tris–glycine buffer, pH 8.8
α, β, γ-chains (bovine skin–type I)	Commercial CE-SDS kit (pH 8.9)
Cyanogen bromide fragments (rat tail tendon—types I and III)	25–100 m*M* Phosphate buffer, pH 2.0–2.5
CNBr fragments (rat tail tendon—types I and III)	100 m*M* Phosphate buffer, 20 m*M* heptanesulfonic acid, pH 2.5
CNBr fragments (cartilage—types I and II)	100 m*M* Phosphate buffer, pH 6; coated capillary
CNBr fragments (rat tail tendon—types I and III)	50 m*M* SDS in 50 m*M* phosphate buffer, pH 2.5
CNBr fragments (rat tail tendon—types I and III)	1% (cca 3.5 m*M*) SDS in 50 m*M* phosphate buffer, pH 2.5
CNBr fragments (rat tail tendon—types I and III)	7.5% Pluronic F127 in 10 m*M* Tris and 75 m*M* phosphate buffer, pH 2.5; 20°C
Bacterial collagenase fragments (rat tail tendon—types I and III)	100 m*M* Phosphate buffer, pH 2.5

at least for the main collagen types and, thus, provides an appropriate way to estimate the amount as well as type of collagen in a particular tissue. The nomenclature of CNBr peptides refers to the parent polypeptide chain: an α_1 polypeptide chain yields a set of α_1CB (i.e., α_1CNBr) peptides (an α_2 chain similarly yields a set of α_2CB peptides). The index, e.g., α_1CB_1, identifies a particular peptide within the set. The number in parenthesis refers to the collagen type, e.g., $\alpha_1(I)CB_1$ means a CNBr peptide of collagen type I. The number attached to each peptide at the end reflects the position of a particular fragment in the elution profile obtained after CM cellulose chromatography.

HPLC

At present, there are several methods in use for CNBr peptide analysis, with classical CM cellulose and phosphocellulose chromatography being those primarily mentioned. The disadvantage of ion-exchange chromatographic procedures is mainly due to their low selectivity, long analysis time, and poor recovery of the separated peptides. In the early 1980s, reversed-phase chromatographic procedures were introduced, which exhibited much higher selectivity and shorter analysis time. The most useful method is based on a separation using a C_{18} reversed phase in an acetonitrile gradient (0–40% acetonitrile over 90 min) containing heptafluorobutyric acid as an ion-pairing agent.

However, the most widely used method for CNBr peptides analysis today is gel electrophoretic separation, originally introduced in 1976.

Capillary electrophoresis

The main problem in separating collagenous peptides is their adhesion to the inner surface of the fused-silica capillary wall. For this reason, the separation of these peptides can only be achieved in an acidic buffer.

In the literature, the separation is carried out in a 25–100 m*M* phosphate buffer (pH from 2.0 to 2.5), applied voltage 8–25 kV (using a fused silica capillary of 70/63 cm total length/length to the detector, 75 μm I.D.). Peptides with higher-related molecular mass (over 13,500) from collagens types I and III demonstrate a linear relationship between mobility and molecular mass; however, peptides with lower related molecular mass (below 4600) do not follow this relationship. This method is also usable for the determination of collagen types I, III, and V based on their specific CNBr fragments ($\alpha_2(I)CB_4$, $\alpha_1(III)CB_2$, and $\alpha_1(V)CB_1$). The separation of lower-molecular CNBr peptides from the higher-molecular ones can be improved by adding an ion-pairing agent, heptanesulfonic acid (100 m*M*) to the separation buffer.
