Metal–Ion Enrichment by CCC

Eiichi Kitazume
Faculty of Humanities and Social Sciences, Iwate University, Iwate, Japan

INTRODUCTION

Countercurrent chromatography (CCC) is a useful method for separating metal ions as well as organic compounds. In addition, highly efficient chromatographic separation has been achieved using a multilayer coil system and strong force field by applying over several hundred revolutions per minute. However, there have been no applications to the enrichment of inorganic elements until quite recently.

The latest study has revealed that CCC has great potential in the ultratrace determination of metals, because it can concentrate minute amounts of metal prior to instrumental multielement analysis, such as by atomic absorption spectrometry (AAS), inductively coupled plasma–atomic emission spectrometry (ICP–AES), and inductively coupled plasma–mass spectrometry (ICP–MS).[2,6,9]

Enrichment of the desired trace elements would not only allow highly sensitive determination of trace elements but also alleviate various problems, including interference, high risk of exposure to toxic chemicals and radiation from radioactive samples, and so forth.

EXTRACTION OF METAL IONS IN THE STATIONARY PHASE

The existence of an extracting reagent in the stationary phase is one of the essential factors in the enrichment of inorganic elements as well as in their separation. However, the values of the distribution ratios, determined by batch extraction measurements in a two-phase system, are sometimes considerably different from those of the dynamic distribution ratios calculated from elution curves. Further theoretical and basic investigations are necessarily concerned with extraction kinetics, as well as the hydrodynamic behavior of two phases in the high-speed CCC (HSCCC) column.[1]

Organophosphorus extractants such as di(2-ethylhexyl)-phosphoric acid (DEHPA), 2-ethylhexylphosphonic acid mono-2-ethylhexyl ester (EHPA), *N*-benzoyl-*N*-phenylhydroxylamine (BPHA), and tetraoctylethylenediamine (TOEDA) are often used due to their solubility properties in the stationary organic phase.[1–3]

ENRICHMENT IN THE EFFLUENT BY CONVENTIONAL ELUTION

After metal ions are enriched in the organic stationary phase, including the extracting reagent in the CCC column, they can be eluted simultaneously or chromatographically into the eluent stream by conventional elution mode.

It has been demonstrated that systems with DEHPA can extract and preconcentrate Zr(IV), Hf(IV), and Nb(V) into the organic stationary phase and can separate them from the majority of other elements.[1] The preconcentration of Zr(IV) and Hf(IV) and subsequent back-extraction, as well as the selective extraction of Zr(IV), Hf(IV), Nb(V), and Ta(V) into a 4 ml volume of the organic phase, can be performed with a mixture of DEHPA and BPHA.

A method has been developed for the separation of the entire group of rare-earth elements from high-purity calcium chloride by CCC, and subsequent determination of the elements by ICP–MS.[2] A solution of diphenyl [dibutylcarbamoylmethyl]phosphine oxide in chloroform (0.5 mol/L) was chosen as reagent for the extraction and preconcentration of trace rare-earth elements from aqueous 5% $CaCl_2$ solution, 3 mol/L in HNO_3, and 0.1 mol/L in $HClO_4$. The analytes are back-extracted into a small volume of water and the aqueous eluent is analyzed by ICP–MS. The performance characteristics of the procedure developed were checked by use of the standard addition technique and a real $CaCl_2$ sample was analyzed. The results obtained demonstrate the applicability of CCC to the determination of ultra trace elements.

The capability of HSCCC was also studied for enrichment and determination of metal ions at trace levels. Separation of selected divalent metal ions was performed using a small coiled column.[3] A hexane solution of EHPA was employed as the stationary phase. Loaded divalent metal ions such as Ni, Co, Cu, and Zn were chromatographically eluted in the order of increasing extractability by passing a mobile phase buffered at a desired pH. Each metal ion showed good linearity between concentrations and chromatographic peak areas of absorbance, as detected by postcolumn reaction with 4-(2-pyridylazo)resorcinol (PAR). Metal ions enriched in the stationary phase from a sample solution were separated into individual metal ions. A trace quantity of Zn in natural mineral water was determined by enrichment separation through an HSCCC column.

A 1000 ml sample solution containing 5×10^{-7} *M* of each rare-earth element was effectively enriched onto the CCC column head using carboxylic acid–toluene including EHPA system.[4] Then, each concentrated element on the column head was eluted chromatographically by the mobile phase with stepwise pH gradient.

Separation of selected lanthanoid elements was performed by HSCCC equipped with a small coiled column of 10 ml capacity.[5] A hexane solution of DEHPA was retained in the tubing column as the stationary phase. The stationary phase retention increased with increasing rotational speed and with decreasing flow rate of the aqueous mobile phase. Mixtures of lanthanoids (Gd, Tb, and Dy) were eluted in increasing order of extractability by introducing the buffered mobile phase. Lanthanoids (Sm through Er) and yttrium were simultaneously enriched in the stationary phase from a large volume of a sample solution, and then separated from each other with reasonable resolution.

Apart from this, the sample preconcentration capability of procedures such as AAS, ICP–AES, ICP–MS, etc. was studied.[6] After metal ions were enriched, they were eluted almost simultaneously by inorganic acid at low pH, because their diffusion in the column is disadvantageous for improvement of the detection limits. It has been demonstrated that metal ions such as Ca, Cd, Mg, Mn, Pb, and Zn were enriched with good recovery at a concentration of 10 ppb each in 500 ml of the sample solution. However, the final enriched sample volume eluted from the CCC column was as large as several milliliters due to longitudinal diffusion as the sample band in the retained stationary phase.[1,6] An additional band spreading occurred in the flow tube when the concentrated solution was eluted with an acid solution for the subsequent analysis.

Also, the mechanism of separation based on displacement chromatography followed by enrichment in a CCC column was studied, and a tenfold enrichment of the transition metal ions was observed in the stationary phase.[7] However, diffusion of the sample is an inherent process in chromatographic elution; spreading of the sample bands in the column is unavoidable in CCC as it is in conventional LC.

Therefore, it may be difficult to obtain highly concentrated metal ions in an extremely small volume of effluent, such as of under-milliliter order, even if a small-bore column is used with higher concentration efficiency.

ENRICHMENT IN THE EFFLUENT BY PH-PEAK FOCUSING TECHNIQUE

Recently, pH-zone refining countercurrent chromatography (pH-ZRCCC), which is a quite unique technique based on neutralization reaction between mobile and stationary phase, has been developed for preparative scale separation and enrichment of various organic compounds.[8] pH-ZRCCC can realize chemical reactions in a quite limited thin area (i.e., the interface between organic and aqueous phase, where there is spreading over a wide area in a small-bore tube). If the pH between two phases in the column is reversed, the stationary phase is continuously neutralized with the mobile phase. Therefore, the pH border, where neutralization has just finished, moves to the tail (outlet) from the head (inlet) of the column. The moving rate of the pH border in the column can be controlled by adjusting the pH in each phase. This means that "another flow rate," concerned with pH, different from the "real flow rate of the eluent," can be realized in the column. Impurities in the sample solution can be quantitatively trapped and enriched in the pH border at a specific condition of the moving rate. This enrichment method for trace organic impurities has been called pH-peak-focusing countercurrent chromatography (pH-PFCCC).

It has been shown that pH-PFCCC can be successfully applied to the enrichment of inorganic trace elements in solution.[9,10] It has great potential for on-line enrichment and subsequent analysis, when CCC is combined with another analytical instrument for solution. The peak intensities for a 10 ml standard sample in the effluent stream were increased over 100-fold, compared with the conventional plasma atomic emission spectrometry. In this method, Ca, Cd, Cu, Mg, Mn, and Zn are chromatographically extracted, in a basic organic stationary phase containing a complex-forming reagent such as DEHPA, by introducing the sample solution into a column rotated at 1200 rpm. When the column is eluted with the acidified mobile phase, metal ions are trapped and concentrated around the sharp pH border formed between the acidic and the basic zones, moving toward the outlet of the column. Enriched metal ions are finally eluted with the sharp pH border as a highly concentrated peak into a less than 100 μl volume.[9]

By selecting appropriate experimental conditions, such as the acidity of the sample, bore of the column, and volume of the sample, each metal separation was achieved due to a longitudinal pH gradient on both sides of the pH border. Metal ions were concentrated at different positions in the moving pH border. When the pH border was sufficiently wide in the final stage of the elution, each concentrated metal could be separated. This method can be successfully applied to trace determination of Cd in tap water, which coexists with relatively large amounts of magnesium.[10]

The conditions of distribution ratio (K) for a two-phase solvent for pH-PFCCC are shown in Fig. 1. In a relatively basic environment at the first stage of sample injection, the metal ion present in the aqueous phase forms a complex with the ligand and partitions into the organic phase with a distribution ratio of K_b, whereas in an acidic environment,

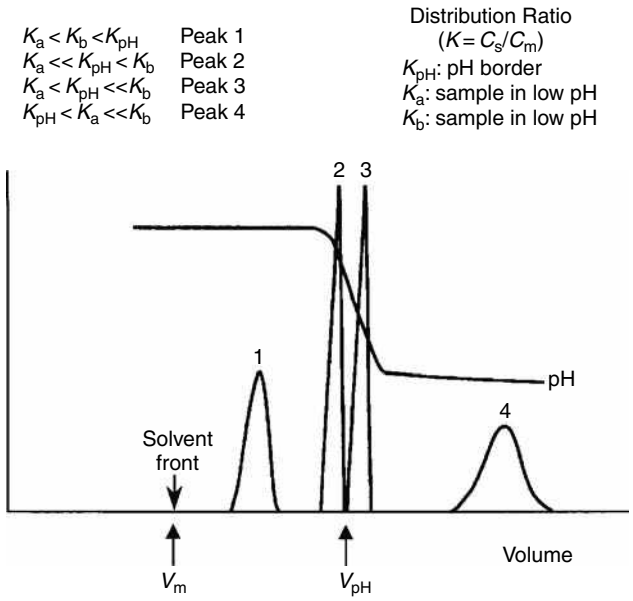

Fig. 1 Conditions of distribution ratio between two-phase solvent for pH-peak focusing.

the metal ion is mainly distributed into the aqueous phase with distribution ratio K_a.

As the elution proceeds, acid (e.g., HCl) present in the mobile phase steadily neutralizes the base (e.g., NH_3) in the stationary phase forming a narrow pH border between the basic front zone and the acidic rear zone. The traveling rate of this sharp pH border through the column is determined mainly by the molar ratio between the base in the stationary phase and acid in the mobile phase, but it is substantially lower than the flow rate of the mobile phase. The metal ion present in the acidic zone quickly moves with the mobile phase passing through the pH border into the basic zone, where it forms a metal–ligand complex and is transferred into the stationary phase. As the pH border moves forward, the complex is exposed to a lower pH, and the metal is displaced by proton (H^+) and released into the aqueous phase in its ionic form (M^+) to repeat the above cycle. Consequently, the metal element is always confined to a narrow region around the sharp pH border and finally eluted as highly concentrated sharp peaks (peaks 2 and 3) in the pH slope as shown in Fig. 1. Thus, the system eliminates longitudinal spreading of the sample band due to the separation process, which is inherent in other liquid chromatographic methods.

In the above method, trapping the metal element by the sharp pH border is essential, and this requires a relationship between the distribution ratios of the metal element and the traveling rate of the pH border through the column, as illustrated in Fig. 1. The distribution ratio is shown as K_a and K_b in the acidic and the basic zones, respectively. V_{pH} shows the volume of the eluent when the pH border comes out on the chromatogram. K_{pH} is assumed as a temporary distribution ratio when the solute peak appears at the retention volume V_{pH}. K_{pH} is adjustable by changing the molarity between the basic phase and the acidic phase. If K_{pH} is greater than K_a and K_b, the metal ion elutes earlier than the sharp pH border (peak 1), and if K_{pH} is smaller than K_a and K_b, the metal ion elutes after the sharp pH border (peak 4). Peak trapping takes place only when K_{pH} falls between K_a and K_b (peaks 2 and 3). The two metal peaks (peaks 2 and 3) may be resolved within a narrow range if there is a substantial difference between the K_a and K_b values, as shown in Fig. 1.

CONCLUSIONS

In contrast to high-performance liquid chromatography (HPLC), CCC has the unique feature that there is no solid support in the column. Because the distribution abilities, including the capacity of the stationary phase, are easy to control, CCC can be applied to the treatment of various inorganics, such as enrichment as well as separation and purification over a wide range of concentration. Moreover, the reproducibility of the enrichment operation has a substantial advantage over other enrichment systems, such as ion-exchange, because the absorber system in CCC is always "fresh" in each operation. In particular, enrichment of trace elements using pH-PFCCC is an ideal preconcentration method for subsequent inorganic determination by modern instrumental analytical methods. It can be combined directly with the flow injection technique, so that there is great potential for a new enrichment (preconcentration) system for the desired trace element prior to determination. Online enrichment and subsequent analysis may take the place of conventional sample preparation using a beaker and separating funnel in future investigations in this field.

Metal-Ion Separation by Micellar HPLC

Subra Muralidharan
Chemistry Department, Western Michigan University, Kalamazoo, Michigan, U.S.A.

INTRODUCTION

The separation of target metal ions from a complex mixture is an extremely important area of research for the purpose of recovery of metal values from wastes and for environmental remediation and restoration. Conventional approaches to metal-ion separation and recovery fall into two broad classes, namely (a) solid–liquid and (b) liquid–liquid separations.

Solid–liquid methods include ion-exchange resins, which involve electrostatic interaction between the positively charged metal ions in solution and a negatively charged functional group on a polymer backbone such as SO_3^-, chelating polymers containing complexing ligands such as iminodiacetic acid, and membrane-mediated separations using solid membranes.

Liquid–liquid methods include solvent extraction with immiscible liquid–liquid systems in which a suitable ligand is dissolved in an organic phase and contacted with a metal ion containing an aqueous phase and liquid membranes. Separations can also be achieved with pseudo-phase systems such as micelles, microemulsions, and vesicles. Such separations can be solid–liquid or liquid–liquid and include separations with normal- and reversed-phase silica, and polymeric supports where the mobile phase contains the organized molecular assembly (OMA) of micelles, microemulsions, or vesicles. Separation of metal ions using the pseudo-phase systems is still in its infancy and a brief account will be provided here.

OMAs

OMAs are inherently capable of providing greater selectivities in separations of both organic compounds and metal ions mainly due to the ability of the organized microenvironments to discriminate among analytes with similar properties. Selectivities in metal-ion separation are best achieved through complexation rather than through ion-pair formation, and, in general, chelating ligands provide higher selectivities than monodendate ligands. The selectivities of the chelating ligands are limited in the conventional approaches using chelating resins and solvent extraction because the ligands are present in random macroenvironments. The incorporation of these ligands into organized microsturcutres such as micelles can provide dramatic improvements in their metal-ion selectivities. The factors that influence metal-ion selectivities are the stability constants of their complexes, the geometry and coordination number of the complexes, and the equilibrium and kinetics of metal complex formation and dissociation reactions, especially in the interfacial region. It is evident that these factors can be better exploited to achieve metal-ion selectivities in an organized microenvironment compared to a random macroenvironment. High-metal-ion selectivities are needed for the separation of target metal ions from complex matrices such as spent catalysts and electrochemical baths, geothermal brines, and nuclear wastes. Organized microenvironments will be key to achieving the selectivities demanded by such complex and difficult matrices.

MICELLES

Separations of metal ions mediated by the OMA micelles will be the focus of this entry. Micelles are formed from surfactants in aqueous solutions above a certain concentration of the surfactants called the critical micelle concentration (CMC).[1] These surfactants can be neutral, such as Triton X-100 and Brij 35, which have the general structure $R(OCH_2CH_2)_nOH$, where R is a long-chain alkyl group (C_{12} and above) and n the number of oxyethylene groups ($n = 9$ for Triton X-100 and 23 for Brij 35), or anionic such as sodium dodecyl sulfate (SDS; $C_{12}H_{25}SO_4^-Na$), or cationic such as cetyltrimethylammonium bromide [CTAB; $C_{16}H_{33}N(CH_3)_3^+Br^-$]. The CMC values of Triton X-100, SDS, and CTAB at an ionic strength of 0.1 are $2 \times 10^{-4}M$, $2 \times 10^{-3}M$, and $1.8 \times 10^{-4}M$, respectively, and their aggregation numbers are 100, 40, and 60, respectively. The neutral micelles in addition to the CMC are also characterized by the cloud point, which is the temperature at which a solution of the neutral micelle separates into two phases, namely the surfactant-rich phase and the water-rich phase. This property has been exploited to achieve cloud point separations analogous to separations employing two immiscible liquid phases. When the micelles are formed in the aqueous phase, the polar head groups of the surfactants, namely OH, SO_4^-, and $C_{16}H_{33}N(CH_3)_3^+$, are present on the surface of the micelles, and the interior of the micelle is hydrophobic like an organic phase in the case of the anionic and cationic micelles. In the case of the neutral micelles, the interior is composed of the oxyethylene groups terminating in an alkyl chain which form the

hydrophobic interior called the corona. Neutral surfactants form reverse micelles in non-polar solvents where the OH group is in the interior and the R group is on the surface. The presence of polar groups on the surface of the normal micelles in the aqueous phase results in an electrical double layer and an interfacial potential, which have significant influence on metal-ion selectivities. This potential is close to zero for neutral micelles, negative for anionic micelles, and positive for cationic micelles.

ADSORPTION OF SURFACTANTS ON SILICA AND REVERSED-PHASE SILICA

The neutral, anionic, and cationic surfactants will adsorb on silica and reversed-phase silica such as octadecylsilanized silica (ODS) from an aqueous solution to form a monolayer of the surfactant on the surface. The adsorption of surfactants on silica surface is more complex than their adsorption on ODS surface. The SiO_2 surface is polar due to the presence of surface silanol groups, and, as a result, the surfactants will adsorb with the polar group on the surface, namely the OH, SO_4^-, and $C_{16}H_{33}N(CH_3)_3^+$, with the alkyl groups pointed away from the surface. The adsorption of the surfactants on SiO_2 is pH dependent as the surface charge changes with pH. This adsorption is also dependent on the concentration of the surfactant with monolayers being formed at low surfactant concentrations and bilayers being formed at high surfactant concentrations. The bilayers are formed when a second layer of the surfactant adsorbs on the initial monolayer through its alkyl chains and the bilayer has the polar head groups pointing toward the bulk aqueous phase. Due to the complex adsorption phenomenon associated with adsorption of surfactants on SiO_2 surface, it is not a useful stationary phase for performing micellar chromatography.

The adsorption of surfactants onto ODS is more straightforward and well understood. Here, the formation of the monolayer of the surfactant on the ODS surface proceeds through the adsorption of the surfactant through its alkyl chain with the polar head group pointing into the bulk aqueous phase. Such an adsorption only results in a monolayer coverage, and the chromatographic behavior of these adsorbed monolayers can be discerned with established principles. The absorbed monolayers of surfactants on reversed-phase silica have been characterized by several spectroscopic methods [2] and will not be discussed here.

MICELLAR CHROMATOGRAPHIC SEPARATIONS OF METAL IONS

The adsorbed monolayers of surfactants on reversed-phase silica can be utilized as stationary phases and an aqueous solution of the same surfactant above its CMC as the mobile phase to separate both organic and inorganic analyte mixtures.[3] In the case of organic analytes, the selectivity between analyte components can be improved dramatically by employing micellar chromatography. The mechanism of separation, as in reversed-phase chromatography, is the distribution of the analyte between the micellar pseudo-phase and the stationary phase containing the adsorbed monolayer of the surfactant. Because the partitioning of the analyte now occurs between the organized microstructure of the micellar pseudo-phase and the adsorbed monolayer, the selectivity between closely related analytes is significantly improved. The separation of metal ions requires the addition of a complexing ligand in order to discriminate among the various metal ions. The SDS adsorbed on ODS as shown in Fig. 1 can function as an ion-exchange column but will not possess any selectivity between metal ions with similar charges analogous to a cation-exchange resin. Metal-ion separations can be achieved, in principle, on neutral, anionic, and cationic surfactants adsorbed on ODS columns, but only the separation with anionic surfactants adsorbed on ODS columns has been studied so far because of its complementary nature to conventional cation-exchange resins. The separations with neutral and cationic surfactants adsorbed are more complex and their behavior needs to understood before they will be useful for the separation of metal ions.

METAL-ION SEPARATIONS ON THE ODS–SDS COLUMN

The separation on the ODS–SDS column is achieved by the addition of a suitable complexing ligand to the mobile phase to discriminate between the various metal ions. The selectivity between two metal ions is achieved through two competing equilibria, namely the complexation equilibrium of the free metal ion in the micellar pseudo-phase and the complexation equilibrium of the metal ion adsorbed on the SDS monolayer and this is shown in Fig. 1. It is evident from this equilibrium that the distribution ratio (capacity factor) of the metal ion M^{2+} is given by Eq. 1, where the subscripts *a* and *s* represent the concentration of the free metal ion in the bulk aqueous phase and the adsorbed monolayer, respectively:

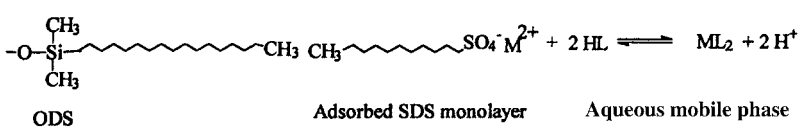

Fig. 1 Mechanism of separation of metal ions by micellar chromatography employing sodium dodecyl sulfate micelles in the mobile phase and octadecylsilanized silica as the stationary phase.

$$D = \frac{[M^{2+}]s}{[M^{2+}]s} \quad (1)$$

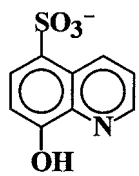
The associated equilibrium constant is defined in Eq. 2, where HL represents the ligand, and the relationship between log D and log[HL] and pH is given in Eq. 3:

$$K_{eq} = \frac{D[HL]^2}{[H^+]^2} \quad (2)$$

$$\log D = \log K_{eq} - 2\log[HL] - 2pH \quad (3)$$

As is evident from Eq. 3, a plot of log D as a function of log[HL] at constant pH and as a function of pH at constant [HL] will yield the stoichiometry of the equilibrium involved in the separation of the metal ion and the associated equilibrium constants.

The above-mentioned separation principle can be understood by the separation of Co(II), Ni(II), Cu(II), and Zn(II) by micellar chromatography employing SDS above its CMC in the mobile phase, ODS as the stationary phase, and 8-quinolinol-5-sulfonic acid ($pK_1 = 3.84$; $pK_2 = 8.35$) as the ligand:[4]



The logarithm of the stability constant for the 1:2 metal: ligand complex of this ligand with Co(II), Ni(II), Cu(II), and Zn(II) are 16.1, 16.77, 21.9, and 14.3, respectively. This separation employing a pH gradient is shown in Fig. 2, from which it is evident that the metal ions are eluted in the reverse order of their stability constants with 8-quinolinol-5-sulfonic acid. This elution order is readily understood from the equilibrium in Fig. 2, which indicates that the metal ion with the larger stability constant will be stripped from the adsorbed SDS monolayer more easily compared to the metal ion with a smaller stability constant. It may also be noted that the chromatographic bandwidths are much larger than those encountered with organic analytes and this is a direct consequence of slow metal complex formation and dissociation kinetics. Information on such kinetics can be obtained by studying the dependence of HETP on the concentrations of ligand and pH. This indicates that in the case of Co(II), Cu(II), and Zn(II), the dissociation of the metal complex is mainly responsible for the band broadening, whereas in the case of Ni(II), both metal complex formation and dissociation affect the efficiency.

Several simple water-soluble chelating ligands such iminodiacetic acid have been employed for the separation of a variety of metal ions. Okada demonstrated the

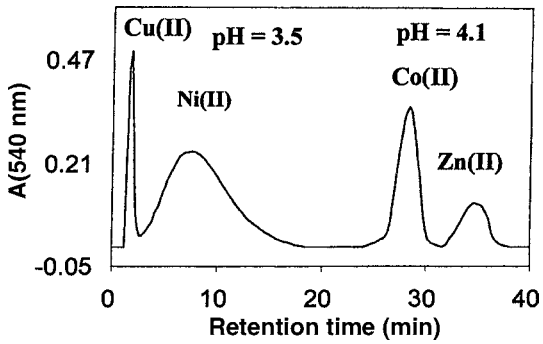


Fig. 2 Separation of Co^{2+}, Ni^{2+}, Cu^{2+}, and Zn^{2+} by micellar chromatography employing a pH gradient. Experimental conditions: mobile phase: [SDS] = 0.004 *M*, [8-quinolinol-5-sulfonic acid] = 0.002 *M*, ionic strength = 0.1; ODS stationary phase. 10 μl of the metal-ion mixture containing 0.002 *M* of each ion was injected at a mobile-phase flow rate of 1 ml/min. Cu^{2+} and Ni^{2+} elute at pH = 3.5 and Co^{2+} and Zn^{2+} elute at pH = 4.1.

separation of several divalent metal ions (Mn^{2+}, Co^{2+}, Ni^{2+}, Cu^{2+}, Zn^{2+}, Cd^{2+}) on ODS column with SDS micelles in the mobile phase and tartaric acid as the ligand.[5] The selectivity between the various divalent metal ions is much smaller than that observed with 8-quinolinol-5-sulfonic acid, which forms complexes with much larger stability constants than does tartaric acid. The stability constants of the metal complexes with a given ligand as mentioned earlier is one of the factors that affect selectivity. Karcher and Krull have published a review of the use of simple water-soluble ligands such as acetic acid, oxalic acid, hydroxyisobutyric acid, citric acid, tartaric acid, oxalic acid, and EDTA in micellar chromatography and with simple ion-exchange columns.[6] The selectivities obtained with these simple ligands is not as large as with ligands of the 8-quinolinol, acylpyrazolone, and aromatic oxime families, which are yet to be extensively investigated. Inorganic anions such as nitrate, nitrite, and phosphate can be separated by micellar chromatography using cationic micelles in the mobile phase and ODS as the stationary phase, as shown by Cassidy and Elchuk.[7]

CHELATING MICELLES

The studies that have been conducted so far have involved the addition of a suitable ligand to the micellar pseudo-phase in order to separate the mixture of metal ions. The location of the ligand in this pseudo-phase is a function of the hydrophilic and hydrophobic nature of the ligand. If the ligand is hydrophilic simple ones such as tartaric acid, then they will be present predominantly in the bulk aqueous phase, and if the ligand is hydrophobic such as 8-quinolinols, then they will distribute into the micellar pseudo-phase. The location of the ligands in the micellar

pseudo-phase is a function of the hydrophobicity of the ligand. Thus, the distribution of the ligand between the bulk aqueous phase and the micellar pseudo-phase introduces uncertainty in the location of the ligand and does not fully exploit the organized microenvironment. The aqueous-micelle interfacial region has a very high-interfacial area and possesses an electrical double layer with an interfacial potential. These can be effectively exploited to achieve even higher selectivities in metal-ion separations if the ligand can be specifically located at the interfacial region. We have recently achieved this by chemically derivatizing neutral surfactants such as Brij 35 such that a chelating ligand like 8-quinolinol or acylpyrazolone is the head group instead of OH. Such chelating surfactants form chelating micelles at CMC values much lower than Brij 35. The charge of the micelle is pH and ligand dependent and can be neutral, anionic, or cationic. In these chelating micelles, the ligand is exclusively present on the surface of the micelle and its chelating properties and metal-ion selectivities are strongly influenced by the interfacial region. We have synthesized chelating surfactants containing 2-methyl-8-quinolinol and 1-phenyl-3-methyl-4-benzoyl-5-pyrazolone as the head groups.[8] We have been able to obtain very large selectivities in the separation of divalent transition metal ions and trivalent lanthanide ions using these chelating micelles. The selectivities that we have achieved in the separation of the trivalent lanthanide metal ions are unprecedented and clearly indicate the tremendous gains in selectivities that can be achieved by the incorporation of ligands into organized microstructures. We have also shown that the mixed system of chelating surfactants with the 8-quinolinol and acylpyrazolone head groups form vesicles which also exhibit unique selectivities in the separation of transition and lanthanide metal ions on an ODS stationary phase. The chelating micelles are also interesting candidates for the separation of metal ions by electrokinetic chromatography, where the interfacial properties of the chelating micelles can be further exploited to achieve very high-metal-ion selectivities.

Metalloproteins: Characterization Using CE

Mark P. Richards
Livestock and Poultry Sciences Institute (LPSI), Agricultural Research Service, U.S. Department of Agriculture (USDA-ARS), Beltsville, Maryland, U.S.A.

INTRODUCTION

Metalloproteins constitute a distinct subclass of proteins that are characterized by the presence of single or multiple metal ions bound to the protein by interactions with nitrogen, sulfur, or oxygen atoms of available amino acid residues or are complexed by prosthetic groups, such as heme, that are covalently linked to the protein. These metals function either as catalysts for chemical reactions or as stabilizers of the protein tertiary structure. Protein-bound metals may also be labile and, as such, be subject to transport, transient storage, and donation to other molecular sites of requirement within tissues and cells.

BACKGROUND INFORMATION

Metalloproteins play critical roles in a wide variety of basic cellular functions, including respiration, gene expression, reproduction, and metabolism. Isolation, characterization, and quantification of individual metalloproteins are each necessary and important steps toward understanding their unique biological functions. Alone or in combination, various types of chromatography, electrophoresis, and spectrometric techniques have been employed to study many unique aspects of metalloprotein structure and function. However, no one technique currently offers the ability to isolate, characterize, and quantify individual metalloproteins in a single step from complex matrices such as tissue extracts or physiological fluids. Therefore, there is an ongoing need for new and more capable methodologies. Because of the small-sample volume requirement, high degree of resolution, and advanced instrument automation capabilities, capillary electrophoresis (CE) has gained increasing popularity in the analysis of proteins.[1,2] In fact, many of the CE-based techniques developed for general protein separations are directly applicable to metalloprotein analyses.[2,3] This entry will emphasize some recent applications of CE and CE-related methodologies and their utility in providing new insight into the structure and function of a variety of metalloproteins.

Table 1 summarizes some of the ways CE has been applied to metalloprotein characterization. Altering capillary temperature, buffer ionic strength and pH, electric field strength (i.e., voltage), and capillary internal surface coating are but a few of the ways that CE conditions can be varied to influence the efficiency and selectivity of metalloprotein separations. Furthermore, different CE separation modes can be applied to gain new information about a specific metalloprotein.[3] For instance, capillary zone electrophoresis (CZE) can indicate a protein's net charge at a given pH; capillary isoelectric focusing (CIEF) gives a rapid estimate of its isoelectric point (*pI*); capillary gel electrophoresis (CGE), in the presence of sodium dodecyl sulfate (SDS), can be used to estimate its apparent molecular mass; and micellar electrokinetic chromatography (MEKC) can be useful in characterizing its surface hydrophobicity.

PROCEDURES

Varying CE separation conditions has been shown to be a particularly effective approach for improving the isolation and characterization of metallothioneins, a heterogeneous family of low-molecular-weight, cysteine-rich, heavy-metal-binding proteins.[4] It was found that (a) phosphate and borate buffers enhanced the sensitivity of detection at 200 nm by significantly reducing ultraviolet (UV) absorption of the background electrolyte, (b) the alkaline borate buffer (pH 8.4) gave rapid analysis times with reasonably high resolution, (c) the acidic phosphate buffer (pH 2.5) completely stripped zinc and cadmium from the proteins, yielding higher resolution and more reproducible separations of the apothioneins (metal-free proteins), (d) capillaries coated on their inner surface with a polyamine polymer that reversed electro-osmotic flow (EOF) or polyacrylamide that greatly suppressed EOF significantly improved resolution, (e) the MEKC mode of CE improved separation selectivity, and (f) photodiode array scanning detection to monitor UV absorption spectra of individual protein peaks separated at neutral pH was useful in determining both the presence and the type of metal associated with each.

CE is a useful tool for monitoring the purity of metalloproteins isolated from either natural or recombinant sources.[3] CZE was used to follow the purification progress of metallothioneins in samples subjected to gel filtration chromatography and reversed-phase high-performance liquid chromatography (HPLC).[3,4] Detection of a unique chromophore arising from the interaction of metal ions

Table 1 Characterization of metalloproteins using CE.

Identification and Purity Assessments
General characteristics (i.e., net charge, molecular weight, isoelectric point, etc.)
Monitoring purification steps
Separation of impurities or degradation products
Detection of unique UV/Visible absorbance (chromophore)
Structural information
Separation of molecular forms (i.e., isoforms, metalloforms, glycoforms, etc.)
Study of macromolecular assembly
Determination of metal-binding sites
Peptide mapping
Stability determinations
Effects of temperature and pH
Buffer additives (i.e., metals and metal chelators)
Activity measurements
Enzymatic activity
Electrophoretically mediated microassay (EMMA)
Isozyme profiling
Metal-binding/electrophoretic mobility shift
Affinity CE (ACE)
Immobilized metal-ion affinity CE (IMACE)
Metal-chelate coated capillaries
REDOX
Oxidation state of protein-bound metal
Elemental analyses
Indirect detection methods
Unique UV/Visible absorbance spectra (chromophore)
Mass spectrometry (CE/MS)
Direct (element-specific) detection methods
Inductively coupled plasma–mass spectrometry (CE/ICP–MS)
Proton-induced X-ray emission (PIXE)

and specific amino acid residues in the protein or with a prosthetic group attached to the protein can be useful. The selectivity achieved under such conditions can greatly reduce or even eliminate the need to purify metalloproteins prior to their analysis by CE. Two good examples of this are the detection of hemoglobin variants separated from red blood cell lysates by monitoring absorbance at 415 nm and the detection of transferrin in serum at 460 nm.[3] Absorbance at these characteristic wavelengths reflects the presence of iron atoms complexed by the heme moiety (hemoglobin) or by iron-binding sites located at the amino and carboxyl ends of the transferrin protein molecule. CE has also been used to characterize surface metal-binding sites on cytochrome-*c* and myoglobin modified with ruthenium-bis (bipyridine) imidazole, which imparts a strong absorbance at 292 nm to the modified proteins or peptides derived from a tryptic digest of the modified proteins.[3]

CE has proven to be useful in characterizing different molecular forms of various metalloproteins like metallothionein, transferrin, and conalbumin.[2–5] Molecular forms arise from differences in the amino acid sequence of proteins (isoforms), differences in the amount or type of metal bound (metalloforms), or from differences in the type and amount of carbohydrate side chains linked to the protein (glycoforms). CZE was used to follow the formation of the oligomeric iron core and its incorporation into ferritin, to detect and quantify ferritin species or ferritin subunit proteins in purified or partially purified states, and to study the interaction of different metal ions with ferritin.[2,3]

Structural stability of metalloproteins can be quickly assessed by CE under different conditions.[2,3] For example, thermally induced conformational changes in calcium-depleted α-lactalbumin and urea-induced unfolding of serum albumin were studied using CZE. The oxidation state of cysteine sulfhydryl groups in the zinc-containing protein, ribonuclease A, has been assessed using CZE to determine the presence or absence of a disulfide bond. Elevated capillary temperature altered the structure of myoglobin, which, in turn, resulted in reduction of the valence state of the iron atom bound to heme associated with this protein. Similarly, CIEF was used to separate and characterize different heme–iron valence hybrids of hemoglobin.[6]

Buffer additives, especially metals and metal chelators, can have dramatic effects on CE-based separations of metalloproteins by causing shifts in their electrophoretic mobility.[3] This observation forms the basis for a unique CE method referred to as affinity capillary electrophoresis or ACE. When a protein forms a complex with a charged metal-ion ligand, there can be a resulting change in electrophoretic mobility of the complexed protein relative to that of the metal-free protein. Scatchard analysis of the change in electrophoretic mobility of the protein as a function of the metal ion concentration in the separation buffer allows for the calculation of a metal-binding constant (K_b). ACE has been used to characterize K_b values for several metalloproteins, including (a) calcium affinity for calmodulin and C-reactive protein[3] and (b) the binding affinity of zinc for two separate sites in a highly basic, zinc-finger protein (NCp7) from the human immunodeficiency virus.[7] Haupt et al.[8] reported the development of an alternative CE affinity method based on immobilized metal affinity chromatography, which they called immobilized metal-ion affinity capillary electrophoresis or IMACE. In IMACE, metal ions (e.g., Cu^{2+}) are fixed to a soluble polyethylene glycol replaceable polymer matrix support added to the CE separation buffer. IMACE was used to study surface-related affinity

characteristics (number and accessibility of histidine residues and histidine microenvironment) for particular immobilized metal-ion chelate ligands in such proteins as cytochrome-*c*, ribonucleases A and B, chymotrypsin, and kallikrein.[8]

Some of the most promising advances in our understanding of unique characteristics of metalloprotein structure and function come from continuing developments in detection methodologies and from further development and refinement of coupled (hyphenated) systems such as CE/MS and CE/ICP/MS. The major difficulties restraining the routine use of such systems, aside from cost, arise from problems in interfacing the CE instrument with MS and ICP–MS instrumentation, although much progress is being made in this area.[9] CE/MS has been used to characterize metallothionein isoforms and metalloforms, the structures of which were deduced from discrete differences detected in molecular mass of the species separated by CE.[10] Using molecular masses calculated from the amino acid sequence and the type and amount of associated metals, it was possible to unequivocally identify distinct molecular forms.

The most definitive assessment of the metal composition of metalloproteins comes from the application of element-specific detection methods. CE/ICP–MS provides information not only about the type and quantity of individual metals bound to the proteins but also about the isotopes of each element as well.[11,12] Elemental speciation has become increasingly important to the areas of toxicology and environmental chemistry. Such analytical capability also opens up important possibilities for trace element metabolism studies. Fig. 1 depicts the separation of rabbit liver metallothionein containing zinc, copper, and cadmium (the pre-dominant metal) using CE/ICP–MS with a high-sensitivity, direct injection nebulizer (DIN) interface. UV detection (200 nm) was used to monitor the efficiency of the CE separation of the protein isoforms (MT-1 and MT-2), whereas ICP–MS detection made it possible to detect and quantify specific zinc, copper (not shown), and cadmium isotopes associated with the individual isoform peaks.

There are a number of emerging CE-based techniques that will greatly benefit the field of metalloprotein analysis in the near future. Major advances in interfacing instrumentation that will result in more efficient separations and more sensitive detection in coupled systems, especially for CE/MS and CE/ICP–MS, are occurring now.[9] Further development of capillary electrochromatography (CEC), new column packing materials, and commercial systems that allow for gradient elution CEC will have a major impact on improving CE separations of metalloproteins. Moreover, coupling CEC to MS or ICP–MS detectors will offer new and more powerful ways to isolate and characterize metalloproteins. The ability to accurately detect and quantify elemental isotopes offers the promise of being able to conduct isotope dilution experiments involving human and animal subjects in which metal metabolism will be studied and the molecular (metalloprotein) level. Finally, the push toward miniaturization of CE instrumentation (CE on a chip) will find increasing application in the analysis of metalloproteins. This will be especially true in clinical/diagnostic laboratories, where sample size may be severely limited.

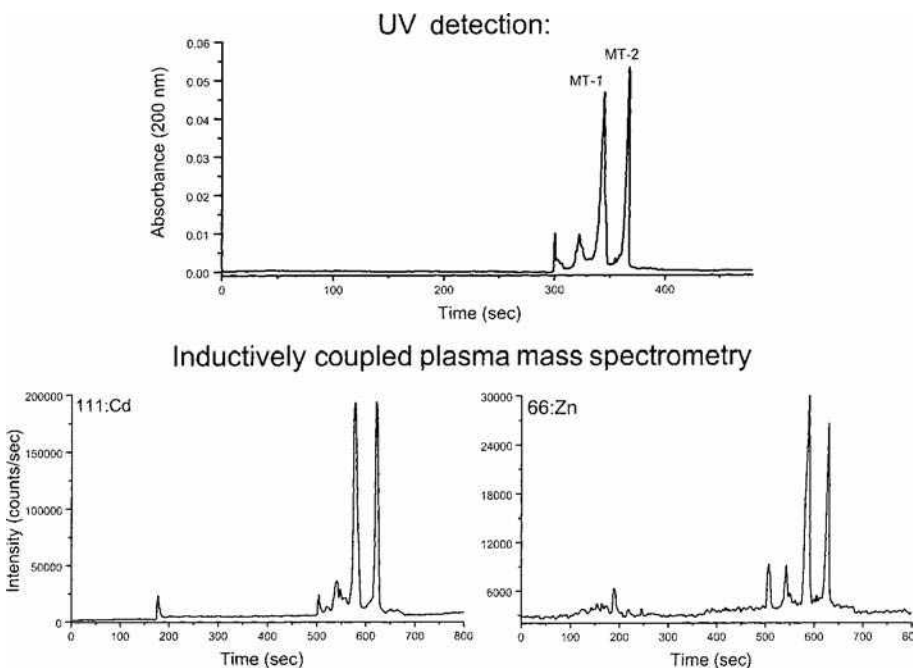

Fig. 1 Separation of rabbit liver metallothionein using CE–ICP–MS. The protein sample (1 mg/ml dissolved in deionized water) was first subjected to CZE with UV detection to optimize CE separation parameters for the major metallothionein isoforms (MT-1 and MT-2) shown in the upper panel. The CE instrument was then coupled to an ICP–MS instrument using a specially modified direct injection nebulizer (CETAC Technologies Inc., Omaha, NB) which enabled the entire capillary effluent from the CE to be directly injected into the ICP plasma torch, thus avoiding postcolumn dilution and band-broadening effects of conventional spray chamber nebulizers. Specific isotopes of cadmium (^{111}Cd) and zinc (^{66}Zn) associated with each isoform peak were monitored as shown by the figures in the lower panel.

Metals and Organometallics: GC for Speciation Analysis

Yong Cai
Weihua Zhang
Department of Chemistry, Florida International University, Miami, Florida, U.S.A.

INTRODUCTION

There has been increasing interest in speciation information of elements present in environmental and biological samples since the toxicological and biological importance of many metals and metalloids greatly depends upon their chemical forms. Frequently, the lack of the speciation information is the major limitation to our understanding of the biogeochemical cycling of an element. Coupling of chromatographic techniques gas chromatography and high-performance liquid chromatography (GC and HPLC) with a highly sensitive and selective atomic spectrometry detector has been widely exploited and accepted for the speciation of metals and organometals. GC has enjoyed particular attention because of its high resolution for separation and simplicity of coupling. In this entry, the sample preparation and derivatization techniques for speciation and analysis of metal and organometallic ions are first discussed. Coupling of GC with atomic spectroscopic techniques and their applications are then reviewed.

BACKGROUND

Speciation analysis of an element is usually defined as the determination of the concentrations of the individual physico-chemical forms of the element in a sample that together constitute its total concentration. The International Union for Pure and Applied Chemistry (IUPAC) has recently recommended the definition of speciation as the distribution of an element amongst defined chemical species in a system.[1] IUPAC defines chemical species as the specific forms of an element defined as to isotopic composition, electronic or oxidative state, and/or complex or molecular structure.

Recently, there has been increasing interest in speciation information of elements present in environmental and biological samples since the toxicological and biological importance of many metals and metalloids greatly depends upon their chemical forms.[2–4] The determination of the total amount of an element is important but is not sufficient to assess its toxicity. Information about concentrations of the individual species of an element, including its organic derivatives, is particularly crucial. Frequently, the lack of the speciation information is the major limitation to our understanding of the biogeochemical cycling of the element.

The identification of the chemical forms of an element has become an important and challenging research area in environmental and biomedical studies. Two complementary techniques are necessary for trace element speciation. One provides efficient and reliable separation, and the other provides adequate detection and quantitation.[5] In its various analytical manifestations, GC is a powerful tool for separation of a vast variety of chemical species. Atomic spectroscopy offers the possibility of selectively detecting a wide range of metals and non-metals. The use of detectors responsive only to selected elements in a multicomponent mixture drastically reduces the constraints placed on the separation step, as only those components in the mixture that contain the element of interest will be detected.[6]

It is not surprising that the coupling of chromatographic techniques (GC and HPLC) with a highly sensitive and selective atomic spectrometry detector has been widely exploited and accepted for the speciation of metals and organometals. GC has enjoyed particular attention because of its high resolution for separation and simplicity of coupling. Multicapillary GC (MCGC) provides an attractive alternative for the conventional capillary GC (CGC). Multicapillary GC offers higher separation speed and a larger sample injection volume without sacrificing efficiency and resolution of separation. For example, the run time for separation of organomercury species using MCGC is up to a factor of 10 faster than CGC without loss of resolution.[7] Of selective atomic spectrometers coupled with GC, atomic absorption spectrometer (AAS) has been successfully used for the speciation of metal(loid)s and organometal(loid)s. Various plasma spectrometry methods, such as inductively coupled plasma mass spectrometry (ICP–MS), microwave-induced plasma atomic emission spectrometry (MIP–AES), furnace atomization plasma emission spectrometry (FAPES), and inductively coupled plasma optical emission spectrometry (ICP–OES), have also been widely investigated for speciation analysis of metallic and non-metallic elements. Details about GC coupled with AAS, MIP–AES, and ICP–MS are discussed here.

SAMPLE PREPARATION

The native species of most metals and metalloids, such as mercury, lead, tin, arsenic, and selenium, are generally present as ionic forms in sample matrices. For GC-based

coupling techniques, these compounds need to be extracted from the sample matrices and be converted to volatile and thermally stable derivatives. Frequently, the derivatives are then concentrated by solid-phase microextraction (SPME),[8] purge and (cryo) trapping,[2,9] stir bar sorptive extraction (SBSE),[10] or extracting into an organic solvent prior to injection onto a GC column.[2] Among these preconcentration methods, SPME is a simple, fast, and solvent-free technique and has been employed for single or multielemental speciation of organometallic compounds of mercury, lead, and tin.[11]

Grignard Reaction

Grignard reaction is one of the most widely used derivatization techniques for speciation of a number of elements.[12,13] The main advantage of this reaction is that different alkyl groups can be chosen to make fully alkylated species. Reactions for mercury analysis can be described as follows:

$$RMgX + R'Hg^{+} \rightarrow RHgR' \quad (1)$$

$$RMgX + Hg^{2+} \rightarrow R_2Hg \quad (2)$$

where R indicates propyl, butyl, or pentyl groups and R′ for methyl or ethyl groups. However, Grignard reagents are very sensitive to water. As a consequence, metals and organometallic compounds have to be extracted prior to derivatization into an organic solvent with the assistance of complexing reagents, such as dithiocarbamates and tropolone. The whole sample preparation can be tedious and time consuming.

Hydride Generation

Several elements (Hg, Ge, Sn, Pb, Se, As, Te, Sb, Bi, and Cd) can be transformed into volatile hydrides, providing the basis of their analysis.[2,4] Sodium borohydride ($NaBH_4$) is commonly used as a derivatization reagent. The reaction for methylarsenicals is shown below:

$$Me_nAsO(OH)_{3-n} + NaBH_4 \rightarrow Me_nAsH_{3-n} \quad (n = 1-3) \quad (3)$$

The usefulness of this procedure for speciation analysis, however, is restricted by either the thermodynamic inability of hydride formation for some species, or considerable kinetic limitation to hydride formation. Nevertheless, the technique is still essential for some classes of compounds.[2]

Aqueous Derivatization with Tetraalkyl(aryl)borates

The restricted versatility of using $NaBH_4$ can, to a certain degree, be overcome by replacing $NaBH_4$ by alkyl or arylborates.[2] The most common derivatization procedure relies on ethylation with sodium tetraethylborate, which was initiated for determining methyllead ionic compounds.[14]

$$Me_nPb^{(4-n)+} + NaBEt_4 \rightarrow Me_nPbEt_{(4-n)} \quad (n = 1-4) \quad (4)$$

$NaBEt_4$ acts as an aqueous-phase ethylation reagent, quantitatively transferring Et^{-} ions to ionic metals and organometals. Direct aqueous-phase ethylation with $NaBEt_4$ has been used for speciation of a variety of metals, such as lead, mercury, and tin in different environmental and biological samples. This reaction has significant advantages since the derivatization reaction is performed in aqueous phase, subsequently reducing the analysis time and eliminating the need for organic solvent extraction. However, this method cannot be used for the speciation of the natively occurring ethylated species, such as ethyllead and ethylmercury.[13]

Several efforts have been carried out to develop alternative aqueous derivatization reagents. The use of sodium tetrapropylborate ($NaBPr_4$) as an alkylation reagent represents the most recent advance. Compared to ethylation, propylation has equivalent or even higher sensitivity and has the advantages of occurring within a wider pH range and with less interferences for analysis of some elements (e.g., for Hg).[15] In spite of the limitation of its commercial availability, $NaBPr_4$ has been used to determine organolead, tin, and mercury compounds.[2,9,15] Phenylation with sodium tetraphenyl borate ($NaBPh_4$) is also a promising technique for the speciation of several metals. Compared to $NaBEt_4$ and $NaBPr_4$, $NaBPh_4$ is much more stable under ambient conditions and is a low cost and commercially available chemical. Its application in organomercury analysis has been comprehensively studied.[16]

COUPLING GC WITH ATOMIC SPECTROMETRIC DETECTION

GC/AAS

GC coupled with AAS has been the most popular hyphenated technique for the speciation of metals and organometals. Among different atomizer designs employed in coupling GC with AAS, electrothermal atomization, especially the electrothermally heated quartz tube, is preferred due to its high sensitivity, simple operation, and low cost.[6] The quartz tube (~100 × 10 mm I.D.) is usually constructed in-house and wrapped with Nichrome resistance wire and ceramic isolation material. A thermocouple is attached to the surface of the quartz burner for temperature control (Fig. 1). If necessary, hydrogen and air can be supplied from side arms of the burner. The furnace can be heated to more than 1000°C by means of a variable transformer.

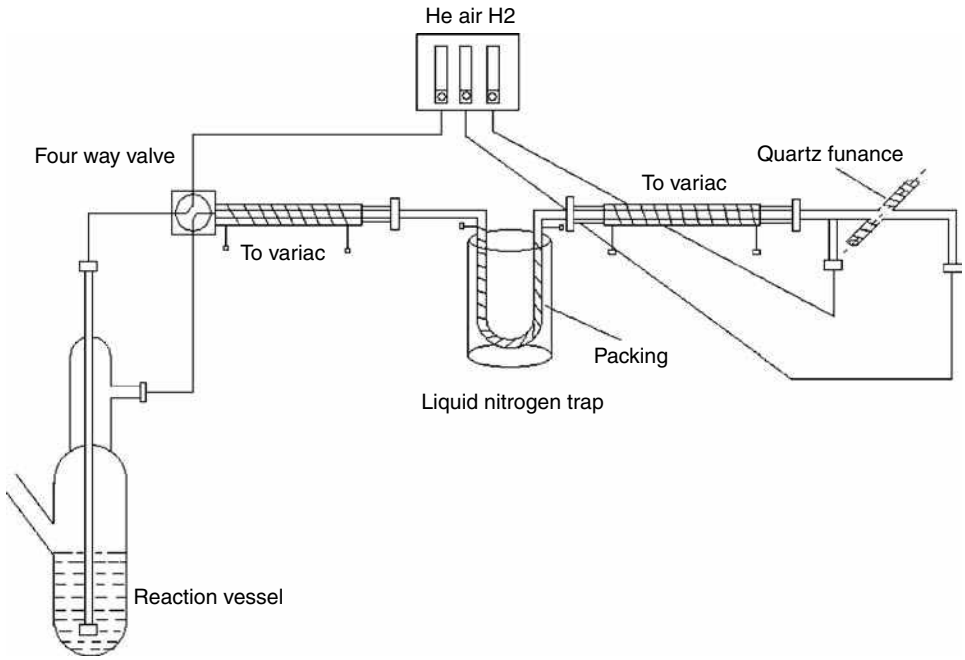

Fig. 1 Schematic diagram of a purge-and-trap GC/AAS system.

Two types of sample introduction/interface coupling GC and quartz furnace have been generally used. Fig. 1 shows a schematic representation of the first design, often called purge-and-trap. The instrumental set-up consists of a reaction vessel where the sample is brought in contact with a reagent, such as $NaBH_4$ or $NaBEt_4$, and a U-tube filled with a GC sorbent. During the reaction, the U-tube is maintained in liquid nitrogen, and the produced derivatives are purged with helium, and then trapped on the sorbent. Once the reaction is completed, the liquid nitrogen is removed and the U-tube is heated electrically. The trapped compounds are then separated according to their volatility and measured by AAS. The principal advantages of this set-up are its very high sensitivity and online aqueous derivatization. However, it suffers from water condensation problem in the U-trap, which limits the length of purge time. A water trap is often instaled upstream from the sorbent tube to avoid its blocking with ice crystals.[2]

The second design is actually modified from a regular GC device equipped with either a packed or a capillary column. The outlet of the GC is directly connected to the entrance of the quartz furnace through a piece of stainless steel tubing, which is electrically heated to avoid condensation of the compounds of interest. In order to use this technique, the target compounds have to be extracted from sample matrices, derivatized with an appropriate reagent, and back extracted into organic solvent before injection. Absolute detection limits obtained with this system are similar to those using purge-and-trap since they use the same detection technique. However, the concentration detection limits can be different as large as several orders of magnitude. With the purge-and-trap system, all target compounds in the sample are online preconcentrated and analyzed at once, while with the regular GC only a small portion of the sample extract is injected for analysis. The regular GC method offers a high versatility because of the possibility of using different Grignard reagents.

GC/MIP–AES

MIP–AES has two basic characteristics that can be utilized when coupling with a GC instrument.[6] The low gas temperature of the MIP allows small amounts of samples, compatible with those of GC solutes, to be introduced without extinguishing the plasma. In addition, sample introduction is easily facilitated as the carrier and plasma gases are the same (helium). These advantages have made the coupled GC/MIP–AES a popular technique and many applications have been reported.[6,16,17] Commercial instrument is currently available.

Helium plasma is maintained within a "cavity," which serves to focus power from a microwave source (usually operated at 2.45 GHz) into a discharge cell (usually a quartz capillary tube). The cavity that has been most used for GC detection, has been the atmospheric pressure TM_{010} cylindrical resonance cavity developed by Beenakker.[18] The effluent from a GC is connected directly to the discharge tube via a heated transfer line to prevent analyte condensation. The GC/MIP–AES requires a consistent supply of high purity gases for optimal performance. Hydrogen and oxygen are often used as plasma gases for metal and metalloid analysis. In addition, the AED spectrometer requires a continuous nitrogen purge.

Advantages of MIP–AES are low cost, simple operation, and high sensitivity. Its sensitivity for mercury analysis is compatible with that using GC coupled with atomic fluorescence detection,[16] which is currently recognized as the most sensitive method for determining mercury. The main drawback is the low tolerance for organic solvents. A venting system has to be used to prevent the solvent from getting into plasma tube.

GC/ICP–MS

Over the last decade, ICP–MS has proven to be a highly sensitive and selective technique for the determination of trace and ultratrace amounts of metals in various samples. It allows multielement detection in a single run and offers isotopic information of the elements of interest.[19–21] Solvent venting to prevent plasma instability is unnecessary, unlike in GC/MIP–AES, and no carbon accumulates as it does on MIP discharge tube. These features make the hyphenation GC/ICP–MS unique.

Coupling GC with ICP–MS is easily accomplished by connecting a column to the inner tube of the torch using a transfer line between the GC oven and the plasma torch (Fig. 2). The transfer line usually consists of an electrically heated stainless steel tube through which a piece of deactivated fused silica is passed. The transfer line capillary ends at the tip of the ICP injector. Generally, the stainless steel tubing is maintained at a temperature that prevents the condensation of the GC effluent in the transfer line. Fluctuation in the transfer line temperature can affect GC peak shape and resolution.

The ICP–MS instrument requires a carrier gas flow rate of approximately 1 L/min, while the capillary GC effluent is less than 5 ml/min. It is, therefore, necessary to introduce argon as a makeup gas. The makeup gas produces a central channel in the plasma and helps to carry analytes from GC column to the plasma. The makeup gas must be heated to avoid condensation of the column effluent, and this has been done by passing the argon gas through heated stainless steel tubing and adding it at the beginning of the transfer line.[19] However, a high flow rate of argon makeup gas results in an undesirable dilution effect. This is not the case for MCGC/ICP–MS since the dilution effect may be minimized or even eliminated due to large carrier gas flow without the need of an additional makeup gas.[7]

This hyphenated technique has been successfully applied to the speciation of a number of metals, including lead,[22] mercury,[23] and tin,[24] The advantages of determining multielements simultaneously and a wide dynamic linear range are obvious.[20] The high resolving capacity of GC and the high sensitivity and multielemental analysis capability of ICP–MS have made the combination most efficient and attractive for speciation analysis.[9] More recently, the remarkable developments in plasma sources, such as the low power plasma and glow discharge (GD) sources, as well as mass analyzers such as the use of collision/reaction cell, time-of-flight (TOF), and double-focusing sector field, have widened the window for elemental speciation using this technique.[9–24]

In addition, ICP–MS offers a unique characteristic of being able to provide isotopic information of an element. By utilizing isotope dilution (ID), GC/ICP–MS has been applied for accurate and precise determination of organotin and organomercury species. Not only is it possible to significantly improve the precision of determination, but it is also competent for studying transformation of species during analysis process by species-specific ID/GC/ICP–MS.[9]

CONCLUSIONS

Speciation analysis of metals and organometallics is a challenging analytical task. Because the native species of most metals and metalloids, such as mercury, lead, tin, arsenic, and selenium, are generally present as ionic forms in sample matrices, these compounds need to be extracted from the

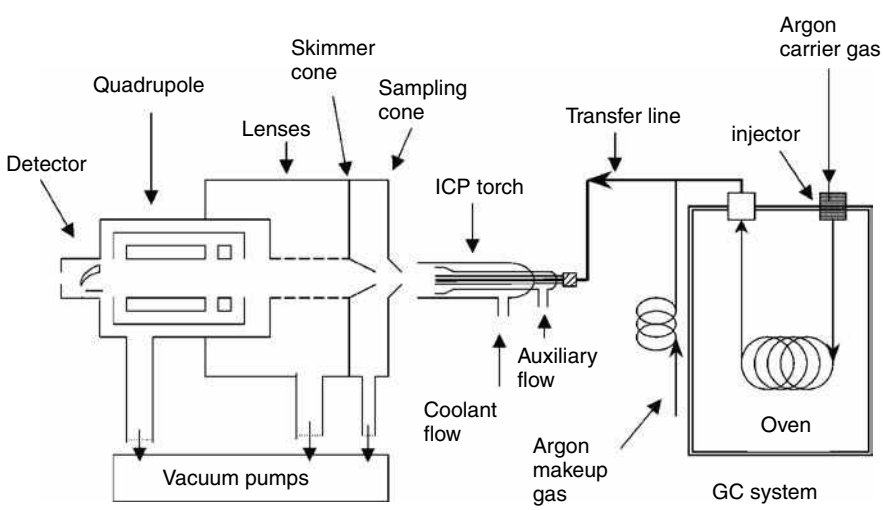

Fig. 2 Schematic diagram of a GC/ICP–MS system.

sample matrices and be converted to volatile and thermally stable derivatives for GC analysis. Hydride generation with $NaBH_4$, aqueous alkylation with $NaBEt_4$, $NaBPr_4$, and $NaBPh_4$ are the most widely used methods for derivatization. Coupling GC with ICP–MS has proven to be a highly sensitive and selective technique for the speciation of trace and ultratrace amounts of metals in various samples. It allows multielement detection in a single run and offers isotopic information of the elements of interest. With the rapid development and improvement of ICP–MS and the substantially reduced cost of using this instrument, coupling GC with ICP–MS will be one of the most powerful tools for metal and organometalloid speciation.

INTRODUCTION

A HPLC method was developed for the simultaneous determination of metformin and glibenclamide in a combined dosage form using a Zorbax XDB C_{18}, 15 cm column. The mobile phase was composed of the buffer and acetonitrile in the ratio 68 : 32, vol/vol; pH was adjusted to 7.5 with orthophosphoric acid. The buffer used in the mobile phase contains 10 m*M* disodium hydrogen phosphate and 10 m*M* sodium dodecyl sulphate (SDS) in double-distilled water. The mobile phase flow rate was 1 ml/min, column oven temperature was maintained at 40°C, and analytes were detected at a wavelength of 226 nm. The developed method was validated and shown to be linear. The correlation coefficients for metformin and glibenclamide were 1.0 and 0.9999, respectively. The relative standard deviations for six replicate measurements intwo sets of each drug in the tablets were always less than 2%.

OVERVIEW

Metformin HCl is 1,1-dimethyl biguanide hydrochloride and glibenclamide is 5-chloro-*N*-[2-[4-(cyclohexylamino)carboxyl]amino]sulfonyl]phenyl]ethyl]-2-methoxybenzamide. A combination of 500 mg of metformin HCl and 5 mg of glibenclamide is available commercially as tablets.[1] It has been concluded, from the comparative study, that combined treatment with metformin and sulphonylurea is more effective than these drugs alone for improving glycemic control in type II diabetes, while also allowing a reduction of the dosage of each drug.[2]

A literature survey revealed that few methods are reported for the individual estimation of metformin and glibenclamide. Both of these drugs are official in the IP[3] and BP;[4] glibenclamide is also reported in the United States Pharmacopeia (USP).[5] The methods for metformin[6–11] and glibenclamide[12–15] are reported for the estimation of these drugs in tablets and plasma. One method is reported for the estimation of metformin and glibenclamide in a combined dosage form.[16] In the reported method,[16] glibenclamide was estimated at 300 nm and metformin was estimated at 232 nm. The estimation of the analytes was performed by preparing two different sample preparations.

In the present article, attempts have been made to develop a simple and rapid method for the simultaneous determination of metformin and glibenclamide. Adequate separation was achieved by using a mobile phase containing 10 m*M* SDS and 10 m*M* disodium hydrogen phosphate in double-distilled water and acetonitrile in the ratio of 68 : 32, vol/vol, with pH adjusted to 7.5 with orthophosphoric acid. In the present developed method, the analytes of the combined dosage form were analyzed using the same sample preparation and were detected at a wavelength of 226 nm. In the reported method,[16] the recovery values for metformin HCl and glibenclamide were 99.37% and 101.57%, respectively. In the present method, the recovery values for metformin HCl and glibenclamide were 99.2% and 100.0%, respectively. The method is validated and shown to be linear, accurate, and precise. The method has been applied for the analysis of the ingredients of the combined dosage forms available in the commercial market.

EXPERIMENTAL TECHNIQUES

Materials and Reagents

Metformin HCl and glibenclamide were obtained from Wockhardt Research Centre (Aurangabad, Maharashtra State, India). SDS and disodium hydrogen phosphate were obtained from E. Merck (India) Ltd. (Worli,

Mumbai, India). Orthophosphoric acid and acetonitrile (HPLC grade) were obtained from Qualigens Fine Chemicals (Dr. Annie Besant Road, Mumbai, India). The 0.45 μm nylon filter was obtained from Advanced Microdevices Pvt., Ltd. (Ambala Cantt, India) and Whatman filter paper 41 was obtained from Whatman International Ltd. (Maidstone, England, UK). The tablets containing a combination of metformin and glibenclamide were purchased from the Indian market. Double-distilled water was used throughout the experiments. Other chemicals were of analytical or HPLC grade.

Chromatographic Conditions

A Thermoseparation Products Company high-performance liquid chromatography (HPLC) was utilized, consisting of the following components: Constametric 3500 pump, AS 3000 autosampler, and UV 1000 detector. A Zorbax XDB C_{18} (5 μm, 4.6 × 150 mm; Agilent Technologies) column was used. The mobile phase flow rate was 1 ml/min and the column oven temperature was maintained at 40°C; the analytes were detected at a wavelength of 226 nm. The injection volume was 25 μl. Data acquisition was performed with the software, PC 1000. Peak purity was checked with a photodiode array detector (UV6000 LP; Thermoseparation Products Co.).

Preparation of Solutions

Mobile phase

The mobile phase was composed of a buffer and acetonitrile in the ratio of 68 : 32, vol/vol. The pH of the mobile phase was adjusted to 7.5 with orthophosphoric acid. The buffer used in the mobile phase consisted of 10 m*M* disodium hydrogen phosphate and 10 m*M* SDS in double-distilled water. The mobile phase was premixed and filtered through a 0.45 μm nylon filter and degassed.

Standard stock solutions

Standard solutions were prepared by dissolving the drugs in the diluents and diluting them to the desired concentration. The buffer and diluents used for the standard preparation and sample preparation were prepared as follows:

- Buffer: contained 10 m*M* disodium hydrogen phosphate in double-distilled water; pH was adjusted to 4.0 with orthophosphoric acid.
- Diluent: contained the buffer and acetonitrile in the ratio 60:40, vol/vol.

Metformin HCl

A 125 mg portion of metformin HCl standard was accurately weighed and transferred to a 50 ml volumetric flask; it was dissolved and diluted to 50 ml with the diluent.

Glibenclamide

A 25 mg portion of glibenclamide standard was accurately weighed and transferred to a 50 ml volumetric flask; 30 ml of acetonitrile was then added and sonication was applied for 5 min. After sonication, 10 ml of the buffer was then added and the volume was made up to 50 ml with the diluent. From this solution, 2.5 ml was transferred into a 50 ml volumetric flask and diluted to the mark with the diluent.

Mixed standard preparation

For mixed standard solution, 2 ml of a metformin standard solution and 2 ml of glibenclamide standard solution were transferred to a 50 ml volumetric flask and diluted to the mark with the diluent. This solution contains 100 μg/ml metformin HCl and 1.0 μg/ml glibenclamide.

Assay preparation

Ten tablets were weighed and finely powdered. A quantity of powder equivalent to one tablet, containing 500 mg of metformin HCl and 5 mg of glibenclamide, was transferred to a 100 ml volumetric flask; 50 ml of acetonitrile was then added and sonication was applied for 5 min. After sonication, 20 ml of buffer was added and further sonication was applied for 20 min with swirling. The solution was cooled to ambient temperature and diluted to the desired volume with the diluent and mixed well. The solution was filtered through Whatman filter paper 41. The first 5 ml portion of the filtrate was rejected and then 1 ml of the filtered solution was transferred into a 50 ml volumetric flask and diluted with the diluent.

RESULTS AND DISCUSSION

Chromatography

A reverse-phase HPLC procedure was proposed as a suitable method for the simultaneous determination of metformin and glibenclamide in a combined dosage form. The chromatographic conditions were adjusted to provide adequate retention and resolution of metformin and glibenclamide. A mixture of buffer and acetonitrile, in the ratio of 68:32, vol/vol, with pH adjusted to 7.5 with orthophosphoric acid at a flow rate of 1 ml/min, was

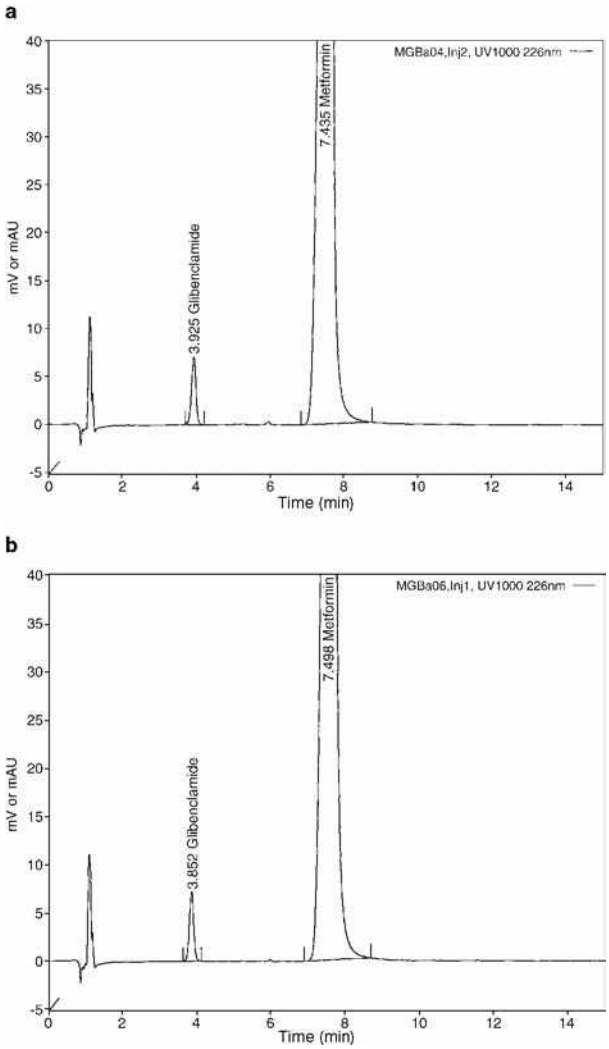

Fig. 1 a, A typical chromatogram of a mixed standard preparation; and b, A typical chromatogram of an assay preparation.

found to be an appropriate mobile phase, allowing adequate separation of active substances of the combined dosage form. Typical chromatograms obtained by using the aforementioned mobile phase, from 25 μl of the mixed standard preparation and assay preparation, are illustrated in Fig. 1A and B, respectively. The retention times of glibenclamide and metformin were 3.9 and 7.4 min, respectively.

Specificity

The specificity of the method was checked with a peak purity test of the assay preparation performed with a photodiode array detector. The peak purity values for metformin and glibenclamide were observed to be 995 and 999, respectively. The results of the peak purity analysis show that the peaks of the analytes were pure and that the formulation excipients did not interfere with the analyte peaks.

Linearity

Linearity of the method was tested from 25% to 150% of the targeted level of the assay concentration (100 μg/ml metformin HCl and 1.0 μg/ml glibenclamide) for the two analytes. The mixed standard solutions containing 25–150 μg/ml metformin HCl and 0.25–1.50 μg/ml glibenclamide were prepared from the standard stock solutions of metformin and glibenclamide. Linearity test solutions were injected and analyzed in triplicate. The calibration graphs were plotted by using peak areas of the analytes against the concentration of the drug (in micrograms per milliliter). In the simultaneous determination, the calibration graphs were found to be linear for both the analytes in the mentioned concentration ranges. The regression equations for metformin and glibenclamide were found to be $y = 74{,}383x + 22{,}660$ and $y = 60{,}424x - 150.79$, and the correlation coefficients for the regression lines were 1.0 and 0.9999, respectively.

Accuracy

The accuracy of the method was studied by recovery experiments. The recovery experiments were performed by adding known amounts of the drugs into a placebo. The recovery was performed at three levels (80%, 100%, and 120%) of the label claim per tablet (500 mg of metformin HCl and 5 mg of glibenclamide). Three samples were prepared for each recovery level. The recovery values for metformin HCl and glibenclamide ranged from 98.5% to 99.9% and from 99.3% to 101.2%, respectively (Table 1). The average recovery of three levels (nine determinations) for metformin HCl and glibenclamide were 99.2% and 100.0%, respectively.

Table 1 Results of the recovery tests for the drugs.

Level of addition (%)	Ingredient	Amount added (mg)	Amount recovered (%) (±SD)	Overall recovery (%) ($n = 9$)
80	Metformin HCl	400.0	99.8 (±0.08)	99.2 (±0.5)
	Glibenclamide	4.0	100.7 (±0.36)	100.0 (±0.6)
100	Metformin HCl	500.0	99.1 (±0.05)	
	Glibenclamide	5.0	99.6 (±0.08)	
120	Metformin HCl	600.0	98.7 (±0.17)	
	Glibenclamide	6.0	99.8 (±0.34)	

Table 2 Assay results of active ingredients in tablets.

Set	Ingredient	Label claim (mg)	Found (mg) (n = 6)	% Label claim (±SD)
Repeatability	Metformin HCl	500	498.0	99.6 (±1.6)
	Glibenclamide	5	5.12	102.3 (±1.6)
Intermediate	Metformin HCl	500	496.0	99.2 (±1.3)
Precision	Glibenclamide	5	5.07	101.3 (±1.5)

Precision

The precision (repeatability and intermediate precision) of the method was determined from one lot of the combined dosage form.

Repeatability

For repeatability of the method, six determinations of the concentrations of each ingredient in the tablets were performed. The results are shown in Table 2.

Intermediate Precision

Intermediate precision of the method was assessed by analyzing the samples six times on different days, by different chemists, by using different analytical columns of the same manufacture and different HPLC systems. The percentage assay was calculated using the area of the mixed standard preparation. The assay results are shown in Table 2.

Determination of the Limit of Detection and Limit of Quantitation

To determine the limit of detection (LOD) and the limit of quantitation (LOQ), the method based on the residual standard deviation of a regression line and slope was adopted. To determine the LOD and LOQ, a specific calibration curve was studied by using samples containing the analytes in the range of the detection limit and the quantitation limit. The limits of detection for metformin and glibenclamide were 0.013 and 0.007 μg/ml, respectively, and the limits of quantitation were 0.040 and 0.021 μg/ml, respectively.

Stability of Analytical Solutions

The stability of the analytical solutions was determined in terms of the assay of the drugs in the standard preparation and the assay preparation at room temperature. These solutions were analyzed at 0, 24, 48, and 72 hr against a freshly prepared standard at each time interval. The relative standard deviations for the assay values, determined up to 72 hr for metformin and glibenclamide in assay preparation and standard preparation, were 0.75% and 0.62%, respectively. The assay values were within ± 2% after 72 hr. The results indicate that the solutions were stable for 72 hr at room temperature.

Table 3 System suitability.

Analyte	RSD (%)	Tailing factor	Theoretical plates	Resolution
Metformin	0.61	1.04	9193	13.6
Glibenclamide	0.62	1.03	6395	

System Suitability

For system suitability studies, five replicate injections of mixed standard solutions were injected and parameters such as relative standard deviation of peak area, column efficiency, resolution, and tailing factors of the peaks were calculated. Results are shown in Table 3.

CONCLUSIONS

The described isocratic HPLC method is validated and shown to be precise and accurate. This method can be used in quality control departments for the simultaneous determination of metformin and glibenclamide in the combined dosage form.

ACKNOWLEDGMENTS

The authors are grateful to the Wockhardt Research Centre and to the Head of the Department of Chemical Technology, Dr. Babasaheb Ambedkar Marathwada University, Aurangabad, Maharashtra State, India, for providing the facilities for this research work.

Microcystins: CE Determination

Dorota Szydlowska
Marek Trojanowicz
Department of Chemistry, Warsaw University, Warsaw, Poland

INTRODUCTION

Determination of microcystins (MC) has gained, in last two decades, a great interest because of the related ecological and public health risks. They are toxins which are produced and accumulated within the freshwater cyanobacterial algae during their blooming, and then enter the aquatic environment after cell lysis.[1–3] Over 70 different analogs of microcystins have been isolated from natural blooms and laboratory cultures of cyanobacteria.[4] Chemically, MC are cyclic heptapeptides, composed of five invariable and two variable amino acids (Scheme 1).

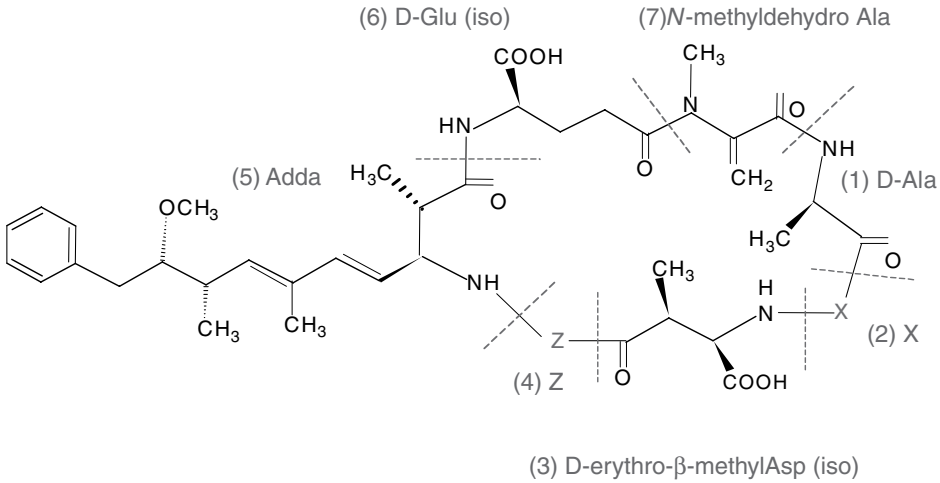
The general structure is cyclo(-D-Ala-L-X-D-erythro-β-methyliso Asp-L-Z-Adda-D-iso-Glu-*N*-methyldehydro Ala), where X and Z represent two variable L-amino acids, and Adda stands for 3-amino-9-methoxy-2,6,8-trimethyl-10-phenyldeca-4,6-dienoic acid. The main differences in variants are based on different variable amino acids in positions 2 and 4 of heptapeptide. Most commonly occurring MC contain leucine (L) and arginine (R) or tyrosine (Y), and their names are abbreviated as MC-LR, MC-RR, and MC-YR, respectively. Microcystins with different structure of Adda (in position 5), such as stereoisomers or 9-*O*-desmethyl-Adda, were also identified. Production of MC by cyanobacteria depends on different factors such as intensity and wavelength of light, temperature, pH, concentration of nutrients such as phosphorus and nitrogen. Their synthesis is an energy (ATP)-dependent process that can be also affected by the presence of some trace metals. Reported occurrences of most common MC in different environmental samples, where different MC are produced by different cyanobacteria are shown in Table 1.[5]

Among different toxins produced during the blooming of cyanobacteria, MC attracted the largest attention, as they have been involved in numerous intoxication cases with humans and domestic animals. They are hepatotoxins, and their related illness spreads through water contact and water consumption and through air. Besides their ability to cause acute poisonings, they can also promote cancer by chronic exposure of humans to low concentration of MC in drinking water. Microcystins are inhibitors of protein phosphatases from animals and higher plants, so they can act as tumor promoters. Regarding the water quality and the public health a maximum level of 1 ppb of MC-LR is recommended in drinking water.[6] Because of this serious health risk caused by these algal toxins, sensitive and specific analytical methods of determination are needed for warning and routine monitoring. At the present stage of development, besides high-performance separation methods discussed in detail here, mostly various type of bioassays are employed, including animal and plant bioassays, enzyme-linked immunosorbent assay (ELISA) using monoclonal or polyclonal antibodies radiometric or colorimetric and fluorimetric protein phosphatase inhibition assays.[7] The best detection limit was reported for inhibition-based enzyme assays, ELISA immunoassay, and high-performance liquid chromatography (HPLC) with fluorimetric and chemiluminescence detection.

HPLC OF MC

Because of the development of analytical methods for determination of MC, especially in last decade, the most widespread analytical techniques for their determination are commercialized; enzyme-linked immunosorbent assays and HPLC with diode array detectors of anion-exchange columns for this purpose were only sporadically reported with UV detection and isocratic[8,9] or gradient[10] elution. For anion-exchange stationary phase functionalized with diethylaminoethylene groups, better resolution for LR and YR was reported than for C18 columns.[8] For separation of cyanobacterial toxins, including MC-LR and -RR, hydrophilic interaction HPLC with gel Amide-80 column[11] and amide C16 column[12] providing comparable resolution to that of conventional reversed-phase C18 columns were applied.

Most commonly used HPLC protocols for the determination of MC rely on the use of high-resolution reversed-phase C18 columns, 15 or 25 cm of length, and 3 to 5μm particles to obtain sufficient resolution of MC. Both isocratic and gradient elution are equally employed, usually with addition of 0.05–0.1% trifluoroacetic acid (TFA), acting as pH modifier and ion-pairing reagent. For isocratic elution, eluents such as water with acetonitrile (ACN) containing TFA[13] or formic acid,[14] ammonium acetate with ACN,[15,16] and phosphate buffer with methanol[17] or ACN have been reported.[18] In gradient elution, most often gradient of ACN is employed,[12,19–22] and also the use of



Scheme 1 General structure of microcystins.

methanol gradient was recently reported; however, for both conventional C18 column and monolithic silica C18 column the best combination of overall performance and high throughput was achieved with ACN gradient.[12] For HPLC separation of polar desmethyl MC and their main variants and also hydrophobic MC, several C18 columns and different eluents and elution modes have been compared[23] (see example recordings in Fig. 1).

Both commonly used elution methods with ammonium acetate/ACN and water/ACN with TFA were suitable for determination of MC, but performance of these methods was strongly dependent on the analytical column used. Addition of water to methanolic standard solutions of MC significantly increased the sensitivity of UV detection and resulted in better chromatography.

Besides various commercial, conventional reversed-phase C18 columns, including microbore columns for HPLC with mass spectrometry detection,[14,18,19] recently for determination of MC a monolithic silica C18 column has been employed.[12] The Chromolith column allowed a reduction in the time of analysis to 2.5 min at a flow-rate 4 ml/min compared to 45–60 min in commonly used chromatographic systems. The elution order of most MC was as predicted by the retention values of the variable amino acid residues. The observed higher limit of detection observed with UV detection with Chromolith column was attributed to the higher background noise resulting from an imperfect mixing of mobile phase components at high flow-rates. The best obtained combination of overall performance and rapid throughput with 2.5 min gradient of ACN is illustrated by chromatogram in Fig. 2.

The most commonly used detection for HPLC of MC is UV at 238 nm, usually performed with photodiode–array detectors,[12,17,18,21–23] which is also employed as reference method, e.g., for MC determination using a novel indirect competitive ELISA method[24] or for a time-resolved fluoroimmunometric assay.[20] The detection limit of MC in HPLC system without any preconcentration or clean-up is too high for practical applications (300–1000 ppb[12]). In the system with UV detection after sample clean-up employing immunoaffinity chromatography (IAP), for detection of main MC—RR, YR, LR, and LA—the limit of detection about 0.02 ppb was reported for determination in tap water.[21] The HPLC system with UV detection was also employed in studies on adsorption of MC-LR on surface of polymers and effect of methanol and ACN used in solutions of MC-LR on quantitative determination with UV detection.[22] The concentration of MC-LR measured by UV detection was found to be strongly affected by the content of mentioned solvents in solutions that was interpreted by changing availability of chromophores of MC-LR for detection by interaction in aqueous solutions.

The second most widely used detection in HPLC system for determination of MC is mass spectrometry, mostly used for the identification of MC, but also for their quantification. Since the middle of 1980s accurate mass measurements and tandem mass spectrometry (MS–MS) are employed to obtain empirical formulae and structural information. Applications of liquid chromatography with MS using frit-FAB ionization technique[25] and nebulizer-assisted electrospray (ion-spray)[26] were used for the identification of MC in cyanobacterial extracts. The tandem mass spectrometry combined with liquid chromatography was employed for analysis of purification MC with demonstration of the possibility of incorporating precursor-ion scans of *m/z* 135, a fragment of the Adda side chain into LC/MS–MS screening method.[27] Atmospheric pressure ionization in ion-spray mode was employed for the analysis of MC isolated from toxic strains of *Microcystis aeruginosa*.[19] The identity of suspected MC was confirmed by LC-tandem MS analysis with collisional activation achieved using argon target gas in the second quadrupole. The assignment of structures of fragment ions was confirmed by comparison of *m/z* values with those obtained from MS–MS spectra of ^{15}N labeled analogs, isolated after stable-isotope feeding experiments. Detailed list of assignment of fragment ions in product spectra of example MC,

Table 1 Occurrence of microcystins in different environmental samples.

Microcystin variant (MC-XZ)	Variable amino acid X	Variable amino acid Z	Cyanobacterial species	Different environmental samples		
				Aqueous samples	Animal tissue samples	Blue-green alga biomass samples
MC-LR	Leucine (L)	Arginine (R)	*Microcystis wesenbergii*, *Morelia viridis*, *M. aeruginosa*, *Anabaena flos-aquae bv. Radiocystis fernandoi*, *Oscillatoria*	Drinking water[17,24] Surface water[14,15,18,36,39]	Rat (liver) Mouse (liver) Fish (liver, kidney, blood, muscle)[21] Mussels (gills, muscle, digestive tract)[44] Crayfish (intestine, heptopancres)[43]	Field samples[11,13,21,23,31,35,39,45] Culture samples[10–12,14,19,20,22–24,30]
MC-RR	Arginine (R)	Arginine (R)	*M. aeruginosa*, *M. viridis*, *Anabaena*, *Oscillatoria*	Drinking water[17] Surface water[14,15,18,36]	Fish (liver blood, muscle)	Field samples[11,13,23,31,35,39,45] Culture samples[11,12,14,23,30]
MC-YR	Tyrosine (Y)	Arginine (R)	*M. aeruginosa*, *M. viridis, Oscillatoria*	Drinking water[17] Surface water[14,15,18]	Not identified	Field samples[14,45] Culture samples[12,13,19,30,31,39]

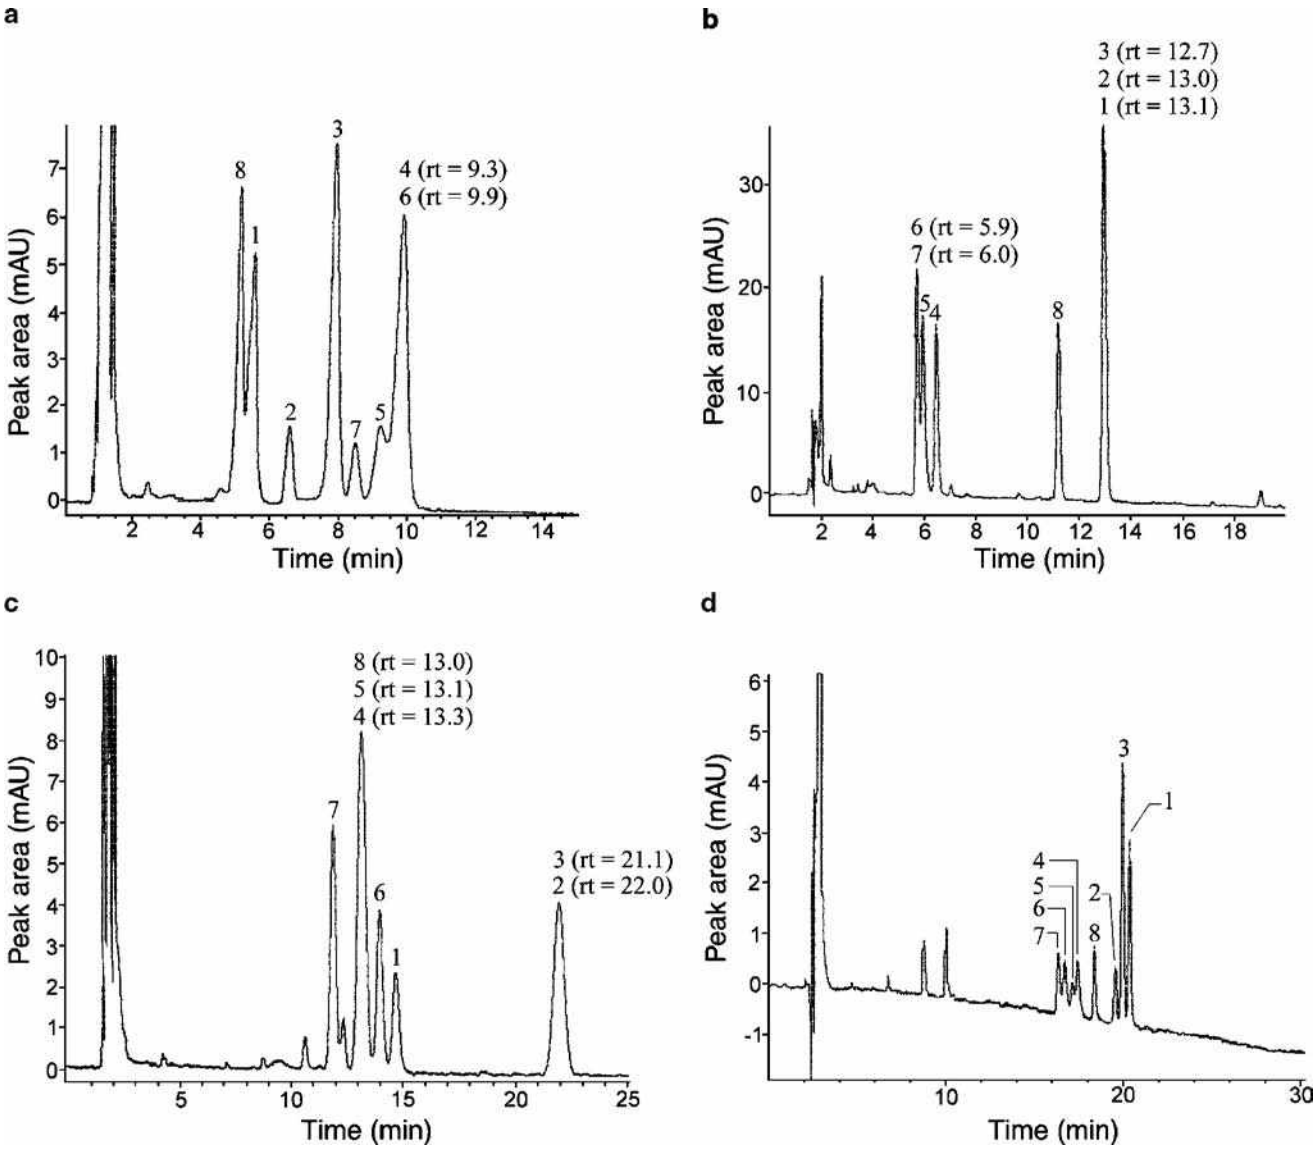

Fig. 1 Chromatograms obtained for mixture of microcystins using different commercial reversed-phase columns and different elution conditions.[23] (a) ODS Hypersil column 100 × 4.6 mm, elution with 10 m*M* ammonium acetate : acetonitrile (77 : 23) at 1 ml/min; (b) Zorbax Eclipse XDB-C18 250 × 3.0 mm, eluent as in A at 0.6 ml/min; (c) the same column as B, elution with 0.05% TFA : acetonitrile (70 : 30) at 0.6 ml/min and then programmed gradient of ACN, (d)-Lichrosper PAH 250 × 3.0 mm, elution as in C. Peaks assignment: 1-MC-LR, 2-[D-Asp^3]MC-LR, 3-[Dha^7]MC-LR, 4-MC-RR, 5-[D-Asp^3]MC-RR, 6-[Dha^7]MC-RR, 7-[D-Asp^3, Dha^7]MC-RR, 8-MC-YR.

namely for natural and ^{15}N enriched MC-LR and desmethyl MC-LR. Fragment ions in MS–MS of MC result mainly from consecutive cleavages of peptide bonds, hence they provide information concerning different peptide segments. A list of *m*/*z* values for characteristic fragment ions for six different MC is also provided. As shown in Table 2, the MS detection provides enhanced detection limit compared to UV detection without analyte preconcentration. Reported studies have shown evidence for two unknown MC-LW and -VF in extracts of *M. aeruginosa*, with Trp and Leu, and with Phe and Val, respectively. The comparison of chromatograms of extract obtained with non-specific UV detection at 214 nm, with detection at 238 nm corresponding to the chromophore of the unconjugated diene of the Adda, and total ion chromatogram obtained by LC–MS is shown in Fig. 3A where MC-LR can be observed as intense peak with retention time 17.4, whereas in Fig. 3B are shown mass spectra taken from LC–MS chromatogram shown in Fig. 3A.

The use of microbore columns in LC–MS system with positive electrospray ionization allowed enhanced sensitivity of MC determination.[14] In the system developed for determination of MC in water samples with 1 mm I.D. column and selected ion monitoring mode, and using sample preconcentration reported earlier on C18 cartridges,[28] detection limits for MC-LR, -RR, and -YR were reported

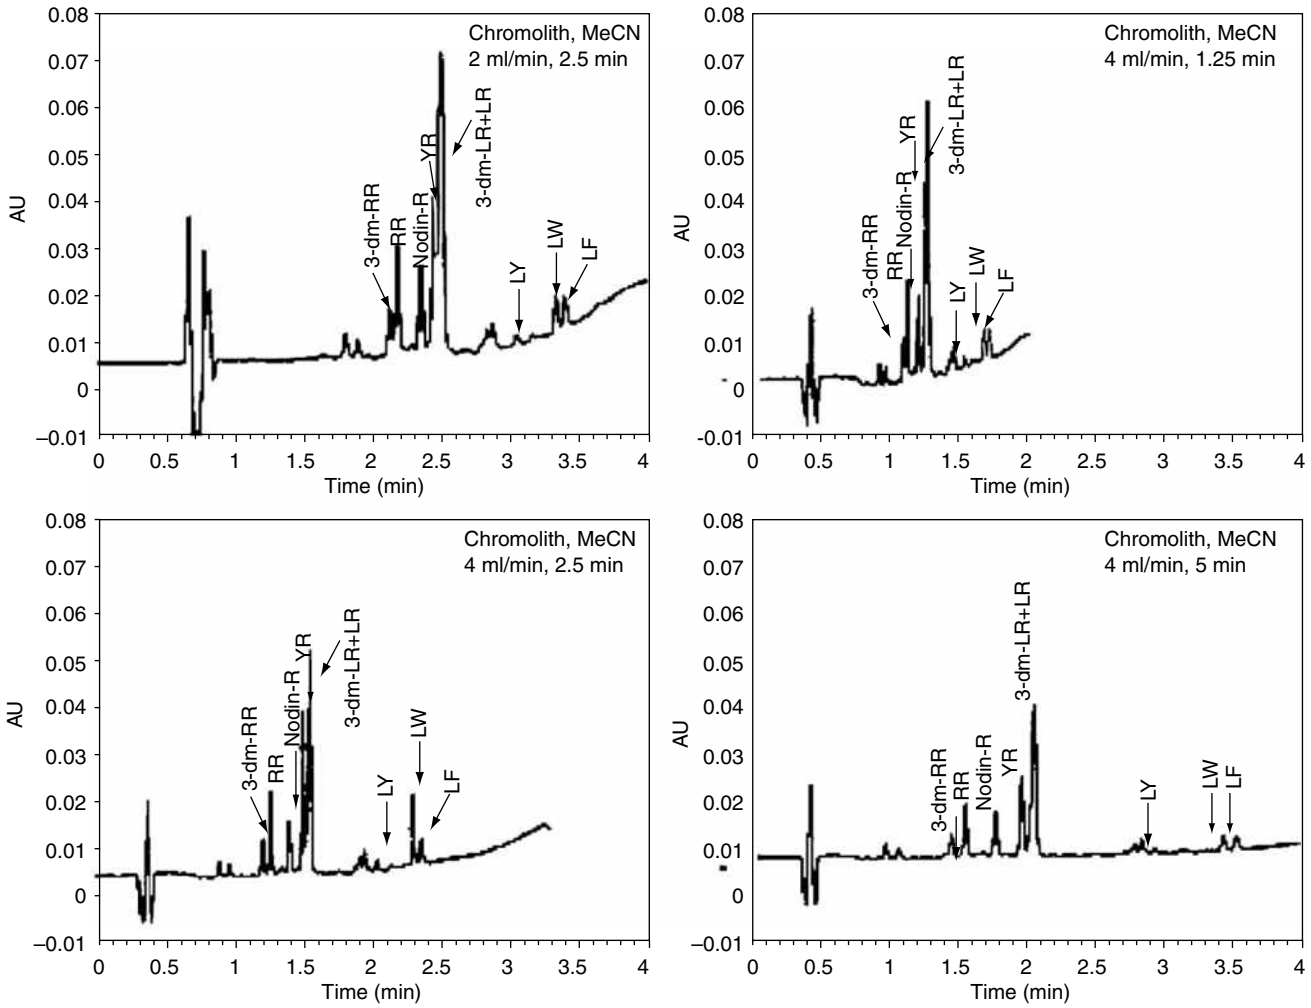

Fig. 2 Chromatograms obtained for mixture of MC with monolithic C18 column Chromolith with TFA-ACN phase (25–70% ACN) with flow rate 4 ml/min and length of gradient 2.5 min.[12] Detection at 238 nm.

in the range from 2 to 14 ppb. In examined natural water samples, MC-LR and -RR have been detected and determined in concentrations from 0.2 to 270 ppb. In LC–MS determination of MC in lake water samples, peaks of MC observed in HPLC with UV detection were successfully and reliably identified by excluding a few of non-MC peaks appearing even after the immunoaffinity purification.[18]

A similar detectability for dansyl-cysteine adducts of most common MC has been archived in HPLC system with peroxyoxalate chemiluminescence detection.[13] For this purpose dansyl-cysteine adducts of MC have to be produced off-line by nucleophilic addition of the thiol group in cysteine to the α,β-unsaturated carbonyl of the *N*-methyldehydroalanine moiety. High-performance liquid

Table 2 Limits of detection reported for determination of microcystins in HPLC systems with different detections.

Method of detection	Species detected	Limit of detection (μg/L)	Refs.
UV at 238 nm	Various	300–1000	[12]
	Various	0.02[a]	[21]

chromatography determination is carried out in the system with two additional pumps for postcolumn addition of imidazole-nitrate buffer and peroxyoxalate reagent.

The electrochemical amperometric detection can be also applied in HPLC for determination of MC, LE, YR, and RR, and also to other species containing electroactive arginine, tyrosine, or tryptophan.[15] In the system with glassy carbon working electrode polarized at +1.2 V vs. Ag/AgCl determination can be carried out using ammonium acetate/ACN mobile phase, however, determinations in natural samples require effective way of sample pretreatment to lower the amounts of impurities. In another published approach, amperometric detection has been applied for determination of MC-LR off-line derivatized with redox-active 6-ferrocenylhexanethiol (Fe-CG-SH). The detection was carried out using a glassy carbon working electrode at +0.3 V vs. Ag/AgCl, and detection limit for determination of MC-LR was only 0.36 ppm.

Data listed in Table 2 indicate that any detection method used in HPLC can be used for determination of MC in sub-ppb level without preconcentration.

CAPILLARY ELECTROPHORESIS

Owing to its outstanding high-performance separation potential also capillary electrophoresis has been employed in different modes and with different detection methods for separation and determination of MC. Both capillary zone electrophoresis (CZE) and micellar electrokinetic chromatography (MEKC), which employs a surfactant above the critical micelle concentration to separate neutral and uncharged molecules based on electromigration principle, have been employed for determination of MC.[19,29–34]

In the simplest CZE system with UV detection as background electrolyte (BGE) a Tris buffer of pH 6 was employed with detection at 200 nm,[29] or with 40 m*M* acetate buffer at pH 4.0 and with detection at 238 nm.[30] The first conditions were employed for determination of MC in fractions from preparative HPLC with detection limit reported for MC-LR as 3 ppm.[29] For the same purpose also, the second-mentioned conditions were suitable, showing impurity of [D-dsp^3]MC-LR in MC-LR samples.[30] Capillary zone electrophoresis with UV detection

can be also carried out with capillaries coated with 5% hexadimethrine bromide and 2% ethylene glycol using as BGE 1 *M* formic acid.[19] To improve detectability of CZE determination of MC, a laser-induced fluorescence (LIF) detection was employed with two-step derivatization process carried out off-line prior to the sample injection into measuring system.[33] In the first step MC were converted into cysteine conjugates, and then labeled with fluorophore fluorescein 5-isothiocyanate. Capillary zone electrophoresis separation was carried with 25 m*M* borate of pH 9.0 as BGE. The electropherograms of derivatized three MC with LIF detection are shown in Fig. 4 together with response observed for mixture of MC.

Especially outstanding separation of 10 MC variants has been reported in MEKC mode of capillary electrophoresis with UV detection.[30] This is preferable method for electrophoretic determination of MC as their separation can be impeded by adsorption of analytes onto the capillary wall, hence separation conditions in basic media with micelles should prevent such interaction. As BGE for such separation 40 m*M* β-(cyclohexylamino)-1-propanesulfonate buffer of pH 10.6, containing acetate and 15 m*M* sodium dodecyl sulfate (SDS), was used and UV detection was carried out at 238 nm. The electropherogram obtained for a mixture of MC isolated with a preparative HPLC from cyanobacterial *Anabaena* 90 strains is shown in Fig. 5.

The identification of the isolated MC was made with an off-line electrospray mass spectrometry. The reported detection limits for MC-LR were 10 ppb with MEKC mode and 1 ppm in CZE mode in both cases at 238 nm. The MEKC measurements with UV detection were also carried out with borate buffer containing SDS and satisfactory separation of MC-LR, -YR, and -RR was reported within 6 min.[32] The migration window can be enlarged about 30% in the presence of 5% ACN or 10% methanol in BGE. The limit of detection for MC-LR in optimized condition was reported as 0.12 ppb without any preconcentration step and UV detection at 230 nm. In similar MEKC system using borate buffer with SDS, a base-line separation of the same MC was reported within 13 min.[31] In the same work CE–MS hyphenated system with formic acid BGE was additionally employed for confirmatory purposes in analysis of extracts of blue-green algae after immunoaffinity chromatography (IAC) clean-up.

The separation conditions mentioned above for CZE with dynamically coated capillaries UV detection and formic acid were also compatible with the operative of electrospray ionization in CE–MS system and CE–MS–MS analyses.[19] It was shown that an essential advantage of CE–MS over LC–MS was the possibility of separation and identification of three desmethyl isomers of MC-LR differing in the Adda, Masp, and Mdha residues.

Preconcentration of MC and Clean-Up of Analyzed Samples

There are two main areas where analytical determination of MC is needed and employed. One of them is identification and quantitation for preparatory purposes in extracts from laboratory-cultivated cyanobacteria. Another one is their determination in environmental samples. Depending on concentration level of MC in analyzed samples various methods of isolation (extraction), preconcentration or

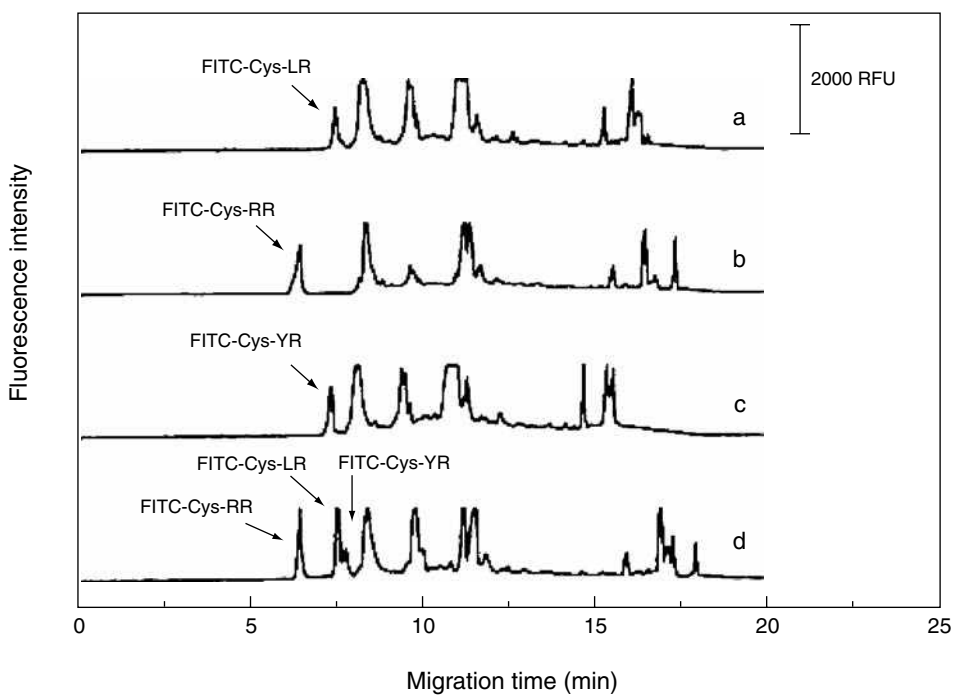

Fig. 4 Electropherograms obtained with LIF detection for MC conjugated with cysteine and derivatized with FITC.[33] Signals for derivatized MC marked in the figure. Capillary 47 cm × 75 μm, separation voltage 15 kV, BGE: 25 m*M* borate pH 9.0.

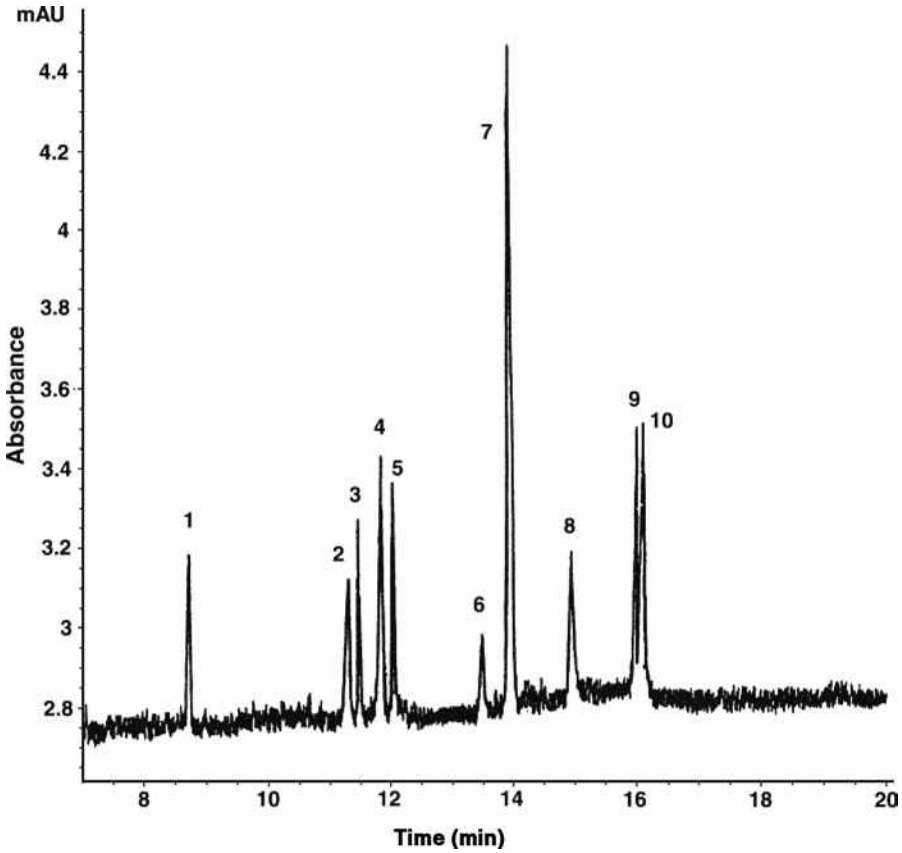

Fig. 5 Electropherogram for MC mixture obtained with MEKC mode using 40 m*M* CAPS buffer with 15 m*M* SDS at pH 10.6 as BGE[30] with UV detection at 238 nm. Peaks assignment: 1-[D-Asp^3, Dha^7]MC-LR, 2-MC-LR, 3-MC-YR, 4-[Dha^7]MC-LR, 5-MC-RR, 6-[Dha^7]MC-RR, 7-[D-Asp3, Dha^7]MC-RR, 8-[D-Asp3]MC-LR, 9-[D-Asp3]MC-RR, 10-MC-YA.

clean-up of analyzed samples can be employed and they have been already quite widely examined. Many of them have been applied in analytical procedures involving at the end the determination with HPLC or capillary electrophoresis with various detection, which were already discussed.

The most commonly used method for extraction and preconcentration of uncharged organic species is solid-phase extraction (SPE) on non-polar sorbents such as silica or polymers functionalized with octadecyl groups C18. On such sorbents MC were extracted from aqueous solutions and then eluted with methanol.[14,19,28,33] For the same purpose also a commercially available C18 disks were used with elution of extracted MC with methanol containing 0.1% TFA.[31] In some cases, a poor recovery of extracted MC from C18 sorbents has been reported, hence it was replaced by Waters Oasis HLB sorbent that can be used both for non-polar and polar analytes.[23] A more polar AccuBond cyano sorbent has been also successfully employed for extraction of MC with elution of preconcentration species with 70% ACN, which was reported to be more efficient than octadecylsilica (ODS) sorbents.[35] Ion-exchange cellulose sorbent functionalized with diethylaminoethyl groups was also applied for this purpose.[10] In a secondary clean-up process after initial clean-up with ODS cartridges, sorbents of various polarity have been reported.[36]

A solventless technique of solid-phase microextraction (SPME) has been also employed for HPLC determination of MC in a natural *Microcystins* sp. bloom in a freshwater, where three dominant MC variants MC-LR, -YR, and -RR were quantified.[37] For this purpose a measuring system with commercial SPME–HPLC interface was employed. Microcystins were sorbed from acidified solutions using SPME fibers with carbowax/templated resin and polydimethylsiloxane/divinylbenzene coating and desorbed at dynamic mode with HPLC eluent, which was used in isocratic elution mode and consisted of water and methanol with 0.05% TFA. For each toxin partition equilibrium was achieved within 60 min and example response obtained in SPME–HPLC system is shown in Fig. 6. The detection limits for all examined MC for 5 ml samples were reported at about 7 ppb.

A more selective extraction of MC from environmental samples or extracts from cyanobacteria can be achieved using IAC, with the use of solid sorbents with immobilized anti-MC antibodies. For this purpose both polyclonal anti-MC-LR antibody can be used[21,24,38,39] exhibiting cross-reactivity to other MC or also monoclonal antibodies.[17,18] Antibodies are immobilized on various supports such as activated silica gel, functionalized Sepharose, or less common ones such as Affi-Gel 10[17] or Formyl-Cellulofione.[18] Some of these immunoaffinity sorbents are also commercially available.[38,39] The preconcentration and clean-up

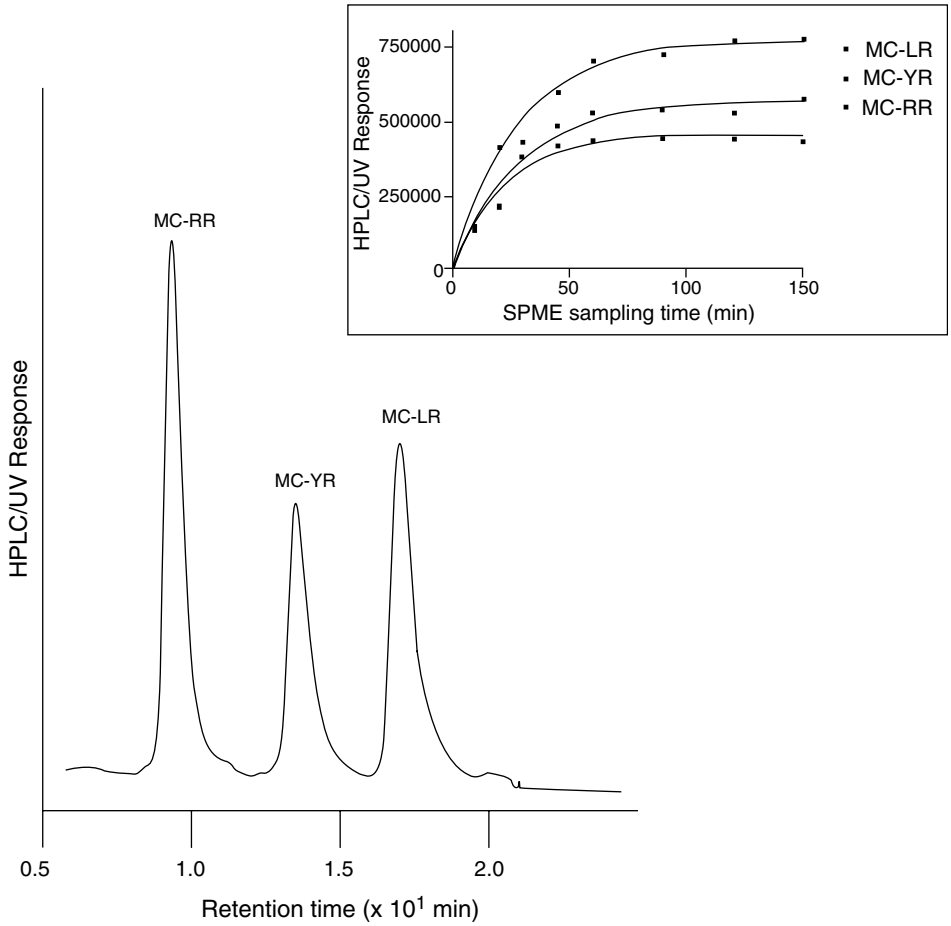

Fig. 6 Chromatogram of mixture of MC (0.6 μg each in 5 ml freshwater) obtained in HPLC system interfaced with solid-phase microextraction.[37] Absorption–time profiles of MC are shown in inset.

with IAC columns are mostly employed for determination of trace amounts of MC in natural waters, but also for extracts from cyanobacterial samples[21,24,39] and fish tissues.[21] The preconcentration is carried out from aqueous solutions, while for elution mostly methanol is used, without or with small content of water and acetic acid. For antibodies coupled to activated immunoaffinity support Formyl-Cellulfine, the elution of retained MC with 100% dimethylformamide was employed.[18] Reversability of IAC columns was reported from up to three times[18] to 43 extractions claimed for commercial silica-based ImmunoSep column.[38] The detection limits for water samples in procedures involving preconcentration and clean-up on IAP columns depend on numerous factors such as, e.g., initial sample volume or capacity of sorbent, and they were reported to be in the range from 0.002[39] to 0.05 ppb.[38]

The efficiency of sample clean-up of IAC columns in determination of MC has been compared by several authors to conventional SPE sorbents.[17,38,39] For clean-up of tap water samples, the use of C18 sorbent did not remove numerous coconcentrated impurities that make identification of MC signals more difficult.[17,39] The functioning of two different IAC columns, silica-based and Sepharose-based ones, has been compared to that of hydrophilic–lipophilic balanced Waters Oasis HPLC extraction cartridge, which contains a porous polymer sorbent consisting of a poly(divinylbenzene-co-*N*-vinylpyrrolidone) skeleton.[38] Chromatograms recorded for the same water samples using extraction with mentioned sorbents are shown in Fig. 7.

In quantitative analysis, results were similar for those of the Oasis HLB cartridge and Sepharose-based IAC. Results for silica-based IAC were lower, particularly for the less polar MC such as LA, WR, and AK. Good recovery was reported for Oasis HLB cartridge when several different sorbents for SPE have been compared.[23] Detection limits for IAC systems were about 0.5 ppb, while for system with SPE 0.1 ppb.

Determination of MC in cyanobacteria, algae, or tissues requires the optimization of additional step in analytical procedure—liquid extraction from these materials. In analysis of cyanobacterial cells, they are most often lyophilized and then extracted with 75% methanol[31,39] or with 80% ACN with addition of formic acid.[11] Double extraction with 75% methanol was also employed for homogenates of algae and fish tissue.[21] In another procedure, extraction of cells with 25% methanol[19] or 5% acetic acid[10] is assisted by sonication. The use of acetic acid instead of methanol is advantageous because of more

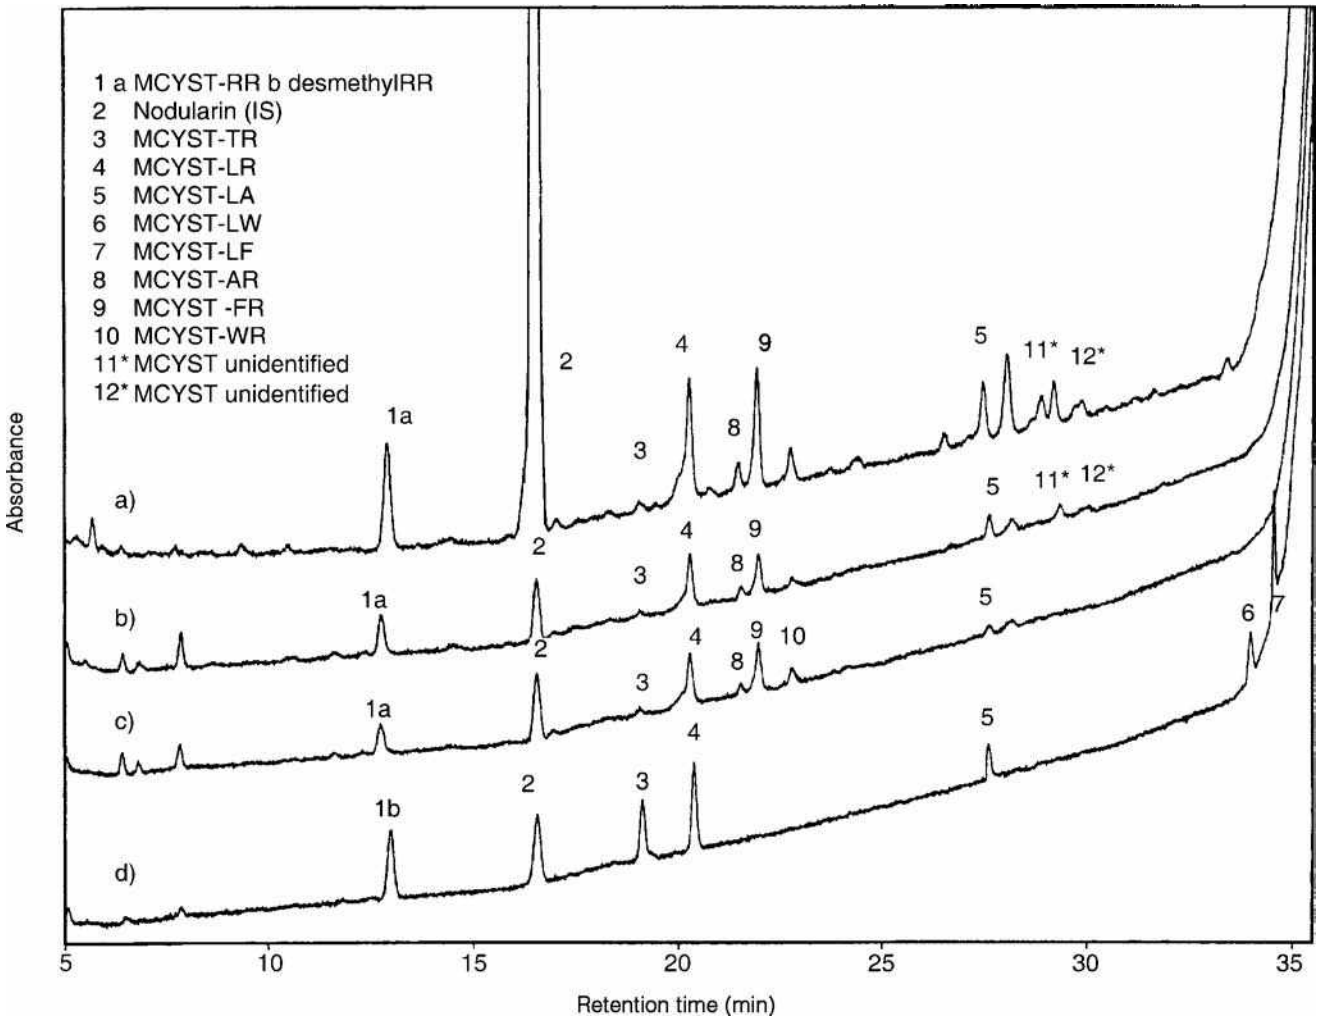

Fig. 7 Chromatograms obtained for water sample a–c) and standard mixture of MC d) in HPLC system with UV detection at 238 mm.[38] Chromatograms for water obtained using extraction with different sorbents: a) SPE with Waters Oasis HLB (50 × concentrated), b) with Sepharose-based immunoaffinity column (10 × concentrated), and c) with silica-based immunoaffinity column (10 × concentrated).

efficient elimination of proteins and possibility of direct use of extracts for preconcentration on C18 sorbents. With methanol solutions, however, a better extraction yield has been reported. In some procedures, aqueous methanol solutions were used for extraction with some content of *n*-butanol. Often methanolic extracts are preconcentrated by evaporation prior to the clean-up with SPE or IAC columns. It has been also observed that long sonication in plastic tubes gives some decrease in extraction yield, hence twice freezing at –20°C and then triple extraction with 5% acetic acid was recommended.[10]

A thorough comparison of sample pretreatment for determination of MC in cyanobacteria cells was reported recently by Rapala et al.[23]. Freezing and thawing (two or three times) and sonication in a water bath were compared for extraction of MC from cells in the water samples, and both were found ineffective. Extraction from water samples by disrupting the cells using a probe sonicator without addition of organic solvents was found to be effective for MC studied, including the hydrophobic variants. During pretreatment procedure the contact of samples with propylene should be avoided because of adsorption of MC on its surface, resulting in loss of analytes compared to the use of glass vessels.

CONCLUSIONS

Numerous HPLC and capillary electrophoresis methods for separation and determination of MC have been developed with various detection. They cannot be used, however, directly for trace determination of MC in natural waters without additional preconcentration and sample clean-up steps. The most promising in lowering the detection limits seem to be HPLC and CE methods with luminescence methods of detection, but further studies on

improvement of derivatization procedures are needed. Hyphenation of HPLC and CE instrumentation with MS or tandem MS setups are methods of choice for identification of MC variants in various samples.

The most effective method of preconcentration and clean-up of samples in determination of MC is IAP; however, sorbents with immobilized antibodies have limited repetitive use and they are expensive for routine monitoring. In some cases they can be replaced by SPE sorbents, but especially promising seems to be the use of imprinted polymers developed for selective binding of MC molecules.[40] With a comparable selectivity to antibodies they should exhibit longer life-time for repetitive use.

For high-performance separation methods suffering of insufficient detectability in determination of MC in environmental samples for routine applications the most effective is preconcentration on immunosorbents. The new advantageous competitors in this field might be enzymatic assays and biosensors based on inhibition of protein phosphatase activity by MC. Some successful attempts in this field have been reported recently as colorimetric assays or electrochemical biosensors.[41,42]

Microcystins: Isolation by Supercritical Fluid Extraction

Huwei Liu
Institute of Analytical Chemistry, Peking University, Beijing, China

INTRODUCTION

Microcystins are an increasingly important group of bioactive compounds, produced mainly by planktonic cyanobacteria. They are a family of cyclic heptapeptides that cause both acute and chronic toxicity. Purified microcystins are utilized in a range of research applications. This review summarizes the isolation of microcystins from the cyanobacteria by supercritical fluid extraction (SFE). The microcystins can be successfully extracted when a modifier is used in supercritical carbon dioxide fluid. The advantage of the method is that the sample handling steps are minimized, thus reducing possible losses of microcystin and saving extraction and purification time.

MICROCYSTINS

Microcystins are a family of more than 50 structurally similar hepatotoxins produced by species of freshwater cyanobacteria (blue-green algae), primarily *Microcystis aeruginosa*.[1] Microcystins are potent toxins that inhibit the regulatory enzymes protein phosphatase 1 and 2A (PP1 and PP2A).[2–4] It is reported that liver is the target organ that shows the greatest degree of histopathological change when animals are poisoned by these cyclic peptides. Therefore their presence in water bodies has caused the death of wild and domestic animals worldwide,[5] and, more recently, they have been implicated in human fatalities.[6,7]

Microcystins are cyclic heptapeptides that share a general structure, as shown in Fig. 1 and Table 1, containing g-linked D-glutamicacid (D-Glu), D-alanine (D-Ala), β-linked D-*erythro*-b-methylaspartic acid (D-MeAsp), *N*-methyldehydroalanine (Mdha), and a unique C20 β-amino acid, (2*S*,3*S*,8*S*,9*S*)-3-amino-9-methoxy-2,6,8-trimethyl-10-phenyldeca-4(*E*), 6(*E*)-dienoic acid (Adda). The other two L-amino acids are variable (denoted X and Z) and are found in positions 2 and 4 of the cyclic structure. The single-letter abbreviation of the variable amino acids is used to distinguish different microcystins; for example, the most commonly occurring microcystin contains leucine and arginine in these positions and is therefore called microcystin LR.[8] Variation in these two amino acids accounts for many of the microcystin variants that have been characterized; however, other minor modifications, such as demethylation, increase the number of microcystin variants to at least 60.[5] The need for extensive research into their detection, toxicology, and the investigation of water-treatment strategies requires the availability of purified microcystins. Therefore the isolation of microcystins is very important and urgent.

ISOLATION AND PURIFICATION MODES

Microcystins were first purified by Botes et al.[9] in 1982, and, since then, many different approaches[10–14] have been adopted for the isolation of microcystins from cyanobacterial cells. The most widely used procedures[13,15–17] are as follows: The lyophilized cyanobacterial cells which contain microcystins are extracted with organic solvents several times, and then the extracts are applied to multistep column chromatography and thin-layer chromatography (TLC).[15] For example, Harada et al.[13] established an effective analysis method for microcystins RR and LR. They used 5% aqueous acetic acid solution as an extracting solvent and isolated microcystins by using preparative or semipreparative liquid chromatography (LC) with octadecyl-silanized (ODS), silica gel, or gel permeation columns.

In this review, we provide an in-depth survey of a rapid method for isolation of microcystin LR from cyanobacterial

cells. The unique feature of the method is that it uses a one-step SFE and a one-step chromatography, instead of multiple extractions with organic solvents and multistep column chromatography.

PRINCIPLE AND INSTRUMENTATION FOR SFE

SFE is a well-recognized alternative to conventional solvent-based extraction techniques, which has the main advantages of being environmentally benign and available as fully automated instruments. Because SFE can minimize organic solvent consumption and increase sample throughput,[18] extraction with supercritical fluids has received wide attention in recent years.

From the chromatographic point of view, the physicochemical properties of a supercritical fluid are intermediate between those of the gases and liquids, and they are dependent upon the fluid composition, pressure, and temperature. Obviously, SFE possesses the following properties:

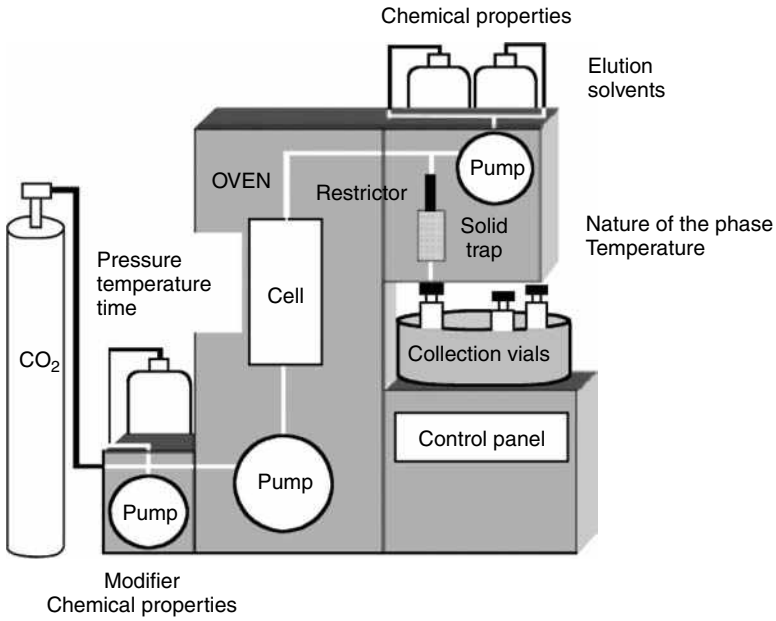

Fig. 2 Principle of an SFE system and influencing parameters.
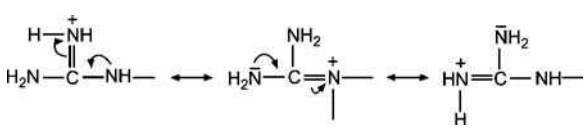
Source: From Recent extraction techniques for solid matrices—supercritical fluid extraction, pressurized fluid extraction and microwave-assisted extraction: Their potential and pitfalls, in Analyst.[24]

low viscosity of gases, higher diffusion coefficients, higher compressibility, and solubilization power of liquids. Therefore SFE possesses a number of advantages including more rapid extraction rates, more efficient extractions, higher selectivity, and easy coupling online to other analytical technologies. In particular, the solvating strength of a supercritical fluid is related to its density, which may be adjusted by varying both the pressure and the temperature.[19] Consequently, the pressure and the temperature of the supercritical fluid are the two most important parameters to be optimized for most SFE experiments.

A typical SFE system comprises three integrated parts (Fig. 2): fluid delivery system, extraction cell of the analytes from the sample matrix, and subsequent collection (trapping) of the analytes.[18,20]

MICROCYSTINS ISOLATED BY SFE

From Fig. 1, both microcystins RR and LR contain a strongly basic functional group (NHCNH–NH_2), i.e., a guanidine moiety. (Microcystin LR contains one guanidine moiety and microcystin RR contains two guanidine moieties.) These microcystins would be present mainly in the following cationic form:[20]



The poor extraction result obtained with neat CO_2 is probably caused by the fact that microcystins consist of fairly polar functional groups. The use of cosolvents can have a profound effect on increasing the solubility levels of polar solutes in supercritical fluids. In addition, water plays an important role in the SFE of microcystins. Dongjin Pyo[21] used aqueous acetic acid modified CO_2 for the extraction of microcystins from cyanobacteria. One of the difficulties with using aqueous acetic acid as a cosolvent was the high fluctuation of the pressure gauge which results from the clogging of the extraction line. Subsequently, Dongjin Pyo used aqueous methanol as a cosolvent, which could avoid the clogging and maintain the pressure of the extracting fluid fairly constant during SFE. Therefore the most suitable medium for the SFE of microcystins is a ternary mixed fluid (90% CO_2, 9.0% methanol, and 1.0% water). When 90% aqueous methanol was used as a cosolvent at 40°C and 250 atm. and the flow rate of the cosolvent and supercritical CO_2 fluid were 0.2 and 2.0 ml/min, respectively, 95% of microcystin RR and 94% of microcystin LR were extracted.[21–23]

PURIFICATION PROCEDURE FOR MICROCYSTIN BY HPLC SYSTEM

The extracts collected from SFE were treated according to the isolation procedures shown in Fig. 3.

Purification of Microcystin LR

Dongjin Pyo also reported some other procedures: The extraction by SFE was performed with a Beckman 116 pump (System Gold programmable solvent module 126), a 15 cm × 10 mm I.D. ODS column and Agilent high-performance liquid chromatography (HPLC) 1100 series diode-array detector. Methanol/0.05 *M* phosphate buffer

(52 : 48), pH 3, was used as a mobile phase at a flow rate of 2 ml/min. The analytical results obtained from real lake samples indicate the viability of the method for the determination of microcystins in real samples.[20]

CONCLUSIONS

SFE is very suitable for extracting thermolabile compounds, as it allows the possibility to perform fast extractions at moderate temperatures (around 40°C).[24] Therefore numerous applications of the technique have been reported. A large field has been covered: environmental matrices, plants, foods and fats, and polymers. As legislation will tend to restrict, or even ban, the use of many common solvents, recent extraction techniques will, in the future, undoubtedly supercede the traditional methods, as SFE considerably reduces the solvent volumes required, along with a reduction in the time devoted to the extraction step. SFE appears, undoubtedly, to be the most potentially selective extraction technique.

The isolation of microcystins by SFE is effective and successful. However, the main drawbacks of SFE are the difficulties in a tedious optimization of SFE methods, as several parameters need to be considered with this technique. In addition, because of the high investment cost of the technique, economic considerations will, in practice, also influence the choice of the extraction technique. Yet future trends will depend on the availability of commercial apparatus.

Micro-ThFFF

Josef Janca
Department of Chemistry, University of La Rochelle, La Rochelle, France

INTRODUCTION

Thermal field-flow fractionation (TFFF) is the oldest of all FFF methods.[1] It is based on the general principle invented by Giddings.[2] In this entry, miniaturization of this technique is discussed.

DISCUSSION

Thermal field-flow fractionation[1] was invented by Giddings.[2] The universal applicability of thermal FFF for the analysis of various polymers had been already demonstrated in 1979.[3] Several applications of TFFF to the analysis of polymers and colloidal particles were published (see Refs.[4,5] for a review); but the contemporary TFFF channels have practically the same dimensions (roughly $50 \times 2 \times 0.01$ cm) as those constructed at the very beginning. Giddings[6] concluded, in 1993, that the miniaturization of the FFF channels could provide only some limited advantages. The experimental study[7] dealt only with the effect of the reduced channel thickness on the performance of TFFF.

Contrary to the conclusions,[6] it has been shown[8] that the miniaturization of the TFFF channel is meaningful; it results in reduced carrier liquid and energy consumption and in an extended range of the operational conditions that can be utilized.

Theoretical and Practical Aspects of the Miniaturization of TFFF

Miniaturization of the FFF channel can be useful only if the resulting performance is higher in comparison with the conventional size FFF channel. The crucial parameter is, thus, the resolution R_s which, for TFFF, is given by:[9]

$$R_s = \left(\frac{1}{8w}\right)\sqrt{\frac{LD_T{}^3\Delta T^3}{6\langle v\rangle}}\left|\frac{1}{D_1}-\frac{1}{D_2}\right| \qquad (1)$$

where $D_{1,2}$ are the diffusion coefficients of two retained species, D_T is the thermal diffusion coefficient, $\langle v\rangle$ is the mean linear velocity of the carrier liquid inside the channel, w is the thickness of the channel, L is its length, and ΔT is the temperature drop across the channel. The mean linear velocity of the carrier liquid, $\langle v\rangle$, and the channel dimensions, L, w, are inter-related. This means that a shortening of the channel, accompanied by a corresponding decrease in $\langle v\rangle$, does not modify the resolution. Consequently, the energy flux can be reduced, proportionally to the shortening of the channel length.[8,9] The other gain can be achieved by the reduction of the thickness w of the channel and its breadth b (the aspect ratio w/b does not change). Such modification leads to an increase in resolution and maintains the same total heat flow across the channel. Reduced w, however, results in a proportional increase in the heat flow across the channel because the temperature drop has to be maintained to obtain the same retentions. A more elegant way is to increase the temperature drop without changing the thickness of the channel, because an increase in ΔT has a more pronounced effect on the resolution in comparison with a reduction of w for the same heat flow increase (see Eq. 1).[8] From a practical point of view, shortening of the channel length L, accompanied by an appropriate decrease in $\langle v\rangle$, maintains the resolution but the total heat flow across the channel is reduced for a given temperature drop ΔT due to the reduced surface area of the main channel walls. Thus, Eq. 1 simplifies to:

$$R_s = \text{const}\sqrt{\frac{\Delta T^3}{\langle v\rangle}} \qquad (2)$$

The validity of Eq. 2 was proven experimentally[9] and the result is shown in Fig. 1.

Limits of Miniaturization

The size ratio of the fractionated macromolecules or particles to the channel thickness must be taken into account. A decrease in channel thickness can lead to an important contribution of steric-exclusion to the mechanism of separation whenever the distance of the center of gravity of the concentration distribution of the retained species from the accumulation wall, l, becomes commensurable with the size of the retained species.[4,5] Whereas the elution order in normal (polarization mode) TFFF is from the small to the large species, it is inverted in purely steric-exclusion mode. Consequently, the fractionation deteriorates in the vicinity of the inversion point. The dependence of the retention ratio R on the particle radius r can be

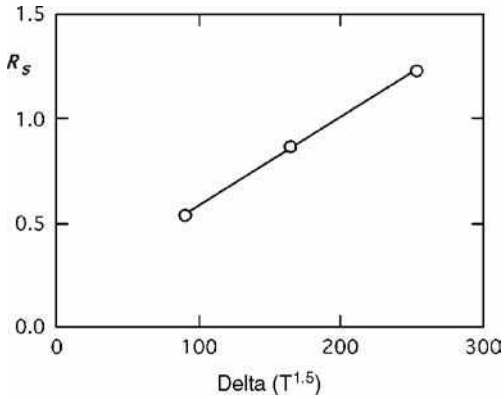

Fig. 1 Dependence of the resolution R_s on the $\Delta T^{1.5}$ in micro-TFFF.
Source: From Micro-thermal field-flow fractionation: new challenge in experimental studies of thermal diffusion of polymers and colloidal particles, in Phil. Mag.[9]

calculated from the theory of FFF for the case when only the polarization mechanism is effective and for the cases when both polarization and steric modes participate in the separation mechanism.[10] The theoretical calculations were compared with the experimental results obtained for a series of polystyrene (PS) standard latex samples.[10,11] The theoretically calculated curves and the experimental data, demonstrated in Fig. 2 and obtained for three temperature drops $\Delta T = 5$ K, $\Delta T = 10$ K, and $\Delta T = 20$ K, agree quite well. Obviously, the resolution is low in the vicinity of the inversion point and passes through zero at this point. Consequently, the optimal w must be carefully chosen in order to avoid undesirable simultaneous action of polarization and steric-exclusion mechanisms within the required size range of the fractionated species.

Extension of Micro-TFFF to Focusing Mode

When increasing the linear velocity of the carrier liquid, lift forces can appear that contribute actively to the

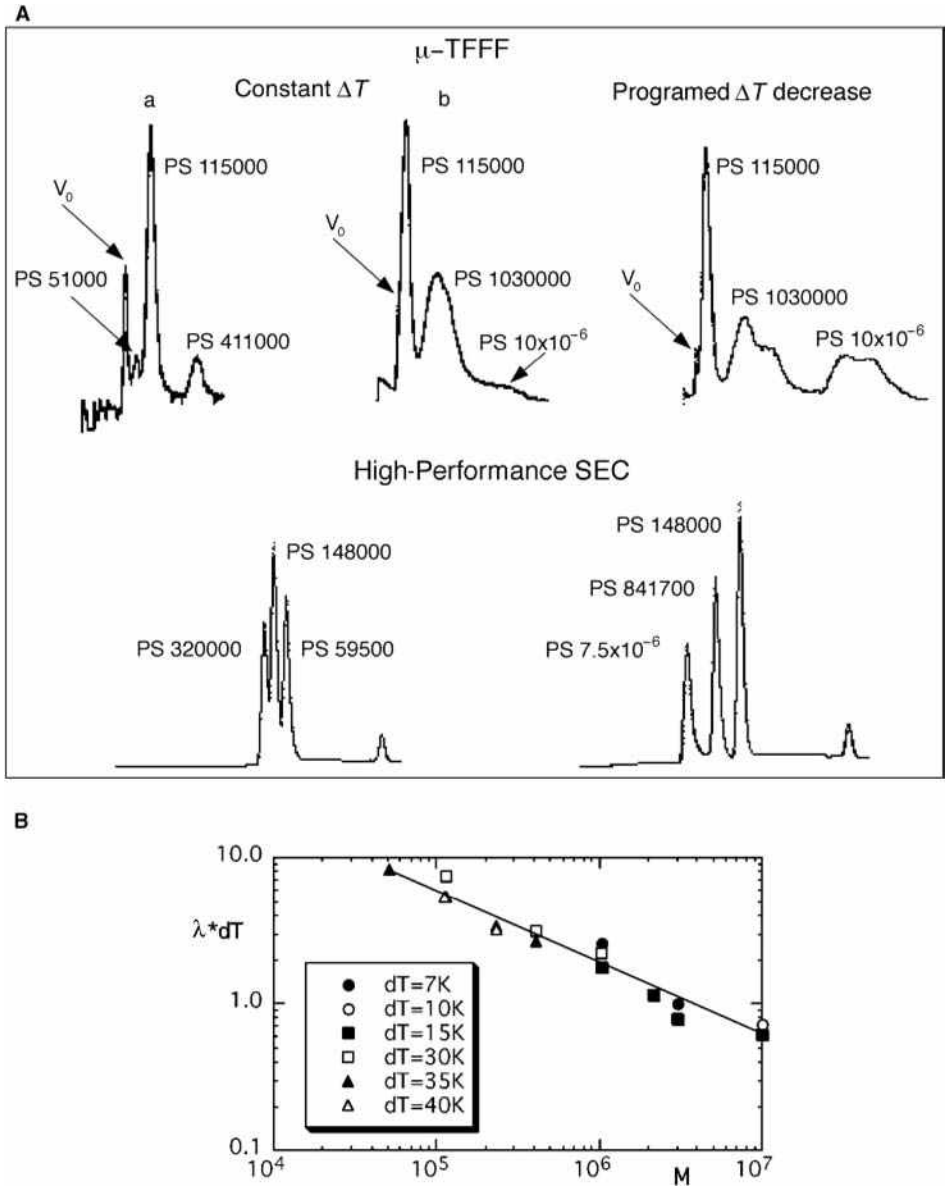

Fig. 4 A, Comparison of the separations of polystyrene standards carried out by micro-TFFF at constant temperature drop ΔT and programed decrease in ΔT with the chromatograms from high-performance size-exclusion chromatography. B, Dependence of the product of retention parameter λ and of the temperature drop ΔT on the molar mass M of polystyrene standards.
Adapted from Janča.[9,13]

separation. Such a transition from steric to focusing mechanism of separation can be seen in Fig. 3,[12] which shows progressive deviation of the experimental dependence of the retention ratio R on the particle size from the theoretical one, calculated for a dominating steric-exclusion mechanism. This deviation increases with increasing flow rate, due to the lift forces. It can be seen from Fig. 3 that "steric" FFF represents rather an exceptional case of the separation. In other words, whenever lift forces participate in FFF processes, it is a focusing mechanism and not a steric-exclusion mechanism that governs the retention in FFF.

The focusing mechanism was actively used in microthermal focusing FFF. The result of high-speed separation of micron-sized PS latex particles is an example of such an application.[11,12] Fig. 3 demonstrates that a substantial increase in the flow rate resulted in high-speed microthermal focusing FFF separation without an important loss of the resolution.

APPLICATIONS

Polystyrene standards were used as model samples to check the performance of micro-TFFF,[8] to compare the results with those obtained previously with the use of a standard size TFFF channel,[13] and to confirm that the ultrahigh molar mass (UHMM) PSs do not undergo shear degradation, observed frequently when separated by SEC.[14,15] The fractogram of three PSs of different molar

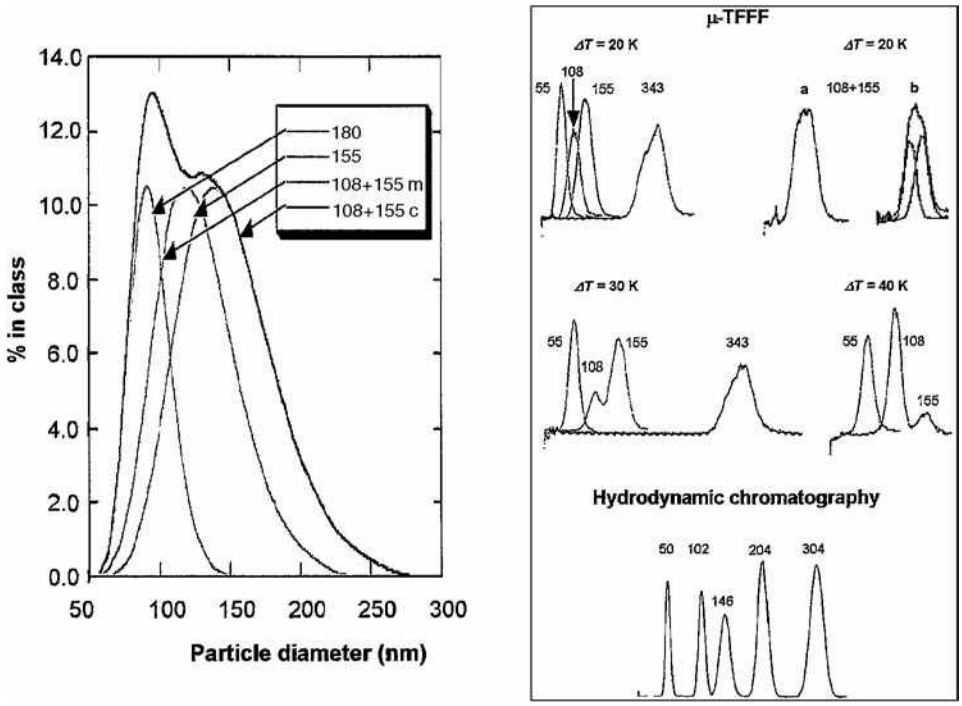

Fig. 5 Comparison of various methods of particle size analysis: Quasielastic light scattering, micro-TFFF, and hydrodynamic chromatography.

masses in Fig. 4 shows good resolution achieved by micro-TFFF, which is comparable with that obtained on a standard size TFFF channel.[13] Higher resolution, in comparison with SEC, was achieved by applying programed decrease in ΔT for a separation of ultrahigh molar mass PS in micro-TFFF.[13] The plot of $\lambda\Delta T$ vs. M, shown in Fig. 4, confirms the linearity of this dependence in log–log scale, found already by Gao et al.,[16] within an extended range of molar masses. A decrease in retention with increased cold wall temperature was found for dissolved polymers[13] as well as for suspended colloidal particles,[17] but higher cold wall temperature should be preferred due to the accelerated transport and relaxation processes.

Micro-TFFF was also applied to separate colloidal particles.[14] The experimental conditions were optimized with respect to the relaxation phenomena and related stop-flow procedure, and to the accumulation wall temperature.[17] An original method was proposed for the determination of the sign of the Soret coefficient,[17] based on the comparison of the retentions of the studied species in horizontally and vertically positioned micro-TFFF channels. The change of the retention in these two positions of the channel is due to the appearance of a convective flow, superposed to the forced flow of the carrier liquid, in the vertical channel.

Comparison of transmission electron microscopy, quasielastic light scattering, hydrodynamic chromatography, and micro-TFFF, applied to the determination of the particle size distribution, demonstrated specific performances of these methods.[18] Some of the results are shown in Fig. 5. The optimization of the operational variables resulted in high-speed micro-TFFF of colloidal particles.[19]

Micro-TFFF was used to characterize micrometer-sized (3–10 μm) silica chromatographic beads. In comparison with the retentions observed when only gravity was acting as the effective field ($\Delta T = 0$ K), the retentions of all studied particles substantially increased when a temperature drop was applied. As a result, micro-TFFF was found to be a rapid and easily applicable method for the characterization of the mean particle size and particle size distribution of the chromatographic beads.[20] Fig. 5 shows one result of this study.

CONCLUSIONS

Miniaturization of the FFF channel can be useful. The size ratio of the fractionated macromolecules or particles to the channel thickness must be taken into account. When increasing the linear velocity of the carrier liquid, lift forces can appear that contribute actively to the separation. Several useful applications of micro-TFFF have been described here.

Migration Behavior: Reproducibility in CE

Jetse C. Reijenga
Department of Chemical Engineering and Chemistry, Eindhoven University of Technology, Eindhoven, The Netherlands

INTRODUCTION

Identification of sample components based solely on migration time in capillary electrophoresis (CE) requires reproducibilities not normally obtained. These are caused, mainly, by two effects: temperature effects and electro-osmotic affects. Migration times in CE are determined by the electro-osmotic velocity υ_{EOF} and effective electrophoretic migration velocity υ_{EFF}; the net migration velocity υ_i is the vector sum of both velocities:

$$\upsilon_i = \upsilon_{EFF} + \upsilon_{EOF}$$

In terms of mobilities, this relationship becomes

$$\upsilon_i = \left(-\frac{\zeta\varepsilon}{\eta} + \mu_i \right) \cdot E$$

in which ζ is the zeta-potential of the capillary, ε is the dielectric constant of the liquid, η is the viscosity of the liquid, μ_{eff} is the effective mobility of the sample component, and E is the electric field strength. From this relationship, it is obvious that migration time reproducibility depends on the reproducibility of a number of parameters. In addition to the ones mentioned, sample matrix effects can also play a significant role.

ELECTROPHORETIC EFFECTS

The reproducibility of the effective mobility is governed by temperature and pH effects. An acceptable run-to-run pH reproducibility can usually be assured, at least in equipment where the effects of possible electrode reactions can be avoided. Again, temperature plays a leading role: The effective mobility has a temperature coefficient of 2–3% per degree. Most buffer solutions, incidentally, have a temperature-dependent pH value, so that changing the temperature in the capillary will, for weak ions, even lead to changing degrees of dissociation and, hence, effective mobility. These effects are, by definition, different for different buffers and different sample components.

SAMPLE MATRIX AND INJECTION EFFECTS

When injecting very dilute sample solutions, a relatively large proportion of the total voltage drop across the capillary will take place over this sample plug, resulting in a proportionally lower field strength in the remainder of the separation capillary. This will lead to systematically longer migration times. In this case, also, identification on the basis of effective mobilities is better than on migration times alone.

Another effect takes place when injecting different sample volumes in the capillary: This may systematically change the migration length and, thus, migration times. A constant injection volume is, therefore, advised in cases of required high migration time reproducibility.

ELECTRO-OSMOTIC EFFECTS

In coated capillaries, the $\zeta\varepsilon E/\eta$ term is small, possibly close to zero, compared to the $\mu_{EFF} \cdot E$ term. If, however, one works with unsuppressed electro-osmosis, the reproducibility of the $\zeta\varepsilon E/\eta$ term plays an important role. Both ζ and η depend on temperature, and in some equipment, thermostating is not perfect, at least not in all parts of the capillary. The viscosity alone accounts for an $\sim$2% per degree dependence. Another effect that might take place is the gradual change in ζ-potential due to adsorption of sample matrix components on the inner capillary surface. The good news is that run-to-run change in electro-osmotic velocity is directly obvious from the electro-osmotic flow (EOF) marker peak in the detection signal, so that changes in EOF can be accounted for in cases where they cannot be avoided. However, this also means that measures have to be taken to assure a clear EOF marker peak [e.g., by addition to the sample of a neutral ultraviolet (UV)-absorbing component, such as mesityloxide]. In complicated samples, such an EOF marker peak may not be possible. For reasons of EOF reproducibility, identification is preferentially based not on migration time but on effective mobility calculation by means of

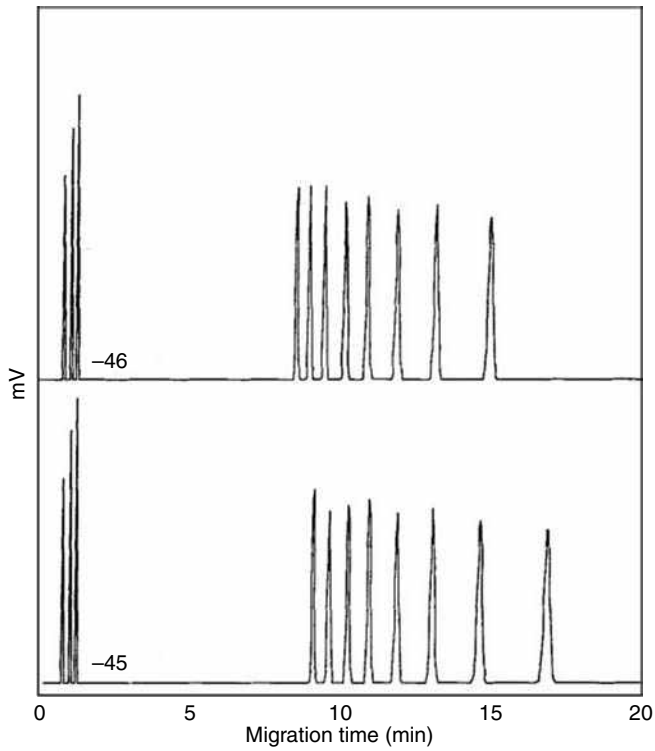

Fig. 1 Effect of capillary ζ-potential on the analysis of a mixture of anions in an uncoated fused-silica capillary in a 10 m*M* Tris/acetate buffer of pH 8. Normal ζ-potentials are around 50 mV at this pH.

$$\mu_{EFF} = \frac{L_d}{t_i E} - \mu_{EOF}$$

in which L_d is the capillary length to the detector and t_i is the migration time of the component i.

For quantitation under conditions of changing migration velocity, peak areas are usually divided by corresponding migration times to make them more independent of run-to-run differences in EOF. Migration times are especially susceptible to small EOF variations in the case of opposite signs for EOF and sample mobility (i.e., usually for anions). This is illustrated in Fig. 1, a separation of three cations before and eight anions after the EOF marker (not indicated in the figure). The traces given are for a ζ-potential of –46 and –45 mV, respectively. This 2% EOF change corresponds to the equivalent of only 1 degree temperature effect.

Milk Proteins: RP/HPLC Separation

I.M.P.L.V.O. Ferreira
Service of Bromatologia, Pharmacy College, University of Porto, Porto, Portugal

Abstract
Milk proteins in soluble and dispersed form are widely valued owing to their nutritional and technological value. Caseins represent about 80–85% of milk proteins, and they play a key role in human nutrition, in dairy industry, and as additives in food, paints, and glues because of their emulsifying properties. The remaining milk protein fraction is composed of the whey proteins, of which β-lactoglobulin and α-lactoalbumin are the main components. Analysis of milk proteins can be used to detect and quantify milk adulterations. Additionally, many bioactive peptides derived from milk proteins, latent in the primary sequences of proteins, and released during proteolysis have been identified. Reverse-phase (RP) high-performance liquid chromatographic (HPLC) methods for application on quality control and detection of species adulteration in dairy products are summarized.

INTRODUCTION

Controlling the quality of milk and its derivatives is a very demanding field with a great need for development of more economical, time-saving, and accurate methods of ensuring product quality. This entry presents various reversed-phase (RP) high-performance liquid chromatography, HPLC/UV methods for analysis of milk proteins, and describes how these techniques are used in the study of bovine, ovine, and human native milk proteins, casein fractions, cheese proteolysis evaluation, detection of product adulteration, enzyme hydrolysis of whey proteins, and peptide separation.

MILK PROTEINS

Proteins are important components in food, for both their nutritional and functional values. Dietary proteins provide amino acids and nitrogen needed by many organisms. In addition, they are believed to have other specific functions, owing to the presence of bioactive peptides in their primary sequences, making them potential health-promoting ingredients. Besides having this biological function, protein components play a major role in species identification and in determining the textural characteristics of food products. A certain number of food proteins, such as milk proteins, are characterized by great heterogeneity with the presence of several molecular forms, more or less phosphorylated or glycosylated, combined with a high degree of polymorphism.

Bovine milk proteins (3.2%) can be divided, according to their solubility at pH 4.6 and 20°C, into two major groups: about 79.5% of caseins that are insoluble at this pH and about 19.3% of whey proteins that are soluble. Another group exists as a minor fraction (about 1.2%), which includes proteins associated with the membrane of fat globules, enzymes, and proteins arising from blood and a polypeptide fraction (named proteose–peptone). The molecular weights of the individual milk protein monomers range from 15,500 to 67,000 Da.[1]

Caseins are quantitatively the most important protein components in bovine milk. This protein complex, known as a micelle, comprises four different caseins (α_{s1}-, α_{s2}-, β-, and κ-caseins), which are held together by non-covalent interactions and appear as a highly stabilized dispersion in milk.[1] During the classical cheese making process, it is the casein fraction that constitutes the cheese curd after the enzyme-triggered milk coagulation step.

The determination of individual proteins, and their degradation products in milk, cheese and other dairy products has been a major task for several years, since it can provide valuable information. Analysis of milk protein has been carried out using 1) classical gel electrophoretic methods, such as polyacrylamide gels with urea (urea–PAGE)[2–8] or sodium dodecyl sulfate (SDS) (SDS–PAGE)[9,10] and isoelectric focusing (IEF);[11] 2) HPLC by ion-exchange,[12,13] hydrophobic interactions,[14,15] gel filtration,[12,16] and reversed-phase[5,17–22] modes; 3) immunological methods;[23] and, more recently, 4) capillary electrophoresis.[24–27] Each method has its own merits, but the use of HPLC has resulted in the development of rapid and automated analyses with good separations and very high resolution, which gave accurate and reproducible results.

This entry describes RP-HPLC/UV methods for analysis of milk proteins that were developed with different

purposes, namely, to study the protein fraction of bovine, ovine, and human milk, characterize genetic polymorphisms, follow the extension of whey protein denaturation by heating, study the evolution of cheese proteolysis, detect milk and cheese adulterations, follow the enzymatic hydrolysis of whey proteins with different enzymes separated, and quantify bioactive peptides. The column was a reversed-phase column, Chrompack P 300 RP, which contains a polystyrene–divinylbenzene copolymer based packing material. In this type of column, separation is based on differences in surface hydrophobicity between the protein molecules and the stationary phase. Hydrophobic amino acid residues of proteins are bonded through hydrophobic interactions to a stationary matrix composed of a non-polar surface. Protein retention is controlled by increasing the concentration of organic solvents such as acetonitrile, thereby altering the polarity of the aqueous mobile phase.

RP-HPLC SEPARATION AND QUANTIFICATION OF BOVINE, OVINE, AND HUMAN NATIVE MILK PROTEINS

RP-HPLC simultaneous separation of the casein fraction and whey proteins, β-lactoglobulin and α-lactalbumin in bovine, ovine, and human raw milk was performed using gradient elution with a mixture of two solvents:[15,20,21] solvent A consisted of 0.1% trifluoroacetic acid (TFA) in water and solvent B consisted of 0.1% TFA in 95% (v/v) aqueous acetonitrile. Proteins were eluted as follows: 0–5 min, 36–47% B; maintaining 47% B for 2 min; 7–12 min, 47–52% B; 12–14 min, returning to initial conditions 52–36% B. The flow rate was 1.0 ml/min. The column was used at ambient temperature, and detection was at 280 nm. The total run time was 14 min.

Milk samples were skimmed by centrifugation for 5 min, filtered, and diluted with deionized water prior to injection. Different chromatographic patterns were obtained, as shown in Fig. 1. Peak identification was performed by comparison of retention times with those of standards from bovine, ovine, and human milk proteins.

Validation of the HPLC method was performed. The external standard method was used to calibrate the chromatographic system for protein quantification. Linearity between the concentration of casein fraction, β-lactoglobulin, and α-lactalbumin in bovine and the UV absorbance at 280 nm was maintained over the concentration ranges of 0.001–0.2, 0.004–0.6, and 0.002–0.2 g/100 ml, respectively. Repeatability of the injection was performed by 10 consecutive injections of bovine, ovine, and human milks. The relative standard deviation (RSD) values for peak areas were all below 2.3%. Recovery studies were carried

Table 1 Casein, β-lactoglobulin, and α-lactalbumin contents of bovine, ovine, and human mature milks (10 samples of each, with 90 ± 10 days of lactation).

Milk type	α-Lactalbumin (mg/ml)	β-Lactoglobulin (mg/ml)	Casein content (mg/ml)
Bovine	2.3 ± 0.10	4.7 ± 0.2	29.3 ± 0.60
Ovine	3.8 ± 0.20	5.9 ± 0.3	35.5 ± 0.50
Human	3.54 ± 0.03	n.d.	3.02 ± 0.01

Results are presented as mean ± standard deviation values; n.d., not detected.
Adapted from Ferriera, Mendes, & Ferriera,[15] Ferriera,[20] and Santos & Ferriera.[21]

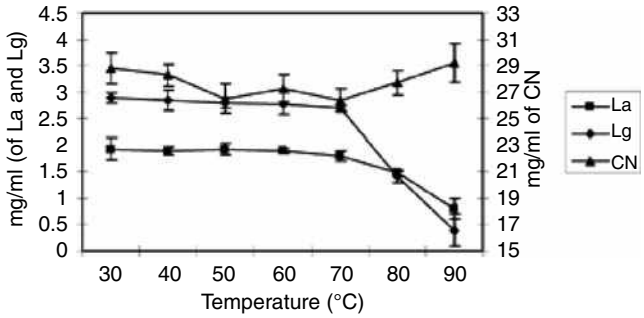

Fig. 2 Evolution of casein (CN), α-lactalbumin (α-La), and β-lactoglobulin (β-Lg) contents in raw milk heated for 5 min at defined temperatures ($n = 5$).

out to determine the accuracy of the method. Recoveries ranged between 96.3 and 99.8%.

Table 1 presents the mean contents of major proteins in bovine, ovine, and human mature milks.

Analysis of protein content in a variety of commercially processed milk and in raw milk samples showed that the Chrompack P 300 RP column enabled quantification of only "native" proteins;[15] thus, it can be used for the evaluation of the degree of heat-induced denaturation of milk proteins during processing by monitoring the remaining native milk proteins (Fig. 2). α-Lactalbumin and β-lactoglobulin were significantly affected by heat denaturation at 80°C ($p < 0.05$), whereas casein content did not present significant differences ($p > 0.05$).

RP-HPLC on polystyrene–divinylbenzene column was used for simultaneous separation and quantification of the major bovine whey proteins including proteose–peptone and caseinomacropeptide (CMP).[28] The optimized method allowed separation of proteins in 30 min and could be applied to the analysis of soluble proteins in a variety of commercial and laboratory whey products. Additionally, some information on protein heterogeneity and quality could be derived from the RP-HPLC analyses, with additional data available from on-line electrospray mass spectrometry. Within- and between-day repeatability over a wide range of concentrations was excellent (RSD < 5%) for all proteins except immunoglobulin G and bovine serum albumin where the RSD value was 7–10%. Analysis of grouped data from whey protein concentrate and whey protein isolate samples gave a detection limit of <0.3% powder mass and a quantitation limit of <1.0% powder mass for all proteins except immunoglobulin G. The detection and quantitation limits were 0.6 and 2.0%, respectively, for immunoglobulin G. Quantitative data obtained by the RP-HPLC method compared very favorably with data obtained by alternative methods of whey protein analysis.[28]

The protein composition of human milk is different from that of bovine milk.[29,30] One major difference is the level of protein, with mature milk containing less than 9 g/L in contrast to bovine milk which contains around more than 33 g/L. Although some of the protein components of human and bovine milk are similar, sequence homology and concentrations are often different.

α-Lactalbumin is the protein in highest concentration in human milk.[31] Human milk α-lactalbumin is not identical to bovine milk α-lactalbumin, although there is a 72% sequence homology[32] (Fig. 1). Concentration of this protein changes during lactation. Published values for the concentration of α-lactalbumin are highly variable, not only because of genetic, environmental, and dietary factors, but also because of the use of analytical methods with different reliability.[20,21,32,33]

RP-HPLC was applied to separate and characterize β-casein and α-lactalbumin fractions of human milk and to quantify milk protein contents.[20] The determinations were performed in the linear range of 0.09–1.5 and 0.45–3.6 g/L for β-casein and α-lactalbumin, respectively. Analysis of variance (ANOVA) showed significant differences ($p < 0.05$) between protein content in milk from different mothers at the same lactation time (1½ months). A significant decrease ($p < 0.05$) was observed for the casein and α-lactalbumin concentrations during the first 6 months of lactation.[20]

RP-HPLC SEPARATION OF CASEIN FRACTIONS: EVALUATION OF CHEESE PROTEOLYSIS

Caseins from milk and cheese samples were extracted prior to injection into an RP-HPLC column.[5] The samples were homogenized in a mortar and 1 *M* HCl was added until pH 4.3 was achieved. The resulting suspension was centrifuged at 4°C for 15 min at 3000 × *g* to recover the precipitated caseins. In order to remove the remaining fat, the sample was washed with acetone and left to dry in a fume hood at room temperature. Finally, the dried powdered casein was stored in a desiccator at 8°C until analysis was performed.

The casein powder was dissolved in a mixture of water and acetonitrile (70:30 v/v) for HPLC analyses. The solution was filtered through a 0.45 μm TR-200104 filter, composed of a mixture of cellulose esters (Teknokroma), and then was stored at –20°C until use.

Gradient elution was carried out with a mixture of two solvents: solvent A consisted of 0.1% TFA in water and solvent B was acetonitrile–water–TFA (95:5:0.1 v/v). Proteins were eluted with a series of linear gradients by increasing the proportion of solvent B from 29% to 100% over 35 min: 1–5 min, 29% B; 5–10 min, 29–37% B; 10–12 min, 37–41% B; 12–14 min, 41–42.5% B; 14–16 min, 42.5% B; 16–17 min, 42.5–43% B; 17–19 min, 43% B; 19–21 min, 43–47% B; 21–23 min, 47% B; 23–25 min, 47–54% B; 25–27 min, 54% B; 27–28 min, 54–100% B; 28–30 min, 100–29% B; 30–35 min, 29% B. The flow rate was 1 ml/min, the column temperature was 46 ± 0.1°C,

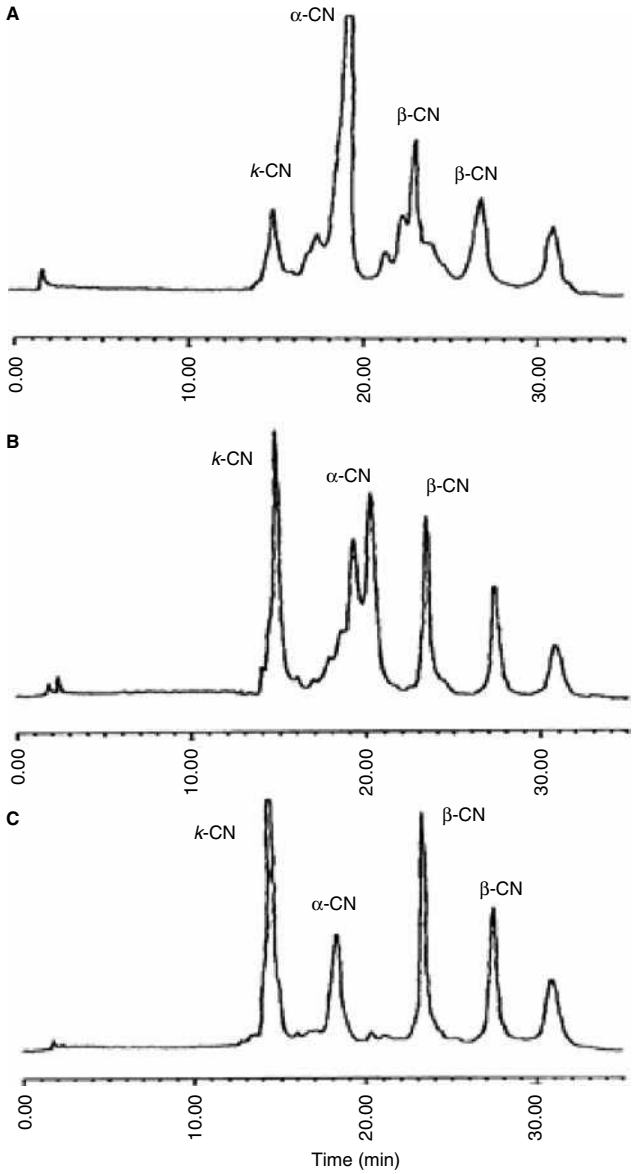

Fig. 3 Typical chromatographic profiles obtained for casein fraction from milk samples: (A) bovine, (B) ovine, and (C) caprine caseins, obtained by RP-HPLC. Detection at 280 nm.

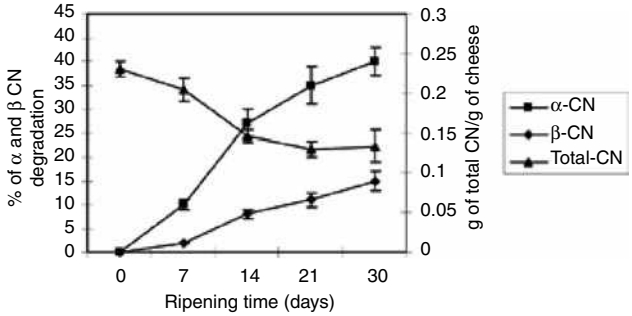

Fig. 4 Evolution of total casein content together with α- and β-casein degradation for 30 days of ripening of ewe cheese.

and the eluate was monitored at 280 nm.[5] This procedure is suitable for separation and quantification of κ-, α-, and β-caseins in raw and processed milks and cheeses because separation of the casein fraction in the three types of milk yielded good chromatographic separations (Fig. 3). Appropriate accuracy, precision, and rapidity are characteristics of the method; thus, it can be used to follow the evolution of casein content during cheese ripening and evaluate the degradation of casein fractions due to proteolysis (Fig. 4).

RP-HPLC separation can be used to evaluate the complexity and specificity of proteolytic development during cheese ripening, namely, the evolution of the four major caseins α_{s1}-, α_{s2}-, β-, and *para*-κ-caseins and its proteolytic products. RP-HPLC resolved not only proteins but also peptides, and provided proteolytic profiles that gave useful information about proteolysis extension and ripening time.[5,7,22,34,35]

The proteolytic process during 30 days of ripening of Terrincho ovine cheese based on the protein patterns obtained by HPLC from the insoluble fractions (at pH 4.3) was evaluated.[8] For that purpose gradient elution was carried out with a mixture of two solvents: solvent A consisted of 0.1% TFA in water and solvent B consisted of 0.1% TFA in 80% (v/v) aqueous acetonitrile. Proteins were eluted with a series of linear gradients: 29% of solvent B during 5 min, from 29% to 37% of B over 5 min, and from 37% to 54% of B over 15 min, keeping these conditions during

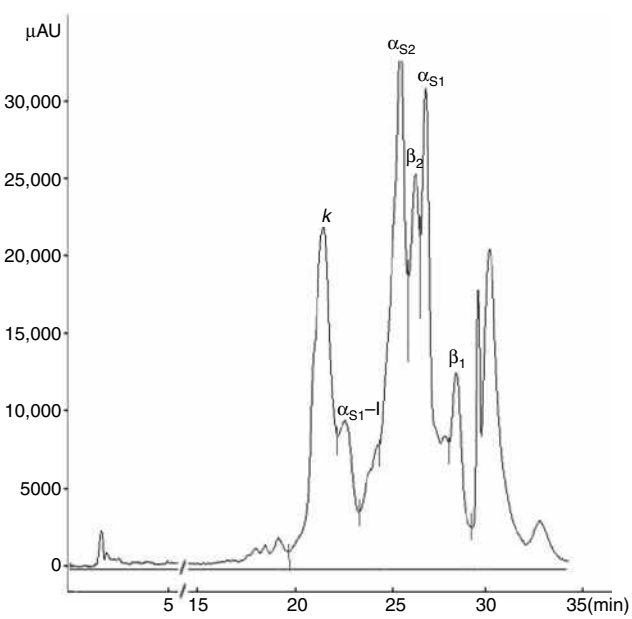

Fig. 5 Chromatographic patterns of Terrincho cheese from the pH 4.3 insoluble fractions at 1 day of ripening. κ, *para*-κ-casein; α_{s2}, α_{s2}-casein; α_{s1} α_{s1}-casein; α_{s1}-I, α_{s1}-I peptide; β_2, β_2-casein; β_1, β_1-casein.

2 min, finishing with 54–100% of B in 3 and 5 min for column re-equilibration. The flow rate was 1.0 ml/min, the column temperature was 46 ± 0.1°C, and the detection was made at a wavelength of 280 nm. Peaks were characterized using caseins from bovine and ovine milks identified according to Visser et al.[36] The areas under the five most representative peaks on the chromatogram, designated *k*-CN (*para-k*-casein), α_{s1}-I (α_{s1}-I peptide), α_{s2}-CN (α_{s2}-casein), β_2-CN (β_2-casein), α_{s1}-CN (α_{s1}-casein), and β_1-CN (β_1-casein) in order of elution (Fig. 5), were used to study the evolution of proteolytic process. It was concluded, with 95% confidence, that there were significant differences in the effect of ripening time of all quantified fractions (κ-CN, α_{s1}-I, α_{s2}-CN; α_{s1}-CN, β_1-CN, and β_2-CN). A significant reduction in the κ-CN, α_{s1}-CN, and α_{s2}-CN contents depending on the ripening time was observed, together with an increase of α_{s1}-I peptide.

Chemometric analysis of the HPLC data was also used to predict cheese ripening time[8] by multiple linear regression analysis with stepwise variable selection; two variables, α_{s1}-casein and α_{s1}-I peptide, and a constant were used. The estimation error was 2.5 days.

RP-HPLC DETECTION OF DAIRY PRODUCTS ADULTERATION

RP-HPLC of milk proteins can also be a useful tool to detect and quantify milk and cheese adulterations. For example, the substitution of bovine milk for caprine milk is a fraudulent practice; RP-HPLC analyses of the casein fraction can be used to detect bovine milk in caprine milk, with a detection limit of 5%.[5]

Adulteration of traditional ovine cheeses with bovine milk presents a problem for food monitoring, and the analysis of milk proteins is a solution for this problem.[35] However, the proteolysis that occurs during cheese ripening incurs a risk of complex formation, i.e., the formation of insoluble new compounds and smaller peptides that can interfere. Examples of these compounds are γ-casein, proteose–peptone fragments of β-casein originating from the action of plasmin, λ-caseins, presumably fragments of α_{s1}-caseins, glycomacropeptides, and *para*-κ-caseins as a result of chymosin action.[35] Discriminant analysis was applied to data from Terrincho, mixture, and bovine cheeses with 30 days of ripening obtained by RP-HPLC.[8] Peaks corresponding only to κ-CN, α_{s1}-I, α_{s2}-CN, and β_1-CN were selected; the peaks that were overlapped in mixture cheeses were excluded. The discriminant analysis indicated that three variables contributed significantly to explaining the variability among the different types of cheeses: κ-CN, α_{s1}-I, and β_1-CN. Differences between Terrincho and mixture cheeses result from higher β_1-CN content in mixture cheeses because this fraction is higher in bovine milk and more resistant to enzyme hydrolysis until 30 days of ripening.

Actually, some types of cheeses, especially protected denomination of origin cheeses, are manufactured from defined amounts of ovine, caprine, and bovine milks; thus, quantitative determination of each type of milk in mixed cheeses is an important issue. RP-HPLC separation of β-lactoglobulin can be used for detecting and quantifying bovine, ovine, and caprine milk mixtures in raw milk and cheeses.[37]

Binary mixtures of bovine and ovine or bovine and caprine raw milks containing 5, 10, 20, 30, 50, 75, and 95% (v/v) of bovine milk as well as ovine and caprine milk mixtures containing 5, 10, 20, 30, 50, 75, and 95% (v/v) of ovine milk were used for cheesemaking.[37] Cheeses were prepared with rennet whey and ripened for 4 weeks. Milk mixtures and fresh and ripened cheeses were analyzed. The whey protein fractions were obtained from the cheese samples (5 g) by extraction with water (15 ml), in a sonicator prior to centrifugation (4000 rpm, 10 min), or from 15 ml of skimmed milk. The supernatant was precipitated by addition of 1 *M* HCl until pH 4.6. After centrifugation (4000 rpm, 10 min), the resultant supernatant was filtered prior to HPLC analysis. All the samples were stored at 4°C.

Gradient elution was carried out with a mixture of two solvents:[37] solvent A consisted of 0.1% TFA in water and solvent B consisted of 0.1% TFA in 80% (v/v) aqueous acetonitrile. Proteins were eluted with a series of linear gradients, increasing the proportion of solvent B from 36% to 56% over 20 min, from 56% to 60% of B over 10 min, finishing with 60–36% of B in 5 min. The flow rate was 0.5 ml/min, the column temperature was 45 ± 0.1°C, and the detection was performed at a wavelength of 215 nm. Different chromatographic profiles were obtained for each type of milk in binary mixtures, as shown in Fig. 6.

A linear relationship was established between the $\log_{10}$ of β-lactoglobulin peak ratio (calculated as peak area ratio) and the $\log_{10}$ of the relative percentage of bovine or ovine milk (Figs. 7–9). The ratio between β-lactoglobulin peaks was not affected by the degree of ripening ($p < 0.05$), thus enabling the quantification of milk type percentage. The detection limit was 2%. This technique allowed quantification of milk species within the concentration range of 5–95%.

Dairy products, such as milk powder, should be prepared exclusively from milk and should not contain solids from whey. The absence of rennet whey solids from milk powder is required according to legislation. Considering the lower price of rennet whey, it can be an attractive adulterant of milk powder. Thus, the presence of CMP can be a good marker to evaluate milk powder authenticity.[38] Whey powders contain about 12% protein and 75% lactose. Caseinomacropeptide can account for more than 16% of the protein content. RP-HPLC can be used to detect rennet whey in milk powder by CMP measurement.[38] For this purpose, powdered milks were reconstituted with deionized water. Skim milks were prepared by separating the fat from the whole milk by centrifugation at 700 × *g* (at 4°C) for 10 min. Caseinomacropeptide and

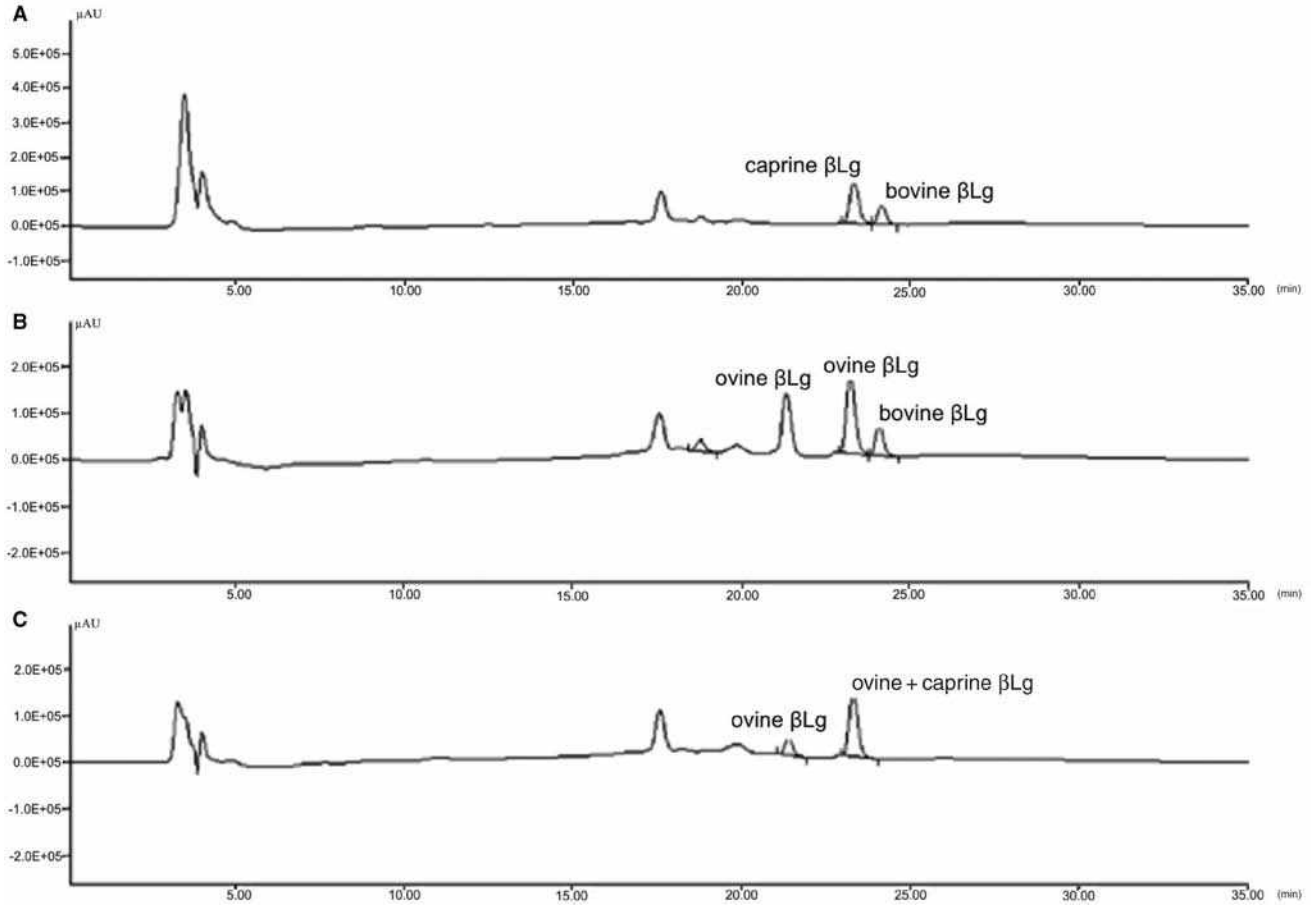

Fig. 6 Typical chromatographic profiles of whey proteins extracted from cheeses manufactured with binary milk mixtures: (A) 20% bovine milk and 80% caprine milk; (B) 20% bovine milk and 80% ovine milk; (C) 20% ovine milk and 80% caprine milk.

other whey protein fractions were extracted after casein precipitation with 1 *M* HCl until pH 4.6, centrifugation at $700 \times g$ (10 min), and filtration of the supernatant.

The column was equilibrated in 80% solvent A [0.1% (v/v) TFA in water] and, after sample injection, a series of linear gradients was applied to 100% solvent B [0.1% (v/v) TFA in 80% (v/v) aqueous acetonitrile] as follows: 1–6 min, 20–40% B; 6–16 min, 40–45% B; 16–19 min, 45–50% B; 19–20 min, 50% B; 20–23 min, 50–70% B; 23–24 min, 70–100% B. The column was re-equilibrated after a 1 min hold at 100% B by a 2 min linear gradient to 20% B, followed by an isocratic period of 3 min. The flow rate was 1 ml/min at room temperature, and the detection was at 214 nm.[38]

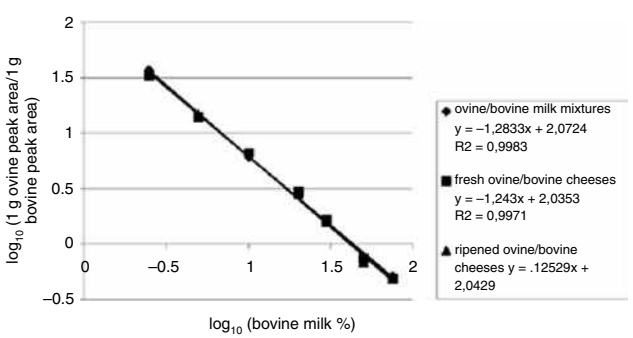

Fig. 7 Relationship between $\log_{10}$ of the ratio ovine β-lactoglobulin peak/bovine β-lactoglobulin peak (calculated as peak area ratio) and $\log_{10}$ of bovine milk percentage.

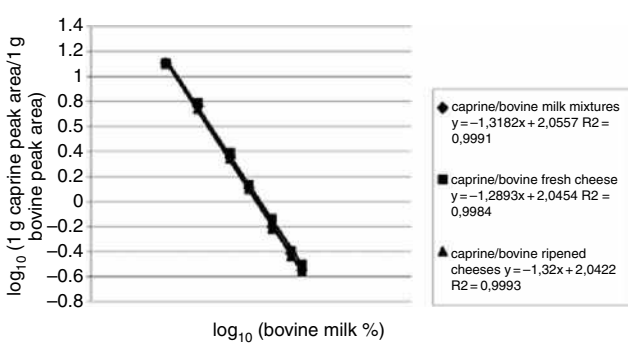

Fig. 8 Relationship between $\log_{10}$ of the ratio caprine β-lactoglobulin peak/bovine β-lactoglobulin peak (calculated as peak area ratio) and $\log_{10}$ of bovine milk percentage.

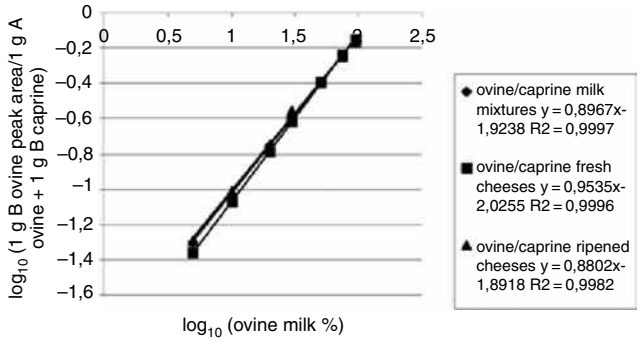

Fig. 9 Relationship between $\log_{10}$ of the ratio ovine β-lactoglobulin peak/ovine + caprine β-lactoglobulin peak (calculated as peak area ratio) and $\log_{10}$ of ovine milk percentage.

Two peaks, corresponding to the aglyco components of the two principal genetic variants (A and B) of CMP, eluted after less-resolved glyco-CMP components.[38] Calibration curves with concentrations ranging from 15 to 200 mg/ml were constructed. The detection limit was 2 mg/ml. Recoveries of 93% and 97% were obtained for concentration levels 0.10 and 0.20 mg/ml, respectively. The RSD was less than 4.87% ($n = 10$). Thus, the HPLC/UV procedure is suitable for detection of adulteration of powdered milk with rennet whey.

RP-HPLC CHARACTERIZATION OF ENZYMATIC HYDROLYSIS OF WHEY PROTEINS

In recent years there has been growing interest in bioactive peptides derived from whey proteins; such peptides have been found to exert various bioactivities both in vitro and in vivo, e.g., protective functions, regulation of digestion and nutrient uptake, and metabolic or physiological regulation of the body.[39] From a dietary point of view, protein hydrolysates can also be used, e.g., to reduce allergenicity or to improve digestibility of foodstuffs. In any case, it has been shown that protein hydrolysates should be rich in low-molecular-weight peptides with dietary advantages.[39] Depending on the type of product in which peptides will be incorporated, the degree of hydrolysis need is different. So far, the most common way to produce bioactive peptides has been through enzymatic digestion. Enzymes such as trypsin, pepsin, and Alcalase® have been used for identification of many known bioactive peptides.[39]

RP-HPLC can be used to determine the extent of degradation of native whey proteins (β-lactoglobulin and α-lactalbumin) by enzymes and to study their kinetics of degradation by monitoring both the disappearance of α-lactalbumin and β-lactoglobulin and the appearance of peptide products.[40] It can also be used to evaluate whether the chromatographic profile obtained is affected by temperature and pH conditions of the environment or is only dependent on the enzyme type.[40]

Gradient elution was carried out with a mixture of two solvents: solvent A consisted of 0.1% TFA in water and solvent B consisted of 0.1% TFA in 80% (v/v) aqueous acetonitrile. Proteins and peptides can be eluted as follows: 0–1 min, 90% A; 1–10 min, 90–80% A; 10–15 min, 80–75% A; 15–20 min, 75–60% A; 20–30 min, 60–50% A; 30–33 min, 50–40% A; 33–36 min, 40–30% A; 36–39 min, 30–20% A; 39–41 min, 20–0% A, and then returning to initial conditions in 4 min. Hydrolysis of whey protein concentrates at different temperatures and pHs using different enzymes, e.g., pepsin, trypsin, and Alcalase, was monitored.[40] The hydrolysis catalyzed by each enzyme results in different peptide profiles that can be used as fingerprints of the type of enzyme used (Fig. 10).

RP-HPLC using a polystyrene–divinylbenzene column was used for separation and quantification of angiotensin-converting enzyme (ACE) inhibitory peptides.[41,42] ALPMHIR, the most potent β-lactoglobulin-derived ACE inhibitory peptide was assayed during hydrolysis of whey protein concentrates with trypsin, and a correlation curve was constructed for the formation of this peptide as a function of hydrolysis time.[41] Two casein peptides (IPP Iso-Pro-Pro, VPP Val-Pro-Pro) presenting potent inhibitory activity of ACE and casein were simultaneously separated and quantified in commercial fermented milks labeled as presenting antihypertensive properties.[42] The detection limits were 0.004 mg/ml for VPP, 0.002 mg/ml for IPP, and 0.02 mg/ml for casein. The RSD values for concentration were below 5.08%, and recoveries ranged between 88% and 98.2%.

CONCLUSIONS

This work reports the results of the examination of the utility of RP-HPLC, using a polystyrene–divinylbenzene packing as stationary phase, for separation of milk proteins and peptides. In this type of column, separation is based on hydrophobicity, a phenomenon of great biological significance, because it is the main force that stabilizes the three-dimensional structure of proteins. Protein retention is controlled by increasing the concentration of acetonitrile, thereby altering the polarity of the aqueous mobile phase. Thus, different chromatographic conditions were used to separate and quantify milk proteins and to follow the extension of whey protein denaturation by heating or the evolution of cheese proteolysis. Detection of dairy product adulteration and study of the kinetics of whey protein enzymatic hydrolysis are other useful applications of RP-HPLC.

No loss in performance of the method or the column due to matrix contamination (e.g., by sugars) was observed during these studies. Also, the use of TFA in the mobile phase did not have adverse effects on the long-term stability of the column and increased peak resolution.

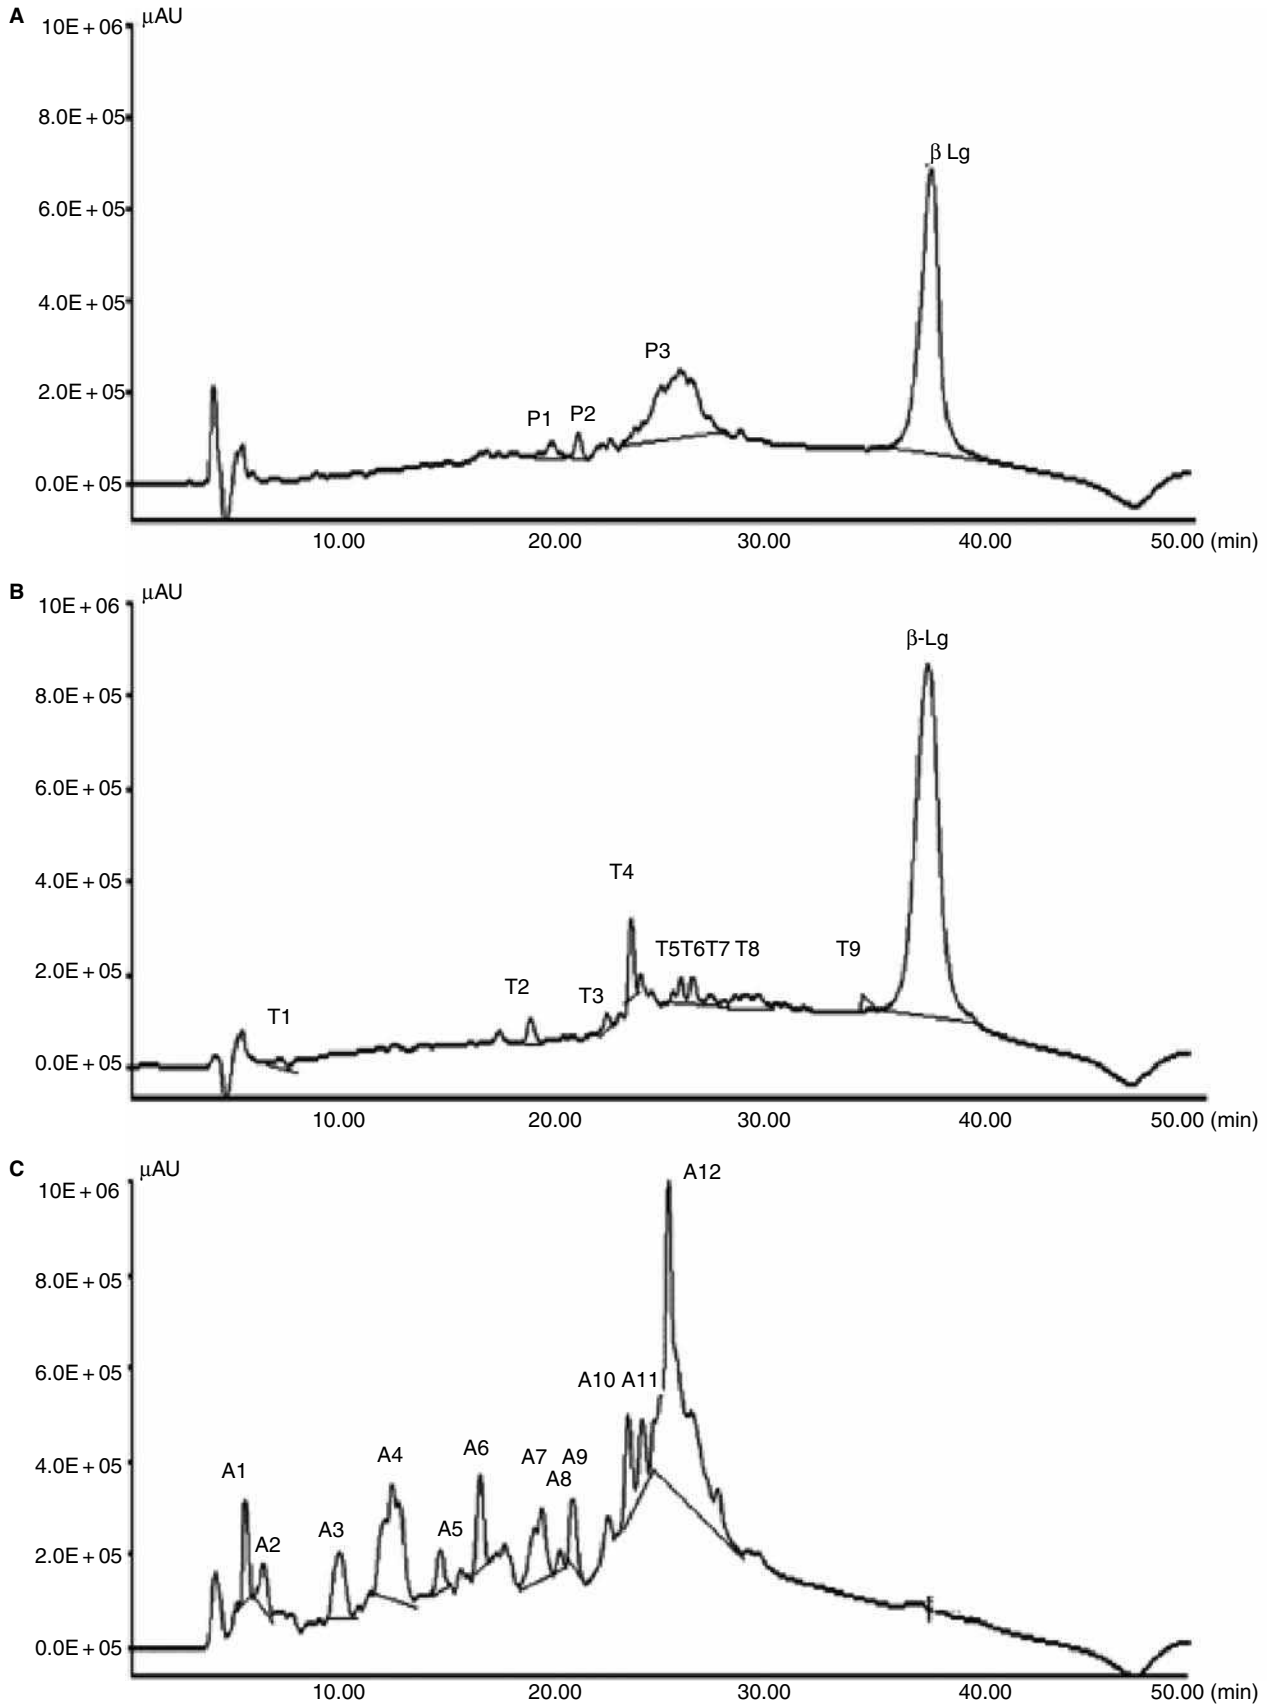

Fig. 10 Typical RP-HPLC profiles of whey protein hydrolysates ($T = 37°C$, 60 min hydrolysis time): (A) pepsin hydrolysis, pH2, three major fractions were designated P1 P3; (B) trypsin hydrolysis, pH 8, nine major fractions were designated T1–T9; (C) Alcalase hydrolysis, pH8, 12 major fractions were designated A1–A12.

Minimum Detectable Concentration or Sensitivity

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

Detector sensitivity or the minimum detectable concentration (MDC) is defined as the minimum concentration of solute passing through the detector that can be unambiguously distinguished from the noise. The size of the signal that will be distinct from the noise (the signal-to-noise ratio) will be an arbitrary choice. In electronic measuring systems, it is generally accepted that a signal can be differentiated from the noise when the signal-to-noise ratio is 2. This criterion has been generally adopted for physical–chemical measurements and is used to define detector sensitivity in chromatography.

DISCUSSION

For a concentration-sensitive detector, the detector sensitivity or MDC is given by

$$X_D = \frac{2N_D}{R_c}\left(\frac{\text{g}}{\text{ml}}\right)$$

where R_c is the response of the detector (i.e., the voltage output for unit change in concentration (V/g/ml) and N_D is the detector noise level (V).

The sensitivity or MDC of a detector is *not* the same as the minimum mass that can be detected. This would be the *system mass sensitivity*, which will depend on the characteristics of the column and the chromatographic properties of the solute, as well as the detector specifications. In all chromatographic systems, the peak becomes broader as the retention increases. Consequently, a given mass may be detected if eluted as a narrow peak early in the chromatogram, but if eluted later, its peak height may be reduced to such an extent that it is impossible to discern it from the noise. Thus, detector sensitivity quoted as the "minimum mass detectable" must be carefully examined and related to the chromatographic system and, particularly, the column with which it is to be used. If the data to do this are not available, then the sensitivity must be calculated from the detector response and the noise level in the manner described earlier.

Some manufacturers have taken the minimum detectable concentration and multiplied it by the sensor volume and defined the product as the minimum detectable mass. This gives values that are very misleading. For example, a detector having a true sensitivity of 10^{-6} g/ml and a sensor volume of 10 μl would be attributed to a mass sensitivity of 10^{-8}g. This is grossly incorrect, as it is the *peak volume* that controls the mass sensitivity, not the *sensor volume*. Conversely, if the peak volume does approach that of the sensor, then a very serious peak distortion occurs with loss of resolution; thus, this way of specifying sensitivity remains meaningless.

Mixed Stationary Phases in GC

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

The desired interactive character of a gas chromatography (GC) stationary phase is usually obtained by choosing a thermally stable substance that contains the appropriate polar and dispersive groups that can provide the necessary molecular interactions for sample resolution.

BACKGROUND INFORMATION

Purnell and coworkers[1] pioneered an alternative approach to stationary-phase polarity control for GC. These workers demonstrated that for a wide range of stationary phases made up of binary mixtures, the corrected retention volume of a solute was linearly related to the volume fraction of either one of the two phases. At the time of discovery, this was quite an unexpected relationship, as it was generally accepted that the expression for the retention volume would take the form of the exponent of the stationary-phase composition. The results of Purnell and his co-workers can be summarized by

$$V_{r(A)}{}' = K_A \alpha V_S + K_B(1-\alpha)V_S$$

where $V_{r(AB)}{}'$ is the retention volume of the solute on a mixture of stationary phases A and B, K_A is the distribution coefficient of the solute with respect to the pure stationary phase A, K_B is the distribution coefficient of the solute with respect to the pure stationary phase B, V_S is the total volume of the stationary phase in the column, and α is the volume fraction of phase A in the stationary-phase mixture; that is,

$$V_{r(AB)}{}' = \alpha V_A{}' + (1-\alpha)V_B{}' \quad (1)$$

where $V_A{}'$ is the retention volume of the solute on the same volume of pure phase A and $V_B{}'$ is the retention volume of the solute on the same volume of pure phase B.

Rearranging Eq. 1,

$$V_{AB}{}' = \alpha(V_A{}' - V_B{}') + V_B{}' \quad (2)$$

This remarkably simple relationship is depicted in Fig. 1.

Purnell carried out three experiments to examine the effect of the composition of binary mixtures of stationary phases on solute retention. In the first experiment, the two fractions were mixed, coated on some support, and packed into the column. In the second experiment, each of the two fractions was coated on separate aliquots of support and the coated supports mixed and packed in a column. In the third experiment, each fraction was coated on a support and each support packed into separate columns and the columns joined in series. Purnell demonstrated that all three columns gave exactly the same corrected retention volume for a given solute.

It was found, however, that where strong association occurred between the two phases, there were exceptions to this relationship. If a strong association took place, the blend would no longer be a simple binary mixture but would contain the associate of the two phases as a third component. It is clear that for a ternary mixture, the simple linear relationship obtained for a binary mixture would not hold. The simple linear relationship for the binary mixture is not surprising. The distribution coefficient of the solute with either pure component is a constant. It follows that the volume fraction of each phase will determine the probability that a solute molecule will interact with a molecule of that phase. This is analogous to the partial pressure of solute determining the probability that a solute molecule will collide with a gas molecule.

Doubling the volume fraction of one phase doubles the probability of solute interaction and, consequently, doubles its contribution to retention. There is another interesting outcome from the results of Purnell and his co-workers. Where a linear relationship existed between the retention volume and the volume fraction of the stationary phase, the linear functions of the distribution coefficients could be summed directly, but their logarithms could *not*. In many classical thermodynamic descriptions of the effect of the stationary-phase composition on solute retention, the stationary-phase composition is often taken into account by including an extra term in the expression for the standard free energy of distribution. The results of Purnell indicate that this is not acceptable, as the solute retention or distribution coefficient is *linearly* not exponentially related to the stationary-phase composition. The stationary phases of intermediate polarities can easily be constructed from binary mixtures of a strongly dispersive stationary

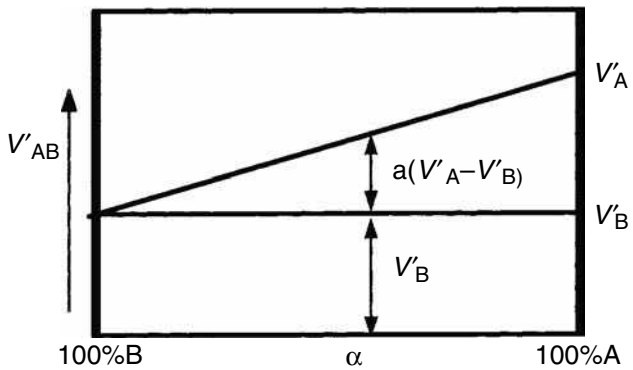

Fig. 1 Graph of corrected retention volume vs. volume fraction of the stationary phase.

phase and one that is strongly polar. This procedure is not commonly used for commercial columns, although it is a simple and economic method for constructing columns having intermediate polarities. Mixed phases are always worth considering as a flexible alternative to the use of a specific proprietary material.

Mixed Stationary Phases: Synergistic Effects in GC

L.M. Yuan
Department of Chemistry, Yunnan Normal University, Kunming, China

INTRODUCTION

It is generally believed that multicomponent stationary phases, or mixed stationary phases, show the average effect of individual pure phases in gas chromatography (GC). Investigations have shown the existence of a synergistic effect in some mixed GC stationary phases and about 18 entries have been published since 1996.[1,2] Some chromatographic properties of the mixtures, such as separation factor (α), retention factor (k'), elution order of Grob test regent, and McReynolds constants, are not the simple addition of the chromatographic properties of the two pure phases. These values of mixed stationary phases may be greater or less than either of the pure stationary phases. It is different from general experimental results. The positive synergistic effect is very useful in the separation of some substance pairs.

SYNERGISTIC EFFECT

The synergistic effect was first discovered in 1957 by Blake in the study of extraction of U(VI).[3] It has been widely studied in the extraction of inorganic and organic compounds. Generally, mixed stationary phases prepared from polar or non-polar stationary phases show the average effect of the corresponding individual pure phases. But for a few isomers, the separation factor (α) obtained by the use of the capillary columns coated with side-chain crown ether polysiloxane (PDB-14-C4) + heptakis(2,3,6-tri-*O*-ethyl)-β-cyclodextrin (PE-β-CD) was greater or smaller than those obtained from the individual columns coated with either PDB-14-C4 or PE-β-CD; a new term, the "coordination effect" was suggested to describe this unexpected and puzzling phenomenon.[1] Yuan et al. studied it carefully and used the "synergistic effect" to describe it because gas–liquid chromatography is actually partition chromatography and its principle is similar to solvent extraction.[4] The purpose of the present paper is to investigate this phenomenon using packed columns containing heptakis(2,3,6-tri-*O*-pentyl)-β-cyclodextrin + $AgNO_3$, heptakis(2,3,6-tri-*O*-pentyl)-β-cyclodextrin + $TlNO_3$, and xylene isomers as sample compounds.[3] They have positive synergistic effects for the separation of *m*- and *p*-xylene isomers, but negative synergistic effects for the *m*- and *O*-isomers (see Figs. 1 and 2).

The packed column gas chromatographic separations of some other aromatic compounds using special selectivity mixed stationary phase consisting of heptakis(2,3,6-tri-*O*-pentyl)-β-cyclo-dextrin + $AgNO_3$, heptakis(2,3,6-tri-*O*-pentyl)-β-cyclodextrin + $TlNO_3$, bentone + $AgNO_3$, and heptakis(2,3,6-tri-*O*-pentyl)-β-cyclodextrin + *O*-methyl-*p*-phenylene-bis-(*p*-heptoxy benzoate) liquid crystalline (BPBHpB) were investigated too. Most of the separations deviated from the additivity, and the synergistic effect was observed.[5] The synergistic effects of packed columns, by mixing the stationary phases before coating the support, were more pronounced than those from columns mixing the two packings.

A great deal of research about the synergistic effect of GC was reported using capillary column GC. Based on the experiences developed in Ref.[3] ethylhexylresorcarene + heptakis(2,6-di-*O*-pentyl-3-*O*-trifluoroacetyl)-β-CD mixed stationary phase was used for isomer separation.[6] Heptakis(2,3,6-tri-*O*-butyl)-β-cyclodextrin + $AgNO_3$ was used for some enantiomer and isomer separations.[7] Synergistic effects were observed on those phases. By investigating the chromatographic properties of the mixed stationary phase containing heptakis(2,3,6-tri-*O*-pentyl)-β-cyclodextrin + PEG-20M, the synergistic effect was observed in this mixed stationary phase.[8] Several similar synergistic effects were shown for the phases mixed with heptakis(2,3,6-tri-*O*-pentyl)-β-cyclodextrin + MPBHpB,[9] BPBHpB + heptakis(2,6-di-*O*-pentyl-3-allyl)-β-cyclodextrin, heptakis(2,3,6-tri-*O*-pentyl)-β-cyclodextrin + Dibenzo-18-crown-6, heptakis(2,3,6-tri-*O*-pentyl)-β-cyclodextrin + resorcarene derivative, and 25,27-dibutoxy-5,11,17,23-tetra-*tert*-butyl-26,28-diundecenyloxy cali[4]arene + permethyl-β-cyclodextrin.[9,10] Mixed cyclodextrin derivatives such as permethylated β-CD + heptakis(2,6-di-*O*-butyl-3-*O*-butyryl)-β-CD and permethylated β-CD + heptakis(2,6-di-*O*-nonyl-3-*O*-trifluoroacetyl)-β-CD had synergistic effects in the separation of enantiomers.[11] Our recent investigation has also shown the existence of a synergistic effect in mixed perpentylated-β-CD + permethylated β-CD stationary phase for the separation of enantiomers.

Besides cyclodextrin derivatives, other mixed special selectivity stationary phases also had synergistic effects in the separation of isomers. Those reported include dibenzo-18-crown-6 + MPBHpB,[12] dibenzo-18-crown-6 and resorcarene derivative,[2] MPBHpB + resorcarene derivative,[13] and 25,27-dibutoxy-5,11,17,23-tetra-*tert*-butyl-26,

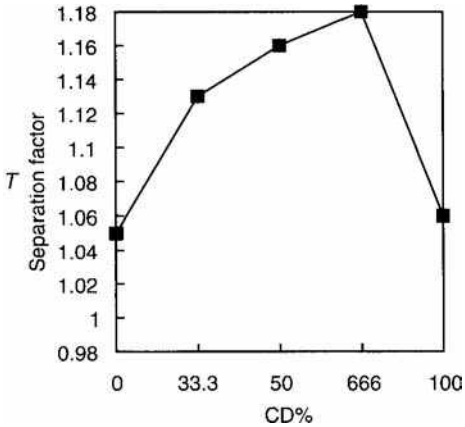

Fig. 1 Plot of $\alpha_{p,m}$ vs. CD% on mixed stationary phases.
Source: From U.S. Atomic Energy Commission.[3]

28-diundecenyloxy cali[4]arene + ω-undecylomethyl-18-crown-6 polysiloxane.[10]

The effects of temperature, linear velocity of carrier gas, and relative amounts of the individual phases in the mixed stationary phase were also examined.[2,4,5,8,9,12,13] These facts show that the synergistic effect is dependent upon the above three factors.

The synergistic effect was only found in mixed stationary phases that have a special selectivity. Those stationary phases were CD, crown ether, liquid crystalline, resorcarene, calixarene, $AgNO_3$, and others. Crown ether, CD, calixarene, and resorcarene possess cyclic moieties with cavity-like structures that are able to form inclusion complexes with metal ions and organic molecules. Liquid crystalline stationary phases have temperature-dependent ordered structures and the retention is governed by the solute's length-to-breadth ratio. $AgNO_3$ retards olefins by the formation of loose adducts. Together with the above special selectivity stationary phases, they have already been the focal point of supramolecular chemistry.

CONCLUSIONS

A synergistic effect of mixed stationary phases that have special selectivity exists in GC. It is based on the "steric fit" and on the probability of simultaneous interaction of mixed stationary phases with the solute pair. It can be assumed that the largest synergistic effect is attained with maximum steric fit and simultaneous interaction probability. This probability may depend on temperature, mixing ratio, linear velocity of carrier gas, and how mixing is accomplished.

Mobile Phase Modifiers for SFC: Influence on Retention

Yu Yang
Department of Chemistry, East Carolina University, Greenville, North Carolina, U.S.A.

INTRODUCTION

Carbon dioxide has been the most common mobile phase in supercritical fluid chromatography (SFC) due to its low critical point, non-toxicity, and wide availability in pure form. However, the polarity and solvating power of carbon dioxide are fairly low, which prevents polar and high-molecular-weight compounds to elute by using pure CO_2 as the mobile phase. Therefore, a small amount of organic or inorganic solvents are often added to CO_2 to enhance the solvating power of the mobile phase, so that polar and high-molecular-weight solutes can be eluted. Both polar and non-polar modifiers have been added to carbon dioxide to alter the chromatographic retention and selectivity.The modifiers and CO_2 can be either premixed in a compressed cylinder, mixed using a saturator column (device), or mixed by using two delivery pumps. Among many modifiers tested in SFC, methanol has been the most popular additive for carbon dioxide. Although binary systems have been used in many applications, ternary systems have also been investigated and found to be very successful in separating organic acids and bases. The modifier influence on chromatographic retention and the mechanism of modifier effect in SFC are also discussed in this entry.

PREPARATION OF THE MODIFIED MOBILE PHASE

There are a number of ways to mix modifiers with CO_2. A mixture of modifier and CO_2 can be purchased as premixed cylinders. Because the modifier is premixed with CO_2 in a cylinder, a modifier gradient cannot be carried out by this approach. Another drawback of this premixing method is that the concentration of the modifier may be increased as the cylinder is evacuated. Modifiers can also be directly introduced into an empty syringe pump that is then filled with CO_2. Again, similar limitations exist in this method. Another way to mix the modifier with CO_2 is to use a saturator column, usually a silica column saturated with polar modifiers. However, because the modifier-holding capacity of the silica column is limited, the amount of modifier dissolved in the mobile phase varies as the mobile phase passes through the saturator column. An improved mixing device in which highly porous stainless-steel filters were used to generate a modified CO_2 mobile phase has been developed to substitute for the saturator column. Although this mixing device can maintain the amount of modifiers dissolved in supercritical CO_2 for a long time, the performance of the modifier gradient remains impossible with this system. The best and most effective (also the most expensive) way of delivering a modifier in SFC is by using two supply pumps. One pump is used for CO_2 delivery and the other for modifier delivery. The modifier and CO_2 meet inside a mixing chamber that mixes the modifier with CO_2 and equilibrates the mixture in a thermostated zone, and then the mixed fluid is delivered to the SFC injection port and column.

METHANOL AS THE MODIFIER

Among the published articles regarding modifiers in SFC, methanol has been involved in at least two-thirds of the works. Therefore, methanol has been the most popular modifier for CO_2 in SFC.The mole fraction of methanol in the mobile phase is generally low, ranging from 1% to 10%. However, methanol concentrations up to 45% have also been tested. Due to the high cost of dual-pump systems, a constant concentration of methanol has normally been used to modify carbon dioxide. Once a dual-pump system is available, a programmed concentration of the modifier is preferred, as better separations can be achieved by using the modifier gradient technique. The methanol-modified mobile phase has been used to successfully separate phenols and their derivatives, amines and their derivatives, carboxylic acids, carbohydrates and their derivatives, herbicides and pesticides, alkylbenzenes, chlorobenzenes, chlorophenyls, higher-molecular-weight *n*-alkanes, polycyclic aromatic hydrocarbons (PAHs) and their derivatives, polychlorinated biphenyls (PCBs), pharmaceutical compounds, active ingredients in natural products, explosives, and other solutes.

TERNARY SYSTEMS

Because methanol is not very polar, the elution of strong organic acids and bases requires a mobile phase with even greater polarity. This has normally been done by adding a very low concentration of acids or bases into methanol, and then the modified methanol is mixed with CO_2 for separation. Citric, acetic, and chlorinated acetic acids have been

used as acidic secondary modifiers, whereas isopropylamine, triethylamine, and tetrabutylammonium hydroxide have been served as basic secondary modifiers. A good example with ternary systems is the separation of benzylamines, as shown in Fig. 1. None of the three tested amines were effectively eluted by pure CO_2 (Fig. 1a); however, some of these amines were eluted with very poor peak shapes when methanol was added to the CO_2 (Fig. 1b). However, the addition of isopropylamine to the methanol-modified mobile phase effectively eluted all of the three benzylamines and dramatically improved the peak shapes, as shown in Fig. 1c.

OTHER MODIFIERS

Besides methanol, many other polar and non-polar modifiers have also been used to successfully improve the separation in SFC. These modifiers include acetone, acetonitrile, acetic acid, butane, butanol, *n*-butyl chloride, carbon tetrachloride,dioxane, ethanol, formic acid, heptane, hexane, *n*-hexylamine, methylene chloride, nitromethane, propanol, proprionitrile, tetrahydrofuran, toluene, triethanolamine, trifluoroacetic acid, trifluoroethanol, trimethyl phosphate, and water.

FID-COMPATIBLE MODIFIERS

One of the major advantages of SFC over highperformance liquid chromatography (HPLC) is its compatibility with the flame ionization detector (FID), a universal and sensitive detector for carbon compounds. Unfortunately, most modifiers used in SFC are incompatible with FID. Therefore, a search for polar modifiers that have less response to FID led to the use of water, formic acid, and formamide. These modifiers produce acceptably low background noise and enable the use of FID. Because both water and formic acid have poor solubilities in carbon dioxide, they have been used as modifiers at very low concentrations. However, the modifier effect is significant even at this low level. For example, when water or formic acid was used as modifiers, the resolution of free fatty acids was significantly improved.

Very recently, the separation of polar analytes has also been performed by using pure water under subcritical conditions. Subcritical water has several unique characteristics. For example, the dielectric constant, surface tension, and viscosity of water are dramatically decreased by raising the water temperature while a moderate pressure is applied to keep water in the liquid state. At 200–250°C, the values of these physical properties are similar to those of pure methanol or acetonitrile at ambient conditions. Therefore, subcritical water may be a potential mobile phase for polar analytes. SFC mobile phases other than CO_2 are reviewed separately in this encyclopedia.

MODIFIER EFFECT ON RETENTION

It is very clear that chromatographic retention is changed by adding modifiers into carbon dioxide. However,

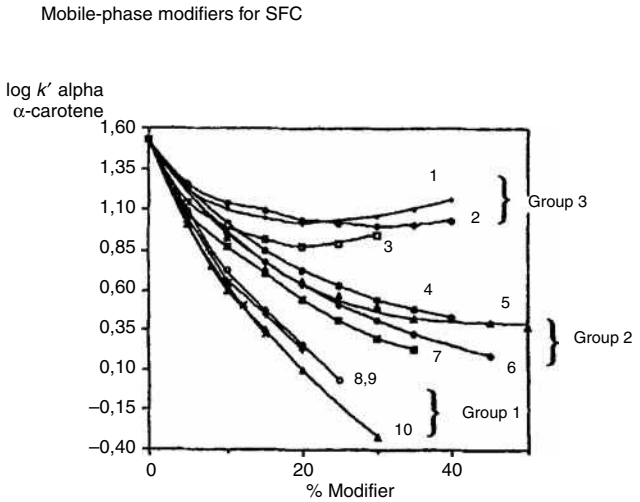

Fig. 2 Variation of the log *k* for α-carotene vs. the percentage of modifier in carbon dioxide.Temperature: 25°C (subcritical); outlet pressure: 150 bar; flow rate: 3 ml/min; UV at 450 nm; column: UB 225 (250 × 4.6 nm; 5 μm). 1. modifiers used in SFC can be classified in three groups, depending on the retention behavior of the solutes. Fig. 2 shows a good example of the modifier effect on the retention of α-carotene. For separations using heptane-, tetrahydrofuran-, and methylene chloride-modified CO_2 (group 1), the retention of α-carotene was decreased rapidly and almost inversely proportional to the modifier concentration, as shown in Fig. 2. The second group of modifiers include ethanol, proprionitrile, acetone, and 1-propanol. A more gradual decrease in the retention of α-carotene was obtained by using modifiers in this group. Methanol, acetonitrile, and nitromethane are in the third group. Even though the retention decreased significantly with increasing modifier percentage up to ~10% for all three modifiers in this group, the retention reached a minimum with acetonitrile- and nitromethane-modified carbon dioxide. For separation using the methanol-modified CO_2 the retention remained almost unchanged at higher methanol concentrations. A similar behavior was observed for separations of many other solutes with methanol as the modifier.

MECHANISM OF THE MODIFIER EFFECT

Although the exact mechanism is not very clear, the following factors may contribute to the modifier effect on chromatographic retention. Polar modifiers may cover the active sites of the stationary phase (deactivation) so that solute retention is reduced. This can be explained by the differences in retention change between packed and open-tubular columns when small amounts of modifiers were used. Open-tubular columns normally do not show the drastic changes in retention or efficiency upon the addition of small amounts (<2%) of modifier as most packed columns do. These less drastic differences were caused by the differences in the degree of deactivation of the packed column stationary phase as compared with the opentubular- column stationary phase. An open-tubular column has fewer active sites present and, thus, fewer active sites are present for the modifier to deactivate.

Modifiers may also swell the stationary phase, causing retention change of solutes.The density of the mobile phase can be increased by most polar and non-polar modi- fiers so that the solvating power of the mobile phase is enhanced. The polarity of the mobile phase is definitely increased by adding polar modifiers; thus, the retention of polar analytes is reduced. Specific intermolecular interactions between the solute and the modifier in the mobile phase may be additional factors for the modifier effect.

In conclusion, both polar and non-polar modifiers can be added to the SFC mobile phase to increase the solvent strength. Unlike pure carbon dioxide, the modified CO_2 can elute polar and high-molecularweight solutes due to its enhanced solvating power. The retention factors are reduced and peak shapes greatly improved by using binary or ternary mobile phases. Although ultraviolet detection can be applied for separations with many modifiers, only water, formic acid, and formamide are compatible with FID.

Molecular Interactions in GC

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

The retention of a solute is directly proportional to the magnitude of its distribution coefficient (K) between the mobile phase (gas) and the stationary phase. The magnitude of K depends on the relative affinity of the solute for the two phases; thus, the stronger the forces between the solute molecule and the molecules of the stationary phase, the larger the distribution coefficient and the more the solute is retained. It follows that the stationary phase must interact strongly with the solutes to be retained and to achieve a separation. Molecular interaction results from *intermolecular forces*, of which there are only two types effective in gas chromatography (GC).

In total, there are three different basic types of molecular force, all of which are electrical in nature. These forces are called *dispersion forces*, *polar forces*, and *ionic forces*. Despite there being many different terms used to describe molecular interactions (e.g., hydrophobic forces, π–π interactions, hydrogen-bonding, etc.), all interactions between molecules are the result of composites of these three different types of molecular force.

DISPERSION FORCES

Dispersion forces[1] arise from charge fluctuations throughout a molecule, resulting from electron/nuclei vibrations. Glasstone[2] described them in the following way:

> Although the physical significance probably cannot be clearly defined, it may be imagined that an instantaneous picture of a molecule would show various arrangements of nuclei and electrons having dipole moments. These rapidly varying dipoles, when averaged over a large number of configurations, would give a resultant of zero. However, at any instant, they would offer electrical interactions with another molecule, resulting in interactive forces.

Dispersion forces are those that occur between hydrocarbons and other substances that have either no permanent dipoles or can have no dipoles induced in them. In biotechnology and biochemistry, dispersive interactions are often referred to as "hydrophobic" or "lyophobic" interactions, apparently because dispersive substance such as the aliphatic hydrocarbons do not dissolve readily in water. To a first approximation, the interaction energy (U_D) involved with dispersive forces has been deduced to be

$$U_D = \frac{3h\nu_0\alpha^2}{4r^6}$$

where α is the polarizability of the molecule, ν_0 is a characteristic frequency of the molecule, h is Planck's constant, and r is the distance between the molecules. The dominant factor that controls dispersive force is the polarizability (α) of the molecule, which for substances that have no dipoles is given by

$$\frac{D-1}{D+2} = \frac{4}{3}\pi n\alpha$$

where D is the dielectric constant of the material and n is the number of molecules per unit volume.

If ρ is the density of the medium and M is the molecular weight, then the number of molecules per unit volume is N_ρ/M, where N is Avogadro's number. Thus,

$$\frac{4}{3}\pi N\alpha = \frac{D-1}{D+2}\frac{M}{\rho} = P$$

where P is called the molar polarizability. It is seen that the molar polarizability is proportional to M/ρ, the molar volume.

POLAR FORCES

Polar interactions arise from electrical forces between localized charges such as permanent or induced dipoles. Polar forces are always accompanied by dispersive interactions and may also be combined with ionic interactions. Polar interactions can be very strong and produce molecular associations that approach, in energy, that of a weak chemical bond (e.g.,"hydrogen-bonding").

DIPOLE–DIPOLE INTERACTIONS

The interaction energy (U_P) between two dipoles molecules is given, to a first approximation, by

$$U_P = \frac{2\alpha\mu^2}{r^6}$$

where α is the polarizability of the molecule, μ is the dipole moment of the molecule, and r is the distance between the

molecules. The energy depends on the square of the dipole moment, which can vary widely in strength. The numerical value of the dipole moment does not always give an indication of the strength of any polar interactions, as there is often internal electric field compensation when more than one dipole is present in the molecule. Although, the *polarizability* of a substance containing no dipoles may give an indication of the *strength of the dispersive* interactions, due to possible self-association or internal compensation, the *dipole moment* of a substance will *not* always give an indication of the *strength of any polar interaction* that might take place with another molecule.

DIPOLE–INDUCED-DIPOLE INTERACTIONS

Compounds, such as those containing the aromatic nucleus and thus π electrons, are polarizable. When such molecules are in close proximity to a molecule with a permanent dipole, the electric field from the dipole induces a counter-dipole in the polarizable molecule. This induced dipole acts in the same manner as a permanent dipole and, thus, polar interactions occur between the molecules. Induced-dipole interactions are, as with polar interactions, always accompanied by dispersive interactions. Aromatic hydrocarbons can be retained and separated in GC purely by dispersive interactions when using a hydrocarbon stationary phase or they can be retained and separated by combined induced-polar and dispersive interactions using a poly(ethylene glycol) stationary phase. Molecules can possess different types of polarity, phenyl ethanol, for example, will possess both a permanent dipole as a result of the hydroxyl group and also be polarizable due to the aromatic ring. More complex molecules can have many different interactive groups.

IONIC FORCES

Ionic interactions arise from permanent negative or positive charges on the molecule and, thus, usually occur between ions. Ionic interactions are exploited in ion-exchange chromatography, where the counterions to the ions being separated are situated in the stationary phase; ionic interactions are rarely active in GC separations.

To achieve the necessary retention and selectivity between the solutes for complete resolution, it is necessary to select a stationary phase that will provide the optimum balance of dispersive, polar, and induced-polar interactions between the solute molecules and those of the mobile phase.

Monolithic Disk Supports for HPLC

Aleš Podgornik
M. Barut
A. Strancar
BIA Separations d.o.o., Ljubljana, Slovenia

INTRODUCTION

Chromatographic columns are typically several centimeters in length, resulting in a high number of column plates, and, consequently, such columns have high efficiency. These properties allow even very similar molecules to be separated. This is especially true for smaller molecules, where the separation is based on selective migration. For large molecules, a different separation mechanism is usually required. Large molecules normally interact with the matrix at several binding sites. Consequently, their adsorption isotherms are very steep, almost rectangular. For such molecules, there exists only a very narrow mobile phase range within which they interact with the active moieties on the stationary phase, but are not irreversibly retained. To elute them from the matrix, a change of the mobile phase composition is required. Therefore the separation is based upon the selective elution and requires the use of gradient chromatographic methods. For this type of separation, the column length is less important and the efficient separations can be achieved even with extremely short columns.

Because it is possible to use short columns, high flow rates can be used because of the low-pressure drop on the column. When this is accompanied with a steep gradient, extremely fast separations of large molecules can be achieved. However, to obtain efficient, fast separation, the mass transfer between the mobile and the stationary phase should also be fast. This might be a problem for large molecules having a very low mobility. Therefore suitable stationary phases should be used. In order to decrease the diffusion limitations, which are especially pronounced for large molecules, convection must be a significant part of the materials' mass transfer characteristics. To overcome a diffusion bottleneck, several types of stationary phases have been proposed, e.g., non-porous and perfusion particles. Despite significantly improved mass transfer in comparison to porous particles, preparation of short columns, as a result of the problems connected with column packing, can be problematic.

An alternative approach is represented by membranes. They are, by definition, very thin and seem ideally suited for the preparation of short columns. In fact, several successful large molecule separations were reported.[1] Membranes possess excellent mass transfer characteristics, enabling the fast exchange of molecules between the mobile and stationary phases. Because of their extreme thinness, several membranes are normally stacked to achieve acceptable binding capacity. This inherently introduces voids between the membranes that decrease the continuous nature of the matrix.

A decade ago, a new type of stationary phase was developed. It is commonly referred to as a monolith to emphasize that the matrix consists of a single piece of a highly porous material. Similar to the membranes, the monoliths have open pores that form a highly interconnected network of channels which are uniformly distributed in all directions. In contrast to the membranes, however, they can be prepared in various shapes and dimensions. The porous structure enables very good hydrodynamic characteristics. The mobile phase flows through the channels, and convection is the predominant transport mechanism. In this way, the mass transfer of large molecules is increased by at least an order of magnitude and, consequently, the analysis times can be significantly shortened without loss of resolution. In addition, chromatographic characteristics such as column efficiency and dynamic binding capacity are practically flow-independent. Similar to other chromatographic supports, monoliths can be prepared with different active groups. It is beyond the scope of this entry to describe in detail the characteristics of monoliths, but those interested in the subject are referred to a recent book entitled "Monolithic Separation Media."[2] Because the monoliths combine the advantageous hydrodynamic characteristics of the membranes with a flexible geometry, they are an ideal matrix for short chromatographic columns.

EFFECT OF THE COLUMN LENGTH ON THE RESOLUTION UNDER THE CONDITIONS OF A LINEAR GRADIENT ELUTION

Several decades ago, the theory of gradient elution was proposed by Snyder and Stadalius.[3] In this work, it was shown that the column length does not influence the resolution. This is especially true for steep gradients, where the separation is entirely based on selective elution. In contrast to isocratic separations, where a longer column normally

results in better separations, the elution time for gradient elutions depends upon the composition of the mobile phase. As a consequence, only a small part of the column is used for the separation. This conclusion is based upon the assumption of instantaneous equilibrium between the sample and the mobile phase. For large molecules, however, this assumption is hardly justified because of the significantly different mobilities of large and small molecules. Indeed, a detailed work by Dubinina, Kurenbin, and Tennikova[4] demonstrated that the gradient should be adjusted to the column length. Furthermore, they demonstrated that longer columns might even decrease the resolution because of pronounced band spreading. They introduced a term of gradient length, which depends on mobile phase velocity, concentration at which the molecule is eluted, steepness of the gradient, and the *Z* factor. The theoretical analysis showed that there is an increase in band spreading in the area where the gradient length is shorter than the column length. The spreading, together with the resolution, increases while the column length approaches the calculated gradient length. When the gradient and the column length are comparable, the bandwidth remains constant. Further increases in the column length result in a pronounced band spreading without improving the separation. The reason for this behavior lies in the equilibrium between the sample and the mobile phase. Once the molecules are released from the active groups, they start to move through the column with the mobile phase. Because of the lower mobility, however, their velocity is lower than the velocity of the eluting mobile phase. Therefore they become surrounded by the mobile phase with higher ionic strength, which, consequently, accelerates them. This results in a so-called sharpening effect resulting in lower bandwidth. When the gradient approaches the physical length of the column, the equilibrium between the sample molecules and the mobile phase composition is achieved at the end of the column. Therefore the mobile phase composition determines the band spreading and, in this way, preserves the resolution efficiency. A longer column does not contribute to a better separation, but only to additional band spreading because of axial dispersion, resulting in decreased resolution. Therefore for molecules that require a steep gradient for an efficient separation, short columns are not only a method of choice, but can even be superior to longer columns.

DEVELOPMENT AND CHARACTERISTICS OF DISK MONOLITHIC COLUMNS

The concept of monolithic columns in the shape of disks was first introduced at the beginning of the 1990s by Tennikova, Belenkii, and Svec.[5] They prepared hydrophobic methacrylate-based monolithic disks with a diameter of 20 mm and a thickness of 1 mm which demonstrated a very efficient separation of a protein mixture. After this initial research, monolithic disks of different diameters and thicknesses were prepared and used for various chromatographic separations. The smallest monolith had a diameter of only 1.8 mm, while the largest had a diameter of 50 mm. The thickness was between 0.3 and 7 mm.[6] In this way, the monolith volume differed by several orders of magnitude. The monolithic disks contained different chemical moieties which were used for separations in ion exchange, hydrophobic, and affinity interactions, as well as reversed phase modes.

Along with the development of the monolithic disks, a suitable housing had to be designed. The housing needed to facilitate the usage of the monolithic disks and enable the connection of the disk monolithic columns to an HPLC/LC or flow injection analysis (FIA) system. In addition, it needed to provide a uniform sample distribution over the entire monolith surface, ensure the mechanical stability of the monolithic disk when a high flow rate is applied, and prevent any bypass of the mobile phase. Furthermore, the peak spreading and the dead volume of such a unit should be as low as possible. Historically, this represented a major challenge. Several attempts to fulfill these requirements have been reported over the last several years.[7] In the initial experiments, the monolith was simply installed at the bottom of a filtration device. Despite the simplicity of such an approach, the large dead volume limited its wide applicability. To overcome this problem, a special housing with optimized sample distribution was constructed. This device enabled excellent separation of proteins within several minutes. The monolithic disk was placed between two sample distributors, and o-rings created a seal around the monolith. Because of the way the monoliths were fixed in the housing, the replacement often damaged the monolith. In 1998, a commercial product under the trademark CIM Convective Interaction Media® was launched.[8] The housing enables highly efficient separations and easy exchange of the monolithic disks. Along with the construction of the housing, the dimensions of the monolithic disks were standardized to have a diameter of 12 mm and a thickness of 3 mm. To provide additional mechanical stability to the monolith, a self-sealing non-porous ring was fixed around the monolith. These commercially available units are shown in Fig. 1.

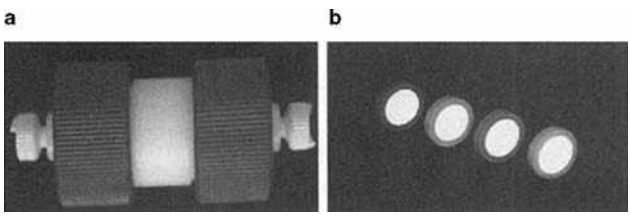

Fig. 1 The outlook of (a) the CIM® Disk Monolithic Column and (b) the CIM® Disks from BIA Separations, Ljubljana, Slovenia.

CHROMATOGRAPHIC CHARACTERISTICS OF MONOLITHIC DISKS

Despite the existing theory claiming that, under the conditions of a gradient elution, resolution does not improve with increased column length, very short chromatographic columns were not routinely used for separations in a gradient mode at the time the monolithic disks were introduced. To evaluate the chromatographic characteristics of the monolithic disks, a detailed analysis of their properties under gradient elution was published in 1993 by Tennikova and Svec.[9] They prepared monolithic disks with different chemistries, enabling ion-exchange (IEX), HIC, and RP separation modes. They investigated the effect of the gradient volume on the separation efficiency and concluded that the monolithic disks obey the same chromatographic rules as conventional particulate chromatographic columns. On the other hand, because of the enhanced transport mechanism, the separation characteristics were almost independent of the applied flow rate. Furthermore, the resolution increased even with the increases in linear velocity, which was explained by the narrowing of the peaks. They estimated that the apparent diffusivity of the proteins, as a result of the convective flow through the pores of the monolithic disk, was four magnitudes higher than the free diffusivity of proteins in solution.

In 1999, a similar analysis was performed for an isocratic separation.[10] The investigators examined the effect of the mobile phase composition and the monolithic disk thickness on band spreading. Again, it was found that, despite an extremely short column length and the monolithic structure, all conclusions for the conventional HPLC columns were applicable to these columns. Separation of oligonucleotides gave a height equivalent of theoretical plate (HETP) value of 18 μm, which is comparable to the chromatographic columns filled with 5–7 μm particles. Investigation of the effects of flow rate demonstrated a slightly improved separation at a higher flow rate. This surprising conclusion was explained by the increased flow through the small pores, which are not "permeable" at lower flow rates.[10] Both works demonstrated that the monolithic disks should be considered as "real" chromatographic columns.

All monolithic disks reported so far were methacrylate- or styrene-based. Because of that, they have a rigid structure, which minimizes compression when high flow rates are applied. This is confirmed by a linear correlation between the pressure drop and the linear velocity. For the commercially available CIM® disks of 12 mm diameter and 3 mm thickness, it was found that there is a pressure drop of about 0.5 bar per each ml/min. A low-pressure drop is very important for working at high flow rates. Because the mass exchange is not a limiting factor, the gradient can be adjusted in a way to optimally match the thickness of the monolithic disk. In this way, efficient separations in a very short time can be obtained. The extremely short separation times were investigated by Strancar et al.[11] (Fig. 2). The authors were able to separate a mixture of proteins within a few seconds at room temperature. For even faster separations, current HPLC equipment becomes a bottleneck.

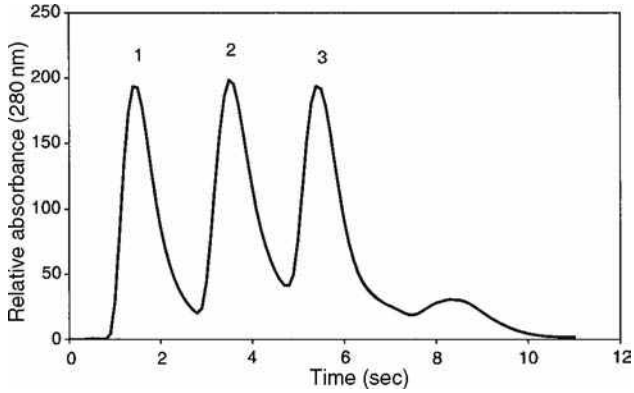

Fig. 2 Separation of test proteins in seconds on a CIM® QA disk monolithic column. Conditions—buffer A: 20 m*M* Tris–HCl buffer, pH 7.4; buffer B: 1 *M* NaCl in buffer A, pH 7.4; flow rate: 10 ml/min; detection: UV at 280 nm; gradient: step gradient at 0%, 20%, and 50% buffer B for 2 sec each; sample: (1) myoglobin (0.5 mg/ml), (2) conalbumin (1.5 mg/ml), (3) soybean trypsin inhibitor (2 mg/ml); injection volume: 20 μl.
Source: From Application of compact porous disks for fast separations of biopolymers and in-process control in biotechnology in Anal. Chem.[11]

Another consequence of the very fast mass exchange between the mobile and the stationary phase are the flow-independent characteristics of these units. In Fig. 3a, the comparison of a protein separation performed at flow rates from 2 up to 8 ml/min is shown. As can be seen, the chromatograms overlap, indicating no loss of separation efficiency. Similar results were achieved for the dynamic binding capacity. In Fig. 3b, breakthrough curves are presented. Again, they match closely, indicating a constant binding capacity.

Because of their small thickness, one might speculate that the monolithic disks can only separate a few substances during a chromatographic run. However, by precise gradient adjustments, more than 10 substances can be separated in a few minutes. In Fig. 4, a separation of 14 oligonucleotides was performed in 3 min at room temperature[12]—a feat hardly achievable with a conventional particulate column.

Monolithic structures enable two additional interesting features. Because of their defined dimension, several monolithic disks can be stacked together forming a single chromatographic column. Such a column has much better performance in comparison to a group of several columns in series comprising a single monolithic disk.[13] In this way, the capacity of the column increases linearly. It is important to note that this can be performed by the user without any additional equipment. Several disks also increase the column length, resulting in an increased number of theoretical plates and, consequently, better

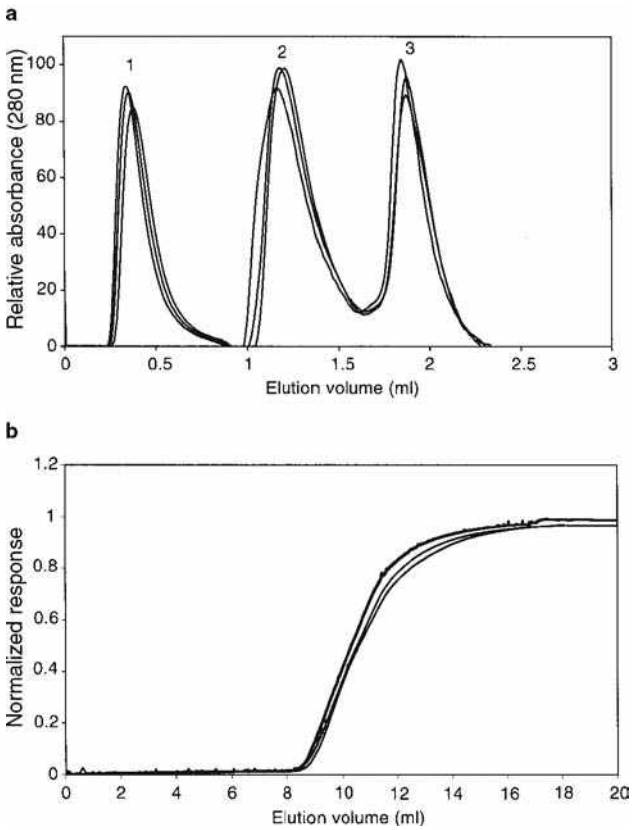

Fig. 3 Flow characteristics of the monolithic disks: (a) flow-independent resolution and B flow-independent dynamic binding capacity. A Conditions—buffer A: 20 m*M* Tris–HCl buffer, pH 7.4; buffer B: 1 *M* NaCl in buffer A, pH 7.4; flow rate: 10 ml/min; detection: UV at 280 nm; gradient: 0–70% buffer B in 30 sec; sample: (1) myoglobin (0.5 mg/ml), (2) conalbumin (1.5 mg/ml), (3) soybean trypsin inhibitor (2 mg/ml); injection volume: 20 μl. (b) Conditions—binding buffer: 20 m*M* Tris–HCl buffer, pH 7.4; flow rate: 2, 4, and 8 ml/min; detection: UV at 280 nm; sample: human serum albumin dissolved in buffer A (1 mg/ml).

efficiency in isocratic separation. In Fig. 5, a separation of organic acids with a monolithic column consisting of four monolithic disks is presented.

A similar approach using monolithic disks of different chemistries enables multidimensional separations. This approach, using monolithic disks, was called conjoint liquid chromatography (CLC).[13] The main advantage is that these columns can be reconstructed by placing the disks in a different order or exchanging some of the disks. This is possible because the stationary phases bearing different chemistries do not mix. An example of such a separation is shown in Fig. 6, applying affinity and ion-exchange disks in a single column.

The features clearly indicate that the monolithic disks enable efficient separations and purification of different types of molecules. This is demonstrated in a number of examples where these columns were used in the separation of complex biological mixtures.

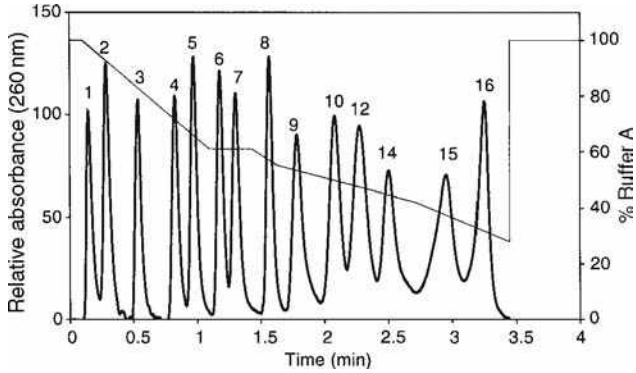

Fig. 4 Separation of oligomers using optimized gradient conditions. Conditions: mobile phase—buffer A: 20 m*M* Tris–HCl buffer, pH 8.5; buffer B: 1 *M* NaCl in 20 m*M* Tris–HCl buffer, pH 8.5; flow rate: 4 ml/min; stationary phase—CIM disk monolithic column comprising of a single disk; sample: oligonucleotides of different lengths (see the section, "Chromatographic Characteristics of Monolithic Disks"). Number near the peak represents the oligonucleotide length. Gradient: as shown in the figure; injection volume: 20 μl; detection: UV at 260 nm.

APPLICATION OF MONOLITHIC DISKS

Monolithic disks have been successfully used in the separation of different types of molecules. Most of the applications, however, deal with the separation of proteins. Initially, the studies were conducted with test solutions to

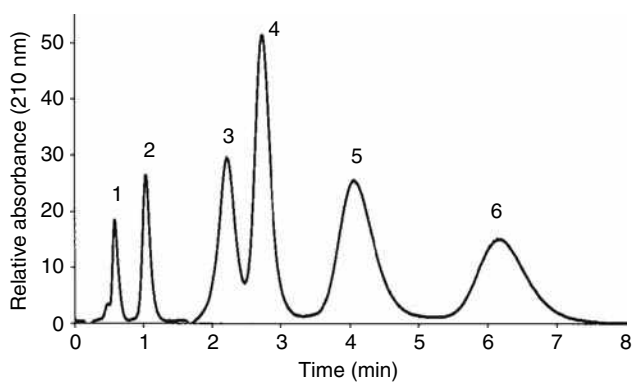

Fig. 5 Separation of the organic acid on CIM disk monolithic column. Conditions—mobile phase: 130 m*M* NaCl in 20 m*M* phosphate buffer, pH 8.0; separation unit: CIM® disk monolithic column comprising of four CIM® QA disks; flow rate: 5 ml/min; sample: (1) 0.03 g/L pyruvic acid, (2) 0.5 g/L malic acid, (3) 0.2 g/L α-ketoglutaric acid, (4) 0.007 g/L fumaric acid, (5) 2 g/L citric acid, and (6) 2 g/L isocitric acid; injection volume: 20 μl; detection: UV at 210 nm.

prove the power of the separation media, but many applications with real samples have also been reported. All of these separations were performed in a short period of time, typically a few minutes or even less. Some of the representative ones are described.

Ion-Exchange, Hydrophobic, and Reverse Phase High-Performance Liquid Chromatography Disk Monolithic Columns

Separation of proteins

There are several reports about the application of the disk monolithic columns for the separation and purification of plasma proteins.[14,15] Purification and monitoring of clotting Factor IX (FIX) from human plasma were performed using the ion-exchange monolithic disks. In addition, separation of vitronectin from FIX was possible. A similar system was used for the separation of a complex between clotting Factor VIII and von Willebrand factor (FVIII–vWF). Another application was the monitoring of α_1-antitrypsin production. Separation of impurities such as human serum albumin and transferrin was achieved in a few minutes.

Another well-studied system was the monitoring and purification of extracellular ligninolytic enzymes from the fermentation broth of fungus *Phanerochaete chrysosporium*. Again, the ion-exchange disk monolithic columns were used. The different enzyme isoforms present in a fermentation broth have similar molecular weights. An efficient separation was achieved in a few minutes, thus reducing the required separation time by an order of magnitude, as compared with a conventional column. The purities of the isoforms were comparable using monolithic vs. conventional columns. The method was also used for monitoring the isoenzyme profiles during the fermentation process.[16]

Separation of polynucleotides

Monolithic disks seem to be very efficient columns for the separation of polynucleotides. They enabled not only the separation of pDNA from RNA, but also the separation of pDNA isoforms: supercoiled, open circular, and linear forms.[14] Besides a separation time of only a few minutes, the most outstanding characteristic of the monolithic disks is their high dynamic binding capacity for pDNA, which is in the range of 10 mg/ml of support.[6] In addition, the monolithic disks seem to be very attractive for the purification of even larger molecules, e.g., viruses.[6]

Small molecules

While most of the papers deal with the separation of large molecules, a few successful separations of small molecules were recently reported.[14] By stacking several disks of the same chemistry into a single monolithic column, it was possible to apply it for monitoring the organic acid formation during the fermentation of yeast *Yarrowia lypolitica*.[17] A similar column was used for the determination of Mn^{3+} tartrate complex in a fermentation medium of *P. chrysosporium*. Very recently, the separation of Zn complexes of citrate, oxalate, and EDTA, as well as hydrated Zn^{2+} species, was compared on an ion-exchange disk monolithic column and Mono Q. The former was found to be more efficient.[18]

More information about the applications of the monolithic disk columns can be found in several reviews.[14,15,17,19]

Affinity Monolithic Columns

Methacrylate-based monolithic disks are very suitable for the immobilization of various ligands because they contain epoxy groups which form very stable covalent bonds with the amino or sulfhydryl groups of the ligand. Recently, an extensive description of different immobilization procedures was published.[20]

Low molecular mass ligands

The first report about the immobilization of a small affinity ligand on monolithic disks was published in 1991.[21]

Immobilized *p*-(amino methyl) benzol sulfonamide, a carbonic anhydrase inhibitor, was used for the purification of carbonic anhydrase. The immobilization of various peptides, including the hormone bradykinin, on a CIM® disk monolithic column, was performed to investigate the possibility of purifying monospecific polyclonal antibodies in serum. Several disks, each with a different immobilized peptide, were placed in a single housing. This CLC approach demonstrated that the simultaneous loading of immunoglobulins can be performed in a few minutes. The specific immunoglobulins were then released from each monolithic disk separately.[21]

An important issue related to the small affinity ligands is their utilization (capacity per unit of ligand) on the matrix. Because of their size, they are more sensitive toward matrix composition and immobilization chemistry in comparison to large affinity ligands. A detailed study of the characteristics of a model peptide with affinity to chicken egg lysozyme immobilized to different supports such as agarose, cellulose, and methacrylate-based supports and via different immobilization chemistries revealed that the highest utilization of the ligand was achieved with the methacrylate-based monolithic disks.[15] This means that the ligand is optimally presented on the matrix surface, which additionally facilitates mass transfer between the mobile and stationary phases.

High molecular mass ligands

Different high molecular mass affinity ligands were successfully immobilized to monolithic disks.[14,20,21] Monolithic disks with immobilized heparin and collagen were used for the purification of membrane proteins and annexins. The heparin unit was also used in the quality control of the preparation of the plasma proteins Antithrombin III and clotting Factor IX. Purification of IgG was successfully performed by immobilizing Protein A, Protein G, and Protein L.[14,20] Because the elution is carried out under harsh conditions, which might cause denaturation, the fast separation enabled by the monolithic disks decreased such a risk. Indeed, the separation on a monolithic disk was performed within a few seconds.

Affinity monolithic disks were not only used in combination with an HPLC system, but also for the monitoring of specific compounds as part of an FIA system. The use of the monolithic disks is beneficial because it is compatible with high flow rates at low to medium pressure, has little to no dependency on the flow rate, is compatible with typical bioprocess samples, has long-term stability, and performs stable immobilization of highly active biologicals such as antibodies and enzymes.[20] The monitoring of recombinant protein G concentrations from a cell lysate of *E. coli* was performed using monolithic disks with immobilized IgG. A similar approach, this time with the enzyme glucose oxidase immobilized, was used for the monitoring of the glucose concentration in a fermentation broth.

Monolithic Disks as Bioreactors

Enzymes immobilized to monolithic disks were not applied only as biosensors, but also as bioreactors.[20,21] The first report, in 1991, describes the immobilization of carbonic anhydrase. Interestingly, an increase in enzyme activity with the increase of flow rate through the bioreactor was observed. Recently, the immobilization of trypsin was reported. Contrary to the previous work, increased flow rate diminished the extent of protein degradation. In contrast to the previously mentioned experiments, where the immobilized enzyme was used for substrate degradation, the synthesis of polyriboadenylate from ADP was studied by polynucleotide phosphorylase immobilized on a monolithic disk.

SCALE-UP OF MONOLITHIC DISK

An obvious approach for scaling-up the monolithic disks is by increasing their diameter. Because of the mechanical properties, however, this approach seems not to be the most appropriate one. The problem of increasing the volume while preserving the short column length was solved with the introduction of the tubular monolithic columns. Furthermore, with the introduction of the tube-in-tube approach, the CLC approach can also be scaled. Detailed information about the preparation and characteristics of the tube monolithic columns can be found elsewhere.[6,22]

CONCLUSIONS

Monoliths represent a novel stationary phase with advantageous chromatographic characteristics. Monolithic disks have proven to be very efficient separation media despite their short column length. Their main advantage is an extremely short separation time. This makes them a promising tool for the in-process monitoring of, for example, preparative chromatographic purification or bioprocesses, where fast analyses of complex mixtures are required to perform real-time actions. In addition, they are well suited for the very fast purification of small quantities of labile compounds, as well as in the fast development of chromatographic methods adapted to a preparative purification on larger monolithic columns.

Monolithic Stationary Supports: Preparation, Properties, and Applications

Aleš Podgornik

M. Barut
A. Strancar
BIA Separations d.o.o., Ljubljana, Slovenia

INTRODUCTION

Chromatographic monoliths are a specific type of chromatographic stationary phase. In contrast to conventional, particle shaped supports, they consist of a single piece of porous material. The pores form a highly interconnected network of open channels through which the mobile phase flows. Therefore, the main transport mechanism of the molecules to be separated is convection. Because of this, mass exchange between the mobile and stationary phase is very fast, similar to that in the membrane supports. In contrast to the membranes, however, monoliths can be prepared in various shapes and dimensions. Besides convective transport, monoliths also exhibit several other unique features:

- Their dynamic porosity greatly exceeds the porosity of the particle shaped supports, reaching values up to 90%.
- Due to their surface accessibility, their dynamic binding capacity is high, especially for very large molecules.
- Their separation, resolution, and dynamic binding capacity are unaffected by the linear velocity, at least within the applicable flow rates.
- Preparation of monolithic columns is easy since there is no need for sieving as is generally required for particles; also, there is no need for column filling, since the monoliths can be prepared in situ in the column housing.

MONOLITHS

Because of their many advantages, monoliths have been implemented in several areas of separation science. Since they can be easily covalently bound to a surface, they are an almost ideal matrix for the preparation of flow-through microchips or capillaries. In fact, several excellent applications in this field have appeared recently.[1–7]

Monoliths are also extensively used on an analytical scale. Silica-based monoliths, commercialized under the trade name Chromolith® (Merck, Darmstadt, Germany), exhibit high resolving power, combined with a very low pressure drop and seem to be an ideal support for many small molecule applications.[8] On the other hand, methacrylate based monoliths, commercialized by BIA Separations (Ljubljana, Slovenia) under the trademark CIM Convective Interaction Media®, are widely used for separation and purification of large molecules such as proteins, DNA, or even viruses.[9]

Despite the significant success of the monoliths on a micro- and analytical scale, few reports in the literature describe applications of large volume monoliths. This is rather surprising, since one would expect that the combination of low pressure drop and flow, unaffected resolution, and especially, dynamic binding capacity, resulting in high productivity, are attractive features for any purification process. The lack of large monolithic units may therefore be attributed to the difficulties related to their preparation.

In fact, very few reports can be found about the preparation of large monolithic columns. Basically, scaling-up of three types of monoliths has been attempted. Silica monoliths have been scaled in the format of conventional chromatographic columns. The largest reported silica monolith has a dimension of 100 × 25 mm, with the volume close to 50 ml.[10] This seems to be close to the upper limit of thickness, since no further scale-up is reported. Preparation of silica monoliths consists of several steps, including the heating of the skeleton up to several hundred degrees Celsius to obtain a proper monolithic structure. For large monoliths, this is a challenging task, since any significant temperature gradients inside the monolith, occurring during heating or cooling, might cause formation of cracks in the structure. Such deformations inevitably cause irregularities in the flow of the mobile phase passing through the monolith, thereby resulting in a decrease of column efficiency. Despite these difficulties, 50 ml silica monolithic columns were successfully implemented in several processes, including simulated moving bed (SMB) technology.[11]

Other reports concerning preparation of large monoliths are related to agarose and methacrylate monoliths. Both types of monoliths are prepared by polymerization, which is an exothermic process that releases significant amounts of heat during the reaction. Temperature gradients formed inside the polymerization mixture during the polymerization process cause deformations in pore size distribution. Consequently, the efficiencies of such units are significantly decreased. There are basically two approaches reported in the literature, suggesting possible solutions for this problem. Peters, Švec, and Frechet[12] suggested preparation of the methacrylate monoliths via slow addition of the polymerization mixture to avoid a temperature increase inside the monolith during the polymerization itself. By properly adjusting polymerization conditions, they were able to prepare monoliths with uniform pore size distribution. Unfortunately, no information about the chromatographic properties or applications of the obtained monolith is given, and there are no reports about further development of the proposed method.

An alternative approach was suggested by Podgornik et al.[13] They implemented radial flow mode and introduced monolithic columns of a well defined thickness. A similar idea was later implemented for the preparation of agarose monolithic columns,[14] which were applied to pseudoaffinity chromatography using Cibacron Blue 3GA as a ligand and as bioreactors with the immobilized enzyme β-galactosidase.

In the following section, details about large volume radial flow methacrylate monolithic columns and the strategy for their preparation are presented.

DESIGN OF LARGE VOLUME RADIAL METHACRYLATE MONOLITHIC COLUMNS

Currently, there is still an ongoing discussion about the proper ways for scaling up the chromatographic columns. To preserve constant quality of the product, as an ultimate goal, several criteria have been proposed, among them constant column height or length, constant residence time, constant L/d_p ratio, etc.[15] Although proposed for conventional chromatographic columns, they can also be applied for the monolithic columns. For some of them, as for the L/d_p criterion, for which the particle diameter should be determined, implementation on the monoliths is not obvious, since it is difficult to define a particle diameter. However, there are still some characteristic dimensions that can be used instead of d_p. For the silica monoliths, Tallarek, Leinweber, and Siedel-Morgenstern[16] described a phenomenological approach, i.e., introducing an equivalent of the particle diameter based on the estimation of friction factor. For methacrylate monoliths, effective d_p was estimated from the measurement of peak broadening and pressure drop.[17]

Besides the abovementioned approaches, methacrylate based monoliths were scaled up following two additional ideas:

- They are mainly intended for the separation and purification of large molecules.
- Their structure should be similar regardless of the size.

Separation of macromolecules has several peculiarities that significantly influence the design of the chromatographic columns. Large molecules normally interact with the surface via several points. Consequently, their adsorption isotherm is extremely steep, almost rectangular. Because of this, there is only a very narrow mobile-phase window within which they can be eluted under isocratic conditions. Therefore, mobile phase gradients are normally applied. For this type of elution, the column length does not play a significant role. In fact, there is an optimal column length for a given system and gradient slope, which can be very short for large molecules,[18] and one can be flexible regarding the column length as well as the design.

The main reason to preserve the structure of the monolith on different scales is to make the transfer of chromatographic methods very simple and straightforward. Keeping a constant structure, the resin efficiency, normally measured in terms of height equivalent of theoretical plate (HETP), is also kept constant. Therefore, method transfer time can be significantly shortened since fewer experiments are required.

The structure of the methacrylate monoliths depends on several factors, e.g., the composition of the polymerization mixture and the polymerization temperature. The latter parameter, especially, is a very powerful tool, since different structures can be obtained without changing the chemical composition of the monolith. The main reason for such a significant influence of the temperature on the monolith's structure is the initiator degradation rate. During degradation, free radicals are released. The higher the temperature, the more radicals are formed per unit time, initiating formation of a larger number of nuclei that grow continuously. Because the total amount of monomer is limited, the larger number of the nuclei means that they are smaller, resulting in smaller pores. This process is extremely sensitive, since change of the polymerization temperature, e.g., 8°C, shifts pore size by almost an order of magnitude.[9] Being an excellent tool for tailoring monolith structure, temperature also represents one of the main problems in the preparation of large volume methacrylate monolithic columns.

Methacrylate polymerization is a highly exothermic reaction, releasing, in the particular case of methacrylate monoliths, around 190 J/g of heat.[19] Since preparation of the monoliths proceeds through bulk polymerization, the heat generated cannot be dissipated fast enough;

therefore, an increase of temperature occurs inside the polymerization mixture during the polymerization. At the maximal polymerization rate, the increase can be as high as 80°C.[9] Taking into account that even one-tenth of this value dramatically changes the pore diameter, it is clear that such increase results in extremely non-homogeneous pore distribution.[9]

To obtain uniform monolithic structure, the temperature increase should be small and well controlled. Since one cannot enhance heat dissipation by stirring, because it would destroy the monolithic structure, or change the physical properties of the polymerization mixture, the monolith thickness is limited.

The appropriate maximal monolith thickness was determined by mathematical modeling. Heat is released through chemical bond formation during polymerization. Therefore, the amount of heat released should be proportional to the reaction kinetics. By measuring the heat release, we were able to determine the reaction order as well as heat release per unit volume of polymerization mixture. Details about determination of reaction kinetics and mathematical modeling can be found elsewhere.[19,20] The outcome of the model is the maximal allowed monolith thickness providing uniform monolith structure, together with the time required to complete polymerization over the entire monolith volume.

As already stated, CIM monoliths were developed to be used for purification of large molecules, typically proteins, oligo- or polynucleotides, or viruses. Therefore, columns with rather short beds can be used. Since we are no longer bound to a chromatographic column of substantial length, different scale-up designs are possible. Especially, three seem to be suitable: rod format, disk format, and tube format. As described in detail elsewhere,[21] the tube format was found to be the most advantageous, since it gives a high degree of flexibility (tube diameter as well as tube height can be varied) combined with a low pressure drop. This is the main reason for the construction of tubular shaped, large volume methacrylate monolithic columns. Currently, four different volumes, specifically 8, 80, 800, and 8000 ml monolithic columns, are constructed, comprising the monoliths shown in Fig. 1. Details about the column features are described elsewhere.[22]

Despite the limitation of the monolith thickness related to the preparation problems, cylindrically shaped monoliths of desired thickness can be easily constructed, by polymerizing several cylinders of appropriate dimensions and inserting one into another, the so-called "tube-in-tube" approach, as shown in Fig. 2. Furthermore, each of the cylinders can have a different chemistry; therefore, a multidimensional chromatographic column, named the conjoint liquid chromatography

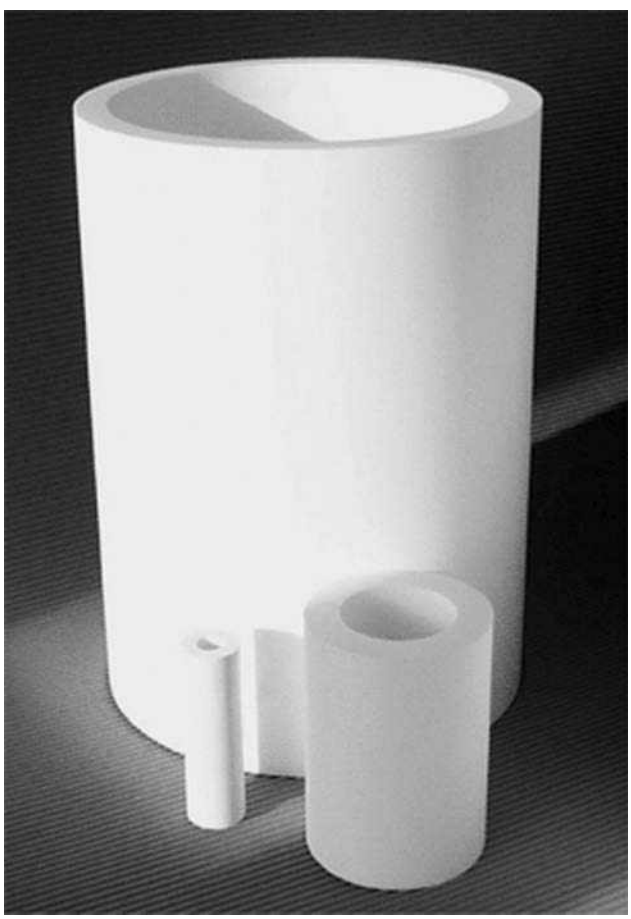

Fig. 1 Large volume cylindrical shaped methacrylate monoliths of volume 80, 800, and 8000 ml. The largest, the 8000 ml monolith, has a height of 41.5 cm and an outer diameter of 30 cm.

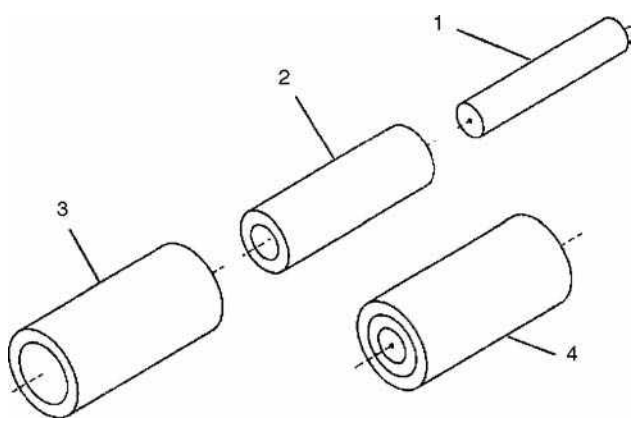

Fig. 2 Construction of a large volume methacrylate monolithic unit of desired thickness. The monolithic unit (4) consists of three monolithic cylinders (1, 2, and 3). The total thickness of the unit (4) is the sum of the thicknesses of monoliths 1, 2, and 3.

(CLC) column for the methacrylate monoliths, can be prepared. In this way, extracolumn broadening, which occurs when several columns are connected in series, is significantly reduced.[23]

RADIAL, LARGE VOLUME METHACRYLATE MONOLITHIC COLUMNS AND THEIR PROPERTIES

To exploit all benefits of the tubular approach, the commonly applied axial flow of the mobile phase has to be changed to a radial one. Entering into the chromatographic column, the mobile phase is directed into the channel extending over the entire outer surface of the monolith. In this way, the mobile phase is uniformly spread over the monolith. Since the monolith is sealed between two plates, the only possible course for the mobile phase is to penetrate into the monolith pores. After passing through the monolith, the mobile phase is collected in the middle hole and directed into the capillary connected with the column exit. The construction is shown in Fig. 3. In this way, the entire monolithic bed is uniformly used. This can be concluded from the capacity per monolith unit, which is the same as that for the monolithic disks of 0.34 ml volume operating in an axial mode.

As already mentioned, tubular shaped monolith can be prepared in various thicknesses by using a "tube-in-tube" approach. Since a radial chromatographic mode is applied, the linear velocity of the mobile phase increases when passing through the monolith.[13] In the case of particle shaped supports, change of linear velocity results in a change of column efficiency, according to the Van Deemter equation. For the monoliths, due to extremely fast exchange between the mobile and stationary phase, diffusion limitations can be neglected, thereby resulting

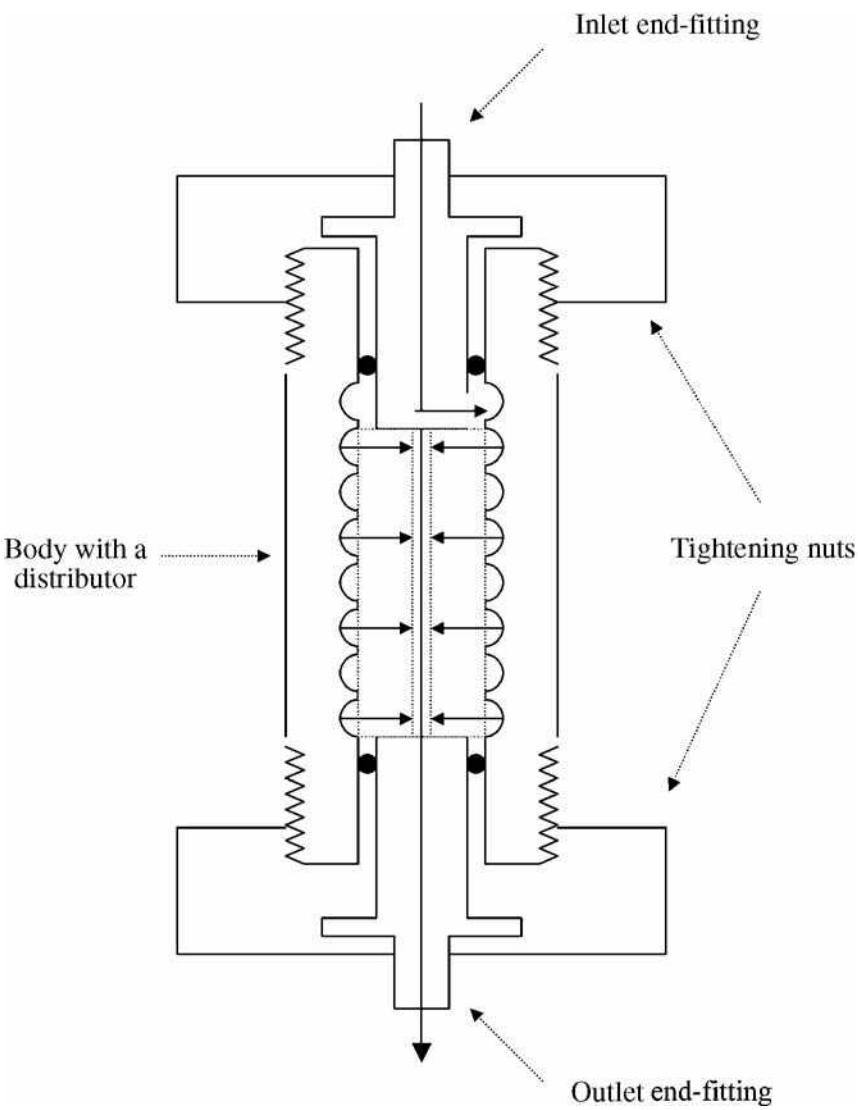

Fig. 3 Schematic representation of the housing for a radial monolithic column. A housing comprises inlet and outlet end-fittings, two tightening nuts and a body with distributor. Four O rings (black circles) assure proper sealing. Solid arrows indicate the direction of the mobile phase.

in flow-independent resolution and dynamic binding capacity. Jungbauer and Hahn[15] investigated the bed usage for the 8 ml tubular shaped monolithic column, assuming a certain linear velocity (critical velocity) beyond which diffusion restrictions become significant. They showed that, for a critical velocity of 1500 cm/hr, which is equivalent to 40 CV/min, over 99% of the bed is used. Such a high flow rate cannot be employed in practice since pressure drop becomes a process bottleneck. These theoretical findings are also experimentally confirmed. Fig. 4 shows that the change of the linear velocity, indeed, does not change either the resolution or the dynamic binding capacity. Therefore, although radial flow is implemented, one cannot distinguish, by performance, a radial monolithic column from an axially operating column.

So far, radial monolithic columns have been successfully implemented for purification of various types of macromolecules. In the field of proteins, anion exchange tubular monolithic columns were used for purification of lignin peroxidase isoforms,[24,25] having very similar molecular masses and isoelectric points, as shown in Fig. 5. Using a combination of pH and salt gradient, purification of manganese peroxidases was also possible.[25] There are several reports describing implementation of radial monolithic columns for purification of clotting factors from human plasma. A quaternary amine (QA) 8 ml unit was used for purification of factor VIII,[26] while an up to 500 ml. DEAE unit was used for purification of clotting factor IX,[27,28] as demonstrated in Fig. 6. All purifications were completed in a shorter time in comparison to those

performed with conventional particle based supports. Large monolithic columns were also successfully used for purification of pDNA.[29] In this case, speed is also accompanied by an extremely high binding capacity,[30] making these columns an attractive option for the purification of polynucleotides.

CONCLUSIONS

Monolithic columns combine several features, such as high porosity, flow-independent resolution, and dynamic binding capacity, which make them very suitable for purification of large molecules. Although preparation of large volume monoliths with uniform structure is a challenging task, using a mathematical modeling approach and appropriate column design, this problem has been successfully solved. Such columns, with volumes up to 8 L, operate at low pressure drop and have already been successfully implemented in an industrial process for pDNA purification. Because of their useful properties, it is expected that they will also be applied in other processes involving macromolecule purification, including purification of viruses.

Multidimensional Separations

Haleem J. Issaq
National Cancer Institute at Frederick (NCI-Frederick), National Institutes of Health (NIH), Frederick, Maryland, U.S.A.

Abstract
Chromatography in all its formats is capable of resolving a simple mixture using one procedure. However the resolution of a complex mixture requires the use of two orthogonal procedures. Here we discuss two-dimensional thin-layer chromatography (TLC), gas chromatography (GC), and high-performance liquid chromatography (HPLC) that have been used for the separation of plant extracts, environmental samples, and cell and serum protein digests to mention a few. Mainly the first dimension is fractionation to simplify the complexity of the mixture while the second dimension is used to enhance the separation of the fractions. Both dimensions have different mechanisms of separation, i.e., they are orthogonal.

INTRODUCTION

Since the separation of a complex mixture is not possible using a single chromatographic or electrophoretic procedure, researchers investigated multidimensional strategies using two-dimensional (2-D) electrophoresis (2DE), 2-D chromatography, or a combination of both. Though we tend to think of multidimensional separations as a recent venture, analytical and bioanalytical chemists began developing better methods to achieve maximum resolution of a complex mixture over half a century ago. Scientists realized the significant advantages of multidimensional separations using one chromatographic mode for fractionation, normally the least resolving mode, followed by a second orthogonal (different selectivity) mode to separate the resulting fractions. Fractionation of a mixture by chromatography or electrophoresis is achieved by manipulations of: 1) the mobile-phase properties, such as slope (time) of the gradient, organic modifier, buffer pH, salt concentration; 2) column chemistry, such as reversed phase, ion exchange, size exclusion, normal phase (e.g., silica), hydrophobic interaction (HILIC), or affinity (e.g., antibody, lectin, aptamer, metal, DNA, etc.); and 3) ampholyte pH range and gel properties in electrophoresis.

The basis for developing multidimensional chromatographic approaches to separate complex mixtures is the work of Martin and his colleagues,[1] using paper chromatography to separate wool hydrolysate. The hydrolysate was applied at one corner of the square filter paper and developed in collidine for 3 days, taken out and dried, turned 90°, and then developed in phenol for 27 hr. A similar approach was also used to separate a mixture of the hydrochlorides of 22 amino acids.

In 1956, Smithies and Poulik[2] realized that "a combination of two electrophoretic processes on a gel at right angles should give a much greater degree of separation than is possible with either separately." Giddings defined 2-D separations as "those techniques in which a sample is subject to two displacement processes oriented at right angle to one another."[3] He also stated that "multidimensional chromatography, or generally multidimensional separation, provides a means of greatly enhancing the peak capacity and thus the resolution of the components of a complex mixture, and that the peak capacity of a multidimensional separation is the product of the peak capacities of its component one-dimensional methods."[4] The multidimensional system selected should allow analysis of the whole sample, and not just selected parts of the first-dimensional fraction, as in heart-cutting procedures that are used in high-performance liquid chromatography (HPLC)[5] and gas chromatography (GC)[6] where only regions of interest are transferred from the first column to a second column for enhanced separation.

OVERVIEW

Multidimensional separations are carried out online or off-line. In an off-line approach, samples are collected as they emerge from the first-dimension column at a specified time and are analyzed using a second orthogonal dimension. There are advantages and limitations to each. An online approach does not generally allow specific fractions to be reanalyzed by complementary techniques. While off-line methods do not approach the speed of online methods, they are typically easier to perform, large samples can be readily analyzed, many different column chemistries and sizes can be used, and collected fractions can be reanalyzed as needed.

Multidimensional chromatographic analyses have been carried out by: 1) thin-layer chromatography (TLC); 2) GC; and 3) HPLC. A few selected examples are presented for each.

1. **Thin-Layer Chromatography (TLC × TLC)**
   TLC is amenable to 2-D separations, preferably by either changing the mobile phase or using a plate that has two different chemistries side by side on the same plate. The 2-D experiment is achieved by successive developments in two perpendicular directions, using two retention mechanisms.[7] Multimodal multidimensional TLC separations are achieved by using plates that have two side-by-side different selectivity groups where the compounds are developed in the same mobile phase or two different mobile phases, or by using plates coated with a single stationary phase such cyano-, amino-, or phenyl-modified silica, which can be developed in two different mobile phases.[8] For example, multimodal TLC separations on a cyano-modified silica gel plate were reported for the separation of Taxol and cephalomannine in a methylene chloride extract of *Taxus brevifolia*.[8] In the first-dimension separation (adsorption), using a mobile phase of methylene chloride:hexane:acetic acid (9:10:1), the plate was dried, turned 90°, and developed in the second dimension (reversed phase) in a mobile phase made of water:acetonitrile:methanol:tetrahydrofuran (8:5:7:0.1). Two side-by-side stationary phases (silica and C-18 reversed phase) plate was used to separate a natural product extract.[9] The first development was done on the silica side, using hexane:acetone (3:2), and the second development was done on the C-18 side, using (85:15) acetonitrile:water.[9]
2. **Gas Chromatography (GC × GC)**
   Separation in GC is achieved by taking advantage of the differences in solute polarity or vapor pressure (i.e., by changing the column temperature). Most of the commercially available columns work on this principle. Another property of the solute that can be used to separate a mixture is the geometry of the molecule (i.e., the length-to-breadth ratio), using a liquid-crystal column. Solutes that elute together on a column that is based on polarity or vapor pressure are resolved on a liquid-crystal column because of differences in their geometry. GC × GC can be done using the heart-cutting technique, whereby selected regions of interest from the first-dimension separation are transferred to the second dimension, or by continuous comprehensive 2-D separation, whereby the total effluent of the first column is transferred to a second column of different selectivity for maximum resolution.

   Issaq, Fox, and Muschik[6] used a low-polarity column (DB-1) in the first dimension and a smectic liquid-crystal column in the second dimension for the separation of coeluting congeners of Aroclor 1242, 1254, and 1260, using the heart-cutting technique. This procedure requires the use of a gas chromatograph equipped with two independent ovens for optimizing the temperature conditions of each column. Excellent baseline separations of the congeners were achieved on multicuts, up to six cuts, of the same injection. This unique 2-D/multimodal capillary GC system, in which the two separation modes of vapor pressure and molecule geometry are employed, is a powerful analytical technique for the separation of complex volatile organic mixtures.

   Comprehensive GC × GC was first introduced in 1991 by Phillips and Liu.[10] In this 2-D GC approach, after completing the separation on the first column, the chromatographer, performs the separation on a different column. The critical, practical part of this approach is the ability to preserve the separation from the first-dimension column while enhancing the separation on the second column. The advantage of GC × GC is that the total mixture is subjected to two orthogonal separation procedures. These procedures result in maximum separation and give every component in the mixture two retention times, which enhances identification based on retention times. The principles and applications of comprehensive GC × GC were discussed by Marriott and Shellie.[11] Comprehensive 2-D GC was applied to the analysis of urban aerosols.[12] Samples were collected onto a glass-fiber filter, extracted by *n*-hexane/acetone, cleaned up on a silver-impregnated silica column, and analyzed by comprehensive GC × GC. A 20 m × 0.25 mm I.D. 5% phenyldimethyl-polysiloxane column was used for the first dimension and a 1 m × 0.1 mm I.D. 14% cyanopropyldiphenylmethylpolysiloxane column was used in the second dimension. Columns were connected to each other by specially made low-volume press fit connectors. A few polycyclic aromatic hydrocarbons and oxygenated polycyclic aromatic hydrocarbons were identified and quantified.
3. **HPLC (HPLC × HPLC)**
   HPLC, with all its different modes of separation [normal phase, reversed phase, ion exchange, size exclusion chromatography (SEC), and HILIC], is well suited for 2-D, or even 3-D. The separation can be carried out online by connecting two different selectivity columns in series or by packing a single column with two different selectivity materials.

   Opiteck et al.[13] and Opiteck and Jorgenson[14] described the 2-D HPLC system for separating complex protein mixtures that used two columns connected in series—the SEC column for the first dimension and the RP column for the second dimension. Peaks eluting from the SEC column were automatically introduced into the RP column to separate similarly sized proteins on the basis of their hydrophobicity.

   A second approach to an online 2-D HPLC separation is the use of a single column packed with two different materials at opposite ends. Washburn

et al. used a single capillary packed with strong cation exchanger (SCX) and RP particles to separate a complex mixture of peptides.[15] A major advantage of this separation technology is that the entire system is coupled directly online with a mass spectrometer (MS), enabling a large number of peptides to be directly identified in a high-throughput manner.

A third approach to 2-D HPLC is an off-line approach that uses two different selectivity columns. In this approach, fractions are collected at specific periods as they elute from the first column and then the fractions are each injected into the head of a different selectivity column and separated. Blonder et al. described a 2-D HPLC procedure for the identification of membrane proteins from mammalian cell/tissue.[16] After extraction, the proteins were digested with trypsin. The resulting peptides were analyzed by SCX in the first dimension, and fractions eluting from the column were collected every minute with the aid of a fraction collector, and were injected on an RP column and detected by MS.

Although 2-D strategies are the most popular methods of enhancing the separation of complex mixtures, there have been experiments that employed a 3-D approach. For example, a protein extract of mouse serum was first fractionated by ion exchange (IEX). Protein fractions were collected, digested with trypsin, and were subfractionated using SCX. The resulting subfractions of peptides were analyzed by RPLC/MS.[17]

CONCLUSIONS

Chromatography in all its formats is capable of resolving a simple mixture using one procedure. However the resolution of a complex mixture requires the use of two orthogonal procedures. Two-dimensional TLC, GC, and HPLC have been used for the separation of plant extracts, environmental samples, and cell and serum protein digests to mention a few. Many approaches have been employed in which the first dimension is fractionation (to simplify the complexity of the mixture) while the second dimension is used to enhance the separation of the fractions.

Multidimensional TLC

Simion Gocan
Department of Analytical Chemistry, Babes-Bolyai University, Cluj-Napoca, Romania

INTRODUCTION

Since the introduction of thin-layer chromatography (TLC), there has been great interest regarding the increase of separation capacity (spot capacity). This interest was motivated by the separation of complex mixtures that contain a great number of compounds. Some of them are difficult to separate because they have similar properties.

TWO-DIMENSIONAL DEVELOPMENT

Two-dimensional thin-layer chromatography (2D TLC) involves the application of a single sample to one corner of a TLC plate, which is subjected to two development processes. The TLC plate is developed with the first mobile phase, dried, and redeveloped in an orthogonal (the plate rotated through 90°) direction with a second mobile phase having different selectivity characteristics. Thus, the components migrate from the point of application into a two-dimensional thin layer, ensuring more space for resolution compared to one-dimensional separation.

Two-dimensional TLC is an analytical separation technique recommended for the separation of sample of compounds that are difficult to separate in a single dimension. This technique has been mostly used for qualitative clinical and biochemical analysis, where high selectivity separation is required.

In 2D TLC, any spot can be defined by a pair of x and y coordinates; the quality of a separation can be established by comparing the distance between all pairs of spots in the chromatogram. High resolution will be obtained when the selectivity between the two directions will be significantly different. In practice, several methods have been used to achieve this purpose. The potential methods for obtaining two different separation mechanisms in orthogonal directions are the following:

1. Two eluent systems of different selectivities for the sample components are used and a single sorbent thin layer for two dimensions is developed.
2. Two sorbent layers (e.g., silica gel and reversed phase) as adjacent zones with different selectivities can be used. The sorbent layer for the first development is a narrow strip (reversed phase), and for the second development, it is a large surface (normal phase). A suitable eluent system has to be used for each sorbent layer.

There are other possibilities, but all of them have the same principle (i.e., the selectivities to be different in the two orthogonal developments). If the selectivities are close to each other, the 2D separation effect will be a diagonal arrangement of the spots. A separation will be considered better when the spots will be uniformly spread along the entire surface of the plate.

2D TLC is used for a great number of compounds. When spot capacity in the first direction is n_1 and is n_2 in the orthogonal direction, then the total spot capacity will be equal to $n_1 n_2$. Refs.,[1,2] should also be consulted for routine procedures.

MULTIPLE UNIDIMENSIONAL DEVELOPMENT

Multiple unidimensional development (MUD) is the simplest approach for enhancement of the separation capacity in TLC.[2] In this approach, the TLC plate is developed for a selected distance, then the plate is withdrawn from the developing chamber and the adsorbed solvent is evaporated before repeating the development process. MUD is a very versatile strategy for the separation of complex mixtures. The main feature of MUD is that it leads to an increase in the spot reconcentration mechanism. There is an optimum number of developments that provide maximum separation.

PROGRAMMED MULTIPLE DEVELOPMENT

The term *programmed multiple development* (PMD) was introduced by Perry et al.[3] for a TLC developing technique and defined as follows: A TLC plate is repeatedly developed in the same direction with the same solvent. Each development run is longer than the previous development step. Following each run, the layer is dried by radiant heat, optionally assisted by a flow of inert gas. The lower edge of the layer remains, at all times, in the contact with the solvent in the reservoir, which is shielded from the radiant heat. The solvent migration distance is controlled, programmed via the lengths of intervals between the heating cycles.

AUTOMATED MULTIPLE DEVELOPMENT

Automated multiple development (AMD) combines the advantages of MUD and mobile-phase gradient elution. This multiple development approach was improved by Burger,[4] who maintained the basic idea of development. The chromatogram is developed in the same direction, stepwise, over an increasing solvent migration distance, but changes all other characteristics. The characteristics of the AMD system, according to Burger, are as follows: An HPTLC plate is developed several times in the same direction with eluents differing in elution power. In general, the polarity of the eluent is decreased step by step over the solvent migration distance. Between each run, the plate is completely dried by vacuum.

Gradient elution in AMD starts with the most polar eluent and is varied toward decreasing polarity. Fig. 1a shows a typical universal elution gradient, made up of the three solvents: methanol, dichloromethane, and hexane. Fig. 1b illustrates the increasing duration of the development cycles. Time increments are chosen to obtain uniform increases of the running distance of ~3 mm/step.

Automated multiple development causes sample fractions to become concentrated into narrow bands. The eluent flows over the lower part of a sample before reaching the upper part, concentrating the sample in the top to bottom direction. This is due to the fact that molecules in the lower part of the sample zone start their upward movement earlier than those in the upper part of that sample zone each time the eluent front passes through that area. A strong solvent used at the beginning of AMD causes concentration effects similar to a plate with a concentration zone. The separation power is increased by factor of 3, as compared with regular highpressure TLC (HPTLC). The combination of the focusing effect and gradient elution results in extremely narrow bands. Their typical peak width is about 1 mm. This means that with the available separation distance of 80 mm, up to 40 components can be completely resolved (i.e., with a resolution greater than 1).

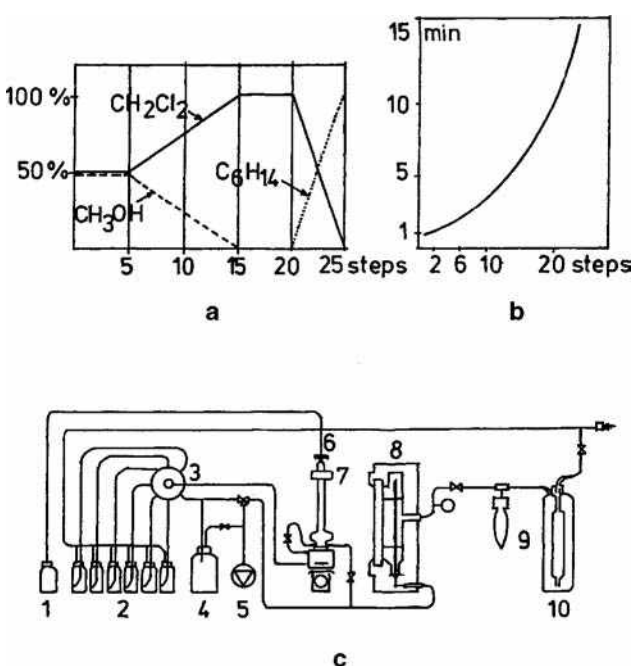

Fig. 1 (a) Typical universal elution gradient; (b) time of development vs. number of steps; (c) AMD system flow diagram.

DESIGN AND OPERATION OF AN AMD SYSTEM[5]

The Camag AMD system consists of two main components: the AMD developing unit (Fig. 1c) and the microprocessor-based controller. This system provides an AMD under reproducible conditions. For the AMD microprocessor-based controller, the following parameters may be chosen: the eluent composition, by selecting the number of solvent reservoir; the number of developing steps; the developing time for each step; the number of preconditions; the option of emptying the mixer after a selected step.

FUNCTIONAL PRINCIPLE OF THE AMD DEVICE

During the development process, the system is controlled by computer. The main component is an enclosed developing chamber (8), which is connected for introducing and withdrawing the developing solvent and for pumping the gas phase in and out. The six reservoir bottles (2) contain the individual solvent components. The gradient mixer (6) is connected, via motor valve (3), to reservoir bottles (2). The gas phase is made up externally by passing nitrogen through the wash bottle (l0) into the gas-phase reservoir (9). At the same time, the mixer is filled with solvent from the solvent reservoir bottle (1). Then, the chamber is equilibrated for 15 s with gas from the reservoir (9). The first step of development can start after filling the chamber (8) with the contents (8 ml) of the upper part of the gradient mixer (6), which is controlled by a light barrier (7).

Migration of the solvent in the layer starts immediately. At the end of the programmed time (determining the migration distance), the liquid solvent is removed by vacuum from the chamber (8) into the waste-collecting container (4). Then, after all liquid solvent has been removed, vacuum is applied by pump (5), thus drying the layer. The drying period is time programmed. Before the next developing cycle is started, the chromatographic thin layer is reconditioned by feeding the gas phase from the blender (9) into the chamber. After reconditioning the chamber, the next development step can start. While

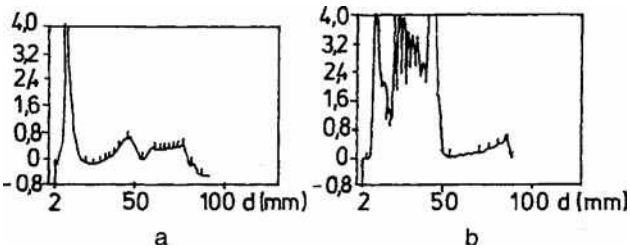

Fig. 2 Densitograms: (a) isocratic development TLC; (b) AMD-TLC.

the drying phase is carried out, the solvent for the next step is made up in the gradient mixer (6).

APPLICATION

When the sample components differ widely in their polarities, they can be separated by using a universal elution gradient. With AMD, it is possible to simultaneously analyze 12 samples. AMD-HPTLC has been applied for screening of pesticides from groundwater or drinking water and soil. A universal gradient based on dichloromethane was used to detect the presence of pesticides from different classes such as organochlorine, organophosphorus, carbamate, phenylureas, triazines, phenoxycarboxylic acids, and others. In this way, 283 pesticides were analyzed using this universal gradient.[6,7]

Plant extracts have a widespread application in the drug and cosmetic industries. For the separation of plant extracts, the AMD-HPTLC method is the most suitable because it has a higher separating power. Isocratic and AMD development are shown in Fig. 2.[8]

ON-LINE COUPLING OF HPLC/AMD-TLC

Combining different separation methods, governed by different separation mechanisms, to multidimensional methods is suitable for multiplying the potential of the individual techniques. Reversed-phase chromatography high-performance columns (RP-HPLC) can be coupled with normal phase TLC.[9,10]

PRINCIPLE

The system for mass transfer HPLC/TLC consists of a column filled with RP-C_{18} sorbent and a modified Linomat (Camag) sample spray unit for TLC. The effluent is transferred, via a capillary tubing, to a TLC applicator unit. While the effluent of the HPLC column is sprayed onto the thin layer with nitrogen, the plate is moved. The separation of 56 pesticide residues in drinking water in a single sample using RP-HPLC coupled with TLC and AMD has been demonstrated. For example, by AMD, a chromatogram of RP-HPLC cut no. 13 was separated and over 10 pesticides were detected through multiwavelength scanning by absorbance between 200 and 300 nm.[11]

Mycotoxins: TLC Analysis

Philippe J. Berny
Toxicology Unit, National Veterinary School of Lyon, Marcy L'Etoile, France

INTRODUCTION

Thin-layer chromatography (TLC) is a widely used analytical technique for many investigative purposes. Detection of mycotoxins by means of TLC has been in use for many years. Official methods of analysis often rely on these techniques for both identification and quantification of several mycotoxins.[1]

Mycotoxins are natural toxins produced by fungi contaminating foods and feeds. They may be extremely toxic [e.g., aflatoxin (*Aspergillus flavus*), which is a potent carcinogen].[2] They may be found in plant-derived products, but also in the tissues of exposed animals, where they can accumulate and, thus, be a serious health hazard for human beings. Consequently, many analytical methods have been developed in order to assess the potential contamination of food derived either from plants or from food-producing animals. A third group of analytical techniques has been developed for diagnostic purposes in animals without any direct public health hazard. In this entry, we will briefly review some of the techniques available to address these three goals.

ANALYSIS OF PLANTS AND PLANT-DERIVED PRODUCTS FOR MYCOTOXINS

Analysis of plants may yield very interesting results, because they are the major carrier of fungi and of mycotoxins. The presence of a genus of fungus may or may not be associated with the production of mycotoxins, depending on the climatic conditions at the time of harvest, for instance.[3] Therefore, it is extremely interesting to have qualitative as well as quantitative methods for the determination of mycotoxins in these matrices. Numerous techniques have been developed to determine the nature and degree of contamination of plants with mycotoxins; it would not be possible to present all of them in a single article.

Extraction and cleanup procedures usually require solid-phase extraction based on commercially available C_{18} cartridges, for instance, after liquid extraction with common organic solvents (methylene dichloride, chloroform, acetonitrile).[3–5] This step appears to be necessary to remove most of the interfering components such as carotenoids or chlorophyls, which are highly abundant in plants. Table 1 gives a list of some of the mycotoxins which can be analyzed by TLC, together with analytical features (plate material, elution, detection/visualization, limit of detection). Of particular interest are the following products: aflatoxins B1, B2, G1, and G2, zearalenon, ochratoxin, and fumonisins B1 and B2 in maize. Recently, high-performance TLC (HPTLC) techniques have also been applied to forage samples commonly infected with an endophyte considered as symbiotic but responsible for disorders in animals.[5] These mycotoxins include lolitrems and ergot alkaloids.

TLC plates used are generally silica gel plates, although C_{18} reversed-phase TLC plates may occasionaly be used.[4] Elution may be monodimensional or bidimensional.[3] The former is more common. Recent automated gradient techniques appear promising for the simultaneous determination of several mycotoxins in a single sample. Solvents used for elution depend on the type of plate used. Most of the time, organic solvents (ethanol chloroform, acetone) are used. One feature of HPTLC is that it uses much less solvent than HPLC and permits analysis of many samples in a very short time.[5]

Detection may be based on several techniques; older systems used postelution derivatization[7] and observation of colored spots. It is more common now to use either ultraviolet (UV)[5] or even fluorescence[3,4] because these techniques allow quantification of mycotoxin residues. More complex systems have been tested (computer imaging[6]) for particular applications, but these techniques are not applied to routine analysis of plants.

ANALYSIS OF ANIMAL TISSUES

Because animals may accumulate mycotoxins in their tissues, and considering the high toxicity of some products, it is a public health concern to have analytical techniques available for routine detection and quantitation of residues of these compounds in edible tissues of food-producing animals. Analysis of animal tissues may be difficult for several reasons:

1. Mycotoxins are poorly concentrated in many tissues or biological fluids (e.g., muscle or milk) and the analytical method employed should be sensitive enough to detect down to a few micrograms mycotoxins per kilogram sample or even less (aflatoxins in muscle samples, for instance).[2]

Table 1 Examples of HPTLC methods for the determination of mycotoxins in biological samples.

Mycotoxin	Plate	Matrix	Elution	Detection	Results	Refs.
Aflatoxins	Si60	Muscle, liver, kidney	1-Hexane/tetrahydrofuran/ethanol	Fluorescence	LOD[a]: 0.01 μg/kg	[2]
B1, G1, M1			2-$CHCl_3$/methanol		(B1, M1) LOD: 0.005 μg/kg (G1)	
Fumonisin	C18	Corn	Methanol/KCl 4% in water	Fluorescamin	LOD : 0.1 (B2), 0.5	[4]
B1, B2				Fluorescence	(B1) μg/kg, recovery > 80%	
Lolitrem	Si60	Forage	CH_2Cl_2/acetonitrile	UV (268 nm)	LOD : 0.1 mg/kg, recovery > 90%	[5]
Patulin	Si60	Fruit	1-Hexane/diethylether, 2-diethylether	UV (273 nm)	LOD : 40–100 μg/kg	[6]
Zearalenon	Si60	Corn	Toluene/ethylacetate/formic acid	Fluorescence	LOD : 2.6 μg/kg, recovery > 63%	[9]

[a]LOD = limit of detection.

2. Tissues and organs may contain interfering substances on chromatograms or densitograms.

For extremely toxic compounds like aflatoxins, acceptable daily intakes (ADI) have been defined and it is, therefore, necessary to check suspected tissues to monitor residues at this level.

TLC and HPTLC offer many advantages over other conventional methods gas chromatography (GC), high-performance liquid chromatography (HPLC), such as rapidity, simplicity, and sensitivity. However, it is usually necessary to extract and purify samples before spraying them onto TLC plates. In the case of aflatoxins, for instance, a commonly employed technique is based on liquid extraction by an organic solvent (chloroform), followed by purification on a silica gel column. The column has to be washed to elute interfering substances (with hexane and ether) and aflatoxins are eluted individually or all together with a specific combination of solvents (chloroform and acetone).[2]

If the purpose of the TLC technology is only to screen samples, the results may be merely qualitative. Older methods were usually based on the visual determination of dark spots on a bright fluorescent plate under UV light. Another use of TLC in the determination of mycotoxin residues is as preparative TLC, in which specific spots are visualized, scraped, and resolubilized for further analysis (Association of Official Analytical Chemistry).

More and more, however, quantitative analysis can be performed by means of scanners (UV, fluorescence), and HPTLC does not need to be completed by another analytical technique for the precise determination of residues. Today, most official methods of analysis for the detection of mycotoxins in foods are based on TLC technology.

DIAGNOSTIC PURPOSES

Mycotoxicoses may induce various pathological disorders in animals as well as in human beings. Considering the poor specificity of the signs observed and the very low concentrations of the toxic compounds in most biological tissues or fluids, it is necessary to be able to analyze, promptly and efficiently, biological samples to evaluate the risk of mycotoxicosis. The most common mycotoxins involved include aflatoxins, fumonisins, ochratoxin, zearalenon, and T2 toxin.[8] Analysis is usually based on foods and feeds (cereals, etc.). In swine, for instance, an epidemiological study conducted on feed samples detected ochratoxin (mean 58.3 μg/kg) and zearalenon (mean 30.3 μg/kg) in corn. These concentrations were associated with respiratory disorders and also infertility.[9] The advantage of TLC/HPTLC in such a situation is that it provides rapid and specific analysis of food samples at a low cost and, therefore, a reasonable cost/benefit ratio for breeders. If the diagnosis has to be confirmed on animal/human tissues or fluids, depending on the compound of interest, HPTLC techniques may also be available and convenient (see above).

CONCLUSIONS

TLC and HPTLC offer many possibilites for the determination of mycotoxins in plant or animal samples. Plant samples usually contain higher concentrations of mycotoxins, but analysis of animal tissues may be necessary either to confirm a suspected mycotoxicosis or to detect potential residues for human food. Many official methods are available, based on TLC, and the recent development of HPTLC also offers many possibilities for

the detection and quantitation of several mycotoxins in various biological samples.

Natural Phenolic Compounds: Planar Chromatography Separation

Maged S. Abdel-Kader

INTRODUCTION

Plant phenolic compounds probably constitute one of the most widespread and diverse groups of secondary metabolites.[1] This term embraces an embarrassingly large array of chemical compounds possessing an aromatic ring bearing one or more hydroxyl groups, together with a number of other substituents. In plants, all phenolic compounds are derived biogenetically from phenolic precursors through skimate pathway and phenylpropanoid metabolism.[2] Phenolic compounds have provoked much interest among chemists, biochemists, botanists, and food technologists.[3]

Phenolic compounds are of great taxonomic significance, owing to their widespread stability, in addition to the fact that they can be detected easily.[4] Plants produce phytotoxic phenolic compounds to suppress the growth of other plant species.[3] The anti-microbial and anti-fungal activities of phenolic compounds, pointed out to their role in plant disease resistance, is a hypothesis supported by many studies and has been formulated into the Phytoalexin Theory of Disease Resistance in Plants.[3,5] Plants respond to different elicitors by production of phytoalexins, which are mainly phenolic in nature.[6] The tannins, a well-known class of these compounds, have been employed since ancient times in tanning skins and manufacturing of ink.[4] Plant phenolic compounds are of great importance in food technology, since they affect the colors and flavors of our food and drink.[3]

Many plant phenolics are of pharmaceutical interest. Flavonoids, lignans, flavolignans, coumarins, phenyl propanoids, and other phenolic compounds show a wide variety of biological and pharmacological activities, such as anti-oxidant, anti-hepatotoxic, spasmolytic, cytotoxic, anti-fungal, and anti-bacterial. Some flavonoids improve capillary resistance while isoflavonoids found in soy and other legumes have estrogenic activity.[7–9]

The important applications of plant phenolics attracted natural product chemists to look for new compounds in plant species with interesting activities. Identification of compounds, usually preceded by obtaining them in a pure form. Different chromatographic techniques were applied for the purification of plant phenolics, as well as other plant constituents or products of chemical reactions.

Planar chromatography is a term originally used to describe techniques including thin-layer chromatography (TLC), paper chromatography, and zone electrophoresis. In all these techniques, the stationary phase is used in the form of a flat thin layer.[10,11]

TLC is regarded as an indispensable tool in both quality control and research laboratories. The technique is easy, fast, and the required apparatus is relatively inexpensive. TLC is widely used to check purity of compounds, monitor chemical reactions, monitor column chromatography, and explore the complexity of mixtures and choice of proper mobile phase for column chromatography. In most of these applications, in addition to the TLC plates, only capillaries and chromatographic tanks are required. Advances in analytical methods led to the development of more sophisticated instruments based on TLC, used for quantitative analyses. Plates with much smaller particle size stationary phases are usually employed in conjunction with these instruments for better results and are described as high-performance thin-layer chromatography (HPTLC).[10,11]

Another important application of planar chromatography is in the use of different types of flat layer stationary phases to obtain pure materials from mixtures. This application is regarded as preparative planar chromatography and it mainly includes preparative thin-layer chromatography (PTLC), preparative paper chromatography (PPC), and centrifugal preparative thin-layer chromatography (CPTLC). Of the three types, the latter only (CPTLC) requires relatively more complex instrumentation.[10,11] However, preparative planar chromatography can take advantages from the recent developments in planar chromatography, such as automated sample application, over pressured layer chromatography, alternatively described as optimum performance laminar chromatography (OPLC) and automated multiple development (AMD).[11,12] Literature survey reveals that these techniques are still of very limited use in preparative work, most likely due to the lack of instrumentation required and the predominance of

HPLC when talking about expensive sophisticated instruments.

One of the serious problems in preparative planar chromatography is the detection of zone locations on the chromatogram. In this regard, one cannot use destructive methods of detection. The great advantage of dealing with phenolic compounds in this regard is their ease of detection. With no exceptions, all phenolic compounds can be detected by the widely used UV lamps, since they all have UV-absorbing chromophores.

CLASSIFICATION OF PLANT PHENOLS

Plant phenols are not only widespread among plants, but also comprise a wide variety of structural diversity. Classification of plant phenols is based on structural similarities, as well as biogenetic pathways from which they originate. Brief notes are given here about the major classes of natural phenolics and their biological importance. Under each class, some structures for corresponding compounds in Table 1 are given.

SIMPLE PHENOLS, PHENOLIC ACIDS, AND RELATED COMPOUNDS

Compounds of this group usually contain one aromatic ring in their structures, and they often possess alcoholic, aldehydic, and carboxylic groups. The occurrence of these compounds in the form of glycosides (linked with one or more sugar unites) is common in nature. Vanillin (Vanilla pods, flavoring agent), capsaicin (*Capsicum*, Counter irritant), salicin (Willow barks, analgesic, and anti-inflammatory), and benzyl benzoate (Peru balsam, anti-parasitic) are examples of this class.[2,9]

COUMARINS AND COUMARIN DERIVATIVES

Members of this group biogenetically originate from cinnamic acid derivatives via the shikimic acid pathway. They are all C-9 compounds having the 2H-1-benzopyran-2-one moiety in their skeleton. Coumarin itself has an unsubstituted basic skeleton. Compounds with hydroxyl or methoxyl substituents are described as simple coumarins. More complex are those bearing prenyl substituents or alkyl groups. In many natural coumarins, a third ring is fused to the benzopyran-2-one nucleus. The most common compounds with third ring are the furanocoumarins, e.g., psoralens used in the treatment of vitiligo.[2,9,13]

FLAVONOIDS

Flavonoids (C-15 compounds) are the largest group of plant phenols. They occur either in the free state or in the form of glycosides. Ring-B of flavonoids is formed from phenylpropane via the shikimate pathway, while rings A and C arise from condensation of acetate units via malonlyl CoA. Flavonoids are classified into several subclasses according to their structural variations (Fig. 1).

Flavonoids and their derivatives, especially anthocyanidines and their glycosidic anthocyanins, are responsible for the colors of plant flowers. In addition to their value as chemotaxonomic markers, recent researches have demonstrated their involvement in the medicinal action of many drugs such as liquorice, chamomile, and gingko. Some flavonoids have anti-tumor, anti-viral, anti-bacterial, anti-fungal, anti-inflammatory, anti-allergic, anti-thrombitic, anti-oxidant, anti-hepatotoxic, vasoprotective, gastric protective, and estrogenic activity.[2,9,14,15]

LIGNANS

Lignans are C-18 natural compounds formed essentially by the union of two molecules of phenylpropene (C-6, C-3) formed from cinnamate derivatives. Lignans are optically active compounds and the union takes place between the middle carbons of the monomers' side chains. Important pharmaceutical examples are the lignans of *Podophyllum*

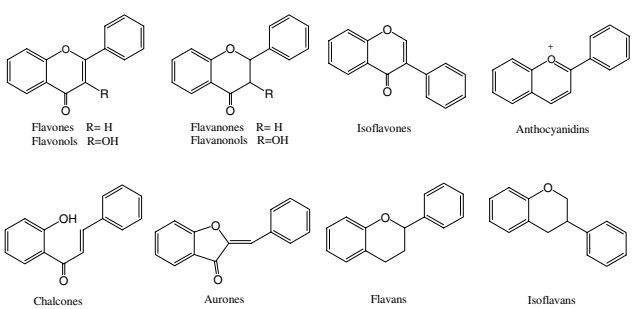

Fig. 1 Structures of flavonoids and their derivatives.

Table 1 Phenolic compounds isolated by PTLC.

Name	Mobile phase*	Refs.
Simple Phenols		
Dillapiole **[1]**	Petrol–EtOAc (49 : 1)	[19,20]
p-Hydroxybenzaldehyde	Petrol–$CHCl_3$	[21]
3-Hydroxy-3′-methoxy-4′-hydroxypropiophenone	Petrol–$CHCl_3$ (2 : 3)	[21]
Isoelemicin	Hexane–EtOAc (9 : 1)	[20,22]
5-Methoxy-6-(2-propenyl)-1,3-benzodioxol **[2]**	Petrol–EtOAc (49 : 1)	[19]
Myristicin **[3]**	Petrol–EtOAc (49 : 1)	[19,20]
Safrole **[4]**	Petrol–EtOAc (49 : 1)	[19]
trans-Sinapaldehyde	Petrol–$CHCl_3$ (2 : 3)	[21]
Syringaldehyde	Hexane–EtOAc (9 : 1) Petrol–$CHCl_3$ (2 : 3)	[22] [21]
Vanillin	Petrol–$CHCl_3$ (2 : 3)	[21]
Chlorogenic acid	EtOAc–HCOOH–AcOH–H_2O (100 : 11 : 11 : 26)	[23]
3,4-Di-*O*-caffeoylquinic acid	EtOAc–HCOOH–AcOH–H_2O (100 : 11 : 11 : 26)	[23]
3,5-Di-*O*-caffeoylquinic acid	EtOAc–AcOH–HCOOH–H_2O–toluene–$HCOOC_2H_5$ (50 : 5.5 : 13.5 : 2.5 : 2) EtOAc–HCOOH–AcOH–H_2O (100 : 11 : 11 : 26)	[24] [23]
4-Hydroxy-3,5-dimethoxybenzoic acid	Petrol–EtOAc (4 : 6, 3 runs)	[25]
4-Hydroxy-3-methoxybenzoic acid	Petrol–EtOAc (4 : 6, 3 runs)	[25]
Leiocarpic acid	$CHCl_3$–Me_2O–HCOOH (90 : 10 : 0.5)	[26]
Rosmarinic acid	$CHCl_3$–MeOH–H_2O (4 : 1 : 0.1)	[27]
3,4,5-Trimethoxybenzoic acid	Hexane:EtOAc (9 : 1)	[22]
4*S*,6*S*-Dihydroxy-6-(14′-nonadecenyl)-2-cyclo-hexanone **[5]**	Hexane:EtOAc (6 : 4)	[28]
1-Hydroxy-3-[14′-phenyldodecyl]benzene	Hexane–EtOAc (9 : 1)	[28]
1-Hydroxy-3-[14′-phenyltetradecyl]benzene	Hexane–EtOAc (9 : 1)	[28]
1-(16′-Phenyl-12′*Z*-hexadecenyl)-4-cyclohexene-(1*S*,3*S*)-diol. **[6]**	Hexane–EtOAc (6 : 4)	[28]

species. The anti-tumor lignan podophyllotoxin is the major active compounds of *Podophyllum hexandrum*.[2,9]

XANTHONES

Xanthones are benzo-γ-pyrone derivatives. Plant derived xanthones are of mixed shikimate-acetate origin. Mangiferin, a *C*-glycosyl xanthone present in the *Hypericum* species possesses anti-inflammatory, anti-hepatotoxic, and anti-viral properties.[9]

NAPHTHALENES

Naphthalenes are a small group of plant phenols formed from mixed shikimate-mevalonate pathways.[2]

QUINONES

Plant quinones show a diversity in their structures and origins, although they share the presence of two conjugated

carbonyl groups. Naphthoquinones are oxidation derivatives of naphthalenes **[41]**. Some highly oxidized diterpenoids with quinonoid moieties are described as diterepene quinones. An important class of quinones is the anthraquinone derivatives present in purgative drugs like *Senna*, *Aloes*, and *Cascara*. Biosynthetically, they are derived from polyketides resulting from the acetate pathway **[42, 43]**.[2,9]

STILBENES

Stilbenes are produced by the coupling of cinnamoyl-CoA with three malonyl-CoAs under the control of the enzyme

PHENOLIC NITROGENOUS COMPOUNDS

These include alkaloids and non-alkaloids that have phenolic functions in addition to a nitrogen atom. Even the alkaloids containing phenolic functions cannot be classified under one group. They may be phenyl alkyl amines, quinolines, isoquinolines, benzylisoquinolines **[47–50]**, carbazole **[51, 52]** and others. However, they are included in this entry owing to their phenolic nature. Some of these compounds, like opium alkaloids, are of great medicinal importance.[2,9]

PREPARATIVE PLANAR CHROMATOGRAPHY

PTLC

This is the most widely used type of preparative planar chromatography, because of many factors. In PTLC, large plates (20 × 20), usually with thick layers (0.5–4 mm), are used, although, in some cases, researchers prefer to use thin layers (0.1–0.2 mm). The choice of the layer thickness is a compromise between the quality of separation and the amount of material that can be obtained from each plate. All TLC sorbents can be used in PTLC; thus, different mechanisms of separation can be utilized. Commercially available PTLC plates are homogenous and give excellent results. Some of these plates are prepared with a concentration zone for sample application to enhance separation. In addition to the cost issue, these plates are limited to certain types of sorbents and definite thicknesses. The alternative use of homemade plates overcomes these limitations and cuts the cost; however, the quality of the separation may be affected. The simplest form of PTLC requires only chromatographic tanks with suitable dimensions. Although TLC is generally more sensitive than other chromatographic methods, detection may be problematic if the materials to be isolated are not UV absorbing. This is, fortunately, not the case when dealing with phenolic compounds, as they are all UV active.[10,11,16] Manual application of samples is usual; however, automatic sample application is available to provide more accurate volumes and homogenous bands. OPTLC, introduced by Tyihak, Mincsovics, and Kalasz in 1979, greatly shortens the required time for separation, with greater resolution.[17] AMD also may be used to improve separation and allow multiple developments with different mobile phases, in a shorter time.[11,12,18]

PPC

PPC is currently of very limited application, in view of the great advances in separation techniques. PPC is generally used for more polar components. The separation is limited to partition and commercially available types of paper for chromatography. The cellulose fibers forming the paper matrix have larger sizes than the adsorbents used in TLC. Moreover, TLC has higher capacity than PC. These two factors make separations on TLC, in most cases, superior to those on PC. Although some development methods can only be used with PC, e.g., descending and horizontal developments, the flow rate is much slower when compared with TLC. The average time for development of a 10 cm TLC with silica gel as stationary phase is 20–30 min, while the same development in PC takes at least 2 hr.[10]

CPTLC

In this method, centrifugal force is used to accelerate the development with the mobile phase. The plates are circular and fixed on a rotor attached to a spindle; they are rotated using a motor. The mobile phase is introduced to the center of the plates by a pump. The instrument used for this type of chromatography is called Chromatotron. The samples are applied to the center of the plate. Mixture components move out radially, forming circles of increasing diameters. The instrument can be used along with a fraction collector. UV detection of zones is possible, thus facilitating the collection of different components in a pure form. Chromatotron plates are commercially available and can also be prepared in the laboratory. The layer thickness ranges from 2 to 8 mm, thus allowing the application of samples up to 4 g at once.[10,11,16] In CPTLC, the plates can be used several times after proper washing with more polar solvents. This gives CPTLC more advantages over PTLC, where plates can be used only once.

CONCLUSION

Different classes of natural phenols have the advantage of bearing chromophores that can absorb UV light. This characteristic makes their non-destructive detection an easy task and that, to some extent, may explain the popularity of their isolation using planar chromatography. Some adsorbents, e.g., alumina, are not used in their isolation since chemical reactions may take place between the acidic phenolic hydroxyl groups and the basic alumina. Normal silica gel is still the most popular adsorbent used for PTLC and is almost the only one used for CPTLC. Among PTLC separations included in this entry, RP 18 (C-18 reversed-phase silica gel) was used in seven references, while powdered cellulose was used in only two references (Table 1). It is worth mentioning that 14 references that used PTLC were excluded, owing to the lack of information about the mobile phase used in the separations. Among the benefits that one can gain from this entry is the convenient presentation of different mobile phases used for various separations. This

Aureusidin 4,6-*di*-*O*-glucoside	15% HOAc, BAW[a] 4 : 1 : 5 (upper phase) and BEW[b] 4 : 1 : 2.2	[114]
Flavanones		
Naringenin 5,7-*di*-*O*-glucoside	15% HOAc, BAW[a] 4 : 1 : 5 (upper phase) and BEW[b] 4 : 1 : 2.2	[114]

[a]BAW = *n*-BuOH–AcOH–H_2O.
[b]BEW = *n*-BuOH–EtOH–H_2O.

Table 3 Phenolic compounds isolated by Centrifugal Chromatography (Chromatotrone).

Name	Mobile Phase	Refs.
Flavones		
Artoindonesianins U, V	Hexane–$CHCl_3$ 1 : 1 and 1 : 2	[115]
Artoindonesianins Q, R, S, T	Petrol–$CHCl_3$, $CHCl_3$, $CHCl_3$–Me_2CO	[116]
Artonin B	Hexane–$CHCl_3$ 1 : 1 and 1 : 2	[115]
Cyclocommunin	Hexane–$CHCl_3$ 1 : 1 and 1 : 2	[115]
5′-Hydroxycudraflavone A	Hexane–$CHCl_3$ 1 : 1 and 1 : 2	[115]
Isoflavones		
Kraussianone 2	CH_2Cl_2	[117]
Kraussianone 5	CH_2Cl_2–Et_2O 8 : 2	[117]
Benzoquinones		
3-Hydroxy-2-methyl-5-(3 methyl-2-butenyl)benzo-1,4-quinone	$CHCl_3$	[118]
2-Methyl-6-(3 methyl-2-butenyl)benzo-1,4-quinone	$CHCl_3$	[118]
Isoquinoline Alkaloids		
Adlumine	Hexane–EtOAc 9 : 1 → 1 : 1	[119]
Bicuculine	Hexane–EtOAc 9 : 1 → 1 : 1	[119]
Capnoidine	Hexane–EtOAc 9 : 1 → 1 : 1	[119]
Protopine	Hexane–EtOAc 9 : 1 → 1 : 1	[119]
Scoulerine	Hexane–$CHCl_3$ 1 : 1 → $CHCl_3$–MeOH 19 : 1	[119]
Tetrahydropalmatine	Hexane–EtOAc 9 : 1 → 1 : 1	[119]
Phenolic Amides		
Feruloyl-tyramine	Hexane–EtOAc 9 : 1 → 1 : 1	[119]

can greatly help in selecting the mobile phases suitable for different separations, based on the nature of compounds to be purified.

In the case of dealing with highly polar compounds, silica gel is not recommended. The earlier alternative is the use of paper chromatography. Only three references in this paper used PPC (Table 2), which have many disadvantages, including the relatively large particle sizes of the cellulose fibers and the slow movement of mobile phases. RP 18 is recommended for polar compounds; however, in the case of PTLC, the choice of mobile phase is limited in the percentage of water that can be used. If the percent in the mobile phase exceeds 50%, the development will not be homogeneous and will be at a very slow rate. The best solution in such cases is to use HPLC with a reversed phase column bearing different chain lengths of hydrocarbons (C-4, C-8, C-18). The composition of the mobile phase in this case is not restricted to 50% water. The highly polar anthocyanins are mainly purified by HPLC. In only two cases, silica gel PTLC was used for separation of three anthocyanins (Table 1).

Although CPTLC has many advantages over PTLC, its application is limited (3 references when compared with 99 for PTLC in this entry) (see Table 3). This is mainly due to the cost of the instrumentation required, as well as the wide spread of HPLC. The chromatotron used for CPTLC can be used only for separation and purification, while HPLC can also be used for both qualitative and quantitative analyses. The resolution in CPTLC is comparable with that of PTLC, since the stationary phases used are of the same particle sizes. HPLC gives much better resolution, however, owing to the use of stationary phases with smaller particle sizes.

Natural Pigments: TLC Analysis

Tibor Cserháti
Esther Forgács
Institute of Chemistry, Chemical Research Center, Hungarian Academy of Sciences, Budapest, Hungary

INTRODUCTION

Various natural pigment classes, such as flavonoids, anthocyanins, carotenoids, chlorophylls and chlorophyll derivatives, porphyrins, quinones, anthraquinones, betalains, and so forth are abundant in many families of the vegetable and animal kingdoms. As consumers generally dislike the color of synthetic dyes, the concentration and composition of pigments in foods and food products exert a considerable impact on the consumer acceptance and, consequently, on the commercial value of the products. It has been proven many times that one of the main properties employed for the commercial evaluation of the quality of products is their color; that is, an adequate color is an important requirement of marketability.

DISCUSSION

Spectroscopic methods for measuring the absorbance of pigment solutions or the adsorbance of the color of product surfaces on one or more wavelengths in the visible range are excellent tools for the accurate determination of the quantity of pigments; however, they do not contain any useful information on the concentration of the individual pigment fractions.

As the stability of the various pigments against hydrolysis, oxidation, and other environmental conditions shows marked differences, the assessment of the pigment composition may help for the prediction of the shelf life of products and the elucidation of the impact of various technological steps on the individual pigment fractions resulting in more consumer-friendly processing methods. Moreover, the exact knowledge of the pigment composition may facilitate the identification of the origin of the product. The advantageous characteristics of TLC (easy to use, low operating costs, no need for complicated instrumentation, manyfold possibilities of detection, etc.) make it a method of preference for the separation and, to a lesser extent, for the quantitative analysis of natural pigments.

The earlier results in the application of thin-layer chromatography (TLC) for the analysis of natural color pigments, in general,[1] and especially in plants,[2] have been reviewed. Pigments are more or less strongly bonded to cellulose, protein, cell-wall components, and so forth in both plant and animal issues; therefore, the efficaceous extraction sometimes is difficult and time-consuming with the traditional extraction methods, and the recoveries sometimes are inadequate. Depending on the character of the accompanying matrix and the solubility of the pigment, a considerable number of extraction solvents or solvent mixtures were proposed and used in the TLC analysis of natural pigments.

Thus, ethanol–water (7:3, v/v) and methanol–water in various ratios for flavonoids, methanol–25% HCl (9:1, v/v), methanol–acetic acid (5%), methanol–trifluoroacetic acid (3%) for unstable anthocyanins, acetone, methanol–acetone mixtures for carotenoids, acetone and petroleum ether for chlorophylls, and so forth. The pigments are fairly stable in their natural environment, but they generally become unstable in extracts; this has to be taken into consideration in the development of new, more efficaceous extraction procedures.

The impact of the extraction conditions using various solvents on the recoveries has never been studied in detail, and the results have never been compared. The introduction of modern extraction methods, such as microwave-assisted extraction, supercritical fluid extraction, and solid-phase extraction, probably will improve the efficiency of extraction, even in the instance of unstable pigments and pigment mixtures. The majority of TLC separations were carried out on traditional silica layers. As the chemical structures and, consequently, the retention characteristics of pigments are highly different, a wide variety of eluent systems has been employed for their separation, consisting of light petroleum, ethyl formate, ethyl acetate, benzene, toluene, chloroform, methanol, *n*-butanol, formic or acetic acid, and so forth.

Besides silica, other direct phase supports such as alumina, diatomaceous earth, cellulose, MgO–diatomaceous earth, and sucrose layers were employed for the separation of various pigment mixtures. Mixed-mode supports (cyano, diol, and aminosilica layers) were also employed in both the direct and reversed-phase elution modes for the separation of natural pigments, but their performance was markedly lower that those of traditional silica layers. Reversed-phase supports (polyamide, octadecylsilica, alumina, silica, and diatomaceous earth impregnated with paraffin oil) were also applied for the separation of color pigments (carotenoids from *Capsicum annuum*, anthocyanins from red wines) and it was found that their separation

Table 1 The R_f values obtained for carotenoids by use of different mobile phases.

No.	Carotenoid	R_f value in mobile phase 1	2	3
1	β-Carotene	0.93	0.92	0.93

capacity was commensurate with those of direct phase layers. The separation of 22 pigment fractions extracted from paprika powders on diatomaceous layers impregnated with paraffin oil, using mixtures of acetone–water, was reported and it was established that baseline separation of each fraction cannot be achieved in one run and at a single mobile-phase composition.[3]

Unconventional layers have also been employed in the TLC analysis of pigments of sour cherry and blueberry. Baseline separations were carried out on corn and rice starch layers in the *n*-butanol–glacial acetic acid–water–benzene (30:20:10:0.5, v/v) mobile phase.[4] A considerable number of carotenoid standards can be separated in one run as demonstrated in Table 1, showing the R_f values of carotenoids in various eluent systems.[5]

Pigment extracts either derived from one plant or one part of a plant generally contain a considerable number of fractions with highly different retention characteristics. The separation of these extracts cannot be successfully achieved by the traditional TLC techniques. Elution methods similar to gradient elution in high-performance liquid chromatography were developed to overcome this difficulty. Stepwise gradient elution can be carried out by introducing eluent fractions with increasing eluent strength to the layer without interrupting the separation process. In programmed multiple-gradient development, the plate is developed to different distances with mobile phases of decreasing elution strength.

The plate is first developed for a given distance with the eluent having the highest elution strength and then the plates are dried. Pigments with the lowest mobility are separated. Then, a new eluent with a lower elution strength is applied for the separation of pigments with a higher mobility. The procedure can be repeatedly employed up to 25 times using eluents with decreasing elution strength. The advantages of programed multiple development were exploited in the separation of complex plant extracts of *Radix rhei* and *Cortex frangulae*.[6] Due to the considerable number of pigment fractions in an extract, the identification of the individual pigments separated by TLC is extremely difficult. Pigments can be identified by spotting an authentic standard on the neighboring track; however, in the instance of natural pigment mixtures, authentic standards are generally not available.

Coupled spectroscopic methods such as TLC–UV (ultraviolet) and visible spectroscopy, TLC/MS, and TLC–FTIR (Fourier transform infrared) have been developed to overcome this difficulty.[7] Their future application in the TLC analysis of natural pigments will markedly increase the information content of this simple and interesting separation technique. The automation of the various steps of TLC analysis (sample application, automated developing chambers, TLC scanners, etc.) greatly increased the reliability of the method, making it suitable for official control and legislative purposes.[8]

Natural Products: CE Analysis

Noh-Hong Myoung
Seoul Metropolitan Government, Institute of Health and Environment, Seoul, South Korea

INTRODUCTION

Natural products chemistry is a science that investigates the identification, metabolism, biosynthesis, distribution, and biological activity of various organic compounds derived from living things. It concerns, essentially, the separation, purification, and structural determination of each compound. It was not until the late 1700s that, in plants or animals, the separation of natural products was carried out; for example, tartaric acid was extracted from grapes, citric acid from lemons, and malic acid from the apple by Scheele, a pharmacist in Sweden. In the nineteenth century, most of the compounds, alkaloid, terpenoid, and glycoside, were first isolated in pure form and elucidated structurally, since morphine was extracted from opium by Serturner. In the twentieth century, natural products chemistry achieved a great promotion through development of micro element analysis and column chromatography, which allowed physiological activity materials in crude form to be isolated with ease. Natural products are the organic and inorganic compounds found in nature: in plants (leaves, roots, barks, rhizoma, flowers, and seeds), in marine organisms (plants, animals, and microbes), in the fungi found in highly diverse and sometimes extreme environments, and in soil.[1]

DISCUSSION

There are two major classes of natural products: primary and secondary metabolites. Primary metabolites are compounds that exist in all organisms and are involved in basal and vital metabolism (e.g., glucose, fatty acids, amino acids, etc.). Secondary metabolites, alkaloids, terpenoids, and flavonoids, are unique to a particular species and vary in their basic structures. Secondary metabolites are usually accumulated, as most of their end metabolites are in plants, but are excreted in animals and microorganisms and some of these are proven to have pharmacological and ecological significance.

The pharmaceutical industry, in its drug discovery efforts, has relied heavily on natural products. Not all natural products are bioactive; in fact, most have little or no measurable activity at all. Simple sugars, lipids, amino acids, flavonoids, and so forth are nature's essential building blocks, and measurements of their quantities are needed for the study of metabolism, disease processes, and aging. In today's public maketplace, there is a growing interest in the so-called crude drugs, where an increasing number of herbal products claimed as health aids, bodybuilding supplements, nutrients, vitamin supplements, cosmetics, and so forth are being sold.

In Asia, plants have been applied in various diseases and studied with their components for many years. For research of their components, at first, fresh plants are dried at low temperature, for short times, in well-ventilated places so as to minimize chemical change of components, and then they are extracted. They are generally finely ground and extracted first with an organic solvent, then by water, to remove the widest possible range of compounds, from the hydrophilic to the most hydrophobic. The solvent is then removed and the crude extracts are tested for biological activity. If they are found to be active, fractionation by a variety of chromatographic techniques is initiated. At each step, the fractions are reevaluated, and only those fractions in which bioactivity is increasing are fractionated further. Finally, a pure chemical and structural identity of the molecule is determined by a combination of nuclear magnetic resonance (NMR), infrared (IR), ultraviolet (UV), mass spectrometry (MS), x-ray crystallography, and other analytical tools. Once the structure and chemical properties of an active compound are known, quantitative and qualitative analytical methods are employed to detect and quantify it. Recently, the pharmacological significance of the crude drugs is highlighted in terms of the suitability of their medicinal value and low number of side effects. Most crude drugs are comprised of more than one component and their number is determined through the analysis of major components.

Although high-performance liquid chromatography (HPLC) and gas chromatography (GC) have been mainly applied in quantitative method of analysis, they have difficulty with simultaneous quantitative analysis of crude drugs and have problems concerning the instability of experimental conditions, poor reproducibility because of pretreatment of crude drugs, efficacy of columns, and delay of separation time. GC has a limitation that components must be volatile. HPLC requires longer times for simultaneous analysis of samples, although gradient could be used advantageously for shortening analysis times.

With capillary electrophoresis (CE), it is possible to carry out simultaneous quantitative analysis with small sample volumes (1–10 nl); the amount of solvent waste generated is in the order of 1–2 ml/day and requires much less analysis time, with outstanding resolution. CE may be able to resolve a component of interest more quickly and with less

effort invested in sample preparation than alternative techniques, because it can resolve neutral as well as ionic compounds using the same column in the same analytical run. Although CE is an excellent micro-analytical technique, its use in a preparative format is limited at the present time. CE in its capillary zone electrophorsis (CZE) and micellar electrokinetic chromatography (MEKC) formats allows the analyst to resolve both ionic and neutral compounds on the same column using simple buffers, with or without an organic modifier, a micelle, a cyclodextrin, or a mixture of all of these. The reproducibility of migration time is the factor requiring improvement with CE, as the longer the migration time is, the more the peak area increases.

The velocity of a solute in the capillary is determined by its electrophoretic mobility and electro-osmotic flow (EOF), which are affected by temperature, and which is influenced by the diameter and length of the capillary, its contents, concentration, and pH of running buffer, applied voltage, current, viscosity, and zeta-potential. The subtle variation of EOF is also a main factor in maintaining high reproducibility if CE is automated by the constant temperature of the capillary and running buffer with proper buffering capacity. However, it is difficult to keep the temperature constant, as EOF depends on the condition of the fused silica.

The zeta-potential present on the silica surface is changed by the cleaning, preconditioning, storage method, and use time. Therefore, it is important to keep the surface condition reproducible. Usually, herb drugs are made of several crude drugs, as extracts, powders, or pills. The components of herb drugs are so varied that their quality control is applied to just one or two of their index components. CE has been applied to the analytical study of various components ever since it was applied to individual components in glycyrrhizin of an herb drug by Iwagami in 1991.[2] Presently, new analysis methods that are combinations of MEKC have been developed for the distribution of samples in an interfacially active agent by Terabe. CZE is able to analyze components with and/or without electric charge.[3]

Micellar electrokinetic chromatography was originally developed for the separation of electrically neutral substances by capillary electrophoresis and has proven to be a highly efficient separation method for various kinds of analyte. Although various ionic substances can be separated by CE alone, the separation of many components in complex mixtures is not always succesful. For example, a number of drugs are ionic, but some of them are not easily separated by CE. MEKC has been shown to be a powerful technique for the separation of complex drug mixtures. Although most of these drugs can be separated by HPLC, MEKC usually gives a better resolution in shorter analysis times.

Compared to HPLC, CE is simpler, faster, more convenient, and has a higher resolution power, which is a necessity when analyzing complex multicomponent mixtures.

A literature search reveals that CE has been used for the analysis of widely different natural compounds from

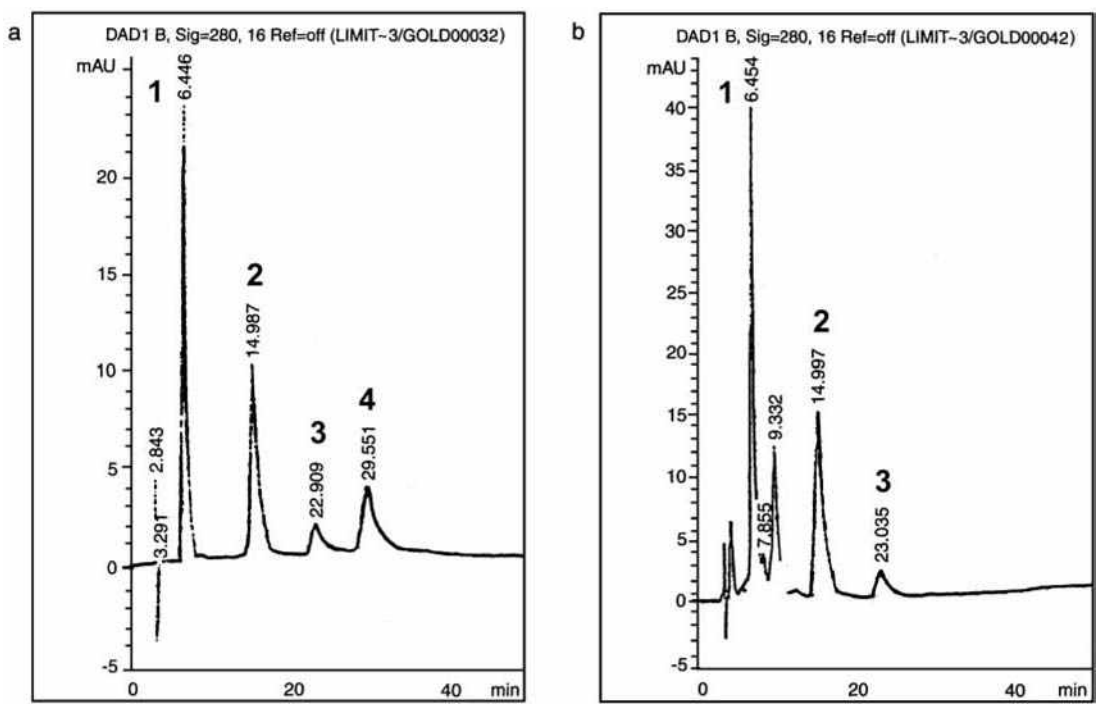

Fig. 1 HPLC chromatogram of standard mixtures (a) and a *Scutellaria radix* extract (b). *Key*: 1, baicalin; 2, baicalein; 3, wogonin; 4, chrysin.

extracts of leaves and needles, bark, roots, marine organisms, moss, soils, and so forth. To illustrate the problems associated with analyzing natural product extracts, especially from plant materials, by chromatography and to demonstrate how CE can overcome some of these problems as a consequence of its high resolving power, we compared the separation of an extract from the radix of the *Scutellaria baicalensis* Georgi by HPLC and CE. *Scutellaria radix* is the root of *Scutellaria baicalensis* Georgi. It is well known and is frequently used in oriental pharmaceutical preparations as a remedy for inflammation, suppurative dermatitis, allergic diseases, hyperlipidemia, and arteriosclerosis.[4]

Flavonoids are major components of *S. radix*, and about 40 kinds of flavonoids have been identified in it so far.[5] These flavonoids are known to have a broad range of physiological activities. The activities of baicalin, which is the main component, baicalein, and wogonin, in particular, have been investigated. From the results, it has been concluded that the most potent antiallergic material is baicalein, and the other flavonoids have low activities. Therefore, the quantitative analysis of individual flavonoids is important for evaluating the quality of *S. radix*. Figs. 1 and 2 show the HPLC chromatogram and CE electropherogram of a crude drug radix extract (*S. baicalensis* Georgi). These samples were obtained by first extracting with 50% ethanol. In the ethanol extract, many compounds are left. It is clear from Fig. 1 that HPLC is not the method of choice in this case. Important characteristics of an analytical procedure are sufficiently high precision and accuracy and also the time of analysis. Therefore, often it is not relevant in method development to simply maximize the resolution of the sample components without fulfilling the demands on analysis time. Decreasing the pH of the buffer leads to an increase in the degree of dissociation of baicalin, baicalein, wogonin, and chrysin. However, crude drugs have many components. As *S. radix* has about 40 kinds of flavonoid, it is very difficult to simultaneously separate baicalin, baicalein, wogonin, chrysin, and other flavonoids in a short time. Based on the dependence of the migration times and resolution on pH and phosphate buffer concentration (Fig. 2), it can be concluded that the most favorable electrolyte system is that with pH 7.0, 35 m*M* phosphate buffer. This

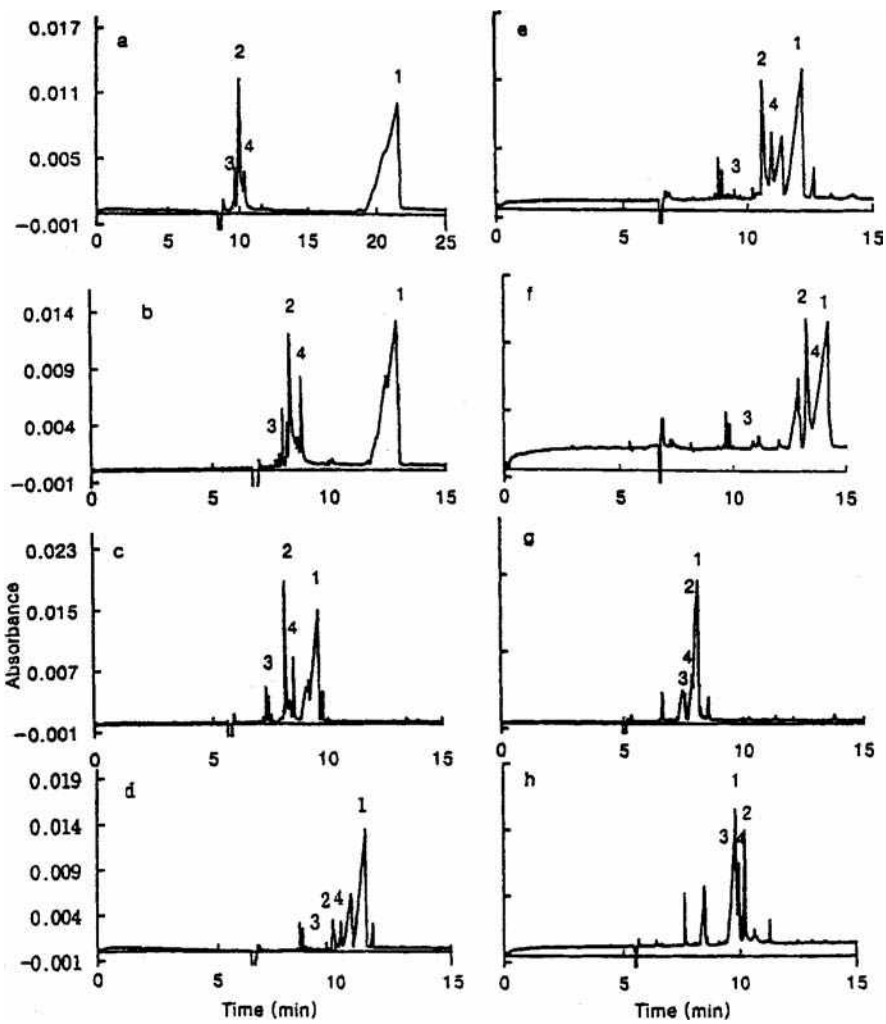

Fig. 2 Effect of running buffer pH and phosphate concentration on the separation of four components in the *Scutellaria radix* CE (1, baicalin; 2, bicalein; 3, chrysin; 4, wogonin). (a) pH 6.0 sodium citrate buffer (20 m*M*), (b) pH 6.5 sodium phosphate buffer (20 m*M*), (c) pH 7.0 sodium phosphate buffer (20 m*M*), (d) pH 7.0 sodium phosphate buffer (35 m*M*), (e) pH 7.0 sodium phosphate buffer (50 m*M*), (f) pH 7.0 sodium phosphate buffer (100 m*M*), (g) pH 7.5 sodium phosphate buffer (50 m*M*), (h) pH 8.0 sodium phosphate buffer (35 m*M*).

system was applied for the determination of baicalin, baicalein, wogonin, and chrysin in the extracts of *S. radix*. A typical HPLC chromatogram obtained from the extract of *S. radix* with a Korea Food and Drug Association (KFDA) regulation is shown in Fig. 1. Baicalin is not clearly distinguished from other components and the analysis time is greater than 35 min.

By comparing the records of Figs. 1 and 2 for the results of HPLC and CE analysis, it is seen that (a) CE provides higher sensitivity than HPLC and (b) the CE analysis time is shorter than HPLC.

CONCLUSIONS

The proposed method is well suited for the rapid and simultaneous determination of baicalin, baicalein, wogonin, and chrysin. The data presented in this report indicates that CE has application for crude drugs. The separation by CE is completed within 15 min and is much faster than HPLC. A comparision of the analysis time for both techniques is made. Resolution, recovery, and reproducibility for four flavonoids in *S. radix*, separated by CE, are greatly improved in crude drug analysis.

Natural Rubber: GPC/SEC Analysis

Frederic Bonfils
C. Char
French Agricultural Research Center for International Development (CIRAD-CP), Montpellier, France

INTRODUCTION

Natural rubber (NR), produced from *Hevea brasiliensis*, a very high molar mass polymer, differs from most of its synthetic counterparts through its more complex structure, due to the interactions of non-isoprene compounds (proteins,[1] lipids[2]) with the polyisoprene chains. This "associative" structure is gradually destroyed, and partly when the polyisoprene is dissolved in a conventional solvent. However, in very many cases, a proportion of the NR remains insoluble in such solvents; this fraction is commonly called the gel phase or *macrogel*,[3] and is usually eliminated and quantified by centrifugation. The soluble fraction contains the polyisoprene macromolecules, and a variable quantity of microaggregates between 1 and 15 μm in diameter,[4] forming the *microgel*.

Numerous *Hevea* varieties, referred to as "clones" in professional jargon, can be found in estates. Subramaniam[5] was the first to study NR from different clone by size-exclusion chromatography (SEC) and to know about the native molar mass distribution (MMD_0). MMD_0 is the molar mass distribution of polyisoprene leaving the tree, without any treatments (drying, shearing) that could modify it. As we see later, MMD_0 is a very important clonal parameter for prediction of some properties of raw commercial NR.

This entry describes the different stages of NR analysis by SEC, concentrating on the points that distinguish NR from other more conventional polymers. The second part of the paper focuses on the evolution of macromolecular structure according to different agronomic or processing parameters.

SEC METHODOLOGY

Dissolving an Eluant

In most cases, tetrahydrofuran (THF) has been used as the mobile phase, except by Bartells et al.,[6] who used cyclohexane. However, using THF to analyze NR by SEC can raise certain problems.[7] As a general rule in our laboratory, the samples of NR are dissolved in cyclohexane (HPLC grade) stabilized with 2,6-di-*tert*-butyl-4-methylphenol (internal standard), at a rate of 60 mg for 30 ml of solvent. The solutions, stored at 30°C, are gently stirred for 1 hr periodically for 14 days.

Equipment

The equipment used consisted of a conventional SEC system [gas extractor, a pumping system, an injector, column(s), and detector(s)]. It is important to use a column oven. At room temperature, injecting NR solutions in SEC can block the columns. The oven temperature depends on the solvent used as the mobile phase. With cyclohexane, the oven temperature must be 65°C to overcome adsorption phenomenon due to the very low polarity of this solvent. When using THF, the oven is heated to 50°C.

Using columns with a porosity of 20 μm is also recommended, in order to shear at least the long chains of the polyisoprene.[8] As molar mass distribution (MMD) in NR is quite wide ($3 < I < 10$), the columns need to offer a considerable separation range.

As cyclohexane does not require an added stabilizer in the mobile phase, it means UV detection at 220 nm can be used. This is important as this type of detector is more sensitive than a refractometer. In fact, as NR is a polymer with a very high molecular weight, it is recommended that low-concentration solutions of maximum 0.2 mg/ml are injected, so as to overcome viscosity effects and avoid excessive shearing of the macromolecules.[9,8] Of course, a light scattering detector or a viscometer can be added to the system to access the branching rate.[10,11]

Calibration

Cyclohexane as the mobile phase requires the use of polyisoprene standards, as polystyrene standards are not soluble in this solvent. It should be noted that calibration by polystyrenes results in an overestimation of molar masses by a factor of around 2 compared to the use of polyisoprene standards.[12] It is therefore necessary to carry out universal calibration or convert molar masses using the Mark Houvink coefficients relative to synthetic or natural polyisoprene.[5,6,10,13,14]

Filtering the Solution Prior to Injection

The solution obtained after centrifugation is diluted to 0.2 mg/ml. It is left to stand for 24 hr and filtered through a disposable filter (glass fiber) with a porosity of 1 μm to eliminate the microgel. The filter porosity is very

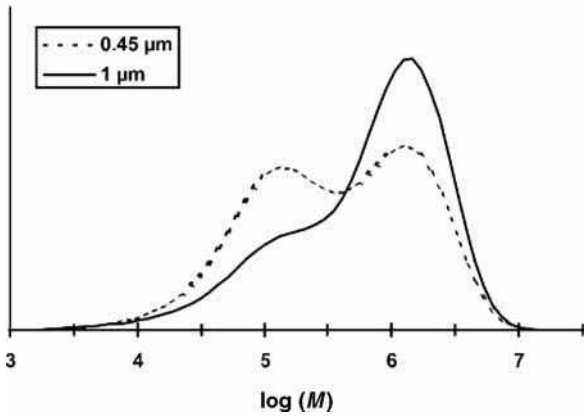

Fig. 1 Influence of the filter porosity on the molar mass distribution.

important, as the MMD observed after filtration through 0.45 or 1 µm is very different (Fig. 1). By filtering through 0.45 µm, shearing is considerable in the case of NR.

Macrogel Quantification

Once solubilization is complete, the solution is centrifuged (35,000 g—1 hr—17°C). The quantity of macrogel is determined by weighing the centrifugation residue after drying.

Microgel Quantification

The determination of microgel rate is possible by knowing the initial concentration of injected solution and the part eliminated by filtration. The latter can be determined from the polyisoprene peak area of the chromatogram.

Using UV detection with SEC, the Beer–Lambert law:

$$A = \varepsilon l C \tag{1}$$

with A being the absorbance, ε the molar extinction coefficient, l the cell length (cm), and C the concentration (mg/ml), implies that the area of the rubber peak, in a given chromatogram, is proportional to the concentration of the injected solution. For a given sample injected into the SEC apparatus, a calibration curve $S = f(C)$ (S is the area of the rubber peak and C is the concentration of the injected solution) gave the concentration of the solution after filtration. The calibration curve $S = f(C)$ is obtained from polyisoprene standards. Thus, the concentration of the solution was known before and after filtration, and the fraction eliminated by filtration, i.e., the percentage of microgel, could be determined.

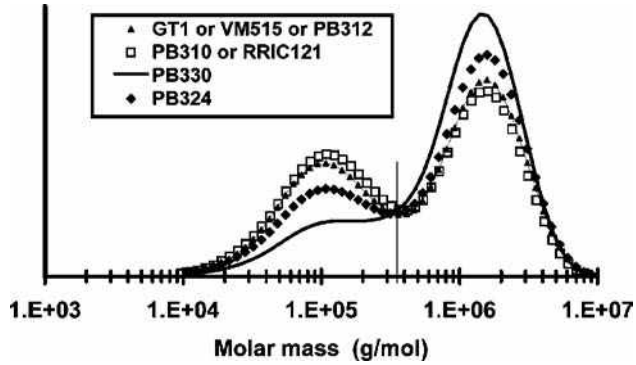

Fig. 2 Native molar mass distribution for different *Hevea* clones.

EVOLUTION OF MMD ACCORDING TO CLONALE ORIGIN OR PROCESSING

Natural rubber is a product of biological origin. This gives to it a structure particularly complex, and variable, according to agronomical parameters, as many polymers from natural origin. The main factor of influence is the *Hevea* clone from which the latex comes (Fig. 2). The MMD_0 show the presence of two main populations of variable relative amounts according to the clone: One of long chains (350–10,000 kg/mol, eq PI) and the other of short chains(10–350 kg/mol, eq PI). According to Angulo-Sanchez and Caballero-Mata,[10] the proportion of low molar masses would be principally linear macromolecules and the high molar masses would be mainly branched macromolecules. However, results of Tanaka, Kawahara, and Tangpakdee[2] allow to doubt this because after methanolysis of NR, a reaction that eliminates interactions involved in macrogel structuring, the bimodal distribution is maintained.

The MMD_0 is an important criterion to predict some properties of NR obtained after processing. The special

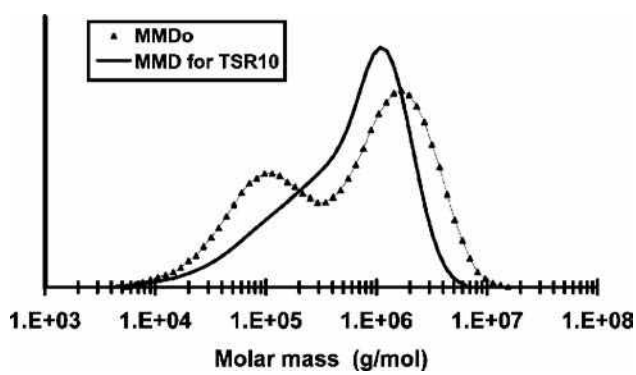

Fig. 3 Native molar mass distribution and molar mass distribution of TSR10 from clone PR107.

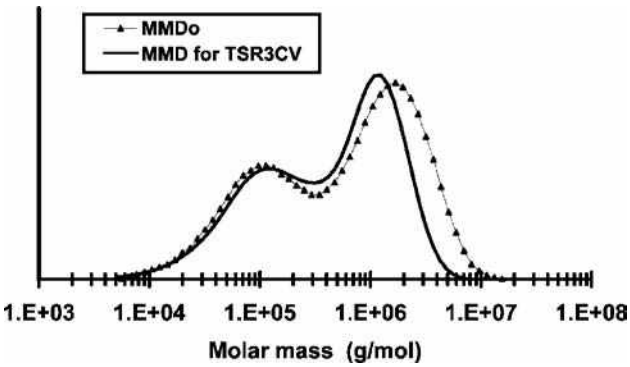

Fig. 4 Native molar mass distribution and molar mass distribution of TSR3CV from clone PR107.

feature of a MMD_0 "bimodal" or "unimodal with shoulder" will condition processed NR properties.[15] The natural coagulation of the latex and the maturation of the coagulum obtained (several days, commercial rubber type TSR10) will modify the macromolecular structure of NR. During these biological processes, the MMD of the dry processed NR lost the initial bimodal distribution of MMD_0 (Fig. 3). On the other hand, if the latex is stabilized with neutral hydroxylamine sulfate and coagulated with acid, with a minimum maturation of the coagulum (<16 hr, commercial rubber type TSR3CV), the bimodal distribution is maintained (Fig. 4).

CONCLUSIONS

Macromolecular structure of NR, as with any synthetic or natural polymers, needs to be known for several aspects (properties, biosynthesis mechanisms, etc.). SEC is probably still the best technique today but with certain obligations, especially the use of columns with high porosity (20 μm). SEC can be used not only for macromolecular analysis but also to determine microgel rate, an important parameter for NR.

Neuropeptides and Neuroproteins by CE

E.S.M. Lutz
Bioanalytical Chemistry Department, AstraZeneca R&D Mölndal, Mölndal, Sweden

INTRODUCTION

Neuropeptides comprise peptide neurotransmitters and neuromodulators occurring primarily in the central nervous system (CNS), but may also be found in peripheral tissues. In order to study their physiological effects and their role in a variety of physiological functions (e.g., sensory information, food intake control, regulation of hormone secretion, and control of the sleep–waking cycle), methods for accurate determination of neuropeptides in biological tissues and fluids are required. Typically, immunoassays are used for this purpose, but cross-reactivity, especially with unknown fragments and matrix components, compromises quantitative analysis. In addition, immunoassays are generally designed for a single analyte, whereas neuropeptide research regularly aims to separately determine several neuropeptides in the same sample. One approach to inducing selectivity and allowing multiple neuropeptide analysis is to employ high-performance separations such as capillary electrophoresis (CE) in combination with appropriate sample handling and sensitive detection.

CAPILLARY ELECTROPHORESIS OF NEUROPEPTIDES AND NEUROPROTEINS

Because peptides and proteins are zwitterionic substances whose charge can be controlled through the pH, CE is well suited to provide high-speed separations with high efficiency, good mass sensitivity, low sample consumption, and high resolution. Differences relative to CE of low-molecular-mass compounds are due to the larger size of peptides and proteins, their secondary and tertiary structures, and their tendency to interact with the wall of bare fusedsilica capillaries. This is valid for peptides and proteins occurring primarily in the CNS and for other peptide and protein analytes. For further reading, see the entry on Capillary Isoelectric Focusing of Peptides, Proteins, and Antibodies as well as to more extensive reviews (e.g., CE on opioid peptides by Lee et al).[1]

Briefly, CE of peptides and proteins is often performed in uncoated fused-silica capillaries. In order to reduce interactions with the wall and to ensure that all peptides and proteins are charged, a buffer with a low pH (e.g., 50 mmol/L phosphate pH 2.5) is commonly used. Consistent rinsing protocols are required between runs, such as 0.1 mol/L NaOH followed by rinsing with the running buffer in order to remove adsorbed contaminants. When such rinsing procedures are not in compliance with the total analytical system or when adsorption of the analyte and/or matrix components hampers analysis, coating of the capillaries may prove useful. Adsorption phenomena can also be influenced by pH adjustment, temperature control, or by adding ionic and non-ionic surfactants, organic solvents, or ion-pairing reagents to the running buffer. Both capillary coating and use of buffer additives affect the electro-osmotic flow leading to a reduction or a reversal of the flow, which, in turn, will affect the time required for separation.

Concentration sensitivities achieved in CE typically lie in the micromoles per liter or nanograms per liter range and are limited by sample loadability and detector path length (often 20–100 μm). Whether such concentration sensitivity is sufficient for a certain biochemical or pharmacological investigation depends primarily on the application. Complexity of the sample, concentration range of the analyte, and sample volume are all factors determining whether CE can be applied to analyze neuropeptides and neuroproteins in real-life samples. Plasma concentrations often are in the picomoles per liter range and can, accordingly, only be analyzed by CE after rigorous sample concentration. For instance, average concentrations of β-endorphin, methionin and leucine–enkephalin in 20 human plasma samples were determined to be 20 ng/ml, 2 ng/ml, and 2 ng/ml, respectively.[2] On the other hand, sampling of discrete areas in the brain can provide small samples with considerably higher concentrations of neuropeptides, and clear differences in concentrations may exist in the healthy and diseased states. For example, base levels of vasoactive intestinal peptide, substance P, and neuropeptide Y in nasal tissue of normal individuals are 28, 16, and 12 pg/μg protein, whereas patients suffering from allergy may have concentrations of 63, 165, and 98 pg/μg protein in perivascular lesion areas in the nasal tissue.[3]

Even though free-solution CE is most commonly used for neuropeptides and neuroproteins, other forms of CE have also been employed. For instance, as an alternative to conventional slab-gel electrophoresis, a method using sodium dodecyl sulfate (SDS) capillary gel electrophoresis was developed. It was applied to low-molecular-mass proteins (β-trace protein, β_2-microglobulin, φ-trace protein, and myelin basic protein) in cerebrospinal fluid.[4]

Advantageous features of capillary gel electrophoresis over slab-gel electrophoresis are compatibility with small sample volumes, shorter analysis times, and more accurate quantification of the analytes.

Generally, integration of sample collection, preparation, and introduction with the analytical separation and detection is decisive for successful application of CE to neuropeptide analysis; why both sample handling and detection will be discussed in this context.

SAMPLE HANDLING

Sample collection and preparation are crucial issues for any bioanalytical application in order to address the complexity of samples originating from biological tissues and fluids. It is necessary to cope with the lack in concentration sensitivity typical for capillary separation techniques, to avoid interference from matrix components as well as to ensure analyte stability. In peptide analysis, a strong focus exists on handling small-volume samples and on selective concentration of the analyte in order to overcome limitations with respect to loadability. In addition, loss of analyte frequently occurs due to degradation by proteases and due to adsorption to surfaces, which accordingly needs to be minimized.

In brain research, microdialysis sampling employing a miniaturized dialysis unit (probe) containing a dialysis membrane of a few millimeters length has become popular. The probe is implanted into the tissue or organ of the test animal and is infused with an isotonic solution (typically at 0.5–25 μl/min). A steady-state osmotic flux across the membrane removes molecules with a mass below the cutoff of the membrane from the extracellular matrix. Microdialysis yields relatively clean samples of volumes in the range 20–100 μl. However, the recovery of neuropeptides can be as low as 0.5–15%, leading to a low neuropeptide concentration in the samples.[5,6]

Problems with recovery are avoided when sampling the extracellular brain tissue by means of a push–pull cannula. A push–pull cannula consists of two coaxial assembled hollow needles (cannulae) which are implanted into the brain. Artificial cerebrospinal fluid is infused through the inner cannula and withdrawn through the outer cannula.[5–8]

In addition, a whole-tissue sample can be taken by means of routine pathological biopsy. Tissue samples are typically homogenized under denaturating conditions (0.1 mol/L HCl), centrifuged, and the supernatant is then used for further analysis.[5] When of interest, even morphologically defined areas can be investigated after being isolated by means of microdissection prior to further sample treatment. For example, nasal tissue biopsies were taken and perivascular lesion tissue or normal tissue 5 mm from the lesion were isolated by means of microdissection preceding further analysis.[3]

As discussed in-depth elsewhere in this encyclopedia, sample composition is important with respect to peak efficiencies achieved in CE. When the sample has a lower conductivity than the running buffer, focusing occurs, which often is referred to as sample stacking. This is a convenient way of increasing concentration sensitivity 5–10-fold. However, when the sample has a higher conductivity than the running buffer, uneven migration of the analyte(s) and zone spreading will occur, resulting in lower concentration sensitivities. Biological samples therefore need to be desalted prior to submitting them to capillary electrophoretic separation.

Desalting of biological samples can be achieved with traditional sample preparation methods, including ultrafiltration, liquid–liquid extraction, and solidphase extraction (SPE). Sample preparation, especially of plasma samples, involves, most often, protein precipitation by means of an acid or an organic solvent (e.g., acetonitrile), followed by SPE. After evaporation of the eluate and reconstitution in the running buffer used for CE, [D-Pen^{2,5}]enkephalin was analyzed in rat serum in this way.[9] These traditional sample preparation methods usually include deproteination, which reduces the protease content of the sample and improves analyte stability. Another option to reduce peptide degradation during sample handling is to add a protease inhibitor (e.g., 1 m mol/L leupeptin).[3]

Even under ideal circumstances, samples that are ready for CE analysis are in the microliter range, whereas typical injection volumes in CE are a few nanoliters. In order to take full advantage of the sample, increased injection volumes without column overload are desirable and can be achieved by coupling (transient) isotachophoresis (ITP) to CE. During ITP, the concentration of the sample introduced into the capillary is adapted to the concentration of the leading buffer, thus focusing the sample in a discrete zone. A discontinuous buffer is used during ITP, and after a change in conditions, separation by capillary zone electrophoresis continues. On-column ITP enables focusing of 10–100 times higher injection volumes (100–1000 nl), but it is limited to the total volume of the analytical system.

Another approach to increase the loadability is to enrich the analyte at the capillary inlet by means of an adsorptive phase, as reviewed in detail in Ref.[10] Reversed-phase materials such as octadecyl-bonded silica have regularly been used in the form of membranes or column materials, thus, in principle, performing miniaturized SPE (μSPE) in-line with CE, allowing injections of 10–15 μl. More selective sample concentration is obtained when using antibodies or Fab fragments for coating the inner wall of the capillary inlet.[3,5]

Often a combination of techniques is used to achieve a sufficient concentration of the sample in combination with selective cleanup—for instance, a combination of microdialysis and immunoaffinity CE,[11] microdissection and SPE,[7] or microdialysis and μSPE.[12]

DETECTION

Detection of neuropeptides in CE is usually performed by ultraviolet (UV) absorbance, fluorescence and mass spectrometry (MS). UV absorbance is widely used for detection in CE, often at 214 nm, because it is inexpensive, robust, and widely available on commercial instruments. Typically, concentration sensitivities lie in the micromoles per liter range, as shown in an application starting from 2.5-ml lumbar cerebrospinal fluid, where detection limits of neuroproteins with UV absorbance detection at 214 nm between 5 and 10 μg/ml, corresponding to 0.1–1 μmol/L, were reported.[4] In order to address the lack of sensitivity achieved with UV absorbance detection, path lengths in the detection window have been increased threefold by means of the bubble cell and 10-fold by applying the so-called *z*-cell.

Tryptophan and tyrosine are intrinsic fluorophores that are present in many peptides, which then can be identified with fluorescence detection. However, most peptides have no native fluorescence, thus making derivatization a prerequisite for fluorescence detection. Derivatization has been described with naphthalene-2,3-dicarboxaldehyde-β-mercaptoethanol for determination of substance P and its metabolites,[6] fluorescamine,[5] and 5-carboxyfluorescein succinimidyl ester[8] for luteinizing hormone-releasing hormone (LHRH), neuropeptide Y, and β-endorphin. Kostel and Lunte[6] compared various postcolumn reactor designs, whereas Advis et al.[5,8] employed precolumn derivatization, among others. In order to improve sensitivity, laser light is frequently employed for exciting the fluorescent molecules referred to as laserinduced fluorescence (LIF) and provides a 500–1000 times improved sensitivity compared to UV detection.

Mass spectrometry is another detection technique widely used in neuropeptide analysis. Concentration sensitivities in CE/MS do not reach those obtained by CE/LIF; nevertheless, tedious derivatization procedures are avoided. In addition, CE/MS has proven to be a powerful tool for structure elucidation as illustrated by the investigation of the in vivo metabolic fate of peptide E by Caprioli's group.[12] After microdialysis and in-line SPE, neuropeptides migrating out of the electrophoresis capillary were deposited directly onto a precoated cellulose target used in matrix-assisted laser desorption–time of flight (MALDI–TOF) MS subsequently. Structural information is then obtained along with the mass of the peptide(s).

More extensive structural information is obtained when using MS-MS, where information on the peptide sequence can be extracted from the fragmentation pattern. So far, CE/MS-MS has predominantly been performed with electrospray ionization (ESI)-triple quadrupole and ESI-ion trap instruments, as reviewed in Ref.[13] The advent of ESI-TOF and ESI-quadrupole-TOF instruments is believed to have a strong impact on CE/MS. TOF instruments require an extremely short time to produce a full mass spectrum and are especially attractive as a detection device for a separation technique producing sharp peaks, as illustrated by the separation of three enkephalins in a time window of 6 sec with detection by means of ESI-TOF.[14]

CONCLUSIONS

In this entry, an overview is given over the implementation of CE in neuropeptide and neuroprotein analysis. So far, relatively few applications in biological matrices, including cerebrospinal fluid, plasma, and neural tissue, have been published; nevertheless, the potential of this approach has been demonstrated over the past years and the number of publications is growing steadily. Accordingly, it is expected that more research groups will be enticed to use CE for neuropeptide and neuroprotein analysis.

Neurotransmitter and Hormone Receptors: Affinity Chromatography Purification

Terry M. Phillips
Ultramicro Analytical Immunochemistry Resource (UAIR), DBEPS, ORS, OD, National Institutes of Health, Bethesda, Maryland, U.S.A.

INTRODUCTION

The isolation of membrane receptors has great application in a number of fields ranging from structural biochemistry to pharmacology and the medicinal sciences. Although many biochemical approaches to receptor purification are available, the application of affinity techniques holds perhaps the greatest promise. The use of selective receptor ligands promises isolation not only of a specific receptor but also possibly in a bioactive form. The use of immobilized receptor ligands often ensures that the integrity of the receptor structure is maintained during the isolation process due to protection of the receptor binding domains by the ligand itself. Additionally, receptors can be isolated either via a chromatographic system or by batch technology. The application of ligand-coated magnetic beads offers a quick and relatively simple approach to receptor isolation and its use is now becoming a standard approach.

AFFINITY LIGANDS

The application of biotinylated receptor substrates is a useful approach, incubating the biotinylated substrates with their specific receptors prior to isolation on an avidin-coated support.[1] In such cases, biotinylation with a cleavable reagent such as Sulfo-NHS-SS-biotin or NHS-Iminobiotin is essential for recovery of the isolated receptor. Alternatively, the receptor can be recovered by substrate competition.

One of the major drawbacks to the application of affinity techniques is the relative low molecular weight or small size of receptor ligands, which makes them difficult to immobilize. However, this factor has not stopped affinity procedures from being applied to the purification of a number of different receptors, although relatively little work has been reported on those involved in the processing of neurotransmitters, neuropeptides, and hormones.[2,3]

Ligands used to isolate neurotransmitter and hormone receptors have ranged from immobilized receptor substrates to immobilized antireceptor antibodies, the latter being used extensively in recent years. This marks the increased availability of specific monoclonal antibodies to specific receptors and/or receptor domains and the increasing popularity of solid-phase extraction techniques over more physicochemical ones. The use of antibodies also circumvents problems arising from the immobilization chemistry required to maintain not only the integrity of receptor ligands but also their correct orientation. The rise of molecular biological techniques has opened a new approach to studying receptor structure and function. Cloning and expression of recombinant receptors in bacterial, yeast, or insect cells allows the investigator to engineer the receptor structure as well as the quantity of materials available for study. This situation has also increased the use of antibodies for the isolation of these recombinant receptors from culture medium.[4]

DISCUSSION

Cosgrove et al.[5] described studies that isolated a recombinant ectodomain of the human insulin receptor using immobilized insulin as an affinity ligand for chromatographically isolating the receptor domain. The efficiency of this system was shown by close similarities between the isolated receptor domain and the native form isolated by physicochemical techniques. The process also allowed for the receptor to be isolated in a bioactive form, as shown by its ability to bind insulin with a K_d of approximately 2×10^{-9} M. Feng et al.[6] approached the isolation of a recombinant human estrogen α-receptor in a different manner. They used a sequential heparin and 17-β-estradiol–17-hemisuccinate–bovine serum albumin affinity chromatography system to first remove the majority of the contaminating materials in the culture medium, followed by selective binding of the receptor to its substrate. This approach easily isolated the receptor, yielding 100-fold purification of a bioactive receptor. Ohtaki et al.[7] employed a biotinylated substrate to isolate a recombinant human pituitary adenylate cyclase-activating polypeptide (PACAP) receptor expressed in both insect cells and Chinese hamster ovary cells. The biotinylated ligand was immobilized on an avidin-coated support, allowing the receptor to be isolated by affinity chromatography.

The use of immobilized antibodies is perhaps the most popular approach to receptor isolation. Andersen and Stevens[8] employed a combination of immobilized metal affinity and immunoaffinity chromatography to isolate a functional recombinant human D_{1A} dopamine receptor

expressed in *Saccharomyces cerevisiae*. This was achieved by engineering both a FLAG and a His6 tag to the C-terminus of the receptor. The histamine tag was used to perform a primary selection via metal affinity chromatography, while immobilized antibodies directed against the FLAG tag were used in the second purification step. In this way, a bioactive recombinant receptor could be isolated in a relatively pure form. Recombinant human β-1 thyroid hormone receptors were isolated using a one-step immunoaffinity chromatography procedure.[9] Antibodies directed against the receptor were immobilized to a suitable chromatographic support, enabling the recovery of a bioactive receptor capable of binding 3,3′,5-triiodo-L-thyronine with a $K_a = 2 \times 10^{-9}$ *M*.

Eckard, Beck-Sickinger, and Wieland[10] isolated a series of rhodopsin-like, G-protein-coupled neuropeptide Y receptors (Y1, Y2, Y4, and Y5) using immunoaffinity chromatography. Antibodies were raised against synthetic fragments of the second (E2) and third (E3) extracellular loops of the Y receptors and used to recover the receptors of interest. In a similar manner, murine glucocorticoid receptors have been isolated from a lymphoma cell line by immunoaffinity chromatography using an immobilized monoclonal antibody.[11] The antibody called BUGR-2 was coupled to protein A-coated Sepharose 4B beads and used in a chromatography system. Recovery of the bound receptors was achieved by epitope competition. This procedure released not only multiple receptors but also the heat shock proteins 70 and 90, suggesting that the murine receptor interacts with these proteins, which may act as chaperones under physiological conditions. Repa et al.[12] also employed immunoaffinity chromatography for the isolation of members of the steroid/thyroid hormone receptor superfamily. Isolation of recombinant retinoic acid receptors expressed in an insect cell line was achieved by immunoaffinity chromatography using a monoclonal antibody to the human γ-retinoic acid receptor. The immunoaffinity-purified receptor was found to be biochemically greater than 90% pure, as revealed by silver-stained electrophoretic gels, as well as functional, binding its ligand with a K_d of approximately 2 n*M*.

Neurotransmitters: HPLC Analysis

Joseph J. Pesek
Maria T. Matyska
Department of Chemistry, San Jose State University, San Jose, California, U.S.A.

INTRODUCTION

High-performance liquid chromatography (HPLC) has proven to be a valuable tool for the analysis of many metabolically important compounds. Neurotransmitters represent a class of compounds that have physiological and clinical significance. Their analysis in biological samples has often been done by gas chromatography/mass spectroscopy but gas chromatography/mass spectrometry (GC/MS) is only possible after extraction and/or derivatization. Because many neurotransmitters lack a suitable chromophore for detection in the UV–Visible spectral range, analysis by HPLC most often utilizes other means, such as electrochemical methods. Mass spectroscopy is a particularly useful detection mode for neurotransmitters when combined with HPLC, since it provides both good sensitivity and positive identification of the analyte. Both electrospray and atmospheric pressure chemical ionization (APCI) have been used as ionization methods for the LC/MS analysis of several of these types of compounds.

APPLICATIONS OF NEUTOTRANSMITTER ANALYSIS BY HPLC

Electrochemical Detection

The absence of a sensitive chromophore for many neurotransmitters has led to the use of other types of detection for these compounds. Because of the presence of an amine functionality in these analytes, electrochemical detection (ECD) is a viable and sensitive approach. Numerous examples of such analyses exist in the literature and, until recently, it was the most frequently used detector for neurotransmitters. ECD is generally done in the amperometric mode where very small currents can be measured, owing to the presence of a low background signal. For example, extracts of biological tissue were analyzed by μHPLC under reversed phase conditions, 82.5 : 17.5 citrate buffer (pH 3.2)/acetonitrile, using a C_{18} stationary phase.[1] Currents were in the low nanoamp range and detection limits on the order of 10 ng/ml. Under similar pH conditions, with a mixed citrate/acetate buffer/methanol 85 : 15 mobile phase, neurotransmitters from rat brain tissue were also analyzed with a C_{18} column.[2]

In addition to standard amperometric analysis on conventional electrodes, several other options exist for ECD. Electrodes can be chemically modified to increase both selectivity and sensitivity for the analytes. Poly(para-aminobenzoic acid) (P-pABA) was used for the analysis of monoamines and their metabolites.[3] These types of neurotransmitters were detected in nerve cells using the P-pABA modified electrode. An example of a separation of these compounds using a C_{18} column and a 5 : 95 methanol/0.1 *M* phosphate buffer (pH 5.0) mobile phase is shown in Fig. 1, using both a modified and a bare carbon electrode for detection. Further improvements in sensitivity and selectivity can be obtained by combining chemically modified electrodes with other electrochemical modes of operation. Neurotransmitters in cerebrospinal fluid were detected after separation by HPLC using cyclic voltammetry and differential pulse voltammetry.[4] It was shown that linear responses of over three orders of magnitude were obtained in these modes with the chemically modified electrodes. Other coatings have included ion-exchange polymers and a gold colloid that included the protein glucose oxidase[5] with detection by differential pulse voltammetry. These electrodes were found to be suitable for monitoring separations of both neurotransmitters and glucose in rat brain tissue.

Mass Spectrometric Detection

Mass spectroscopy is rapidly becoming the universal detector of choice because of its excellent sensitivity and specificity in identifying analytes. Costs for MS detectors have dropped considerably and they are more affordable to a greater number of laboratories. Operation of mass spectrometers is more straightforward and interfaces to HPLC systems are more rugged. Thus, it is logical that an increasing number of studies, as well as established methods for neurotransmitters, utilized MS detection. The analysis (total ion chromatogram) of a four-component catecholamine mixture on two hydride-based stationary phases in the reversed phase mode is shown in Fig. 2.[6] The elution order on the two columns is the same, but with higher retention on the cholesterol column. The identity of each peak in the chromatogram was verified from the mass spectral data.

Mobile phase 5 : 95 acetonitrile/25 m*M* ammonium formate. Solutes: **1** = l-methyl-dopa (10 μg/ml); **2** = norepinephrine (3 μg/ml); **3** = epinephrine (10 μg/ml); **4** = dopamine (10 μg/ml).
Source: From Evaluation of hydride-based stationary phases for LC/MS, in Chromatographia.[6]

When trying to analyze more complex samples, the versatility, sensitivity, and the more extensive positive identification power of tandem mass spectroscopy (MS/MS) is increasingly being utilized for the analysis of neurotransmitters. These capabilities were highlighted for the measurement of several neurotransmitters and cocaine in brain fluids.[7] A rapid, sensitive, and positive identification method was developed for these analytes. The analysis of the target compounds was completed in 4 min and detection limits were in the pM range for the neurotransmitters and sub-pM for cocaine. A specific assay for the inhibitory neurotransmitter γ-aminobutyric acid was developed by a combination of HPLC and MS/MS.[8] The method encompassed a linear calibration curve of over two orders of magnitude and the detection limit was approximately a factor of 10 below the concentrations encountered in physiological samples. Similar LC/MS/MS methods have been, and are continuing to be, developed for many neurotransmitters using a variety of biological sources and preparative methods.

Other Detection Modes

Despite the apparent advantages of using electrochemical or mass spectroscopic methods of detection, other

approaches have been developed for those laboratories not possessing these types of equipment or, in some instances, for the specific analysis of a particular neurotransmitter. Similar to other types of analyses, improved detectablity and, hence, sensitivity is provided by derivatizing the analyte. Fluorescence spectroscopy is one mode of detection that is often used to improve sensitivity with respect to the more commonly used UV–Visible absorption technique. In the case of neurotransmitters based on amino acids, derivatization with dansyl chloride has been shown to be an effective means for determining these particular analytes.[9] Fig. 3 illustrates the separation of the derivatized amino acid standards, as well as target analytes in biological samples. Derivatization usually occurs before separation so that the HPLC properties of the target molecules are altered. In the case of dansyl modification of amino acids, the compounds become more hydrophobic and, hence, more amenable to

separation by reversed phase methods. Some derivatives, such as the dansyl moiety, allow a choice of either fluorescence or absorbance for detection.[9] In certain cases, specific reagents have been developed for targeted compounds in biological samples. One example is the use of *O*-phthaldialdehyde-mercaptoethanol derivatization for the analysis of glutamate and aspartate.[10] Depending on the reagent used and the desired analyte(s), the chromatographic method can be either isocratic[9] or gradient.[10] Other variables that must be considered in optimizing the method include choice of organic modifier, buffer, and pH. The latter is particularly important, since most of the neurotransmitters have ionizable groups, usually bases.

For physiological studies, it has been demonstrated that the use of radioactively labeled compounds can be used to follow the fate of a neurotransmitter and its metabolites. Dopamine metabolism can be elucidated through the use of a tritiated derivative, which was followed in vivo in rats.[11] The samples are extracted, from biological tissue by microdialysis and subsequently separated by standard HPLC methods (generally reversed phase on a C_{18}-bonded stationary phase). Detection of analytes via liquid scintillation measurement offers high sensitivity that, in most instances, is equal to or greater than that obtained from fluorescence spectroscopy or mass spectroscopy.

CONCLUSIONS

The analysis of neurotransmitters is a challenging and rapidly changing application area of HPLC. In most cases, conventional reversed phase methods are used for the separation aspect of the analysis. Because of the polar and, in many cases, basic character of these compounds, other options do exist, such as normal phase (organic and aqueous) and ion-exchange, which are also possible. The crucial feature in developing new methods for neurotransmitters often depends on the method of detection. Owing to the lack of strong chromophores in most neurotransmitters, conventional optical detection by UV–Visible absorption is usually not a viable option. Since the analysis of neurotransmitters often involves extracts from biological tissue or clinical samples, high sensitivity is an important criterion. Therefore, other methods of detection have been preferred, particularly for practical applications. Electrochemical methods and, more recently mass spectroscopy, have dominated method development for these compounds. In the case of ECD, the technique has high sensitivity with some selectivity. MS offers both high sensitivity and selectivity. Fluorescence spectroscopy and radiochemical methods are other options that can provide the sensitivity required for biological samples.

Nitrofurans: HPLC Analysis

Mochammad Yuwono
Gunawan Indrayanto
Faculty of Pharmacy, Airlangga University, Surabaya, Indonesia

INTRODUCTION

Nitrofurans are a class of synthetic, broad-spectrum antibiotics which have been widely used in the form of feed additives for the prophylactic and therapeutic treatment of infections caused by bacteria and protozoa in food-producing animals, (e.g., cattle, pigs, poultry, cultured fish, and shrimps). Nitrofurans have also been used as animal growth stimulants, as well as for increasing egg production in layers.[1–3] The most common nitrofurans are furazolidone, furaltadone, nitrofurantoin, and nitrofurazone, which are characterized by the presence of a 5-nitro group. These drugs are rapidly metabolized by animals with in vivo half lives of a few hours, generating related metabolites that are stable during weeks as residues bound to tissue proteins. The metabolites of furazolidone, furaltadone, nitrofurantoin, and nitrofurazone are 3-amino-2-oxazolidinone (AOZ), 3-amino-5-methylmorpholino-2-oxazolidinone (AMOZ), 1-aminohydantoin (AH), and semicarbazide (SC), respectively (Fig. 1).

Furazolidone and its related compounds are used in human medicine for the treatment of urinary tract infections and gastrointestinal diseases. In veterinary practice, the use of nitrofurans can leave drug residues that can be found as contamination in foods of animal origin and in the environment. Residues of these drugs can cause serious health problems for humans, leading to increased drug resistance of microorganisms. Several reports have indicated that nitrofurans have a mutagenic effect, which has been observed in fungi, bacteria, and in submammalian systems. It has also been stated that furazolidone and AOZ, which is the main metabolite of furazolidone, are genotoxic and carcinogenic.[1,4] Therefore, nitrofurans have been banned for food-producing animals by the European Union, the United States, and some other countries. The EU Commission Decision of March 13, 2003 has set minimum required performance limits (MRPLs) at 1 μg/kg for each nitrofuran metabolite.[5]

Numerous analytical methods have been developed for the analysis of nitrofurans in various samples. These include microbiological,[6] thin-layer chromatography (TLC),[7,8] and high-performance liquid chromatography (HPLC) techniques. HPLC is the most widely used technique for determining nitrofurans of food sample origin, such as shrimps,[9] fish,[10] milk,[11] egg and chicken tissues,[12,13] honey,[14] plasma and urine,[15] and animal feeds.[16] One difficulty in the analyses of nitrofurans in biological samples is the complexities of the sample matrices. In addition, the use of nitrofurans in veterinary practice results in trace levels of the parent compound in edible products, due to a rapid metabolism of the compound in the animal. With HPLC techniques, it is possible to reduce interfering background peaks on chromatograms and increase specificity. The combination of HPLC separation and mass spectrometric (MS) detection is a valuable analytical technique that is increasingly being applied to identify nitrofuran in complex matrices, because it offers high sensitivity and selectivity in the analysis of nitrofurans based on its metabolites.

SAMPLE PREPARATION AND HPLC CONDITIONS

Several approaches to sample preparation for nitrofuran analysis have been reported, including using a single solvent to extract the analyte(s) from samples, followed by a single or several clean-up steps. The drugs have been extracted from samples primarily with acetonitrile, ethyl acetate, or dichlormethane. Liquid–liquid extraction using ethyl acetate, followed by evaporation and reconstitution in the mobile phase was reported by Muth et al.[15] for the determination of nitrofurantoin in plasma and urine. The reported recovery of nitrofurantoin was 84%–86% over the concentration range of 0.12–0.24 μg/ml. Hormazabal et al.[17] used acetonitrile for the extraction of furazolidone in meat tissues. The organic layer was separated and evaporated to dryness and then injected into the HPLC system. The recovery was reported to range from 97 to 100%. Liquid–liquid partition procedures are frequently applied as a clean-up step prior to solid–liquid partition using a column or cartridge. Solid phase extraction (SPE) with C_{18} cartridges is generally used in clean-up procedures, where they provide high recovery of the analyte(s). Degroodt et al.[10] reported a method for simultaneous determination of the nitrofuran derivatives furazolidone, furaltadone, nitrofurazone, and chloramphenicol residues in meat and fish. The samples were extracted with ethyl acetate, then purified with petroleum ether and *n*-pentane. The recoveries were reported in the range of 69–88%. A two-stage SPE clean-up was used by Cooper et al.[18] for the multi-residue determination of some veterinary drugs, including nitrofuran

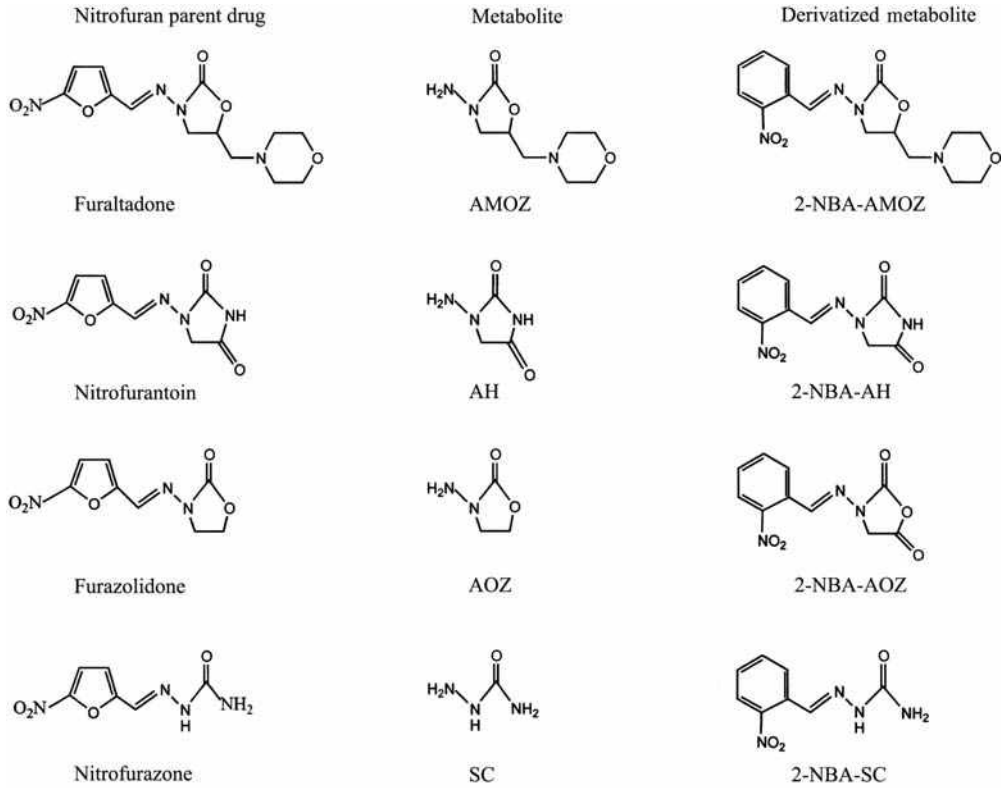

Fig. 1 Chemical structures of nitrofuran parent drug compounds, the metabolites, and their 2-NBA nitrophenyl derivatives.

derivatives, using C_{18} and silica cartridges. The proposed method was applied for screening pig kidney samples, achieving a limit detection of 2–18 μg/kg at recoveries of 40–70%. A one-step extraction/derivatization, followed by SPE clean-up using polymeric cartridges, was described by Edder et al.[9] for the analysis of nitrofuran metabolites in food. Gel permeation chromatography (GPC) has also been reported as the clean-up procedure for the determination of nitrofurans and their cyanometabolites, after liquid–liquid extraction with acetonitrile.[19]

The separations of nitrofurans have been carried out, in most instances, with a reversed phase (RP) column. As summarized in Table 1, C_{18} columns were selected as the analytical column for LC in most reports; however, the use of a C_8, CN, and cyanopropyl-modified silica analytical column has also been described. The parent compounds, as well as their metabolites, are satisfactorily separated by C_{18} columns with commonly used mobile phases, such as mixtures of acetonitrile with phosphate buffer, acetate buffer, or water. The mobile phase elution for HPLC analysis can be isocratic or as a gradient system. Acetonitrile-0.1 *M* aqueous solution of sodium perchlorate (28:72), with 0.5% glacial acetic acid, was reported by Galeano Diaz[20] as an optimum mobile phase for the separation of the three nitrofuran derivatives: nitrofurantoin, furazolidone, and furaltadone in milk. Lin et al.[16] used an acetonitrile gradient with an initial hold time of 1 min at 0% acetonitrile, followed by an increase to 50% acetonitrile over 10 min for the simultaneous separation of furazolidone, nitrofurazone, carbadox, olaquindox, and nitrovin in feed.

UV detection and diode-array detection (DAD) have been widely used, coupled to HPLC, for the analysis of the parent compounds of nitrofurans. The detection wavelengths of nitrofurans have been set at 368 nm,[19] 365 nm,[21] 360 nm,[10,22] 270 nm,[23] or at 254 nm.[24] An HPLC method, with electrochemical detection, has also been described for the monitoring of furazolidone and furaltadone hydrochloride in chicken tissues and eggs.[11]

Typical HPLC chromatograms and UV-spectra, obtained by injecting standard mixtures of nitrofurans (furazolidone, furaltadone, nitrofurazone, and nitrofurantoin) and standard mixtures of nitrofuran metabolites (AOZ, AMOZ, AH, and SC), are presented in Figs. 2 and 3, respectively. Fig. 4 shows a typical chromatogram and UV-spectra of standard mixtures of nitrofuran and its metabolites. Unfortunately, nitrofurantoin and furazolidone, as seen in Fig. 4, cannot be well separated. The optimization to separate the peaks at our laboratory is in progress.[25]

CONFIRMATION PROCEDURES

As described above, the nitrofurans used in veterinary practice are quickly metabolized by the animal,

generating protein-bound metabolites that are detectable for several weeks after administration. Consequently, methods for the analysis of nitrofuran based on the parent drugs are inappropriate. Recently, the analysis of nitrofuran drug residues has been based on the detection of the protein-bound metabolites of their nitrofuran parents. Since the protein-bound metabolites cannot be separated from the tissue protein by liquid–liquid extraction, a hydrolysis step using aqueous hydrochloric acid is usually applied in the sample preparation to hydrolyze the metabolites from the tissue protein. After hydrolysis, it is also necessary to derivatize the nitrofuran metabolites, owing to their small molecular weights. For this purpose, the most commonly used derivatizing reagent is 2-nitrobenzaldehyde (2-NBA), which forms a nitrophenyl derivative (Fig. 1).

Particularly, in a residue analysis, identification of detected analytes is required to confirm a result. For nitrofurans analysis, there are a few confirmatory methods reported, including the use of the photodiode-array system and MS detection. The use of a photodiode array detector coupled to HPLC (HPLC–DAD) offers advantages that the target peak can be identified by its retention time and absorption spectrum. In this case, the continuous spectral data generated during the analysis are collected to check for interfering substances by comparing the spectra of samples with those of the standards. However, the specificity and the limit of detection are not sufficient to determine or identify

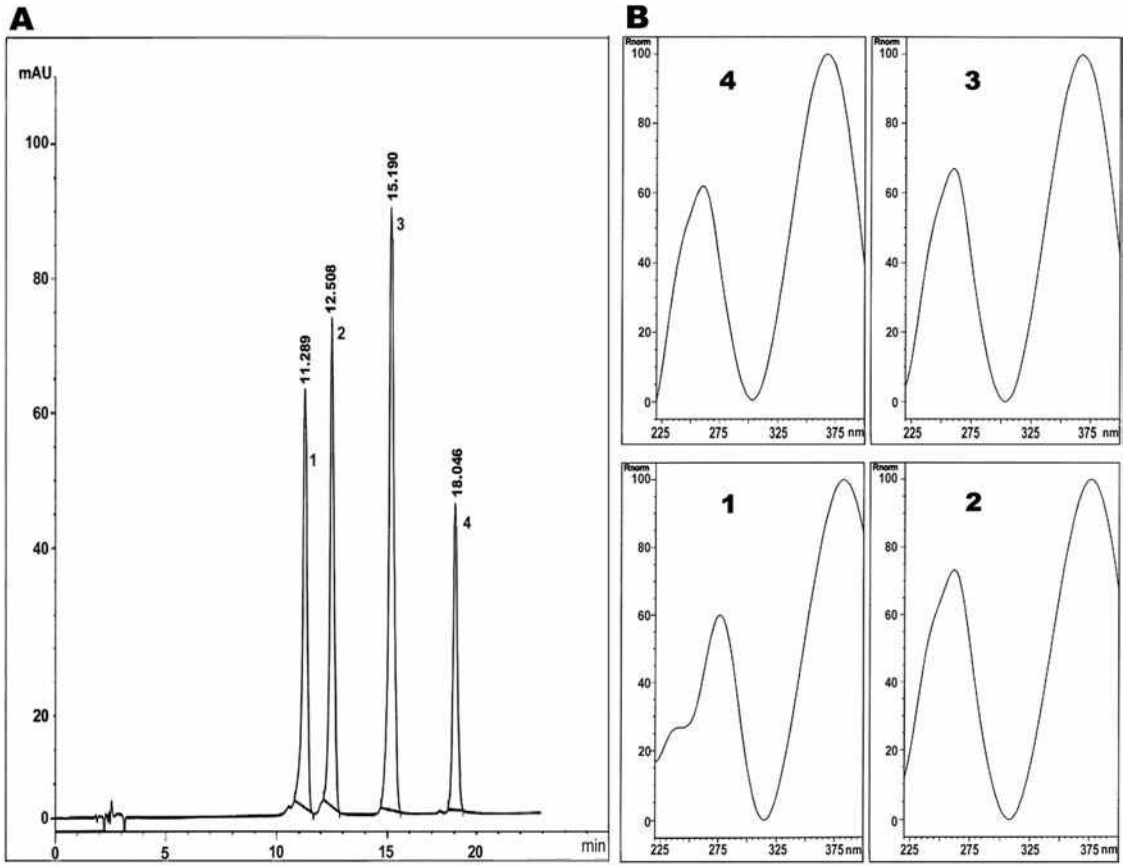

Fig. 2 High-performance liquid chromatography (HPLC) chromatograms (A) and UV-spectra (B) of standard mixtures of nitrofuran parent drugs nitrofurantoin (1), nitrofurazone (2), furazolidone (3), and furaltadone (4).

trace levels of the nitrofuran metabolites in samples. Considerable progress has been made recently in the detection of nitrofuran metabolites by the use of MS techniques[38] and tandem MS, owing to its high sensitivity and specificity. Draisci et al.[39] presented HPLC–DAD and HPLC–MS methods for the confirmation of the identities of nitrofurazone, furazolidone, and furaltadone residues. The HPLC–DAD limit of detection, based on a signal-to-noise ratio (S/N) of 3, was estimated to be 2.5 μg/kg for nitrofurazone and furazolidone and 5.0 μg/kg for furaltadone, whilst the HPLC–MS limits of detection were estimated to be 3.2, 1.6, and 1.0 μg/kg for nitrofurazone, furazolidone, and furaltadone, respectively. Recently, Leitner et al.[40] described a liquid chromatography-electrospray ionization tandem mass spectrometry (LC–ESIMS/MS) procedure for the simultaneous analysis of four nitrofuran metabolites in animal muscle tissues, at limit of detection of 0.5–5 ng/g. The bound metabolites are released from samples by acidic hydrolysis and subsequently derivatized using 2-NBA freshly prepared in DMSO. In this study, SC, as its 4-nitrobenzaldehyde derivative, was used as internal standard. Further sample preparation was improved by the use of SPE, leading to an effective sample clean-up with recoveries of 92–105%. Finzi et al.[41] proposed a similar LC–ESIMS/MS method that allows the simultaneous analysis of the metabolites of four commonly used nitrofuran drugs (AOZ, AMOZ, AH, and SC) in poultry muscle and eggs. The procedure involves an acid-catalyzed release of protein-bound metabolites, followed by their derivatization as described by Leitner et al.[40] A single step liquid–liquid extraction was performed for the sample clean-up before LC–MS/MS analysis. Two deuterated internal standards (AOZ-d4 and AMOZ-d5) were used during the study to mimic the analyte extraction. Limits of quantification of 0.5 ng/g were achieved using electrospray ionization in positive mode in an analytical run of 5 min. Mottier et al.[42] developed a confirmatory and quantitative method based on isotope dilution LC–ESIMS/MS for the determination of four nitrofuran metabolites in meat, e.g., furazolidone, furaltadone, nitrofurantoin, and nitrofurazone. Four isotope-labeled internal standards were used during this study. Liquid–liquid extraction and a polymeric SPE were carried out, after acid hydrolysis and derivatization into 2-NBA imine type derivatives. The method was fully validated following the European Union criteria and applied for monitoring nitrofuran residues in food. The author reported that the method is robust with decision limits ranged between 0.11 and 0.21 μg/kg.

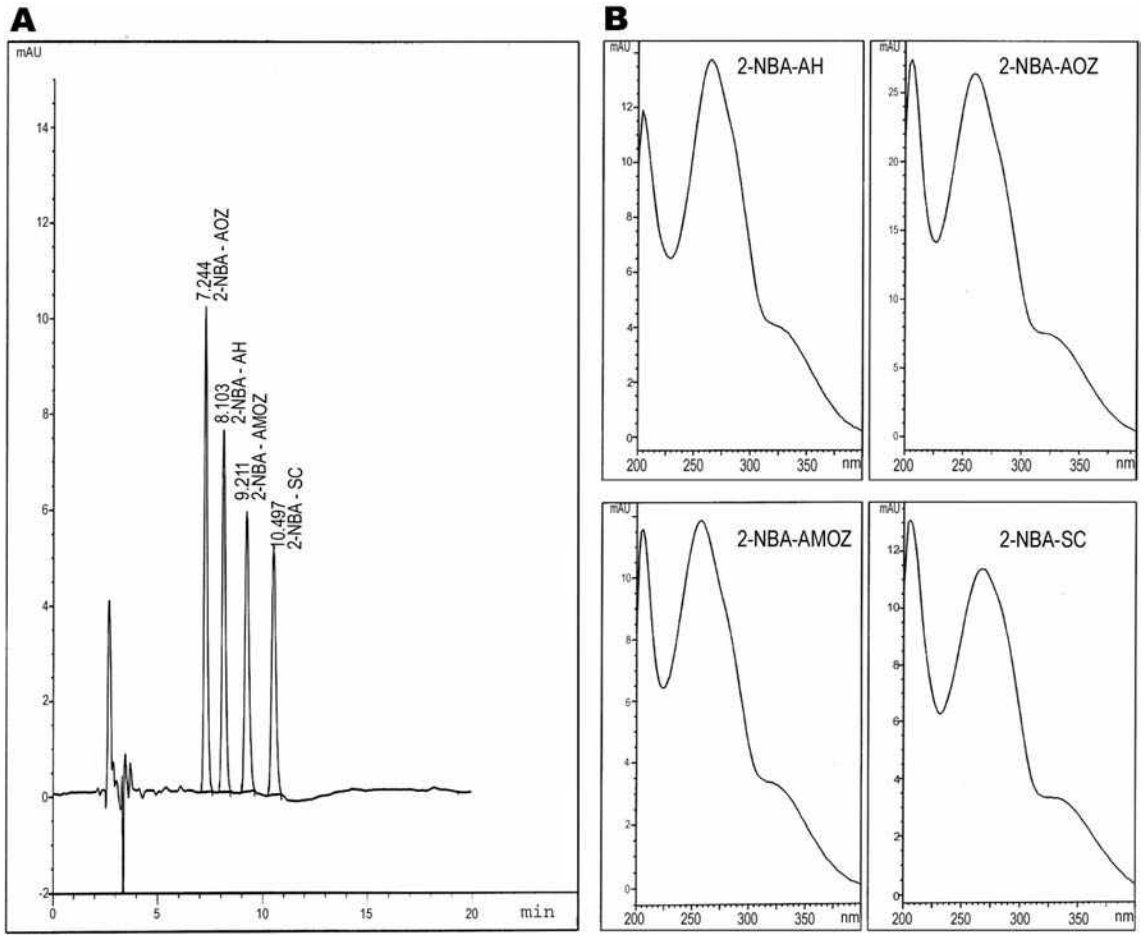

Fig. 3 High-performance liquid chromatography (HPLC) chromatograms (A) and UV-spectra (B) of standard mixtures of nitrofuran metabolites AOZ, AMOZ, SC, and AH after derivatization with 2-NBA.

CONCLUSIONS

High-performance liquid chromatography is the method of choice for the analysis of nitrofuran antibiotics furazolidone, furaltadone, nitrofurantoin, and nitrofurazone in food animal origin. The drugs are characterized by rapid metabolism, leading to trace levels of parent drugs found in samples. However, the metabolites (AOZ, AMOZ, AH, and SC), bound to protein tissues, are toxic and more stable within several weeks. Therefore, some authors have recently focused on the detection of protein-bound metabolites for the analysis of nitrofurans. For this purpose, LC–MS/MS is presently the most modern and promising method, due to its high sensitivity, reproducibility, and specificity.

ACKNOWLEDGMENTS

The authors wish to thank Prof. Dr. Rainer Ebel and Mr. Arnulf Diesel (Institute of Pharmaceutical Biology and Biotechnology, University of Düsseldorf, Germany) for the providing of recent references; DAAD (Deutscher Akademischer Austauschdienst), Bonn, Germany for the financial support during our short visit at some German universities in 2005; Ms. Nur Yanti S.Si, Apt and Mr. Fadjar Zulkarnaen Lubis (Assessment Service Unit, Faculty of Pharmacy Airlangga University, Surabaya-Indonesia) for the valuable technical assistance. Optimization of HPLC procedures for nitrofurans presented in this work is financed by the Indonesian Ministry of Education, DP2M through the research grant "Penelitian Hibah Bersaing XIV.1/2006."

Nitrogen Chemiluminescence: SFC Detection

William P. Farrell
Pfizer Global Research and Development, Pfizer Inc., La Jolla, California, U.S.A.

INTRODUCTION

Supercritical fluid chromatography (SFC) with nitrogen chemiluminescence detection (NCD or CLND) is a chromatographic technique that can be used to obtain quantitative results for nitrogen-containing analytes without the use of matching standards. For industries where sample throughput is an issue, such as combinatorial chemistry, SFC/NCD could reduce the need to isolate large numbers of standards and improve the speed of chromatographic characterization of synthetic reaction products. This entry will discuss the fundamental parameters that need to be considered to make SFC and NCD interfacing successful. Two other forms of nitrogen detection used with SFC will also be mentioned, but they fall outside the scope of this entry.

DISCUSSION

Supercritical fluid chromatography utilizes a compressed or dense gas as a mobile phase (i.e., carbon dioxide) and has been shown to be a powerful separation technique. The low viscosity and high diffusivity of supercritical fluids allow for the use of longer columns than in high-performance liquid chromatography (HPLC) without increasing runtimes. The increased number of theoretical plates available, combined with optimum linear velocities (μ_0) three to five times greater than in LC, can provide more separations per unit time. Berger has written a more detailed description of the functionality of packed column SFC.[1]

Supercritical fluid chromatography has some of the same characteristics of both HPLC and gas chromatography (GC). Packed column SFC uses the same column technology as HPLC, and when used with binary or tertiary solvents, has a broad range of applicability.[1] This range is much broader than GC, because compounds need not be volatile or thermally stable. As in GC, SFC can be coupled to most modern chromatographic detectors, such as element-specific detectors. These detectors are often very selective for the element under study, with detection limits below parts per billion.[1] Coupled to an SFC, an element-specific detector can become a powerful tool that offers selectivity, sensitivity, and speed.

Two other types of element-specific detector for nitrogen currently in use coupled to SFCs are the nitrogen phosphorus detector (NPD) and the thermal energy analyzer (TEA). The NPD uses a hot, catalytically active solid surface immersed in a layer of dissociated and to form electronegative N and P ions which are detected on a nearby electrode.[2] NPD has been shown to have broad application in SFC, especially in the agrochemical industry.[3] The TEA, as described by Fine et al.[4] uses low-temperature pyrolysis, followed by ozone-induced chemiluminescence, for the detection of compounds containing groups. The TEA has been used for the determination of tobacco-specific nitrosamines and explosives.[5] Both of these detectors require specific standards of the analytes of interest for quantitation.

The use of NCD, especially in pharmaceutical applications, have focused on exploiting the chemiluminescence properties of nitrogen dioxide (NO_2) formed from the high-temperature combustion of nitrogenous compounds.[6–8] This type of detector, originally developed for GC by Parks and Marietta,[9] forms nitric oxide followed by ozone-induced chemiluminescence. The reaction is characterized as follows:

$$\begin{aligned} R - N + O_2 &\rightarrow NO + \text{or other compounds} \\ NO + O_3 &\rightarrow NO_2{}^* + O_2 \\ NO_2{}^* &\rightarrow NO_2 + \text{light } (600 - 3200\,\text{nm}) \end{aligned} \quad (1)$$

Excited-state nitrogen-dioxide-mediated chemiluminescence occurs on a 1:1 molar ratio with solute nitrogen, provided that the combustion products form NO (and not). With complete combustion of the solute, the NCD can directly provide a quantitative measure of the amount of nitrogen in a chromatographic peak. This means that a single calibration curve using a stable nitrogen-containing compound can be used to quantify nitrogen content of any unknown peak in a chromatogram.[6] With a linear range of at least three orders of magnitude and picogram detection limits, SFC/CLND can provide an efficient technique for the quantification of nitrogen-containing compounds.[6]

The basic setup of a NCD system is shown in Fig. 1. In almost all cases, only a portion of the entire SFC mobile phase is diverted to the CLND detector using a fused-silica capillary or restrictor.[6–8,10,11] Use of a restrictor minimizes the effects of the SFC decompressed carbon dioxide (CO_2) and solvent composition on the pyrolysis reaction and chemiluminescence. The CO_2 flow rate, dictated largely by the SFC outlet pressure, can affect the residence time of the solute in the pyrolysis chamber and the

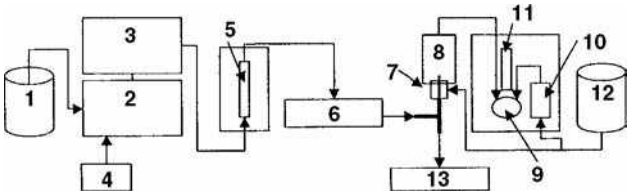

Fig. 1 Schematic diagram of SFC/CLND system: (1) CO_2 tank, (2) SFC pumping system, (3) autosampler, (4) modifier pump, (5) column, (6) UV detector, (7) pyrolysis inlet with linear restrictor, (8) pyrolysis chamber, (9) reaction cell, (10) ozone generator, (11) photomultiplier tube, (12) O_2 tank, (13) back-pressure regulator.

efficiency of the ozone reaction. The addition of modifiers to the SFC mobile phase (e.g., methanol) can compete for the available pyrolysis oxygen and can reduce signal response. High concentrations of modifier can dramatically affect the detection limits of some compounds.[7] Moreover, the sample concentration also appears to be limited by competition for oxygen, resulting in incomplete combustion.

The parameters that need special consideration for the successful coupling on an SFC to a CLND are restrictor position, ozone generation, combustion efficiency (temperature and oxygen flow rate), and quenching. Each of these will be discussed in detail.

RESTRICTOR POSITION

An important aspect for maintaining peak integrity using any split flow into a detector is the position of the restrictor tip relative to the detector source. Because SFC utilizes a gas under pressure, the rapid release of that pressure causes localized adiabatic cooling at the restrictor tip. On the other hand, at high temperatures, the mobile phase expands while the fluid density drops dramatically, resulting in precipitation of solutes at the end of the restrictor.[1] Careful attention to the restrictor placement should eliminate solute precipitation, maintain peak integrity, and provide sufficient mixing with oxygen for combustion. Several articles have discussed optimized placement of the restrictor for the Antek 705D CLND.[6,7,10] Inserting the restrictor beyond the inlet oxygen port to the pyrolysis chamber appears to provide both adequate solute nebulization and mixing prior to introduction into the furnace.[7]

OZONE GENERATION

Because ozone is very expensive to obtain in pure form and is quite unstable over long periods of time, CLND detectors utilize an ozone generator. Some of the oxygen flow is diverted over an electric arc to form ozone, which is then fed directly into the reaction cell. Because chemiluminescence occurs on a 1:1 molar ratio with NO, as described in Eq. 1, there must be excess ozone for chemiluminescence of NO independent of the other combustion products. Inlet oxygen flows of 5–10 ml/min appear to be adequate for most of the SFC/CLND experiments reported.[6,10,12]

COMBUSTION EFFICIENCY

Because detection is based on the formation of NO, the combustion conditions must be sufficient to completely convert the nitrogenous analytes to NO in the presence of mobile-phase modifiers. Temperatures ranging from 1050°C to 1100°C appear to provide the best environment for combustion. The amount of available oxygen for combustion is also highly dependent on the application. Table 1 outlines some of the conditions that have been reported. These conditions cover a wide range of mobile-phase flow rates (as decompressed CO_2) and modifier percentages. Shi et al. reported that too high an oxygen flow may reduce the residence time of the solute in the pyrolysis chamber and can negate any increase in combustion efficiency.[7]

QUENCHING

Nitrogen chemiluminescence takes place in a reaction cell, under vacuum, where the emitted light is measured using a photomultiplier tube. The primary combustion products from a methanol-modified SFC mobile phase are CO_2 and H_2O. Excessive CO_2 and water can increase the total number of colliding molecules in the reaction cell and reduce the signal. The addition of a membrane drier to selectively remove water has been shown to increase the detection limit of sulfamethazine by an order of magnitude.[11]

Table 1 Reported oxygen flow rates for several SFC/CLND applications.

CO_2 flow rate (ml/min)	Restrictor inner diameter (mm)	Modifier (%)	Oxygen flow (ml/min)	Refs.
3	0.025[a]	0	48	[5]
1200	0.025	8	185–200	[11]
600	0.075	10	50	[3]
150	0.075	15	50	[4]

[a]Open-tubular SFC.

Careful attention to the above-described parameters should allow for the successful interfacing of a CLND detector to an SFC system. Combining the separation efficiency of SFC with the specificity and sensitivity of CLND results in a powerful analytical technique for the quantification of nitrogenous solutes.

Nitrogen/Phosphorus Detector

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

The nitrogen/phosphorus detector (NPD) is extremely sensitive [more so than the flame ionization detector (FID)] but is also highly selective. As its name suggests, it responds strongly to substances containing nitrogen and/or phosphorus. Physically, the design appears very similar to that of the FID but, in fact, operates on an entirely different principle. A diagram of an NPD detector is shown in Fig. 1.

DISCUSSION

The essential change that differentiates the NPD sensor from that of the FID is a rubidium or cesium bead contained inside a heater coil and situated close to the hydrogen flame. The bead, heated by a current through the coil, is situated above a jet, through which passes the helium carrier gas from the column mixed with hydrogen from a separate supply. If the detector is to respond to both nitrogen and phosphorus, then the hydrogen flow is arranged to be minimal so that the gas does not ignite at the jet. If the detector is to respond to phosphorus only, a large flow of hydrogen can be used and the mixture burned at the jet.

The detector functions in the following manner. The heated alkali bead emits electrons by thermionic emission, which are collected at the anode, providing a base current across the electrode system. When a solute that contains nitrogen or phosphorus is eluted, the partially combusted nitrogen and phosphorus materials are adsorbed on the surface of the bead. This adsorbed material *reduces* the work function of the surface and, as a consequence, the emission of electrons is increased, which *increases* the current collected at the anode. The sensitivity of the NPD is very high and only about an order of magnitude less than that of the electron capture detector ($\sim 10^{-12}$ g/ml for phosphorus and 10^{-11} g/ml for nitrogen).

A significant disadvantage of this type of detector is that its performance deteriorates gradually with time and eventually does not function at all. Reese[1] examined the performance of the NPD in great detail. The alkali salt employed as the bead is usually a silicate and Reese demonstrated that the loss in response was due to water vapor from the burning hydrogen converting the alkali silicate to the hydroxide and free silica. Unfortunately, at the normal operating temperature of the bead, the alkali hydroxide has a significant vapor pressure and, consequently, the rubidium or cesium is continually lost during the operation of the detector. Eventually, all the alkali is evaporated, leaving a bead of inactive silica. This is an inherent problem with all NPDs and, as a result, the bead needs to be replaced regularly if the detector is in continuous use. The detector can be made "linear" over three orders of magnitude, although no values for the response index appear to have been reported. Like the FID, it is relatively insensitive to pressure, flow rate, and temperature changes but is usually thermostatted at 260°C or above.

The specific nature of the NPD response to nitrogen and phosphorus, coupled with its relatively high sensitivity, makes it especially useful for the

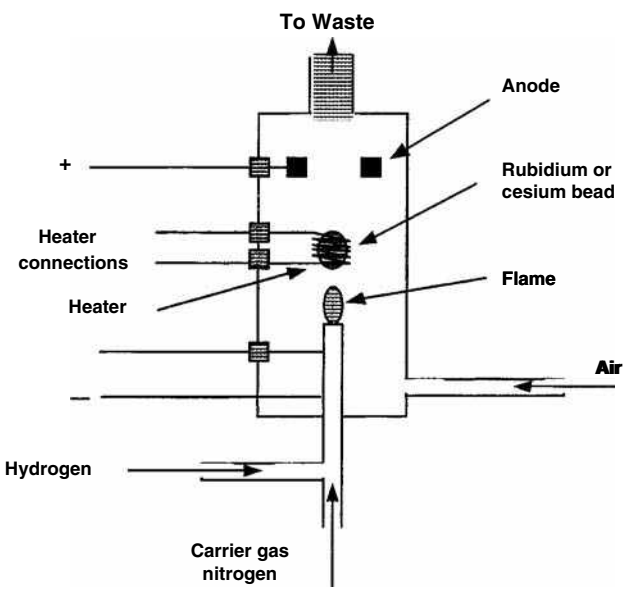

Fig. 1 The nitrogen/phosphorus detector.

analysis of many pharmaceuticals and, in particular, in environmental analyses of samples containing herbicides. Employing appropriate column systems, traces of herbicides at the 500 pg level can easily bedetermined. Virtually all the basic drugs presently employed in medicine contain nitrogen. Consequently, the specific detection of the NPD allows these drugs to be selectively monitored and quantitatively assayed, even when they are eluted among a large number of other unresolved compounds not containing nitrogen.

Nonionic Surfactants: GPC/SEC Analysis

Ivan Gitsov
College of Environmental Science and Forestry, State University of New York, Syracuse, New York, U.S.A.

INTRODUCTION

Non-ionic surfactants are one of the most important and largest surfactant groups. They are amphiphilic molecules composed, in most cases, of poly(oxyethylene) blocks (PEO) as the water-soluble fragment and fatty alcohols, fatty acids, alkylated phenol derivatives, or various synthetic polymers as the hydrophobic part.[1] This class of surfactants is widely used as surface wetting agents, emulsifiers, detergents, phase-transfer agents, and solubilizers for diverse industrial and biomedical applications.[2] Several of them have been used for many years under different trade names: Brij (ethoxylated fatty alcohols), Synperonic (PEO copolymers) and Tween (ethoxylated sorbitan esters) by ICI Surfactants; Igepal (PEO copolymers) by Rhone-Poulenc, Rhodia; Pluronic [poly(oxyethylene)-*block*poly (oxypropylene) copolymers] by BASF; Triton DF (ethoxylated fatty alcohols) and Triton X (ethoxylated octylphenols) by Union Carbide; and others. The exploitation characteristics of non-ionic surfactants depend on the oligomer distribution, the molecular weight characteristics of the constituent blocks, and the hydrophilic/hydrophobic ratio of their chemical composition. Therefore, the quantitative determination of these factors is of primary importance for their performance evaluation.

DISCUSSION

Several high-performance liquid chromatography (HPLC) separation techniques have been used in combination with different detection methods to characterize poly(ethylene glycol)s and their amphiphilic derivatives.[3] SEC is a particularly attractive analytical tool for the investigation of non-ionic surfactants because it can provide information for their composition, molecular weight, and molecular-weight distribution along with their micellization in selective solvents. This entry will survey briefly both applications with major emphasis on the choice of the most appropriate eluent and stationary phase.

Molecular-weight determinations are performed in good solvents for both blocks of the PEO copolymers. The most widely used analysis conditions are as follows: eluents–tetrahydrofuran (THF) and chloroform (CHL); flow rate—1.0 ml/min; detection—differential refractive index (dRI) detector. The temperature interval is between 20°C and 40°C. The stationary phase is typically a polystyrene–divinylbenzene cross-linked matrix supplied by different vendors: Phenogel (Phenomenex, USA); PL Gel (Polymer Laboratories, U.K.), PSS Gel (Polymer Standards Service, Germany), TSKgel (tosoHaas, U.S.A.); Ultra Styragel (Waters Corporation, U.S.A.); and others. The pore size range of the column set should be adjusted to the molecular-weight range of the investigated materials. The SEC analysis in THF requires low-dRI response correction factors (1.66 for $M_n = 106$ and 1.00 for $M_n = 20{,}000$),[4] whereas the low-molecular-weight PEO derivatives are almost invisible in CHL. On the other side, the solubility of PEO in THF decreases with the molecular weight, as evidenced by steeper calibration curves and broadening of the peaks in the eluograms (Fig. 1). This complicates the precise molecular weight calculations of PEO copolymers and the choice of calibration standards becomes crucial.[5] The increasing content of PEO in the copolymer results in lower hydrodynamic volumes in THF and, consequently, yields lower apparent molecular weights, regardless of the macromolecular architecture of the analytes.[6–8] The problems with calibration mismatch can be avoided to some extent by using the universal calibration approach with online differential viscometry. This method provides accurate molecular-weight information for most linear and comb-graft PEO copolymers but has been proved less precise for copolymers with complex linear-dendritic or hyperbranched architecture. Online laser-light-scattering detection eliminates the need for a calibration curve and yields correct M_w values for macromolecules with molecular weights higher than 500 g/mol. The precision of the method depends largely on accurate *dndc* values that need to be measured for each copolymer investigated.

The self-assembly process of non-ionic surfactants in aqueous media differs in several aspects from the micellization of amphiphilic copolymers:

1. Micelles constructed of low-molecular-weight surfactants have much lower molecular weights than that of polymeric ones.
2. The critical micelle concentration (CMC) is much lower for polymer surfactants.
3. The vast majority of polymer micelles have spherical shape in dilute or semidilute solutions, whereas low-molecular-weight surfactants form structures that are

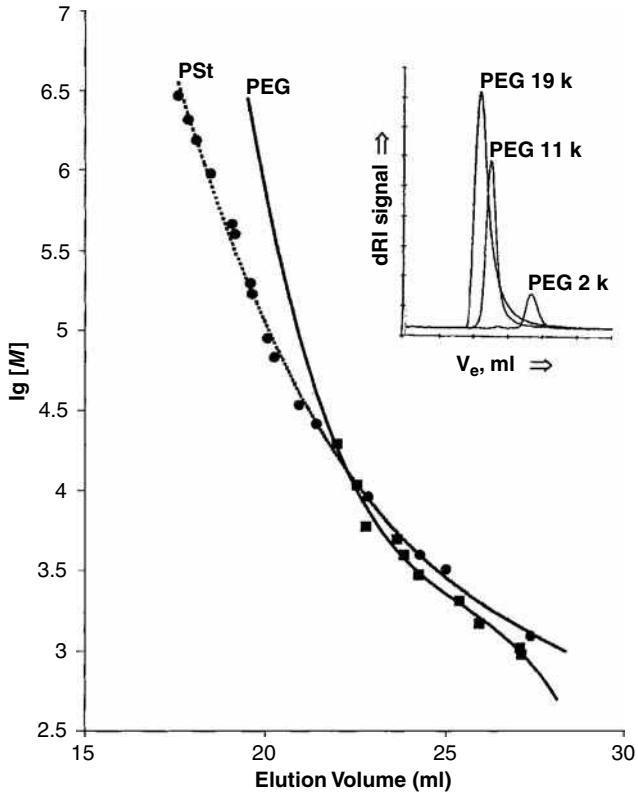

Fig. 1 Polystyrene, PSt, and poly(ethylene glycol), PEG, calibration curves obtained on PL Gel column set (Mixed C, 10^3 Å, 5×10^2 Å, and 10^2 Å). Eluent: THF; flow rate: 1 ml/min; temperature: 40°C. Inset: SEC elution profiles of poly(ethylene glycol)s (PEGs) at the same analysis conditions.

strongly concentration dependent: lamellae, sheets, rods, and spheres.

4. The kinetics of micelle formation and the dynamics of the micelle–unimer equilibrium are considerably slower for polymeric surfactants.

The last factor is particularly important for the successful utilization of aqueous SEC in the investigation of the micellization process. In order to provide a realistic picture for the micellization equilibrium, the chromatographic system needs to meet several strict requirements: The packing material and the eluent should be appropriately chosen to prevent the occurrence of non-size-exclusion phenomena and adsorption of micelles in the stationary phase. In all cases, mass balance of the material injected and recovered from the columns must be performed in order to verify the absence copolymer entrapment. Cross-linked copolymers containing either poly(vinyl alcohol) or poly(glycidyl methacrylate) as the hydrophilic component are the most widely used column packing materials for aqueous SEC. Both Shodex Protein KW (Showa Denko, Japan) and Micropak TSK-gel PW (Toyo Soda, Japan) columns have been reported to afford good information on the micellization behavior of PEO copolymers without interference of side effects.[9,10] The mobile phase is methanol-water (1 : 1, v/v) or pure water eluting at 1.0 ml/min. The analysis temperature is between 22°C and 40°C. Historically, the major concern for the use of SEC in the investigation of micellar systems has always been the lack of suitable calibration and, consequently, the inability of the method to furnish accurate information for the size (hydrodynamic volume) of the micelles and their molecular weight. The incorporation of light-scattering and viscosity detectors for online measurement seems to eliminate this problem. With no solute-column interaction present and slow unimer-micelle equilibrium, a multiangle light-scattering detector (DAWN-DSP, Wyatt Technology, U.S.A.) provides accurate information for the molecular weight and radius of gyration of the micelle using Zimm's formalism:

$$\frac{R_\theta}{K^* c} = kM_w P(\theta) - 2A_2 c M_w^2 P^2(\theta)$$

where R_θ is the excess Rayleigh ratio, K^* is an optical constant that includes the differential refractive index increment (*dndc*) of the solvent–solute mixture, c is the concentration of the solute molecules in the analyzed solution, M_w is the weight-average molecular weight, $P(\theta)$ is a form factor, and A_2 is the second virial coefficient. If the *dndc* value for the copolymer above CMC is known, the extrapolation to zero concentration and zero angle will yield the *Z*-average of the radius of gyration and A_2, respectively. The double extrapolation to zero angle and zero concentration will afford M_w. The hydrodynamic radii can be calculated using an online viscometric detector (Viskotek, U.S.A., and Waters) and the following relationship:

$$R_\eta^{\ 3} = \frac{3[\eta]M}{10\pi N_A}$$

where the value of $[\eta]M$ could be extracted directly from the universal calibration and is Avogadro's number (6.022×10^{23}). It should be pointed out, however, that this formula is strictly valid only for spherical structures. The hydrodynamic radius can also be measured by a combination of SEC and dynamic light scattering (Precision Detectors, U.S.A.) or NMR spectroscopy.[11] However, the same assumption for a spherical shape of the investigated macromolecules has to be made.

In conclusion, modern SEC is a versatile technique for the investigation of non-ionic surfactants in aqueous and organic media. In combination with different spectroscopic and viscometric detectors it will provide useful information for the molecular weight characteristics, chemical composition and solution behavior of this important class of materials.

Normal-Phase Chromatography

Fred M. Rabel
EMD Chemicals, Inc., Gibbstown, New Jersey, U.S.A.

INTRODUCTION

There are four basic separation modes in liquid chromatography (LC)—adsorption, normal-phase partition, reversed-phase partition, and ion exchange. Of these, normal-phase partition is the least practiced based on published references. Although similar to the well-known adsorption mode, both this and the normal-phase modes have been relegated to positions of decreased use by the ever-popular reversed-phase mode. Each mode, however, has to be evaluated on its own merits and what successes it could bring to the analysis problem.

As practiced, normal phase is very much like the adsorption mode (polar stationary-phase surface and non-polar mobile phase), the only difference being that the normal-phase separation is done on a less-polar surface. This is because the sorbent used in normal-phase separations is bonded with a polar-bonded phase, such as propyl cyano, propyl amino, or organo-diol (from a reagent derived from glycerol). Although selectivities are similar to the adsorption mode, the reproducibility is greatly increased due to less sensitivity to moisture in the mobile phase due to a lower silanol content.

The normal-phase mode, like the adsorption mode, is able to separate components that vary greatly in polarity. Samples of wide polarity are often found when natural products or biological system samples need to be analyzed. Often, this adsorption or normal phase is a first cleanup step, when it is necessary to fractionate the sample into more manageable parts for subsequent analyses. Other separations for which the adsorption mode is known to perform well (geometric isomers, *cis–trans* isomers) can also be done in the normal-phase mode with fewer reproducibility problems.

DESCRIPTION

There are a number of modes or mechanisms into which chromatography is divided. These include adsorption, normal-phase partition, reversed-phase partition, and ion exchange. Often, the term "partition" is deleted from the discussions of the differences and similarities of these modes. The inclusion of the word "partition" began to be used when supports had to be coated with liquid phase (and the mobile phases saturated with them) to accomplish separations with these two modes. Today, bonded-phase versions of these liquid phases are available, making them easier to use with greater reproducibility. Perhaps it has been the use of these bonded supports that have allowed the name of these modes to be simplified.

The reasons for distinguishing between these modes are as follows:

1. To better understand the operating parameters of each mode.
2. To understand what type of separations (isomers, equal polarity, different polarity) each is able to do better than another mode.

Often the modes can be complementary, allowing various types of selectivity. This is advantageous when doing separations of unknown substances, as different mechanisms will allow unique selectivities, thereby guaranteeing more complete separation. Applying different modes of chromatography to a single-separation problem is often called "multidimensional" chromatography.

Before bonded phases became available, all normal-phase partition—and reversed-phase partition—separations were done on silica and other supports, which were only "coated" with different polar and non-polar phases or oils. Obviously, their use presented many problems since it was absolutely necessary to keep both the mobile phase and the stationary phase saturated with these phases. The saturation level in both, of course, changes with temperature; hence, this had to be carefully controlled for reproducibility. The laboratory work of the analytical chemist was made infinitely simpler with the introduction of bonded phases, which this entry addresses.

Normal-phase (NP) chromatography is a close parallel to adsorption chromatography. Briefly, adsorption chromatography most often uses polar silica gel as the stationary phase and a mobile phase that is predominately non-polar, possibly with some polar modifier. An example of such a mobile phase would be hexane with 2% ethanol. When increasing the percentage of the polar modifier, the elution times decrease. When a sample containing a wide range of polarities (i.e., a lipid mixture) is encountered, then the normal-phase mode can be used with a gradient to separate the sample into fractions that are easier to analyze.

Normal-phase chromatography generally uses the same types of mobile phases as for the adsorption mode. The difference, however, is the nature of the stationary phase.

Table 1 The usual structures of polar-bonded phases.

Cyano	$Si–O–SiR_2–(CH_2)_3–CN$
Amino	$Si–O–SiR_2–(CH_2)_3–NH_2$
Nitro	$Si–O–SiR_2–(CH_2)_3–NO_2$
Diol	$Si–O–Si–O–CH_2OH–CHOH$

The R groups may be $–OCH_3$–OCH_2CH_3,–H,–CH_3,–CH_2CH_3, or others. Combinations of reagents or active groups are also possible. One manufacturer, for instance, offers a polar aminocyano (PAC)-bonded phase.

In NP chromatography, the packing is silica gel that has been bonded with a polar phase. The usual polar phases widely available from many manufacturers include cyano, amino, nitro, and diol phases. These are illustrated in Table 1. The first three often have a propyl group between the Si–O– and the X groups. The diol phase is derived from glycerol bonded to the silane reagent. Of course, each manufacturer uses a different silica, reagents, reaction conditions, and final workup; thus, any given polar-bonded phase from the various suppliers can differ in relative selectivity and/or retention times.

There are two major differences between using silica gel (for adsorption) and a polar-bonded phase (for normal phase) for a separation. First, the polar-bonded phase adds a different surface to the silica gel, which can impart unique selectivities (i.e., separation characteristics) to an analysis. This is because the stationary-phase surface is no longer as polar as it was before bonding. Many of the silanols are replaced with the organo-polar groups. As with any bonded phase, perhaps only 50% of the available silanols are actually bonded, because of their incomplete accessibility to any reagent. It is possible to also endcap (a second-step bonding reaction, with a trimethylsilyl reagent) more of the remaining silanols. This is not generally done; hence, there is often some definite silanol interaction, and, also, with amino and diol phases, where they would themselves react with the reagent, silanizing them. This would defeat the purpose of trying to produce a different selectivity packing.

The second difference comes from the fact that if there are fewer silanols available on the surface of the packing, it will be less sensitive to any moisture that gets into the mobile phase. One of the biggest problems observed by the uses of silica gel separations in the absorption mode is the control of the separation's reproducibility. Unless one is very careful in using dry solvents, or "controlled water content" mobile phases, the retention times of their compounds can change dramatically from analysis to analysis. If more water gets onto the silanols, they are deactivated, and any sample component elutes more rapidly. Removing water, with an exhaustively dried solvent combination, for instance, removes moisture from the silanol groups, and components are then retained longer. As a result, with less silanols available for deactivation by water, the polar-bonded phases are more reproducible and often preferred by chromatographers.

If variable retention times become a problem in the absorption mode, a switch to a polar-bonded phase column is often the simplest solution. When using the same solvent mixture as was used on the bare, unbonded silica gel column, it is often found that the elution order is often the same or very similar. Of course, a switch in mode would necessitate identifying the sample components, to guarantee that their elution order is, indeed, unchanged. With fewer silanols, however, the components of the mixture will elute faster; hence, readjusting the mobile phase is required to insure adequate resolution. As mentioned earlier, this polar-bonded-phase separation will be much less sensitive to small moisture variations in the mobile phase. Moisture in the mobile phase should, nevertheless, be controlled, but will present few, if any, problems over the time the samples in a study are being run.

As with adsorption chromatography, the normal-phase mode is separated on the basis of solubility in the mobile phase (so it dissolves relatively non-polar compounds) and the differences in the polarities of the components in the mixture and their attraction to the solvated polar-bonded phase. Relatively non-polar components elute first; more polar components elute later. These relative polarities and elution orders are summarized in Table 2.

At the non-polar end of the elution scheme, the elution of alkanes to ethers with perhaps only hexane or heptane would be expected. For elution of moderate-to-polar compounds, a polar modifier has to be added to the major non-polar component of the mobile phase. Much of the guesswork as to which solvent combinations to use has been simplified by the work of Snyder and Kirkland.[1] Their work has grouped solvents of similar selectivities (i.e., alcohols give identical elution order sequences; only the elution times change from one alcohol to another). As a result of their studies, the recommended solvents to be mixed with hexane or heptane to effect the greatest possible selectivity differences are diethyl ether, chloroform, and methylene dichloride.

It is possible to separate more polar components by introducing a gradient from a low concentration

Table 2 Relative group polarity and elution order in normal-phase partition chromatography.

$RH < RX < RNO_2 < ROR < RCOOR < RCONHR < RNH_2 < ROH$
RCRO R_2NH
RCHO R_3N
Increasing polarity of organic structures/groups → →
Increasing retention of compounds containing these structures/groups → →

The more functional groups in the compound, the greater its polarity. For polyfunctional compounds, the *most polar* groups determines the retention of the compound.

(0–10%) of a polar modifier to a higher concentration of this same polar solvent (to 90%, for example). The important consideration is the solubility limits of the polar component in the non-polar component. Thus, methanol is only soluble in hexane to about 5%, but ethanol can be brought up to 20% before reaching maximum solubility. If more polar samples are to be separated, then hexane can be replaced by ethyl acetate or chloroform. One constraint with the normal-phase mode, as with the adsorption mode, is that certain solvents are not transparent in the ultraviolet range most used in standard LC systems. The refractive index detector or the evaporative light-scattering detector can, of course, be used with any solvent(s) but are not standard components in most LC laboratories. With the growing use of LC/MS systems, which are compatible with less-polar-mobile phases, this detection problem is not as great a concern as in the past.

Using the normal-phase mode does not limit the chromatographer to only relatively non-polar-mobile phases. Much work with these bonded phases is also done with polar solvent mixtures, such as methanol–water or acetonitrile–water. They might appear to be reversed-phase separations, but this may not be the case. Often, when a CN (cyanopropyl) phase is used, it is used as a slightly more polar-bonded phase than would be a C4-bonded phase. Then, the polar organic–water combinations used almost always invoke the reversed-phase mode.

One widely used application using NP chromatography in which the mobile-phase composition is deceptive in the actual mode being used is the separation of sugars (carbohydrates) and oligosaccharides. The packing used is an NH_2 (aminopropyl, most often) bonded phase and the mobile phase is acetonitrile–water in the ratio of 20–35% water. This mobile phase might lead one to suspect a reversed-phase mechanism at work, but, in fact, adding more water (the polar component) to the mobile phase decreases the retention times of the sugars, proving it is, indeed, a normal-phase partition mode being used (if it were reversed-phase mode, the addition of more water would increase the retention of the compounds).[a]

It is also possible to use an NH_2-bonded phase as an ion exchanger, since it will form the quaternary ion, $-NH_3^+$ in buffers between pHs of 2 and 6 (i.e., a weak cation exchanger). This can also be a problem when doing the sugar separation described earlier, if acidic components in the mixture inadvertently transform the NH_2 to the $-NH_3^+$ form. The separation will not work as well, if at all. This, fortunately, is reversible by taking the column to pure water, then passing through 10 column volumes ($V_M \times 10$) of 0.01 *M* NH_4OH, and later pure water, to regenerate the free base.

Other possible problems with this reactive-bonded phase is that it can form Schiff bases with aldehydes and ketones; hence, samples containing these should be avoided. The NH_2 group can also be easily oxidized; hence, peroxides in any easily oxidizable solvents (i.e., diethyl ether, dioxane, and tetrahydrofuran) should be avoided.[2]

The types of compounds that can be separated in the normal-phase mode is as vast as for the adsorption mode. Likewise, because the range of solvents that can be used in this mode is virtually unlimited, it will lend itself to even more sample types. Unfortunately, not as many references exist for normal-phase separations as for reversed-phase separations. As a guide to the types of solvents to be used in the normal-phase mode, one may refer to the many studies on silica gel or the adsorption mode. As mentioned, usually only minor changes, if any, need be made to the mobile phase when adapting to the normal bonded-phase column.

CONCLUSIONS

Normal-phase chromatography and the bonded-phase sorbents that are used for this mode of chromatography have been discussed. It can be used with fewer reproducibility problems than the adsorption mode simply because the bonded sorbents used for NP chromatography have fewer silanols. Fewer silanols mean less sensitivity to water than is often found in variable amounts in the solvents used for high-performance liquid chromatography (HPLC).

Depending on the polar-bonded phase used, different selectivities can be found for the same mixture. This allows subtle optimization should the different bonded phases be tried during the method development phase.

Although the adsorption and normal-phase modes are not often used by many chromatographers, both have great potential for solving HPLC problems. Although mostly used with non-polar solvents with a polar modifier, polar-bonded-phase HPLC columns can also be used with organic/water combinations for additional unique selectivities.

C. Marutoiu
Department of Chemistry, Lucian Blaga University of Sibiu, Sibiu, Romania

INTRODUCTION

In nature, the macromolecules of nucleic acids are found either free or as nucleoproteins with various topochemical distributions in the acellular (i.e., viral) and cellular (i.e., prokaryotes, eukaryotes) structures. The presence of these macromolecules in prokaryotes is not necessarily correlated with a defined morphologic structure. The localization in eukaryotes is generally in the cellular nucleus, but it is also present in the cellular cytoplasm, mitochondria, and plasmids.[1]

In slightly alkaline medium, the macromolecules of nucleic acids are broken into fragments named oligonucleotides, or even mononucleotides (often simply referred as "nucleotide") by advanced hydrolysis. These mononucleotides are, in fact, the structural blocks of the nucleic acids.

Further hydrolysis (acidic, basic, or enzymatic) of the mononucleotides leads to the corresponding nucleosides and phosphoric acid. The nucleosides can be hydrolyzed in nucleobases and pentose.[2]

SEPARATION OF NUCLEIC ACIDS

The nucleosides have been separated on cellulose plates (Avicel 1440, Schleicher & Schuell) using various mobile phases:

- *n*-butanol–*iso*-butyric acid–ammonium hydroxide conc.–water (75:37.5:2.5:25, v/v);
- ammonium sulfate (saturated solution)–0.1 *M* sodium acetate (pH 6)–isopropanol (79:19:2, v/v);
- *iso*-butyric acid–0.5 *M* ammonium hydroxide–0.1 *M* EDTA (100:60:1.6, v/v);
- *tert*-butanol–0.08 *M* formic acid–isoamyl alcohol (50:50:2, v/v);
- acetonitrile–ethyl acetate–*n*-butanol–isopropanol–0.04 *M* ammonium formiate (pH 7.6) (7:2:1:1:2.7, v/v);
- *tert*-amyl alcohol–methyl-ethyl-ketone–acetonitrile–ethyl acetate–water–formic acid, conc. (4:2:1.5:2:1.5:0.18, v/v).

The development of the spots was performed at 20–21°C, and the migration distance was 15 cm from the start. The nucleosides were visualized in UV light at 254 nm.

The nucleosides obtained by enzymatic digestion of t-RNA were separated by bidimensional chromatography using Merck cellulose layered on 20×50 cm^2 aluminum sheets. The elution in the first direction was performed with *n*-butanol–isobutyric acid–ammonium hydroxide, conc.–water (75:37.5:2.5:25, v/v) mixture for 24 hr at 20–21°C, in an unsaturated chamber. The chromatographic plate was dried with a fan for 3 hr at 20°C, after the first elution. Elution in the second direction was performed for 4 hr with the mixture ammonium sulfate (saturated solution)–0.1 *M* sodium acetate (pH 6)–isopropanol (79:19:2, v/v). The separated compounds were visualized in UV light at 254 nm.

The separated nucleosides were quantitatively determined by elution from spots with 0.5 ml water and then analyzed with a Beckman spectrophotometer (25 Model) at pH = 6, 1, and 13.[3]

The thin-layer chromatography (TLC) method was used for purifying the intermediary products obtained from the synthesis of the oligonucleotide dendrimers. The separations were performed on silica gel plates using various solvent mixtures as mobile phases, e.g., methanol–methylene chloride (1:9, v/v), methanol–chloroform (1:30, 1:9, v/v), hexane–dichloromethane (1:3, v/v), hexane–ethyl acetate (3:1, 1:1, 4:1, v/v). The separated compounds were visualized in an iodine atmosphere.[4]

Inosine monophosphate (IMP) can be detected in nucleotides following TLC purification. In the first stage, the sample is introduced into a mixture of water (10 μl) and 100 m*M* non-radioactive 5 IMP (1 μl); 2.5 μl from this mixture is spotted onto the chromatographic plate at 2.5 cm from the side of the plate. After drying of the spots, the plate is introduced into a methanol atmosphere (10 min), dried, and then bidimensionally developed on polyethyleneimide (PEI)–cellulose.[5]

The spots on the developed chromatographic plates were visualized in UV light. In the second stage of the purification, the sample is redeveloped with 1 *M* sodium formiate (buffer solution, pH 3.4) and it is dried in an anhydrous methanol atmosphere. The next step for the purification was the development of the plate with

saturated ammonium sulfate solution–isopropanol–0.1 *M* sodium acetate, pH 6.0 (79:2:19, v/v) mixture. The compounds were visualized in UV light and [^{32}P]IMP was identified by autoradiography, after drying of the plates.[6]

In the diagnosis and classification of brain tumors, TLC is used for the separation and identification of nucleotides obtained by DNA hydrolysis, according to the following procedure: the dried sample of DNA (1 μg) was dissolved in succinate buffer (pH 6) containing $CaCl_2$ (10 m*M*) and digested with spleen phosphodiesterase II (0.001 units) and micrococcal nuclease (0.02 units) in 3.5 μl total volume for 5 hr at 37°C. The DNA digest (0.17 μg) was labeled with 2 μCi [γ-^{32}P]ATP (4500 Ci/mmol; ICN, Irvine, CA; in stoichiometric amounts) and T_4 polynucleotide kinase (1.5 units) in 3 μl of 10 m*M* bicine–NaOH (pH 9.7) buffer containing $MgCl_2$ (10 m*M*), DTT (10 m*M*), and spermidine (1 m*M*). After incubation for 35 min at 37°C, 3 μl apyrase in bicine–NaOH (10 m*M*; 10 units/ml; pH 9.7) was added and incubation was continued for 35 min. The 3′-phosphate of a nucleotide was cleaved off with RNaseP1 (0.2 μg) in ammonium acetate buffer (500 m*M*; pH 4.5). Separation and identification of [γ-^{32}P]m^{5}dC was performed by a two-dimensional chromatography on cellulose TLC plates (Merck, Germany) using isobutyric acid–NH_4OH–H_2O (66:1:17, v/v) in the first dimension and 0.1 *M* sodium phosphate (pH 6.8)–ammonium sulfate–*n*-propyl alcohol (100 ml/60 g/1.5 ml) in the second dimension. Intensity analysis was done with the PhosphorImager Typhoon (Pharmacia, Uppsala, Sweden) and Image Quant Software.[7]

The nucleotides were separated on PEI-cellulose in 0.9 *M* guanidinium chloride. After separation, the plate was introduced, for 10 min, into absolute methanol and then dried in air. The plate was irradiated in a nuclear reactor for 96 hr, with a 4×10^{12} neutrons/cm/sec flux. The nucleotides with phosphorus (^{31}P) are activated at ^{32}P by this irradiation and can be detected by autoradiography. By this technique, nucleotides series such as ATP, ADP, AMP, GMP, GDP, and GTP were separated and identified. This method allows the quantitative determination of the separated and neutron-activated compounds.

CONCLUSION

TLC analysis of nucleotides by several unidimensional and bidimensional methods has been described. Optimal solvent systems were given.

Nucleic Acids, Oligonucleotides, and DNA: CE

Feng Xu
Yuriko Kiba
Yoshinobu Baba
Department of Medicinal Chemistry, University of Tokushima, Tokushima, Japan

INTRODUCTION

As one of the basic analytical techniques in the modern molecular biology laboratory, capillary electrophoresis (CE) plays a prime role in nucleic acid separation. CE is carried out through a simple system that consists of a high-voltage power supply, one capillary or several capillaries, and an online detector. The separation is performed by applying a high voltage in narrow capillary tubes (10–300 μm inner diameter) filled with a gel or a polymer solution as the separation matrix. The high surface-to-volume ratio of the small tube can efficiently dissipate the Joule heat generated during electrophoresis. Thereby, the electric field strength can be very high, only limited by the onset of biased reptation. The solutes are detected by either Ultraviolet (UV) or laser-induced fluorescence (LIF) detection. Nowadays, more than 96 capillaries can be mounted in an electrophoresis apparatus to provide parallel analysis of multiple DNA samples at a time; thus, the running cost is considerably reduced. CE in a microfabricated chip (chip-CE) was developed in the early 1990s.[1] Its goal is to constitute truly automated micrototal analysis systems (μTAS), incorporating genomic DNA extraction from cells, polymerase chain reaction (PCR) amplification, electrophoretic sizing, and detection in a single unit. The technique has the benefits of low sample/reagent consumption, high throughput, fast separation, full automation, and portability.

Due to the fact that nucleic acids have nearly the same charge-to-mass ratio when they are larger than 400 bp,[2] separation in free solutions is difficult. By using some special techniques to break the charge-to-mass symmetry, e.g., attaching an uncharged, friction-generating large label such as protein streptavidin at the end of all DNA molecules, nucleic acids can be separated in free solutions, the so-called end-labeled free-solution electrophoresis (ELFSE).[3] The label has no charge and is easily attached to DNA via a biotin complex. In order to extend the read lengths of DNA fragments for practical use, larger friction-generating labels are still needed.

Most nucleic acids are separated by using sieving matrices. Cross-linked gels like polyacrylamide, directly coming from slab gel electrophoresis, were employed in early CE.[4] The capillary is prepared by in situ polymerization to form a cross-linked and three-dimensional network, which provides high-efficiency DNA separation. But several detrimental factors hinder the large-scale application of the gels. Bubble formation, clogging of pores, and gel degradation by hydrolysis in the alkaline buffer pH make the capillary lifetime short and the reproducibility low. Nowadays, gel-filled capillaries are gradually replaced by non-cross-linked polymer solution-filled capillaries, though the former are still used in some limited areas, such as separation of oligonucleotides and sequencing of reaction products,[5] in which the column can be thrown away after use.

Polymer solution-filled channels have the advantages of ease of replacement. Because bonded microfluidic devices cannot withstand high matrix loading pressure, viscosity is an important property to be considered. The recently developed viscosity-adjustable thermoresponsive polymer solutions are attractive. They can switch between low and high viscosity state through a modest temperature change, and have high separation ability. Another recent development is artificial sieving networks, such as entropic trapping (ET) techniques,[6] for the separation of long DNA fragments. Several hundred kilobases of DNA can be quickly separated by using only a direct circuit field in a solution containing no polymer matrix, which shows promise for use in μTAS platforms.

This review gives an overview of current advances in nucleic acid separation by CE and microchip electrophoresis. The focus is on the separation mechanisms during CE, conventional separation matrices and thermoresponsive polymers solutions, UV and fluorescence detection, microchip-based CE, and entropic trapping networks.

THEORY

Separation in Semidilute Regime Polymer Solutions

For a polymer solution, the intrinsic viscosity, $[\eta]$, is fitted to the empirical Mark–Houwink–Sakarada equation:[7]

$$[\eta] \simeq KM_w{}^a \quad (1)$$

Table 1 Characteristic constants for some polymers used in CE.

Polymer	K (ml/g)	a
Polyacrylamide	6.31×10^{-3}	0.80
Poly-*N,N*-dimethylacrylamide	2.32×10^{-2}	0.81
Polyoxyethylene	1.25×10^{-2}	0.78
Hydroxyethylcellulose	9.53×10^{-3}	0.87
Methylcellulose	0.316	0.55
Dextran	4.93×10^{-2}	0.60

Source: From Viscosity–molecular weight relationships and unperturbed dimensions of linear chain molecules, in Polymer Handbook.[7]

where K and a are characteristic constants for a given polymer–solvent system (Table 1) and M_w the molecular weight.

In a dilute polymer solution, polymer chains are hydrodynamically isolated and do not interact. As the concentration is increased, the polymer chains begin to interact and overlap. If the polymer concentration is too high (concentrated regime), the viscosity is so high that the polymer cannot be used in CE. In the semidilute regime, the polymer concentration is raised sufficiently for polymer coils to begin to interact and overlap in solution. The transition from dilute to semidilute regime occurs at an overlap threshold concentration, c^*, where the polymer chains begin to be densely entangled, and the bulk concentration equals the local concentration inside a polymer chain (Fig. 1). Only dilute and semidilute regimes are utilized for nucleic acid separation by CE. The entanglement threshold can be determined by[8]

$$c^* = \left(\frac{1.5}{K}\right) M_w{}^{-a} \tag{2}$$

For example, methylcellulose has a K value of 0.316 ml/g and an a value of 0.55 (Table 1), so the c^* value of methylcellulose (M_w 400 kDa) can be estimated to be 0.4%.

An entangled solution can be characterized as a network with an average mesh size, ξ_b. The mesh size is expressed as a function of the polymer concentration, c:

$$\xi_b = 1.43 \left[\frac{1.5^{1+1/a}}{2.5 N_A}\right]^{1/3} K^{-1/3a} c^{-(a+1)/3a} \tag{3}$$

where N_A is Avogadro's number. The higher the polymer concentration, the narrower the mesh size. For example, the mesh sizes of methylcellulose at various concentrations are estimated to be: $\xi_b = 48$ nm (if $c = 0.4\%$), 39 nm (0.5%), 33 nm (0.6%), 28 nm (0.7%), 25 nm (0.8%), 22 nm (0.9%), and 20 nm (1.0%).

Eqs. (2) and (3) seem to suggest that two solutions of the same polymer type with the same concentration but different molecular weights have the same mesh size, as long as

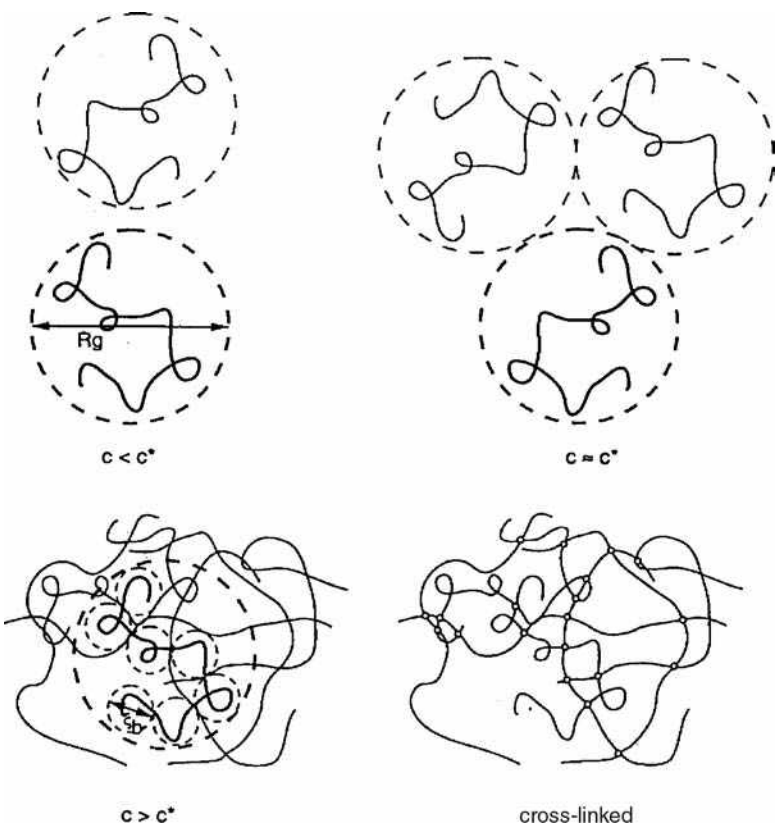

Fig. 1 Illustration of flexible polymers in dilute solution ($c < c^*$), entanglement threshold ($c = c^*$), and semidilute solution ($c > c^*$) regimes, as well as cross-linked chain. One chain is drawn as a thick line for easier visualization. The small circle in the semidilute solution regime represents the "blobs" of size ξ_b.
Source: From The separation matrix, in *Analysis of Nucleic Acids by Capillary Electrophoresis*.[41]

they are entangled. However, their viscosities are different, dependent on their molecular weights. Thus, one can choose the low-viscosity polymer as the separation matrix. For example, separation of oligonucleotides needs a polymer mesh size of about 8–10 nm. If a number of linear polyacrylamides (LPAs) are candidates, through Eq. 3, we obtain the corresponding concentration of LPA to be about 5–6%. Then, from Eq. 2, the LPA that can form an entangled solution at the concentration should have a molecular weight > 50 kDa. Above this limit, all degrees of polymerization give the same mesh size. If one wants to keep the viscosity low, one can choose the smallest possible M_w of 50 kDa.

The Ogston and the reptation models are commonly used to explain the electrophoretic behavior of DNAs. On the basis of the Ogston model, the separation matrix is treated as a random network of fibers, having a distribution of pore sizes and an "average pore radius." A DNA molecule is assumed to be an undeformable spherical particle that migrates through the network, diffusing laterally until it encounters a pore large enough to allow it to pass through. The network of the polymer matrix is a round pore. The DNA mobility, μ, is expressed as:

$$\frac{\mu}{\mu_0} = \exp(-CTN) \tag{4}$$

where T is the polymer concentration, N is the length of the DNA chain expressed in nucleotide units, C is a constant, and μ_0 is the DNA mobility in free solution. This formula predicts the existence of a linear relation between the logarithm of mobility and the DNA size (N) and polymer concentration (T). The Ogston model is successful in fitting experimental data for small DNA fragments with radius of gyration (R_g) much smaller than average pore size (ξ_b) in the limitation of low electric fields. The smaller fragments migrate faster as they can easily access the pores. For larger molecules with $R_g > \xi_b$, the Ogston model predicts that the DNA mobility will rapidly approach zero. But the fact is that they can still migrate even when $R_g \gg \xi_b$. This implies that the assumptions in the Ogston model are invalid for larger DNA molecules.

Reptation theory is another important model. The large DNA molecule is assumed to be an unraveled coil, unfolded from head to tail in a snakelike fashion. DNA chains move through the "tubes" in the polymer network, and the friction coefficient, ξ, is proportional to chain length (L), $\xi = \xi_0 L$, where ξ_0 is the friction coefficient per unit length. DNA is assumed to consist of N units of nucleotides (length of each unit $= a$). The total length of the DNA equals Na. In the model, only the force along the DNA chain (longitudinal force) is taken into account in the electric field. The DNA mobility, μ, is then expressed by

$$\mu = \frac{Q\langle x^2\rangle}{\xi_0 a L^2} \tag{5}$$

where Q is the total DNA charge, and x is the head-to-tail distance of the molecule in the direction of the electric field.

At low electric fields, a DNA molecule of medium size can be considered as a random coil with some degree of flexibility. Electrophoretic mobility is expressed as

$$\frac{\mu}{\mu_0} \propto \frac{1}{N}, \quad N < N^* \tag{6}$$

This is the so-called reptation-without-stretching, which is the typical phenomenon for DNA size shorter than a critical length, N^*, needed to pass through a gel at a low electric field. In this case, the mobility is inversely proportional to the DNA size.

Under a high electric field, DNA is no longer considered to move as a random-polymer coil, but moves with extended rod-like conformation. If DNA is completely extended, it moves in a straight fashion in the electric field direction, $\langle x^2\rangle = L^2$; then

$$\frac{\mu}{\mu_0} \propto N^0, \quad N > N^* \tag{7}$$

This regime is the so-called reptation-with-stretching. A mobility plateau is observed for large DNA (above the critical length, N^*) in the case of high electric field and resolution approaching 0. Fig. 2 shows the dependence of DNA mobility on its size.

Separation in Dilute Regime Polymer Solutions

Barron, Sunada, and Blanch[9] found that DNA fragments can be separated in a polymer solution at a concentration well below its entanglement threshold ($c \ll c^*$), and put forward a transient entanglement coupling mechanism. Such separation is believed to be impossible within the framework of the existing Ogston and reptation models. The new transient coupling mechanism explains that the DNA molecule undergoes collisions with neutral polymers, and the average number of polymers that the DNA drags along is dependent on the molecular weight of the DNA. So long DNA molecules have a higher probability of encountering polymer chains, and experience a greater decrease in mobility.

It should be noted that although the separation of DNA can occur in dilute polymer solutions, semidilute solutions give better resolution than dilute ones. In dilute solutions, a narrow ratio of mobility exists between small and large DNA fragments. Therefore, for high-resolution applications, semidilute solutions are preferred. However, if high resolution is not a necessity, dilute (and therefore less viscous) polymer solutions could be used, permitting easier

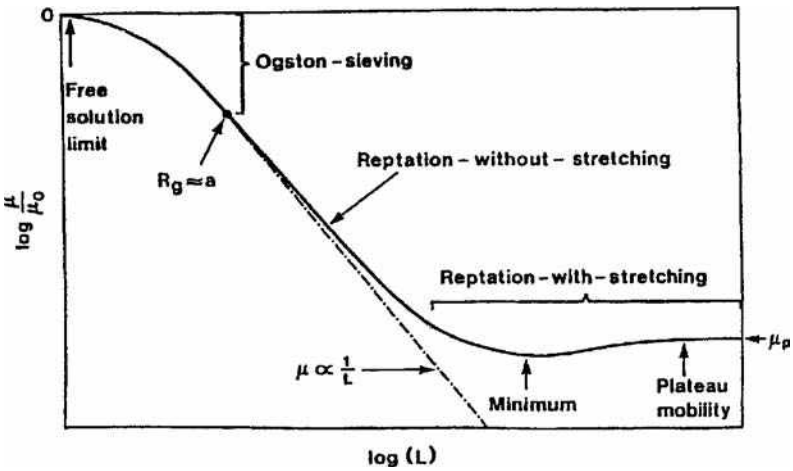

Fig. 2 Electrophoretic behavior of DNA in CE.

filling in microchannels and faster separation. By using dilute solutions of high-M_w polymers, it is also possible to separate large DNA and supercoiled DNA molecules.

DETECTION

UV and LIF are two common CE detection methods. UV detection of DNA fragments is based on the UV absorption of the nucleotide bases. The wavelengths for the UV absorption maxima of DNA bases are 260 nm for adenine, 254 nm for guanine, 267 nm for thymine, and 271 nm for cytosine. Nucleic acids are commonly detected in the UV region from 250 to 280 nm. The sensitivity of UV detection still suffers in CE because of the short optical path length provided by the internal diameter of the separation channel.[10] Laser-induced fluorescence detection is more sensitive than UV; however it requires fluorescent intercalating dyes added to the CE sieving matrix or chemically labeling fluorescent dyes to label nucleic acids. Ethidium bromide is the most common intercalating dye in CE. There are a number of other intercalating dyes, either monomeric or dimeric molecules. Thiazole orange (TO), TO-PRO-1, oxazole yellow (YO), YO-PRO-1, SYBR Green I, etc. are monomeric dyes. TOTO-1, YOYO-1, YOYO-3, etc. are dimeric dyes. These dyes have low background and high sensitivity. Regarding the aspect of detection sensitivity, the monomeric dyes TO, YO-PRO-1, and SYBR Green I are better than most dimeric dyes. Another LIF detection scheme for nucleic acid analysis in CE involves direct labeling of analytes with a suitable fluorophore. The most widely used fluorescent labels are the so-called ABI dyes, viz., FAM, JOE, TAMRA, and ROX. Fluorescently labeled probes and primers are used in many molecular biology applications involving PCR, DNA sequencing, and multicolor detection. New types of labeled agents, such as the energy-transfer (ET) primer, now have widespread application in DNA sequencing.

To make CE useful in high-throughput applications, scanning detection and multisheath flow confocal fluorescence detection have been used in commercial 96-capillary array electrophoresis devices. They have greatly facilitated the completion of the Human Genome Project.

SEPARATION MATRICES

Buffers and Additives

High-viscosity gels (e.g., the high-M_w LPA) require either in situ polymerization or very high pressure to replace them in the capillary. In contrast, many of the low-viscosity polymer solutions do not require polymerization by the user. It is necessary only to dissolve a known amount of the polymer in basic buffers, such as tris-borate-EDTA (TBE) or 3-[[tris(hydroxymethyl)methyl]amino] propanesulfonic acid (TAPS) (pH 8–9), or isoelectric buffers, such as His or Lys. Because the low conductivity of the isoelectric buffers minimizes Joule heating, high electric fields can be used for rapid separation.[11] For oligonucleotide separation, where the DNA is single stranded, denaturation by urea and formamide are also utilized.

Adding polyhydroxy compounds,[12,13] such as glycerol, mannitol, and glucose, to hydroxypropylmethylcellulose (HPMC) matrix can remarkably enhance the resolution of DNA fragments. Some intercalating dyes (e.g., ethidium bromide, YOYO, TOTO, and 9-aminoacridine)[14] can also enhance the resolution of DNA separation by modifying the DNA helix or persistence length.

Non-Cross-Linked Polymer Solutions

The separation matrix is the most important factor in CE separation of nucleic acids. Different polymers have different optimal concentration ranges for the separation of DNA fragments (Table 2). For DNA fragments ranging from 300 to 5000 bp, 0.5% cellulose derivative solution could be

Table 2 Proposed concentration range of polymer matrices for separation of DNA fragments.

	Polymer concentration (%, w/v)		
DNA size (bp)	**LPA**	**HEC, MC**	**PEG, PEO**
1–100	8.0–12	1.0–3.0	6.0–8.0
100–300	7.0–8.0	0.7–1.0	3.0–6.0
300–1000	5.0–7.0	0.5–0.7	2.0–3.0
1000–10,000	3.0–5.0	0.3–0.5	0.5–2.0
10,000–30,000	2.0–3.0	0.01–0.3	

LPA = linear polyacrylamide; MC = methylcellulose; HEC = hydroxyethylcellulose; PEG = poly(ethylene glycol); PEO = poly(ethylene oxide).

selected. For short DNA fragments smaller than 300 bp, the concentration of cellulose derivative should be higher. A more dilute polymer solution (less than 0.3%) is suitable for the separation of DNA fragments larger than 5000 bp. Most commercially available CE instruments are able to fill and empty capillaries with such solutions. An electric field strength between 50 and 800 V/cm is commonly used. When dilute polymer solutions are applied, wall-coated capillaries are usually needed to eliminate electro-osmotic flow (EOF). The inner wall is covalently coated by LPA,[15] polyvinyl alcohol (PVA),[16] etc. Some coated capillaries are commercially available (e.g., DB-17 from J&W Scientific). In contrast, coating the inner wall of microchips, especially in plastic substrates, is not easy. So the use of sieving matrices that do not necessitate wall coating is advantageous, such as poly-*N*,*N*-dimethylacrylamide (pDMA), poly(ethylene oxide) (PEO), and poly(-vinyl pyrrolidone) (PVP).

Linear polyacrylamide has the longest read length in DNA sequencing, due to its high hydrophilicity and thermostability. Solutions of high-molar-mass LPA are extremely viscous and need special loading facilities for injection into precoated separation channels. Short-chain LPA may provide low viscosity. For a given LPA, a higher LPA concentration improves the resolution of short DNA fragments, while a lower LPA concentration favors long DNA fragments. Copolymers of LPA with allyl-β-D-glucopyranoside, allylamide gluconic acid, and allylamide lactobionic acid have self-coating, low viscosity, and good separation abilities for oligonucleotides and small DNA molecules.[17]

Poly-*N*,*N*-dimethylacrylamide has good self-coating and separation abilities at low viscosity (75 cP).[18] Without surface reconditioning between runs, the uncoated capillary is quickly ready for use after replacing pDMA, and allows > 100 runs. Increasing the molar mass of pDMA beyond 98 kDa only slightly improves the resolution but adversely increases the viscosity. The performance of pDMA is a little lower than that of LPA, due to its slightly lower hydrophilicity. The performance can be improved by a copolymer of pDMA and LPA, which combines the excellent performance of LPA with the good self-coating property of pDMA.[19]

Poly(vinyl pyrrolidone) also has better self-coating, low viscosity, and DNA separation abilities. A mixture of polyacrylamide and PVP can form good interpenetrating networks for DNA separation.[20]

Poly(ethylene oxide) has self-coating property. The PEO-filled capillary is regenerated by flushing with HCl and PEO solutions for 2 hr. Low-molar-mass PEO solution provides higher efficiency for smaller DNA fragments, while high-molar-mass PEO solution favors larger DNA fragments. Mixing short and long PEO chains strikes a balance between high resolving power and low viscosity. A mixture of 0.5% PEO 1 MDa and 0.1% PEO 8 MDa successfully separates a range of DNA fragments from 80 to 40 kb (Fig. 3). Xu, Jabasini, and Baba[21] utilized an orthogonal designing technique to quickly optimize a series of mixtures of four PEO matrices, each PEO with a narrow but different range of molecular mass, through only 25 experimental runs in bare polymethylmethacrylate

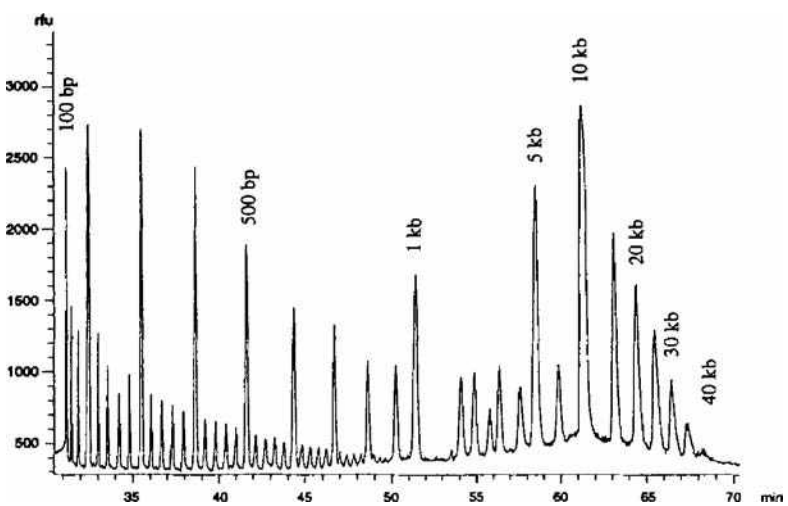

Fig. 3 Capillary electrophoretic separation of DNA fragments from a mixture of 20 bp, 100 bp, 1 kbp, and 5 kbp ladders (65 fragments ranging from 20 bp to 40 kbp) in a mixed matrix consisting of 0.5% PEO (M_n 1 MDa) and 0.1% PEO (M_n 8 MDa). Electrophoretic conditions: PEO in 1 × TBE with 2 nm TO-PRO-3 and 10 μ*M* 9-aminoacridine; 108 V/cm.

(PMMA) microchips. The matrices are suitable for the analysis of DNA fragments ranging from 20 bp to 40 kbp.

Celluloses are described by the type of substituent carried by the cellulose backbone and the viscosity. They can separate DNAs at low concentrations (<2%). Hydroxyethylcellulose (HEC) is a linear derivative with bulky ethylene oxide side chains terminating in hydroxyl groups. In aqueous solutions, it has a stiff, extended conformation. It has relatively high viscosities at the entanglement concentration. A mixture of HEC of different sizes offers a wide range of DNA separation from 100 bp to 23 kbp.[22] Hydroxypropylcellulose (HPC) solution provides similar separation ability, and it has 2–3 times lower viscosity than HEC solution.

DNA separation by CE has been applied to many studies, such as PCR product and digested fragment analysis, restriction fragment length polymorphism analysis, single-stranded conformational polymorphism analysis, variable number of tandem repeat analysis, microsatellite analysis, hybridization, monitoring of DNA-based drugs,[23] etc. Capillary affinity gel electrophoresis, which combines the high specificity of affinity ligands with the high separation power of capillary gel electrophoresis, has been developed for the recognition of specific DNA bases.[24]

Oligonucleotides are generally short single-stranded DNA (<150 bases). Denatured cross-linked polyacrylamide gels, in which the concentration varies from 3% to 8% T and the degree of cross-linking varies from 3% to 5% C (% T is the monomer concentration; % C is the cross-linker concentration), have been used for the separation of oligonucleotides by CE. High-concentration polymer solutions with short M_w have also been adopted, which do not increase the viscosity much. Antisense DNAs are in generally rather small molecules (12–15 bases) and their separation is commonly performed at 13–18% LPA concentration under denaturing conditions (7 *M* urea and 30% formamide).[25] RNA molecules are single-stranded nucleic acids that can form complicated second and tertiary structures. Using CE, total RNA and ribosomal RNA extracted from cells or at the single-cell level (without extraction) are successfully separated with semidilute polymer solutions as the separation matrix.[26]

Thermoresponsive Polymer Solutions

Thermoresponsive matrices have different viscosities at varying temperatures. So they are "ideal" polymers that allow rapid microchannel loading under low viscosity and provide high separation power at high viscosity. The matrices can be classified into two categories: thermoassociating and thermothinning solutions.

Thermoassociating Polymer Solutions

At room temperature or below, thermoassociating polymer solutions have low viscosities. Elevation of temperature leads to hydrophobic association and higher viscosities, suitable for DNA separation. For example, a low-M_w triblock copolymer, $PEO_{99}PPO_{69}PEO_{99}$ [M_w 12.7 kDa, where PEO is poly(ethylene oxide), and PPO is poly(propylene oxide)], demonstrates viscosity-adjusting and self-coating properties. At 5°C, the 25% w/v matrix has a low viscosity of 50 cP (suitable for loading). At 20°C, the viscosity reaches 250 cP and a gel-like structure is formed. The PPO blocks form the core and the PEO blocks dangle outside to form a corona.[27] The effective pore size of the matrix is small due to high PEO concentration (above 20%), which is particularly suitable for small DNA molecule separation. Another similar copolymer solution, $PEO_{106}PPO_{70}PEO_{106}$ (M_w 13 kDa), can flow easily into capillaries at 0°C (100 cP, 20% w/v solution), but rapidly transform into a gel-like, liquid-crystalline phase of spherical micelles at room temperature, suitable for the resolution of oligonucleotides.[28]

A blended copolymer of 4% $PBO_6PEO_{46}PBO_6$ (M_w 2.9 kDa) and 4% $PBO_{10}PEO_{271}PBO_{10}$ [M_w 13 kDa, where PBO is poly(butylene oxide)] also shows thermoassociating and self-coating properties.[29] A resolution of 1.3 could be achieved for the separation of a 123 bp/124 bp doublet. Another copolymer, comprising an LPA backbone and poly(*N*-isopropylacrylamide) (pNIPA) comblike side-chains, has low injection viscosity at room temperature (<300 cP, 3–5% solution), and high viscosity (10,000 cP) at 66°C. It provides better resolution than pDMA solutions.[30] pNIPA-*g*-PEO ($M_w > 10$ MDa) is a different comblike copolymer, which uses long-chain pNIPA as the backbone densely grafted by short PEO chains.[31] When the temperature is raised above 36°C, the copolymer chains become insoluble and then collapse to nanoparticles, with pNIPA inside the core and the hydrophilic PEO chains on the shell. A resolution of 1.4 for the separation of 123 bp/124 bp fragments in pBR322/*Hae*III DNA digest is achieved within 12.5 min in an effective separation length of 10 cm at 200 V/cm by using 8% w/v copolymer.

Thermothinning Polymer Solutions

Polymer solutions of this category are opposite in temperature response compared with thermoassociating solutions. Because the moderately hydrophobic copolymers in the matrices may form an entangled network in aqueous solution, they have high viscosity at room temperature; however, at an elevated temperature, the solution viscosity drops quickly due to a solubility-to-insolubility phase transition. For example, the copolymer of *N*,*N*-dimethylacrylamide (DMA) and *N*,*N*-diethylacrylamide (DEA) has both self-coating ability and a low viscosity of 10 cP at 70°C. Single-base resolution of DNA is observed at 40°C, at which the solution becomes re-entangled. The temperature-dependent viscosity behavior is thermally reversible, facilitating easy medium replacement at low

viscosity. Another blended matrix of thermoresponsive polymer (1.4% w/v HPC) and non-thermoresponsive polymers (0.5% w/v HEC) has a low viscosity of 30 cP at 50°C, and a high viscosity of 1000 cP at 20°C. The matrix provides a thermally tunable mesh size, i.e., "dynamic porosity." Maximum selectivity is observed at 31°C for small DNA separation, while a significant increase of selectivity of large DNA molecules occurs at 36°C. In a temperature ramping experiment, high-resolution separation of both small and large DNA fragments has been achieved in a single run due to the changeable mesh properties of the matrix.

Thermoresponsive matrices appear to be quite promising for DNA separation, though their performance still lags behind that of the non-thermoresponsive LPA matrix, mainly due to the hydrophobicity of the former, which causes them to form less stable networks than LPA.

MICROCHIP ELECTROPHORESIS SEPARATION

Microchips are fabricated using either photolithography, chemical wet-etching methods on glass/silicone substrates, or molded plastic for a micromachined template. Then the channel plate is thermally bond with a top plate. By providing a set of intersecting channels and applying high voltages in reservoirs, it is possible to control the flow direction and flow rate of analytes. The microchip channels are commonly several centimeters in length, 10–100 μm in width, and 10–100 μm in depth. Although silicon can act as a substrate material for microchips, its semiconductor property is incompatible with the high voltage used in microchip electrophoresis. At present, glass, quartz, and various plastics, such as PMMA, polydimethylsiloxane (PDMS), polyacrylate, and polycarbonate are common substrates.

The use of microfabrication and array technologies for DNA separation has undergone quick development. The first DNA separation was carried out on a microchip channel in 1994.[5] Later, with the success of both chip and detection designs, microfabricated capillary array electrophoresis (μCAE) of 12-channel to 96-channel chips[32] appeared. PCR and μCAE can be functionally integrated on a single chip, where the DNA sample is amplified in a microfabricated PCR chamber and then injected electrophoretically into an electrophoresis chip. The total time of PCR and electrophoresis is only 20 min for a β-globin gene target and 45 min for a *Salmonella* genomic DNA target.[33] Rapid detection of deletion, insertion, and substitution mutations by combining allele-specific DNA amplification with heteroduplex analysis by microchip electrophoresis has been accomplished within 130 sec.[34] A 96-lane radial microchannel plate layout together with a rotary four-color confocal fluorescence scanning detector has been used for high-throughput genotyping.[35] Compared to the traditional CE methods, the analytical speed of microchip electrophoresis shows more than tenfold improvement. It is quite important for clinical diagnosis.

SEPARATION OF LARGE DNA MOLECULES

Field-Inversion Capillary Electrophoresis

Conventional CE in continuous electric fields cannot separate DNAs above 40 kb, due to reptation and loss of resolution. One has to resort to pulsed-field gel electrophoresis. This technique makes use of periodically varied direction and strength of an electric field (the net field direction is forward). The DNA molecules not only migrate in the direction of the field but also stretch out lengthwise. The time required for relaxation is directly proportional to the molecule length. Longer molecules relax less than shorter ones when the current is changed. DNA molecules are forced to reorient and are separated according to their sizes.

Nevertheless, the pulsed field run commonly takes longer than 10 hr. The pulsed field is also not easily implemented in CE, except for periodical reversion of field direction (the so called field-inversion CE, FICE). The technique uses alternating electric fields with a frequency >100 Hz. Equal pulse durations in FICE provide the best resolution, while dilute polymer solutions provide the fastest separation. DNA fragments of 200 kbp–1.6 Mbp are separated within 13 min in a dilute methylcellulose solution.[36]

Entropy-Based Separation

During the electrophoresis of long DNA molecules, aggregation of the DNA is a serious problem due to electrohydrodynamic instability triggered by dipole–dipole interaction.[37] In addition, the constituting multiplexed capillaries are also complicated. These problems can be solved by artificially microfabricated obstacles, which mimic polymer gels. Internal conformation entropy is one of the dominant properties of flexible DNA macromolecules, and is directly proportional to the molecular length. Electrophoretic "entropic trapping" (ET) separation is based on nanofluidic channels with narrow constrictions to create mobility differences for separating long DNA molecules (>5 kbp) without the use of polymer solutions and pulsed electric fields. Entropic trapping occurs when the radius of gyration (R_g) of the DNA molecule is comparable to the mean pore size of a separation "gel," e.g., one of the dimensions of a channel is smaller than R_g. Craighead's group designed several entropic devices (one is shown in Fig. 4). When driven by a d.c. field, DNA molecules in the 5–160 kbp range migrate through the periodic deep and shallow regions and become trapped at the entrance of the shallow constrictions before they manage to escape. In the thick region, DNA molecules can form spherical

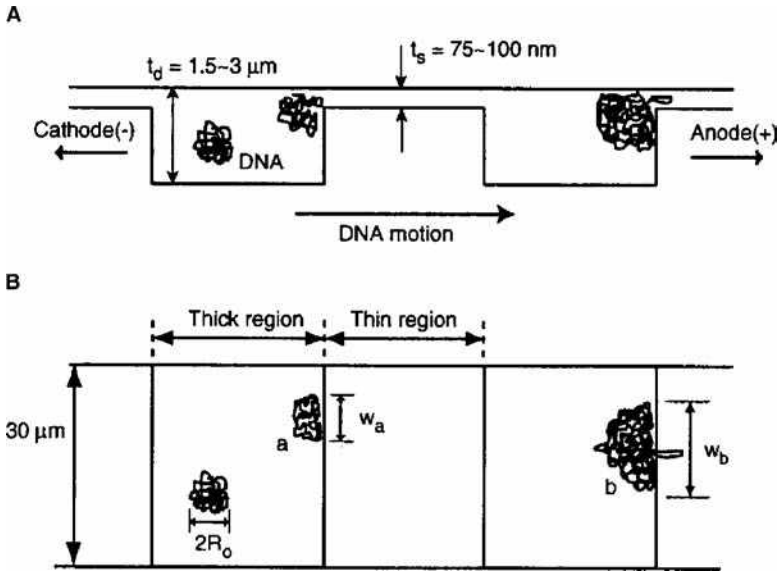

Fig. 4 Nanofluidic separation device with many entropic traps. A, Cross-sectional schematic diagram of the device. DNA molecules are trapped whenever they meet a thin region, because their R_g is much larger than the thin region depth. B, Top view of the device. Trapped DNA molecules eventually escape, with a probability of escape proportional to the length of the slit that the DNA molecule covers (w_a and w_b). Larger molecules have a higher escape probability because they cover wider regions of the slit ($w_b > w_a$).
Source: From Separation of long DNA molecules in a microfabricated entropic trap array, in Science.[6]

equilibrium shapes because the thickness here is larger than R_g, whereas in the thin region, DNA molecules are deformed. DNA molecules repeatedly change their conformation, and consume entropic free energy. The mobility becomes length dependent. Ueda et al.[38] investigated the electrophoretic behavior of large DNA based on the curvature effect of a nanofabricated chip with a curved channel. The DNA chain must endure deformation in the narrow and curved channel, and the ET effect is related to the problem of barrier crossing for flexible DNA molecules to pass through.

Turner, Cabodi, and Craighead[39] fabricated a quasi-two-dimensional nanofluidic structure, in which some regions are populated with a dense array of nanopillars of 35 nm diameter. The height of the fluid gap between the floor and ceiling is determined by the thickness of a sacrificial layer. Long DNA molecules can be electrophoretically driven through the closely spaced pillared region (160 nm apart). The DNA must elongate in order to migrate downfield, at a great cost of conformational entropy. When the field is turned off, molecules that have partially entered this pillar region quickly recoil in the pillar-free region to maximize their conformational entropy. Longer DNA molecules take longer to enter the pillared region than shorter molecules, thus making separation possible.

Fractionation of long DNA molecules is also demonstrated in microfabricated hexagonal arrays and asymmetric structures.[40] Statistical data show that nanopores can distinguish between DNA molecules of similar length and composition that differ only in sequence. Nanopores can quickly discriminate and characterize unlabeled DNA molecules at low copy number. Artificial gel on microchips alleviates the difficulties associated with the irreproducible architecture of gels and viscous polymer solutions. It is able to optimize the geometry of the system to both increase the separation speed and reduce the diffusion by the use of the deformation that the chain endures in the narrow passages. The main disadvantage of the promising technique is that the production of entropic trapping devices is a sophisticated and costly procedure with little tunability after construction.

CONCLUSIONS

We hope that this brief review has given the reader a general feeling of the development and application of CE in the separation of nucleic acids. With the advent of capillary array electrophoresis and microchip electrophoresis, as well as remarkable improvements in separation matrices, CE has become a standardized and cost-effective technique in the separation of nucleic acids. Novel thermoresponsive polymer solutions combine the merits of different monomers, and offer the possibility to fine-tune the desirable properties of polymer molecular architecture and chemical composition. Artificial entropic trapping systems obviate the use of viscous polymer solutions, and even offer fast, unattended, miniaturized, and multiplexed platforms. Optimizing the geometry of these electrophoretic systems to both increase the separation and reduce the diffusion (band broadening) is the main topic for future research.

Octanol–Water Distribution Constants Measured by CCC

Alain Berthod
Laboratory of Analytical Sciences, University of Lyon I, Villeurbanne, France

Abstract
The octanol–water partition coefficient ($P_{o/w}$) of a compound is the most universally accepted physicochemical parameter related to its polarity and/or hydrophobicity. $P_{o/w}$ can be measured directly without any approximation by countercurrent chromatography (CCC). CCC uses two liquid phases to separate mixtures. When the stationary phase is octanol and the mobile phase is water, the retention volume of all injected components is directly proportional to their respective $P_{o/w}$ coefficient.

INTRODUCTION

Hydrophobicity, from the Greek *hydro* (water) and (*phobia*) aversion, is a term referring to the way a molecule "likes" or "does not like" water. A compound with a high hydrophobicity will not be water soluble. It is apolar. Conversely, a compound with low hydrophobicity is said to be hydrophilic or polar. It is likely to be water soluble. In between the two extremes, hydrophobicity varies. A scale is needed. The problem is that hydrophobicity, or the polarity of a compound, depends on several parameters such as the dipole moment, the dielectric constant, the polarizability, the proton donor or acceptor character, or even the boiling point to molecular mass ratio. Since the end of the nineteenth century, the *octanol–water partition coefficient*, which should preferably be termed *distribution constant*, $P_{o/w}$, has been used with success as a measure of molecular hydrophobicity. The log $P_{o/w}$ is a convenient scale. Compounds with a positive log $P_{o/w}$ value are more and more hydrophobic or apolar as the value increases. Compounds with a negative log $P_{o/w}$ value are hydrophilic or polar.[1]

It is of paramount importance to be able to measure accurately the $P_{o/w}$ and log $P_{o/w}$ value of a compound, because they are the accepted parameters used by the Food and Drug Administration (FDA) and the Environmental Protection Agency (EPA) and many other international drug and environmental agencies to estimate the tendency of an organic chemical to bioconcentrate into living cells. A new drug cannot be considered by the FDA and EPA without the $P_{o/w}$ parameter.

Countercurrent chromatography (CCC) is a liquid chromatography (LC) technique in which the stationary phase is a support-free liquid phase.[2] Since the mobile phase is also a liquid, a two-phase liquid system must be used (see *CCC/MS*, p. 323). Octanol and water are two solvents very partly miscible. They form a biphasic liquid system. Octanol can be used as the stationary phase in CCC with the aqueous phase, saturated in octanol, being the mobile phase.

DISTRIBUTION CONSTANT, PARTITION COEFFICIENT, AND DISTRIBUTION RATIO

The first step is to define clearly the terms used. The *distribution constant* (K_D) is the ratio of the concentration of a solute in a single definite form in the organic phase to its concentration in the same form in the aqueous phase at equilibrium, e.g., for a solute A:

$$(K_D)_A = \frac{[A]_{org}}{[A]_{aq}} \quad (1)$$

A good synonym for K_D is *partition ratio.* The term *partition coefficient* is not recommended by IUPAC.[3] The *distribution constant* is proportional to the retention time in CCC if and only if the solute exists in a single definite form (no ionization, no complexation, no chemical reaction possible). In that case, $K_D = D$, the *distribution ratio.* The *distribution ratio* (D) is the ratio of the *total* analytical concentration of a solute in the liquid stationary phase, regardless of its chemical form, to its total analytical concentration in the mobile phase. As defined, the *distribution ratio* can vary with experimental conditions, e.g., pH, presence of complexing agents. It should not be confused with *distribution constant*, K_D (or *partition coefficient*, P, the term not recommended but still commonly used, especially as $P_{o/w}$), which applies to a particular chemical species and is by definition invariable. The *distribution ratio* of a solute is directly proportional to its CCC retention time or volume, not necessarily the *distribution constant*.

Let's make this delicate point clear using benzoic acid as an example. Benzoic acid does partition between octanol and water. However, in the aqueous phase, benzoic

acid can ionize, becoming the benzoate anion with very little or no affinity for the octanol liquid phase. Also, in the octanol phase, two molecules of benzoic acid can associate, forming a dimer. To make things simple, it is assumed that there are no benzoate anions in the octanol phase and no dimers in the aqueous phase. According to Eq. 1, the octanol–water distribution constant or partition coefficient of benzoic acid, φCOOH, is:

$$P_{o/w} = \frac{[\varphi\text{COOH}]_{oct}}{[\varphi\text{COOH}]_{aq}} \tag{2}$$

The distribution ratio that is measured by the retention time of benzoic acid observed in CCC is expressed by:

$$D_{o/w} = \frac{\left([\varphi\text{COOH}]_{oct} + [\varphi\text{COOH}_2]_{oct}\right)}{\left([\varphi\text{COOH}]_{aq} + [\varphi\text{COO}^-]_{aq}\right)} \tag{3}$$

Using the acid dissociation constant, K_a, and the dimerization constant, k_2, of benzoic acid, the relationship between the distribution ratio, $D_{o/w}$, and the distribution constant, $P_{o/w}$, is given as:

$$D_{o/w} = P_{o/w}\left(\frac{1 + k_2[\varphi\text{COOH}]_{oct}}{1 + \frac{K_a}{[H^+]}}\right) \tag{4}$$

From a practical point of view, the octanol–water partition coefficient of benzoic acid is 74 ($\log P_{o/w} = 1.87$), its acid dissociation constant is 6.3×10^{-5} ($pK_a = 4.2$), and its dimerization constant, k_2, is about 0.04.[2] At physiological pH of 7.4, benzoic acid is exclusively in the benzoate anion form. Eq. 4 gives a $D_{o/w}$ value of 0.05 whatever be the benzoic acid concentration injected (the buffer capacity is assumed to be high). When 1 *M* benzoic acid is injected in a pH 1 buffered aqueous phase, the measured $D_{o/w}$ value will be 77. A 0.1 *M* injection at pH 1 would produce a $D_{o/w}$ value of 74.3. In all cases, the $P_{o/w}$ coefficient is 74. The peak position of benzoic acid in the CCC chromatogram critically depends on the aqueous phase pH and marginally on the injected concentration.

CLASSICAL $P_{O/W}$ MEASUREMENT METHODS

The most extensive and useful sets of $P_{o/w}$ data were obtained by simply shaking a solute with the two immiscible octanol and water phases and then analyzing the solute concentration in one or both phases. For many solutes, when there is repeated inversion (say ~100) of a 25 ml tube ~0.01 *M* solute, the two phases establish equilibrium in ~15 min. Very vigorous shaking can produce troublesome emulsions. The solute can be analyzed in only one phase and the concentration in the other can be obtained by the difference. The phase analysis is most often done by gas chromatography, liquid chromatography, or ultraviolet (UV)–Visible spectroscopy. The shake flask method gives reliable results over the wide 10^{-4}–10^4 range. However, it requires highly pure solutes and is very sensitive to the smallest contamination.

Reversed-phase liquid chromatography (RPLC), capillary electrophoresis (CE), micellar liquid chromatography (MLC), and electrochromatography (EC) can be used to estimate values of $\log P_{o/w}$ from the corresponding $\log k$ values; k is the retention factor directly related to the retention parameter of the solute of interest. Good correlations are generally found between $\log k$ and $\log P_{o/w}$ for structural congeners. Unfortunately, the correlations are much poorer with dissimilar compounds. Trace amounts of octanol were added in the mobile phase to enhance $\log k$ – $\log P_{o/w}$ correlations with a wide variety of solutes. The range is 1–$10^{5.5}$. The advantages of the RPLC method are its relative simplicity and the fact that it does not need highly pure solutes. At the moment, the correlation remains the main drawback. Today, CE with micellar mobile phases is becoming a commonly used tool in industry to rapidly obtain a good estimation of the $\log P_{o/w}$ of a particular solute.[4]

DIRECT $P_{O/W}$ MEASUREMENT BY CCC

The decisive advantage of CCC in measurement is that there is no correlation at all. Water saturated with octanol is the mobile phase. Octanol saturated with water is the stationary phase. The octanol–water distribution constant of a given solute is the only physicochemical parameter responsible for the solute retention. If the solute is not highly pure, it is likely that the impurities will have differing values. This means that if the impurities have differing retention volumes, they are separated during the measurement from the solute of interest.

The $P_{o/w}$ value is easily derived from the CCC retention equation:

$$V_R = V_M + PV_S \tag{5}$$

using

$$P_{o/w} = \frac{(V_R^- V_M)}{V_S} = 1 + \frac{(V_R^- V_C)}{V_S} \tag{6}$$

In these equations, the volume subscripts R, M, S, and C stand for retention, mobile phase, stationary phase, and column volume, respectively.

If octanol is the stationary phase and water the mobile phase, $P_{o/w}$ is the octanol–water distribution constant (partition coefficient) without any assumption but with the condition that no chemical change can affect the

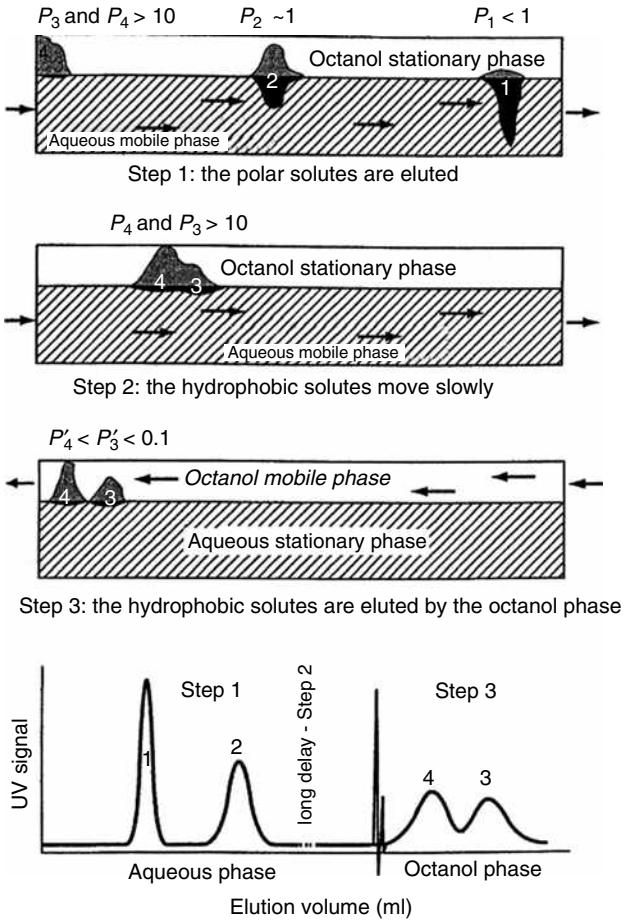

Fig. 1 Dual-mode CCC: Steps 1 and 2, classical elution mode. Step 3, both the nature and flowing direction of the mobile phase are changed.

solute (especially no ionization). Correlations of the $P_{o/w}$ or log $P_{o/w}$ values obtained with the same liquid system by the shake flask method and by CCC produce straight lines with a slope of unity and a negligible intercept. The validity and solidity of the method were assessed by Gluck and Martin for $P_{o/w}$ coefficients.[5] The $P_{o/w}$ range that can be obtained directly by CCC is limited to 0.05–200.[1,2] It is limited on the high side by the experiment duration. A value of 200 corresponds to a V_R retention volume of 6 L with a V_S value of only 30 ml (Eq. 5). This is 1200 min or 20 hr with a 5 ml/min flow rate. The lower-side limitation is due to experimental precision. The difference between the retention volume V_R and the dead volume V_M is equal to PV_S (Eq. 5). With a 30 ml V_S volume, the $P_{o/w}$ value of 0.05 corresponds to a $V_R - V_M$ value of only 1.5 ml. Such a low value may be difficult to evaluate with an acceptable accuracy. To increase the measurable range, the fact that the CCC stationary phase is a liquid can be used. This led to the dual-mode use of CCC and the cocurrent operation.

DUAL-MODE CCC

The idea is simple: Solutes with very high $P_{o/w}$ values move very slowly in the octanol phase; they need too long a time to emerge from the apparatus. To force them out of the CCC apparatus, the role of the aqueous and octanol phases and their flow directions are reversed after some reasonable flowing time in the normal direction. The dual-mode operation is illustrated in Fig. 1. It was demonstrated that the $P_{o/w}$ value can be simply expressed by

$$P_{o/w} = \frac{V_{aq}}{V_{oct}} \tag{7}$$

in which V_{aq} is the aqueous-phase volume passed in the normal way (descending or head to tail, Steps 1 and 2) and V_{oct} is the octanol-phase volume passed in the reversed way (ascending or tail to head, Step 3). The highest $P_{o/w}$ value that can be measured is again limited by the lowest volume that can be accurately determined. Because of band broadening, the practical minimum V_{oct} value is about 3 ml.[1] Then, with a 6000 ml V_{aq} volume, the corresponding $P_{o/w}$ value is 2000. Table 1 shows the experimental conditions corresponding to the dual-mode measurement of some $P_{o/w}$ values in the 40–3000 range. It was shown that the error on the $P_{o/w}$ determination was minimized when the octanol flow rate in the reversed mode was very low.[1]

COCURRENT CCC

The cocurrent CCC operation takes advantage of the liquid nature of the stationary phase. If a lipophilic solute stays too long inside the CCC apparatus, why not push it out, pushing the liquid stationary phase slowly in the same direction as the mobile phase? The theoretical treatment[6] and the practical promise of the method were established.[7] Three pumps are needed. Pump 1 allows the adjustment of the aqueous-phase flow rate in the few milliliters per minute range. Pump 2 governs the octanol phase flow rate in the microliter per minute range. Pump 3 is used to add a clarifying agent to the phase mixture leaving the CCC apparatus. The clarifying agent can be 2-propanol; it solubilizes the trace amounts of octanol present in the aqueous phase. The method is interesting in that there is no abrupt change; that is, it is continuous. The octanol volume retained in the CCC system is very stable, more stable than with other methods, because there is a constant input of octanol. The octanol volume changes, due to dissolution that was noted in the direct method or due to phase reversal as noted in the back-flushing method, do not exist with the cocurrent CCC method. The volume was determined using a test solute (2-chlorophenol, $P_{o/w} = 147$ in Ref. 7). Another very important effect that was experimentally observed is the increased peak efficiency due to the octanol flow rate. The measurable $P_{o/w}$ range was

Table 1 Octanol–water distribution ratio measured using different CCC methods.

extended up to 20,000 (log $P_{o/w} = 4.3$). Table 1 lists the actual conditions of some measurements by the cocurrent CCC method. The CCC methods presented here were extensively used to measure the value of molecular compounds.

IONIZABLE COMPOUNDS

The method was recently adapted to measure the $P_{o/w}$ values of ionizable compounds using buffered octanol-saturated aqueous phases.[8] Charged entities may well partition somewhat with octanol so that the $P_{o/w}$ coefficient for the molecule is associated to a K_D^- constant for its anion. In the case of an ionizable AH compound giving the A^- anion, the distribution ratio, D, can be expressed by modifying Eq. 3 as:

$$D = \frac{[AH]_{oct} + [A^-]_{oct}}{[AH]_{aq} + [A^-]_{aq}} \quad (8)$$

Using the AH dissociation constant K_a, the distribution constant can be expressed as:

$$D = \frac{P_{o/w} + K_D^- \left(\frac{K_a}{[H^+]}\right)}{1 + \frac{K_a}{[H^+]}} \quad (9)$$

K_D^- is the $P_{o/w}$ distribution constant of A^-, the anionic form of AH. Eq. 9 clearly shows that the D value measured by CCC for an ionizable compound is not $P_{o/w}$. It is highly dependent on the pH and solute pK$_a$. It was demonstrated[8] that three measurements at three pH values around the pK$_a$ value allows the determination of the molecular $P_{o/w}$ value of the solute as well as the $P_{o/w}$ value of its corresponding anion. Even though the $P_{o/w}$ values of the ions were always small as expected for such hydrophilic entities, they were not nil. CCC may be the only experimental method allowing estimation of the hydrophobicity of ions.[4,8]

On-Column Injection for GC

Mochammad Yuwono
Gunawan Indrayanto
Faculty of Pharmacy, Airlangga University, Surabaya, Indonesia

INTRODUCTION

The injection system in a gas chromatography (GC) analysis provides a means of introducing the sample onto the column. This is normally a simple injector design when packed columns are used. Capillary or open tubular columns require, however, more sophisticated design than do packed columns, because of their very low capacities and small internal diameters. A number of different injector designs have been recently developed. Unfortunately, no universal injector has so far been commercially available to handle all sample types. This entry will discuss various approaches to sample injection.

SELECTION OF INJECTION MODE

The selection of the most suitable injection system becomes important, especially when samples containing widely different boiling point components and different concentrations are to be analyzed.[1,2] Today, the most commonly used injectors for capillary GC fall into one of four techniques, i.e., split, splitless, on-column injection, and programmed-temperature vaporizers (PTV). The split injection mode was the first sample introduction system developed for capillary GC which, as the name signifies, splits the vaporized sample into two unequal portions, allowing only the smaller portion of it into the column and venting the larger from the system. The injector involves a heated chamber including a glass liner, into which the sample is introduced through an injection septum. For many applications, it is the most convenient sampling method, as it is very easy to operate, producing perfect peak shapes and good resolution after injecting concentrated samples in the same manner as for packed column systems.[3] A major drawback of the split injection technique is the so-called sample discrimination due to the uneven flash vaporization of the sample. The discrimination means that not all components of the vaporized samples are brought quantitatively into the column. When a sample containing compounds with widely different boiling points is analyzed with the split sampling technique, the less volatile components are discriminated. Consequently, the resultant chromatogram does not truly describe the real composition of the sample components; so the quantitative analysis becomes unreliable.[3,4] To minimize or prevent this, the use of other injection techniques is suggested, such as cooled needle injection, very fast injection, cold on-column or programmable vaporization.[5] Using an internal standard or an autosampler can also greatly enhance the accuracy of the results. With split techniques, problems arise also in analyzing thermally labile compounds which may decompose at the injection operating temperature. Introducing the samples using cold on-column injection technique is the best solution to solve this problem.[5,6] Because the split technique is beneficial for analysis of samples containing compounds at high concentration, the splitless injection mode was then developed for analyzing trace-level compounds. In this splitless technique, the entire vaporized sample volume is directed into the column by closing the split vent (purge off mode). In this way, the sample is transferred completely and slowly into the column; this ensures quantitative and representative sample introduction. Most split injectors today can operate in the splitless mode. These injectors are normally called split/splitless injectors, which can be operated first in a splitless mode (usually less than 1 min), allowing to gradually force the majority of the vaporized sample to the column inlet. The mode is then operated in split mode to purge the excess solvent. The method does not need fast vaporization, so that it is advantageous for the analysis of thermally unstable compounds. However, the solvent focusing techniques and other parameters must be gently optimized; otherwise, the results obtained are not reproducible and are low in accuracy.[5,7] The splitless injection technique is still used for the routine determination of trace-level compounds, such as for pesticide residues, drug impurities, etc. Direct and on-column flash vaporization injection has also been applied recently, which offers some advantages over the splitless technique for trace samples.[8] For the same purpose, cold on-column injection is also increasing in popularity as a technique for the analysis of the trace compounds, because of its higher precision and accuracy.

DIRECT AND ON-COLUMN INJECTION

Direct injection is often confused with on-column injection. Direct injection allows the injection of liquid samples into a heated injection port. After injection, the

sample is subsequently vaporized and then completely directed onto the column.[5,9] The evaporation of sample occurs in the inlet, which is heated independently from the column oven. The most commonly used inlet is a glass liner, and no sample splitting or venting occurs during or after injection. Direct injection is limited to widebore or megabore columns.[5] In on-column injection, the sample enters the column directly from the syringe and does not contact other surfaces. On-column injection generally indicates cold on-column injection for capillary columns.[5] The terms "hot on-column injection" and "on-column flash vaporization" are elsewhere introduced.[9] The hot on-column mode is different from the direct injection in the inlet that is used and in the termination point of the syringe needle during injection.[8] The technique is called direct injection when a glass inlet sleeve is used, and the evaporation of the injected sample occurs outside the column. With an on-column injection, a specially designed liner or a part of the column is used as inlet which allows the injection of the liquid sample inside the column and the evaporation of the sample also occurs on the column wall surface.[5,9] This simple technique is usually used for packed column GC. However, it has recently become popular because it can also be used with capillary columns (0.32 and 0.53 mm I.D.).

Specially designed injection port inlet sleeves have been available on the market for direct and hot on-column injection.[7,8] In the direct injection mode, 2–4 mm I.D. inlet sleeves are commonly used, which permit a sufficient space for sample evaporation; however, the on-column mode is usually performed by inserting a 26-gauge needle inside a 0.53 mm I.D. column. Direct injection is more favorable because it is less problematic than the hot on-column mode.[9] Because the liner can trap non-volatile residues before entering the column, this technique is suitable for dirty samples. Compared to the splitless mode, the direct injection is advantageous, involving less adsorption of the solutes and better sensitivity. However, with this technique, the adsorption of the sample may occur on the inlet sleeve during the evaporation process.[9] In this case, the hot on-column mode offers more benefits.

COLD ON-COLUMN INJECTION TECHNIQUE

As the name indicates, the cold on-column injector allows the injection of the sample directly as a liquid onto the column, of which the inlet and/or outlet section is maintained at a lower temperature than the oven. After the solutes are focused in the inlet section of column, the sample is then vaporized as the oven temperature is increased. In this way, all of the sample components are transferred into the column, so that the sample discrimination attributed to the syringe needle heating during injection is eliminated; it is also convenient for the analysis of thermally labile compounds.[1,10] The possibility of peak broadening is due only to band broadening in space.[5,11] This technique yields excellent quantitative precision and accuracy for samples that contain less volatile and highly volatile compounds.[12–14] Unlike the on-column flash vaporization injection, cold on-column is the true on-column technique, because both the injection of the sample and the evaporation occur inside the column.

An injector device for on-column work was first introduced by Schomburg in 1977.[15] In 1978, Grob and Grob[16] developed an excellent injector design which requires, principally, a syringe guide and a stop valve. A standard syringe with stainless steel needle of 0.23 mm I.D. (32-gauge) and 8 cm in length was used for the commonly used 0.32 mm I.D. glass capillary column. The needle is introduced through a conical aperture into the 0.3 mm inlet channel, close to the stop valve. By pushing down the syringe and guiding the needle into the capillary column, the sample is injected onto the column. After injection, the syringe is moved back, the valve is closed, and the syringe is finally withdrawn. The bottom of the body is cooled by a fan-driven air circulator to maintain the low temperature of the column inlet. This is called primary cooling. Complete construction of the design was described by Grob and Grob.[16] Further development of the cold on-column injection device included the use of secondary cooling, which is done by circulating air directed from a jacket surrounding the capillary inlet toward the injection area of the column.[17] The secondary cooling system is to cool the area of the column where the sample is actually injected. The use of secondary cooling can totally eliminate syringe discrimination and ensures that the temperature of the needle channel can be controlled to avoid solvent evaporation. The secondary cooling is advantageous, especially when the injector is combined with temperature programming.[1,18] Fig. 1 shows a typical on-column injector with provision for secondary cooling of the column inlet. The evolution of the cold on-column injection technique occurred because syringes with fused silica needles had been introduced to replace commonly employed metal needles; the injection onto a capillary column of 0.22 mm I.D. then became reality. The fused silica needles are inert and perfectly straight.[5,7] This innovative work makes the on-column injection technique gain more acceptance. The programmed-temperature on-column injector was then developed, in which the column inlet is housed in a separate injection oven, so that the column inlet temperature can be programmed from subambient to about 350°C and thermostated independently of the column oven.[1] For thermally labile compounds, it is suggested that the temperature is programmed at a low heating rate,

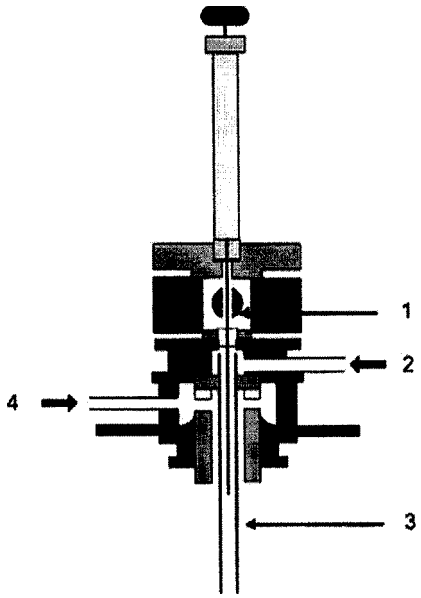

Fig. 1 Schematic diagram of a typical cold on-column injector with provision for secondary cooling of the column inlet. 1: Rotating valve, 2: carrier gas, 3: capillary column, 4: secondary cooling.

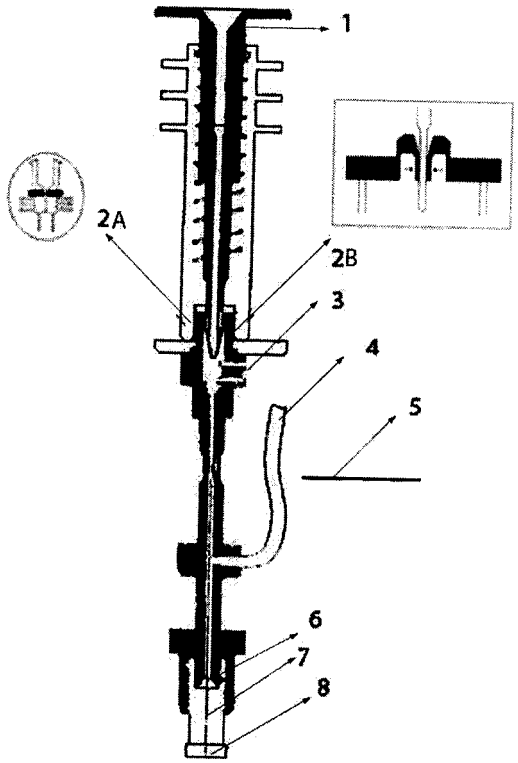

Fig. 2 Schematic diagram of a cross section of a cold on-column injector with a duck-bill valve. 1: Cool tower needle guide, 2A: disk septum for automated injections, 2B: isolation valve for manual injections, 3: frit, 4: carrier gas, 5: oven wall, 6: ferrule, 7: capillary column, 8: column nut.
Source: From Sample introduction, in *High Resolution Gas Chromatography*.[5]

whereas a rapid rise is favored for vaporization of samples containing highly different boiling point components.[6,7] A version of an on-column injector design that offers a low thermal mass, which facilitates cooling, has been developed. In this injector, a duck-bill valve constructed from a soft elastomer, such as in a flexible septum, is applied to form a gas-tight seal compressed by the column inlet pressure. When the needle guide is depressed, the isolation valve is parted and the metal guide is forced through the duck-bill valve.[5] This permits the syringe needle to pass the valve and enter the column. When the plunger is released, gas flow through the column is restored. The system can be performed for manual and automated injections. The duck-bill valve is modified with a disk septum when automated cool on-column injection is applied (Fig. 2). A movable on-column injector has also been introduced to facilitate the up-and-down movement of the column oven wall.[13] The cold on-column injection technique can now be operated in the constant-pressure, constant-flow, or pressure-programmed modes, allowing the reduction of analysis times. Moreover, electronic pressure programming offers the advantages that column pressure can be controlled accurately and precisely, resulting in very low relative standard deviations of retention time reproducibility.[5] The most suitably used carrier gas is hydrogen.[5,6]

The attractive features of cold on-column injection are that they allow analysis at a low temperature; thus it is the most convenient method for analysis for thermally unstable compounds. Compared with the flash vaporizing injection technique, it is also the method of choice for analysis of the samples with widely different boiling point components, because the cold on-column injection technique enables quantitative transfer of a sample and thereby provides a more accurate result. However, there are also difficulties with this method, such as peak splitting and peak spreading due to band broadening in space. These effects frequently result when large volume injections are performed. Because the sample enters the column inlet as a liquid plug, the injection of larger sample volumes forms several meters of a layer distributed on the column wall and they remain there until the column temperature increased. This is called a flooded zone situation, which is responsible for peak broadening and double peaks. The length of the flooded zone is related to the volume sample injected, the polarity difference between the solvent and the stationary phase, and the column temperature used. Injecting a small sample volume (<1 μl) can minimize the peak distortion and yield good results in terms of the peak shape and analytical precision. The speed of injecting the sample

into the column also has an effect on sample loss during on-column injection. It is suggested to inject the samples rapidly at the temperature of the column oven, but not higher than the boiling point of the solvent. Depressing the plunger at a slow rate causes a part of the sample to adhere to the needle, and the sample component is discriminated. As the detection level is restricted by the small injection volume, a large volume sampling method is frequently required to enhance the detectability, especially for trace analysis.[19] Using a technique called "retention gap," which allows the injection of a large volume of sample (>2 μl), can minimize the peak distortion. The retention gap is a length of fused silica tubing connected to the front of the analytical column by means of a suitable connector. It is actually a precolumn that does not contain any stationary phase, and the surface is deactivated to reduce solute interaction. Unlike the usual fused silica column, the retention gap has, consequently, a low or negligible retention character. To obtain a uniform sample film on the column wall, the solvent used should be selected in such a way that it wets the surface of the retention gap. Injection of the sample into the retention gap is followed by the evaporation of the solvent, leading to focusing of the sample components. When the solvent has completely evaporated, the solutes are sharply focused on the stationary phase. This approach has shown great success to improve peak shapes for many types of samples. As a general rule, typically used retention gaps are 25 to 50 cm in length, or about 25–30 cm for each microliter of solvent injected. A retention gap of 7 m × 0.32 μm I.D. enables injection of volumes up to about 50 μl; whereas 250 μl can be injected using a 10 m × 0.53 μm I.D. uncoated precolumn. The use of a retention gap offers some advantages; it allows the operation of an automated injection with regular syringe needles.[20,21] Moreover, the retention gap can act as guard column which reduces contamination when "dirty samples" are analyzed.[4,6] On-column injection with a retention gap technique performs better than PTV solvent splitting for the analysis of volatile, labile, and high-boiling components, but it is sensitive to contamination of the precolumns with non-evaporating sample by-products. Large-volume, cold on-column injections are increasing in popularity as methods for analysis of trace-level components and, especially, for environmental analysis.[22–25]

CONCLUSIONS

Cold on-column injection is an injection technique for GC which offers some advantages: elimination of sample discrimination, elimination of sample alteration, and high analytical precision and accuracy. Peak splitting or peak distortion, which may occur as a result of polarity mismatches of solvent, stationary phase, and solutes, can be reduced by means of a retention gap. Today, the cold on-column technique using a retention gap is one of the most commonly employed techniques for large-volume injections

Open-Tubular and Micropacked Columns for SFC

Brian Jones
Selerity Technologies, Inc., Salt Lake City, Utah, U.S.A.

INTRODUCTION

Supercritical fluid chromatography (SFC) with opentubular columns was first demonstrated in 1981 by Novotny and coworkers.[1] This technique, known as capillary SFC, was made available to the analytical community through the introduction of several commercial instruments in 1986. Initially difficult to use, improvements in instrumentation and hardware, coupled with a wider array of columns and restrictor options designed specifically for the technique, becoming available, have led to a general acceptance of the method in many laboratories. Not only useful as a research tool, capillary SFC is firmly established as an essential analytical method for production support and quality control in many industries. Some of these include chemical and petroleum manufacturing, pharmaceuticals, polymers, and environmental monitoring.

Packed columns have also been used in SFC for many years, predating capillaries by nearly 20 years. Many columns originally developed for liquid chromatography (LC) have found utility in SFC and have varied in internal diameter from smaller than 50 μm to very large-preparative-scale sizes. Definitions vary, but for purposes here, micropacked columns are considered to have internal diameters less than 2 mm. These smaller diameter columns are also in wide use and offer significant benefits with regard to mobile-phase consumption and detector compatibility than their large-bore counterparts. The selectivity and performance of micropacked columns are complimentary to those of capillaries, and instrumentation is available that is compatible with both separation techniques, allowing for the separation of a wide range of analytes and rapid switchover between methods. Several reviews have been published.[2–4]

PRESSURE DROP EFFECTS

Elution of a particular compound in SFC is a function of its extent of interaction with the column stationary phase and the solvating strength of the mobile phase, with the latter being a direct function of density. The density is affected by temperature and pressure and, in the case of separations with capillary columns that are inherently open and exhibit little pressure drop across their length, it is essentially constant throughout. By contrast, packed columns exhibit much more resistance to mobile-phase flow and can experience a considerable density drop during SFC analysis, producing a potentially significant loss in separation efficiency. Commercial packed columns, tested only by high-performance liquid chromatography (HPLC), may not show these deficiencies in their test reports. The only reliable gauge of suitability of a column for SFC is a performance test in the SFC mode. Columns tested under SFC conditions and tested for suitability for a specific SFC method have been commercially available for some time.

The pressure drop effect limits the usable length of packed columns to approximately 25 cm, although micropacked columns prepared specifically for SFC can be used to longer lengths.[5] The particle size also plays a role, with packing materials smaller than 5 μm producing the highest pressure drops. Whereas short columns dominate in packed column SFC, typical parameters for capillary columns are 3–10 m in length, 50 μm in inner diameter, and a stationary-phase film thickness of 0.25 μm, which give the best compromise in loadability, analysis speed, and efficiency.

Calculated practical efficiencies for a compound with a capacity factor of 2 and a CO_2 mobile phase are shown for each type of column in Table 1. It is clear that capillary columns are capable of delivering high efficiency separations in SFC, but at the expense of analysis time when compared to packed columns.

ACTIVITY

Silica surfaces are the chief source of activity in columns for SFC and, even though many of the columns are well deactivated, the residual silanol sites can lead to tailing or adsorption of analytes. The low surface area of capillary columns is responsible for much higher levels of inertness than their packed counterparts based on silica particles. Capillary columns have been used successfully in the analysis of active compounds, including isocyanates, acid halides, organic acids, amines, peroxides, azo compounds, and many others. The low temperatures required for elution make analysis of active and labile compounds viable.

Silica particles have high surface areas and usually contain a large number of exposed residual silanol groups after derivatization. These groups impart a significant degree of polarity to packed columns and can be used to advantage, for example, in the determination of aromatics in fuels.[6] For more active solutes, modifiers are used to reduce tailing and improve quantitation.

Table 1 Calculated practical efficiencies for compound with a capacity factor of 2 and CO_2 mobile phase.

Column type	Particle diameter, internal diameter (μm)	Length (m)	Plates at low density (100 atm, 100°C)	Plates at high density (100 atm, 100°C)	Linear velocity (cm/sec) at low density	Linear velocity (cm/sec) at high density
Packed	5	0.1	5,200	9,100	0.6	2.1
Capillary	50	10	102,000	19,000	2.5	5.8

MODIFIERS

The addition of cosolvents to the mobile phase can be effective in adjusting selectivity and improving sample solubility. As the most dramatic effect with polar modifiers is seen in the interaction with the surface silanol groups, even small amounts of cosolvents change the elution characteristics of packed columns. With capillary columns, the effect is related more to solvent strength of the mobile phase than surface modification, and higher modifier levels are required to produce significant changes in retention.

One of the drawbacks of using modifiers is their response in some of the detectors. The flame ionization detector (FID) is very popular with capillary and micropacked columns in SFC because of its near-universal response and high sensitivity and the lack of response of CO_2 as the most popular mobile phase. The low mass flow rate of the mobile phase in small columns allows for a direct interfacing of the column to the FID and other detectors without flow splitting or back-pressure regulation.

SAMPLE INTRODUCTION

The small internal volume and low mobile-phase mass flow rates in capillary and micropacked column SFC place significant demands on the injection system and connections. The injector must deliver a small, narrow band of material onto the head of the column and must not contain any void volume or unswept area in the flow path. Several methods of injection are in common use, including the following:

1. Split, where the column is placed in the injector such that it intercepts a portion of the sample stream with the excess carried past and out of the system through a flow restrictor. This method gives the highest efficiencies, but it can produce some sample discrimination.
2. Timed-split, where the sample loop is placed in the flow stream for short periods, and the time in the inject position determines the amount on column. This is the most popular injection method and gives good efficiency and reproducibility. It requires fast actuation and an internal sample loop.
3. Split-splitless, which is performed with a split assembly and a split vent shutoff valve. This method enables larger volumes to be admitted onto the columns and the split activates to reduce tailing by sweeping residual amounts of material out of the system.

The use of a retention gap can allow for higher efficiencies and larger injection volumes on capillary columns.[7] The retention gap is a section of uncoated tubing placed between the column and the injector, which allows the analytes to refocus into a narrow band at the head of the column. This uncoated section can be built right into the capillary column such that no additional connections are required.

RESTRICTORS

Restrictors are required at the ends of SFC columns to maintain supercritical conditions throughout the column and to limit overall flow. Several options exist, with frit restrictors being the most popular, followed by integral and linear formats. The frit restrictor is made by casting a porous ceramic material inside fused-silica tubing with the flow rate dependent on length and pore size. These restrictors are robust and are easily tuned to the desired flow rate by trimming small sections off of the frit end. The multiple flow paths are also resistant to plugging. Frit restrictors are supplied in varied porosities in the end of deactivated 50 μm inner diameter tubing and are attached to the end of the column using low dead-volume connectors. Integral restrictors are made by heating fused-silica tubing to its melting point and allowing it to collapse to a single orifice of very small diameter.The end can be ground to form a larger opening, but this process requires considerable patience. This type of restrictor can be fabricated in the end of the column such that no connectors are required, but the single orifice is more susceptible to plugging with stray particles than are other types. Linear restrictors are made from short lengths of fused-silica tubing with narrow internal diameters. These are interfaced to the column with low-dead-volume connectors, but the long pressure drop across the tubing length can cause some analytes to precipitate prematurely and produce detector spiking.

STATIONARY PHASES

A wide variety of stationary phases and bonded-phase particles for SFC are available. Capillary columns are coated with substituted and cross-linked polysiloxanes, which exhibit good inertness, efficiency, and stability. There are three main classes of capillary column stationary phases for SFC: apolar, polarizable, and polar.

Apolar

Methyl silicone, 5% phenyl-substituted silicone, and 50% octyl-substituted silicone separate generally on the basis of solute volatility. The most significant interactions are inherently weak van der Waal's. These phases have the highest diffusion properties and give the highest efficiencies. Highly polar materials overload easily on these columns and produce wedge-shaped peaks.

Polarizable

The 50% phenyl-substituted silicone and 30% biphenyl-substituted silicone stationary phases are moderately polar and contain polarizable aromatic rings that exhibit induced dipoles in the presence of dipolar solutes such as alcohols, phenols, amines, nitriles, ketones, and so forth. They give selectivity without extended retention of polar solutes because the dipole-induced–dipole interaction is relatively weak. Temperature affects the extent of this polarization and can be used as a variable in optimizing separations.

Polar

The 25% and 50% cyanopropyl phases exhibit permanent dipoles that interact strongly with polar solutes. Because this translates into longer retention times for polar solutes, only lower-molecular-weight materials of this type can be eluted. Polarizable (aromatic and unsaturated hydrocarbons) and weakly dipolar solutes are good candidates for analysis with these phases. Aliphatic hydrocarbons overload easily but elute rapidly.

Micropacked columns are available with most of the bonded-phase packings used in HPLC. Porous and nonporous silica particles are optionally functionalized with covalently ound silanes or other strongly adsorbed materials. Alkyl-bonded silicas produce separations, generally based on solute volatility, but with the potential for selectivity differences based on interaction with silanol groups. Underivatized silica is popular for petroleum separations of aliphatic and aromatic hydrocarbons. Silver-ion-containing silica columns are selective for olefin separations. Fluoroalkyl-bonded silicas produce unique selectivities and show good sample capacities for fluorocarbons. Polybutadiene-derivatized zirconia particles have also been used in SFC as have particles based on cross-linked organic polymers. These latter types show different selectivities because of the absence of surface silanol groups. Chiral-bonded phases capable of resolving enantiomers are seeing wide use, particularly in the pharmaceutical market.

RECENT ADVANCES

Recent developments in capillary and micropacked column SFC have centered on making the technique easier and more reliable to use. Columns are available that are fitted with restrictors, performance tested by SFC, and are ready to install. Dead-volume issues have been resolved with low-mass couplers and auto-depth-adjusting fingertight fittings suitable for high-pressure use. Packed columns have been developed and optimized for SFC use that have low pressure drops and high stabilities. The future should see a continuation of this trend, with more column options and formats becoming available and additional methods utilizing them seeing wide acceptance.

Open-Tubular Capillary Columns

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

Open-tubular columns were discovered by Golay[1] in the late 1950s and the first commercial columns were introduced in the early 1960s. The first capillary columns were fabricated from copper tubing 0.01 in. I.D. but, due to their somewhat variable geometry, were quickly replaced with the more rigid cupronickel tubing and, subsequently, by stainless-steel tubing.

DISCUSSION

Metal capillary columns need to be cleaned to remove traces of extrusion lubricants by washing them with methylene dichloride, methanol, and then water. They should also be washed with dilute acid to remove any metal oxides or corrosion products that remain adhering to the walls. The acid is removed with water and the tubing is again washed with methanol and methylene dichloride and dried in a stream of hot nitrogen.

Metal columns provide the expected high efficiencies and were used successfully for the analysis of low-polarity materials such as petroleum and fuel oils and, today, they are still extensively used for the analysis of hydrocarbons. Metal columns, however, although easily coated with dispersive stationary phases (e.g., squalane, Apiezon grease, etc.), do not coat well with the more polar stationary phases such as Carbowax®. In addition, the hot metal surface can cause decomposition and molecular rearrangement of many thermally labile materials that are being separated (e.g., the terpenes in essential oils). Metal can also react directly with some solutes by chelation and, as a result of surface adsorption, produce asymmetric and tailing peaks. Nevertheless, metal columns are rugged, easy to handle, and easy to remove and replace in the chromatograph, so their use has persisted in many applications despite the introduction of fused-silica columns.

In an attempt to eliminate surface activity, Desty et al.[2] introduced the first silica-based columns and invented an extremely clever device for drawing soft glass capillary columns. Desty produced both rigid soft glass and rigid Pyrex capillary columns, although their permanent circular shape rendered them a little difficult to connect to the injector and detector. It was found that, with special surface treatment, the rigid glass tubes could be coated with polar stationary phases. The demand for special surface processing evoked a large number of proprietary methods for column treatment. Fortunately, the frenetic interest in the surface deactivation of soft glass capillary tubes was curtailed by the introduction of the flexible fused-silica capillary columns by Dandenau and Zenner.[3]

The quartz fiber drawing technique used in the manufacture of data transmission lines was used to produce flexible *fused-silica* tubing. Basically, the solid quartz rod used in quartz fiber drawing was replaced by a quartz tube. In a similar manner to that used in the quartz fiber production, the quartz tubes were coated with polyimide to prevent moisture from attacking the surface and producing stress corrosion. Soft glass capillaries can be produced by the same technique at much lower temperatures,[4] but the tubes are not as mechanically strong or as inert as quartz capillaries. Flexibility was the main advantage to quartz capillaries, as it greatly facilitated the installation of the columns in the chromatograph. However, surface treatment is still necessary with a fused-quartz column to reduce adsorption and catalytic activity and render the surface wettable for efficient coating. The treatment may involve washing with acid, silanization, and other types of chemical treatment, including the use of surfactants.

Deactivation procedures used for commercial columns also tend to be highly proprietary. Adeactivation program for silica and soft glass columns that is suitable for most applications would first entail an acid wash. The column is filled with 10% (w/w) hydrochloric acid, the ends sealed, and the column then heated to 100°C for 1 hr. The column is then washed free of acid with distilled water and dried. This procedure is believed to remove traces of heavy metal ions that can cause adsorption and peak tailing. The column is then filled with a solution of hexamethyldisilazane, sealed, and heated to the boiling point of the solvent for 1 hr. This procedure blocks any hydroxyl groups on the surface that were generated during the acid wash. A polar or semipolar silane reagent might be preferable to facilitate coating if a polar stationary phase is to be used. The column is then washed with the pure solvent, dried at an elevated temperature in a stream of pure nitrogen, and is ready for coating.

Open-tubular columns can be coated internally with a liquid stationary phase or with polymeric materials that are subsequently polymerized to form a relatively rigid polymer coating. The two methods of coating are the *dynamic method of coating* and the *static method of coating*. In the dynamic coating procedure, a plug of solvent containing

the stationary phase is placed at the beginning of the column. The strength of the solution, among other factors, determines the thickness of the stationary-phase film. In general, the film thickness of an open-tubular column ranges from 0.25 mm to about 1.5 mm. As an estimate, a 5% (w/w) solution of stationary phase will provide a stationary film thickness of about 0.5 mm. After the plug has been run into the front of the column (sufficient solution should be added to fill about 10% of the column length), a gas pressure is used to force the plug through the column at about 2–4 mm/sec. When the plug has passed through the column, the gas flow is continued for about 1 hr. The gas flow should not be increased too soon, as ripples of stationary phase solution will form on the walls of the tube, which produces a very uneven film. After 1 hr, the flow rate is increased and the column stripped of solvent. The last traces of the solvent are removed by heating the column above the boiling point of the solvent at an increased gas flow rate.

In static coating, the entire column is filled with a solution of the stationary phase and one end connected to a vacuum. As the solvent evaporates, it retreats back down the tube, leaving a coating on the walls. The optimum concentration will depend on the stationary phase, the solvent, the temperature, and the condition of the wall surface. This process is very time-consuming but can proceed without attention and is often carried out overnight. This procedure is more repeatable than the dynamic method of coating, but, in general, it produces columns having a similar performance to those dynamically coated.

However-well the column may be coated, the stability of the column depends on the stability of the stationary-phase film, and thus on the constant nature of the surface tension forces holding it to the column wall. These surface tension forces can change with temperature or be effected by the samples used for analysis. As a consequence, the surface tension can be suddenly reduced and the film break up. It follows that the stationary phase should be bonded in some way to the column walls or polymerized *in situ*. Such coatings are called immobilized stationary phases and cannot be removed by solvent washing.

Some stationary phases that are polymeric in nature can sometimes be formed by coating the monomers or dimers on the walls and then initiating polymerization either by heat or a suitable catalyst. This locks the stationary phase to the column wall and is thus completely immobilized. Polymer coatings can be formed in the same way using dynamic coating. Techniques used for immobilizing the stationary phases are highly proprietary and little is known of the methods used. In any event, most chromatographers do not want to go to the trouble of coating their own columns and are usually content to purchase proprietary columns.

POROUS-LAYER OPEN-TUBULAR COLUMNS

There are two basic disadvantages to the coated capillary column. First, the limited solute retention that results from the small quantity of stationary phase in the column. Second, if a thick film is coated on the column to compensate for this low retention, the film becomes unstable resulting in rapid column deterioration. Initially, attempts were made to increase the stationary phase loading by increasing the internal surface area of the column. Attempts were first made to etch the internal column surface, which produced very little increase in surface area and very scant improvement. Attempts were then made to coat the internal surface with diatomaceous earth, to form a hybrid between a packed column and coated capillary. None of the techniques were particularly successful and the work was suddenly eclipsed by the production of immobilize films firmly attached to the tube walls. This solved both the problem of loading, because thick films could be immobilized on the tube surface, and that of phase stability. As a consequence, porous-layer open-tubular (PLOT) columns are not extensively used. The PLOT column, however, has been found to be an attractive alternative to the packed column for gas–solid chromatography (GSC) and effective methods for depositing adsorbents on the tube surface have been developed.

The open-tubular column is, by far, the most popular type of GC column in use today. As a result of its small internal cross section, however, extracolumn dispersion can become a serious problem. This means that open-tubular columns must be used with special types of injector and reduced volume connectors, and certain detectors must have specially designed sensor cells to avoid impairing column performance.

Open-Tubular CEC

Joseph J. Pesek
Maria T. Matyska
Department of Chemistry, San Jose State University, San Jose, California, U.S.A.

INTRODUCTION

In capillary electrochromatography (CEC), there are two general approaches to this hybrid technique that combine features of both high-performance liquid chromatography (HPLC) and capillary electrophoresis (CE): the packed column configuration that utilizes stationary phases similar to HPLC, and the open tubular format where the stationary phase is immobilized on the capillary wall. A smooth transition exists from μ-HPLC to packed capillary CEC by adjusting the ratio of pressure-driven flow to electrically-driven flow. This adjustment results in an infinite number of hybrid techniques that can be generated from pure μ-HPLC (no electric field component) to pure packed capillary CEC (no pressure component). The transition region between CE and packed capillary CEC is not so smooth. The bridge is provided by open tubular capillary electrochromatography (OTCEC). There are not, however, the infinite number of choices that can be generated as in the bridge between μ-HPLC and packed capillary CEC. In all forms of CEC, there are two major separation mechanisms: solute-bonded phase interactions (as measured by the capacity factor, k') and electrophoretic mobility (μ_{ep}).

DEVELOPMENT AND USE OF OTCEC

The first effective OTCEC separations indicating chromatographic interactions were demonstrated a number of years ago by Tsuda and coworkers[1] using an octadecyl modified 30 μm I.D. capillary. A more definitive way of proving that chromatographic effects are possible in the open tubular format can be obtained through the separation of optical isomers. A number of chiral selectors, such as cyclodextrin and several cellulose derivatives that were bonded to the inner wall of fused silica capillaries, resulted in the separation of enantiomers.[2,3] Since the two optical isomers have identical electrophoretic mobilities, separation can only be achieved through differences in solute/bonded phase interactions. It has also been demonstrated that molecularly imprinted polymers bonded to the inner wall of a fused silica capillary can be another approach for a stationary phase in OTCEC.[4] Another, more often tested, approach involves immobilizing a relatively thick polymeric film[5,6] on the inner surface of the capillary. In this case, the bonded material is extended from the wall so that analytes have a shorter distance to travel in order to produce solute/bonded phase interactions (i.e., a chromatographic separation mechanism). Each of these early studies showed that OTCEC was feasible, at least for the limited number of samples and experimental conditions tested.

The focus of OTCEC for improving separation capabilities is with column technology. In the simplest approach, stationary phases are bonded to the inner wall of a fused silica capillary using standard organosilanization reactions, because free silanol groups exist on the surface. In this format, the OTCEC technique is often hampered by two fundamental problems that seriously limit its potential as a viable separation method: the low capacity of the column due to the small area available for bonding a stationary phase, and the long distance that molecules would have to migrate to interact with the bonded moiety. The latter problem could be addressed by reducing the column I.D., but this is often an unsatisfactory solution because such a decrease further limits the sample size, as well as the detection path length, in absorbance measurements and, hence, the detection limit of the analyte. Small diameter capillaries generally necessitate the use of higher sensitivity fluorescence detection or mass spectroscopy.

Column technology in OTCEC utilizes coating or direct bonding of various organic moieties to the capillary wall, as well as a number of approaches that are designed to increase the amount of stationary phase in the capillary. The simplest approach involves the physical adsorption of molecules to the wall. One successful example of this approach involves coating the inner wall of the capillary with a polymeric surfactant, very often a polyelectrolyte multilayer (PEM).[7] Direct bonding of a stationary phase to the fused silica wall often involves the use of organic groups with a high specificity for certain analytes. Examples of such compounds are calixarenes[8] that function as a host phase, or aptamers[9] that also have a high degree of molecular recognition. One method for increasing the amount of stationary phase and reducing the distance that solutes must travel to interact with it is to create a thin film on the surface. Thin films (0.15–0.20 μm) of molecularly imprinted polymers have been successful for enantiomeric separations.[10]

More extensive measures, beyond simple coatings, are necessary to expand OTCEC from a technique for a few specific applications to a more general method that can solve a broad range of analytical problems. One approach to accomplish this goal is to create a porous layer on the inner wall of the capillary. For example, a porous silica layer was deposited inside a narrow bore capillary (<10 μm I.D.) and then modified with a C_{18} stationary phase.[11] This column was able to separate a number of polycyclic aromatic hydrocarbons. A more widely used methodology for increasing the loadability and capacity factors in OTCEC utilizes sol–gel processes[12] that are based on the polymerization of alkoxides, such as tetramethoxysilane or tetraethoxysilane. This approach results in a porous silicate network on the surface of the capillary with variable chemical properties being produced as other substituted silanes are added to the sol–gel reaction process. The retention characteristics of the sol–gel phases are controlled by the amount of monomeric species in the initial solution.[13] Phases with hydrophilic, hydrophobic, and chiral properties have been fabricated.

Another approach for increasing the limited loading capacity for an ordinary fused silica capillary involves coating the wall with nanoparticles. Both latex[14] and gold[15] nanoparticles have been shown to be feasible. The latex materials, which are bound electrostatically to the wall, are composed of a quaternary ammonium ion exchange functionality and have been used for the separation of inorganic anions. The gold nanoparticles have the advantage of being covalently attached to the wall through an aminopropyl linkage. One reagent used was dodecanethiol, which leads to a relatively hydrophobic surface for reversed phase applications. An example of a separation done on a gold nanoparticle coated capillary is shown in Fig. 1.

A final capillary format utilizes both an increase in the surface area, as well as a different approach to the chemical modification of the surface for the stationary phase.[16] In this method, the surface is etched with ammonium bifluoride, a reagent that produces the same effects as HF but does not have the inherent safety risks. This etching process can increase the surface area of the capillary by a factor of 1000 or more and the etching agent becomes a part of the new wall matrix, making it more biocompatible and suitable for the analysis of basic compounds. After etching, the surface is modified by a silanization/hydrosilation reaction protocol to attach an organic moiety as the stationary phase, but it also converts virtually all of the silanols to hydride species. The high resolving power of this particular format is demonstrated in Fig. 2, which shows the analysis of PEGylated proteins.[17] These modified proteins can exist in a large number of similar chemical structures, making the separation of all species particularly difficult.

A possible new application for OTCEC exists in microfluidic chips, where open channels are the most common and easiest to fabricate configuration. Often, these devices utilize channels of just a few microns is diameter. These relatively small dimensions allow some separations to be

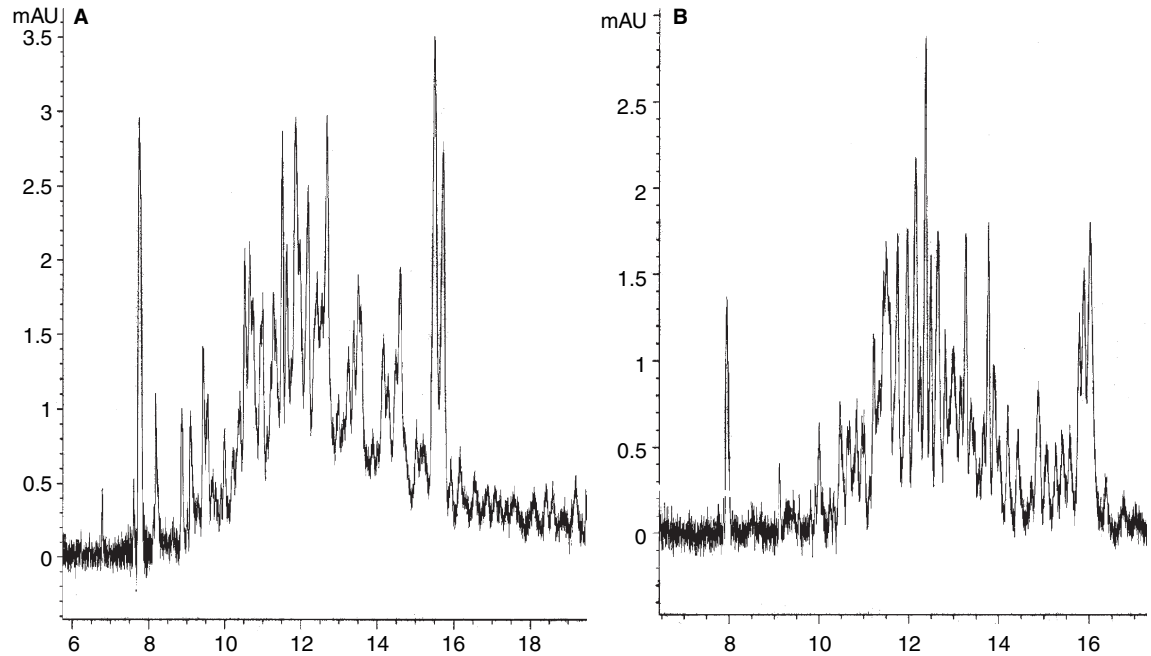

Fig. 2 Separation of PEGylated proteins on an etched cholesteryl modified capillary. A, PEG-catalase and B, PEG-protease. I.D = 50 μm, $L = 58$ cm, $l = 49.5$ cm, $V = 20$ kV, Buffer pH 2.14, injection 5 sec @ 50 mbar, detection at 210 nm.

achieved in just a few seconds. However, these small channel dimensions make detection difficult, so that only the most sensitive methods, such as laser-induced fluorescence are practical. An example of a proteomic analysis for a trytpic digest of a protein is shown in Fig. 3.

CONCLUSIONS

While OTCEC has been a known technique for a number of years, recent developments in column formats have advanced the technology so that it is a viable method for an increasing number of analyses. The dual mechanisms of electrophoretic mobility and chromatographic interactions offer a wide range of variables that can be used to optimize difficult separations. The development of miniaturized and microfluidic versions of OTCEC are likely to have significant impacts in pharmaceutical, forensic, and environmental analyses.

Open-Tubular Columns: Golay Dispersion Equation

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

The open-tubular column or capillary column is the one most commonly used in gas chromatography (GC) today. The equation that describes dispersion in open tubes was developed by Golay,[1] who employed a modified form of the rate theory, and is similar in form to that for packed columns. However, as there is no packing, there can be no multipath term and, thus, the equation only describes two types of dispersion. One function describes the longitudinal diffusion effect and two others describe the combined resistance to mass-transfer terms for the mobile and stationary phases.

DISCUSSION

The Golay equation takes the following form:

$$H = \frac{2D_m}{u} + \frac{f_1(k')r^2}{D_m}u + \frac{f_2(k')r^2}{K^2D_s}u \tag{1}$$

where H is the height of a theoretical plate or the variance/unit length, D_m is the diffusivity of the solute in the mobile phase, D_s is the diffusivity of the solute in the stationary phase, r is the column radius, k' is the capacity ratio of the solute, K is the distribution coefficient of the solute, and u is the mobile-phase linear velocity.

Open-tubular columns behave in exactly the same way as packed columns with respect to pressure. The same mathematical arguments can be reduced which results in the modified form of the equation shown in Eq. 2. As the column is geometrically simple, the respective functions of k' can also be explicitly developed.

$$H = \frac{2D_m}{u_0} + \frac{(1+6k'+11k'2)r^2}{24(1+k')^2D_{m(0)}}u_0 + \frac{2k'df^2}{3(1+k')^2D_s(\gamma+1)}u_0 \tag{2}$$

where u_0 is the exit velocity of the mobile phase and $D_{m(0)}$ is the diffusivity of the solute measured at the exit pressure. As the film is thin, $r \gg df$; then,

$$\frac{(1+6k'+11k'2)r^2}{24(1+k')^2D_{m(0)}} \gg \frac{2k'df^2}{3(1+k')^2D_s(\gamma+1)}$$

and, thus,

$$H = \frac{2D_{m(0)}}{u} + \frac{(1+6k'+11k'2)r^2}{24(1+k')^2D_{m(0)}}u_0 \tag{3}$$

By differentiating Eq. 3 and equating it to zero, expressions can be obtained for u_{opt} and $H_{\min}$ in a manner similar to the method used for a packed column:

$$u_{0(\text{opt})} = 2\frac{D_{m(0)}}{r}\left(\frac{12(1+k')^2}{1+6k'+11k'2}\right)^{1/2} \tag{4}$$

$$H_{\min} = \frac{r}{2}\left(\frac{1+6k'+11k'2}{3(1+k')^2}\right)^{1/2} \tag{5}$$

The approximate efficiency of a capillary column operated at its optimum velocity (assuming the inlet/outlet pressure ratio is small) can be simply calculated. If only the dead volume is considered (i.e., $k' = 0$), Eq. 3 reduces to

$$H = \frac{2D_m}{u} + \frac{1}{24}\frac{r^2}{D_m}u \tag{6}$$

Differentiating and equating to zero,

$$\frac{dH}{du} = -\frac{2D_m}{u^2} + \frac{1}{24}\frac{r^2}{D_m} = 0 \quad \text{or} \quad u = \frac{\sqrt{48}D_m}{r}$$

Substituting for u in Eq. 6 and simplifying,

$$H = \frac{2D_m r}{\sqrt{48}D_m} + \frac{1}{24}\frac{r^2}{D_m}\frac{\sqrt{48}D_m}{r} = 0.289r + 0.289r = 0.577r$$

Thus, the efficiency of a capillary column of length (l) can be assessed as

$$n = \frac{l}{0.6r} \tag{7}$$

The column efficiency will be inversely proportional to the column radius and the analysis time will directly proportional to the column radius and inversely proportional to the diffusivity of the solute in the mobile phase.

Optical Activity Detectors

Hassan Y. Aboul-Enein
Pharmaceutical and Medicinal Chemistry Department, Pharmaceutical and Drug Industries Research Division, National Research Center, Dokki, Cairo, Egypt

Ibrahim A. Al-Duraibi
Pharmaceutical Analysis Laboratory, King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia

INTRODUCTION

Optical activity detectors are capable of specifically detecting chiral compounds, taking advantage of their unique interactions with polarized light. Much of the work on the development of prisms and other devices for the production of polarized light was done in the early part of the nineteenth century. However, the measurement of optical activity is often used for enantiomeric purity determination of chiral compounds, which by definition have either a center or plane of asymmetry. Enantiomers rotate the plane of polarized light in opposite directions, although in equal amounts. The isomer that rotates the plane to the left (counterclockwise) is called the levo isomer and is designated (−), whereas the one that rotates the plane to the right (clockwise) is called the dextro isomer and is designated (+). Questions of optical activity are of extreme importance in the field of asymmetric chemical synthesis and in the pharmaceutical industry.

DETECTION PRINCIPLE

Fig. 1 shows the basic optimal system of the optical rotation detector, which is based on the non-modulated polarized beam-splitting method. The light radiated from the light source is straightened by the plane polarizer, then to the lens for beam formation and concentration, and then to the flow cell.

The plane-polarized light which goes through the flow cell is rotated by optically active substances (chiral compounds) according to their specific optical rotations and concentrations. The light then enters the polarized beam splitter and is divided into two beams according to the polarized beam directions. These beams are detected by two photodiodes as shown.

The angle of the plane polarizer is adjusted so that the two photodiodes may receive the same beam intensity when no optically active substance is present in the flow cell.When optically active substances are present in the flow cell, the difference between the beam intensities received by the two photodiodes is not zero. Therefore, the difference has a linear relation with specific optical rotation and concentration of the optically active substance and can be expressed by where is the difference of beam intensities received by the two photodiodes (i.e., output of signal level), K is a constant determined by cell structure and light intensity of the light source, $[\alpha]$ is the specific optical rotation of the chiral compound, and C is the concentration of the chiral compound.

POLARIMETRY THEORY

Most forms of optical spectroscopy are usually concerned with the measurement of the absorption or emission of electromagnetic radiation. Ordinary, natural, unreflected light behaves as though it consists of a large number of electromagnetic waves vibrating in all possible orientations around the direction of propagation. If, by some means, we sort out from the natural conglomeration only those rays vibrating in one particular plane, we say that we have plane-polarized light. Of course, because a light wave consists of an electric and a magnetic component vibrating at right angles to each other, the term "plane" may not be quite descriptive, but the ray can be considered planar if we restrict ourselves to noting the direction of the electrical component. Circular polarized light represents a wave in which the electrical component (and, therefore, the magnetic component also) spirals around the direction of propagation of the ray, either clockwise ("right-handed" or dextrorotatory) or counterclockwise ("left-handed" or levorotatory). If, following the passage of the plane-polarized ray through some material, one of the circularly polarized components, say the left circularly polarized ray, has been slowed down, then the resultant would be a planepolarized ray rotated somewhat to the right from its original position. In addition, lasers have been incorporated into two optical rotation methods to date: polarimetry and circular dichroism.

OPTICAL ROTATION AND OPTICAL ROTATORY DISPERSION

A polarimeter measures the direction of rotation of plane-polarized light caused by an optically active substance. The

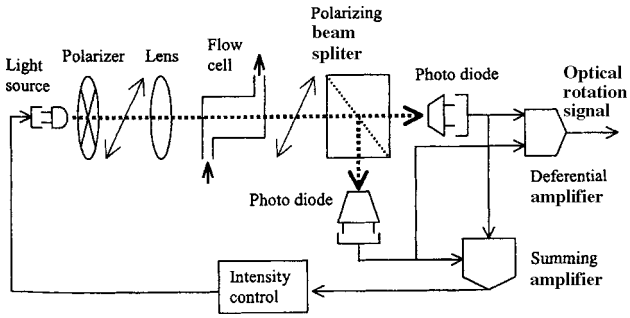

Fig. 1 Optical rotation detector.

specific optical activity of an asymmetrical molecule varies with the wavelength of the light used for its determination. This variation is called optical rotatory dispersion (ORD). In ORD, rotations are measured over a range of wavelengths rather than at a single wavelength, usually covering the ultraviolet (UV) as well as the visible region.

CIRCULAR DICHROISM

In this technique, the molecular extinction coefficients of a compound are measured with both left and right circularly polarized light, and the difference between these values is plotted against the wavelength of the light used. The phase angle between the projections of the two circularly polarized components is altered by passage through the chiral medium, but their amplitudes will be modified by the degree of absorption experienced by each component. This differential absorption of left- and right-circularly polarized light is termed circular dichroism (CD). So, circular dichroism measurements provide both absorbance and optical rotation information simultaneously.

CIRCULARLY POLARIZED LUMINESCENCE SPECTROSCOPY

Circularly polarized luminescence spectroscopy (CPLS) is a measure of the chirality of a luminescent excited state. The excitation source can be either a laser or an arc lamp, but it is important that the source of excitation be unpolarized to avoid possible photoselection artifacts. The CPLS experiment produces two measurable quantities, which are obtained in arbitrary units and related to the circular polarization condition of the luminescence. It is appropriate to consider CPLS spectroscopy as a technique that combines the selectivity of CD with the sensitivity of luminescence. The major limitation associated with CPLS spectroscopy is that it is confined to emissive molecules only.

VIBRATIONAL OPTICAL ACTIVITY

The optical activity of vibrational transitions has been conducted. The infrared (IR) bands of a small molecule can easily be assigned with the performance of a normal coordinate analysis, and these can usually be well resolved. One of the problems associated with vibrational optical activity is the weakness of the effect. Instrumental limitations of infrared sources and detectors create additional experimental constraints on the signal-to-noise ratios. Two methods suitable for the study of vibrational optical activity have been developed:

- *Vibrational Circular Dichroism*: Vibrational circular dichroism (VCD) could be measured at good signal-to-noise levels. Vibrational optical activity is observed in the classic method of Grosjean and Legrand.
- *Raman Optical Activity*: The Raman optical activity (ROA) effect is the differential scattering of leftor right-circularly polarized light by a chiral substrate where chirality is studied through Raman spectroscopy.

FLUORESCENCE-DETECTED CIRCULAR DICHROISM

Fluorescence-detected circular dichroism (FDCD) is a chiroptical technique in which the spectrum is obtained by measuring the difference in total luminescence obtained after the sample is excited by left- and right-circularly polarized light. For the FDCD spectrum of a given molecular species to match its CD spectrum, the luminescence excitation spectrum must be identical to the absorption spectrum.

FACTORS AFFECTING THE MEASUREMENT OF OPTICAL ROTATION

The rotation exhibited by an optically active substance depends on the thickness of the layer traversed by the light, the wavelength of the light used for the measurement, and the temperature of the system. In addition, if the substance being measured is a solution, then the concentration of the optically active material is also involved and the nature of the solvent may also be important. There are certain substances that change their rotation with time. Some are substances that change from one structure to another with a different rotatory power and are said to show mutarotation. Mutarotation is common among the sugars. Other substances, owing to enolization within the molecules, may rotate so as to become symmetrical and, thus, lose their rotatory power. These substances are said to show racemization. Mutarotation and racemization are influenced not only by time, but also by pH, temperature,

and other factors. Of course, rotations that determined for the same compound under the same conditions are identical. Therefore, in expressing the results of any polarimetric measurement, it is, therefore, very important to include all experimental conditions.

TEMPERATURE

Temperature changes have several effects on the rotation of a solution or liquid. An increase in temperature increases the length of the tube; it also decreases the density, thus reducing the number of molecules involved in the measurement. It causes changes in the rotatory power of the molecules themselves, due to association or dissociation and increased mobility of the atoms, and affects other properties. In addition, temperature changes cause expansion and contraction of the liquid and a consequent change in the number of active molecules in the path of the light.

The unique ability of the optical rotation detector to respond to the sign of rotation allows precise enantiomeric purity determination even if the enantiomers are only partially resolved. The sign of rotation is also useful in establishing enantiomer elution order.

Because the optical rotation detectors only respond to optically active compounds, enantiomeric purity determination to precisions of better than 0.5% can be achieved and is possible in even the complex mixtures. The detection can also be used as part of a flow injection analysis system to determine amount and enantiomeric purity of a drug in dosage form.

The applications using optical rotation detectors include the following:

1. Qualitative analysis of chiral compounds, including drugs, pesticides, carbohydrates, amino acids, liquid crystals, and other biochemicals
2. Determination of enantiomeric purity of chiral compounds
3. Monitoring an enzymatic reaction
4. Qualitative analysis of proteins
5. Use as a conventional polarimeter

However, the disadvantages of optical rotation detectors may be limited by shot or flicker noise, which are dependent on the optical and mechanical properties of the system or by noise in the detector electronics. Generally, the usefulness of this technique has been limited by the lack of sensitivity of commercially available instruments.

Optical Quantification or Densitometry in TLC

Joseph Sherma
Department of Chemistry, Lafayette College, Easton, Pennsylvania, U.S.A.

INTRODUCTION

Direct optical quantification in thin-layer chromatography (TLC) involves sample preparation, application of standard and sample zones, layer development, and in situ measurement of zones with a slit-scanning densitometer, diode array scanner, videodensitometer, or flatbed scanner. High-sample throughput (cost efficiency) and excellent accuracy, precision, sensitivity, linearity, robustness, and ruggedness are possible by use of high performance layers developed by capillary action or forced flow with optimized mobile phases; proper instrumental or manual application techniques; development of standards and multiple samples on the same plate under controlled conditions; uniform manual or semiautomated derivatization (detection) procedures; and computerized, automated scanning and data handling. The open-bed, simultaneous-development operation of TLC offers inherent advantages compared to single-sample quantitative column methods such as high-performance liquid chromatography (HPLC).

Densitometry was first used to directly measure the amount of light absorbed by radioactive spots on films or stained protein bands on electrophoresis gels in the transmission mode. TLC slit scanners were then developed to directly measure the diffuse reflectance of colored, ultraviolet (UV) absorbing, and fluorescent zones on a layer, followed by videodensitometers for documentation and quantification of layer images. Most recently, a commercial diode array scanner and office flatbed scanners (as purchased or modified) have been used for quantitative TLC.

Some non-densitometric methods that can be used for TLC quantification are described only briefly in this entry. The majority of the coverage is given to densitometry, which is the most widely used, highly sensitive [typical detection limits are in the medium picogram (fluorescence) to low nanogram (absorbance) range of analyte per zone], versatile, convenient, and reliable quantitative TLC method.

NON-DENSITOMETRIC QUANTIFICATION

Quantitative evaluation of thin-layer chromatograms can be performed by direct, in situ visual and indirect elution techniques. Visual evaluation involves comparison of the sizes and intensities of color or fluorescence between sample and standard zones spotted, developed, and detected on the same layer. The series of standards is chosen to have concentrations or weights that bracket those of the sample zones. After matching a sample with its closest standard, accuracy and precision are improved by respotting a more restricted series of bracketing standards with a separate sample spot between each of two standard zones. Accuracy no greater than 5–10% is possible for trained personnel using visual evaluation. The determination of ochratoxin A in coffee[1] and pharmaceutical dosage forms[2] are examples of practical applications of visual comparison of fluorescent zones and derivatized (colored) or UV-absorbing (fluorescence-quenched) zones, respectively.

The elution method involves scraping off the separated zones of sample aliquots and bracketing standards, and elution of the substances from the layer material with a strong, volatile solvent. The eluates are concentrated and analyzed by use of a sensitive spectrometry method (e.g., UV–Visible, infrared, or mass spectrometry), gas chromatography (GC), HPLC, immunoassay, electrophoresis, or electroanalysis. Scraping and elution must be performed manually because the only commercial automatic micropreparative elution instrument has been discontinued by its manufacturer. The scraping/elution method is tedious and time consuming and prone to errors caused by incorrect choice of the sizes of the areas to scrape, incomplete collection of sorbent, and incomplete or inconsistent elution recovery of the analyte from the sorbent. It is used today mostly as an off-line interface with spectrometric and other chromatographic methods for confirmation of the identity of sample zones (qualitative analysis) and seldom for quantitative analysis.

PRINCIPLES AND THEORY OF DENSITOMETRY

In order to achieve the optimum accuracy, precision, and sensitivity, most quantitative analyses are performed by using high-performance TLC (HPTLC) plates and direct quantification by means of a modern optical densitometric scanner with a fixed sample light beam in the form of a rectangular slit that is selectable in height (e.g., 0.4–10 mm) and width (20 μm–2 mm). Densitometers measure the difference in absorbance or fluorescence signal between a TLC zone (in the form of a peak) and the empty plate background (baseline) and relate the measured signals from a series of standards to those of unknown samples through a calibration plot. Modern computer-controlled densitometers can produce linear or polynomial calibration plots relating

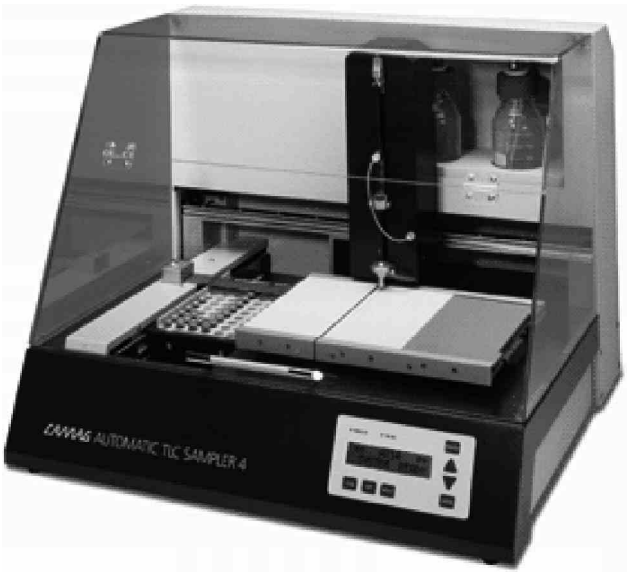

Fig. 1 Automatic TLC Sampler 4 used for fully automated application of precisely controlled volumes of samples and standards between 0.1 and 50 μl from a rack of vials as spots or bands to preselected origins on a plate.
Source: Photo courtesy of Camag Scientific Inc., Wilmington, North Carolina.

absorbance or fluorescence to weight of the standards and can determine bracketed unknowns by automatic interpolation from the plot. Samples and standards are usually applied manually onto plates with a preadsorbent (or preconcentrating zone) or using an automated or semiautomated instrument such as the one shown in Fig. 1. Zones in the form of bands usually produce better quantitative results than round spots.

The usual Lambert–Beer Law that is the basis of solution spectrometry is not valid for densitometry because both absorption and scattering of radiation occur during direct zone measurement on a layer. The Kubelka–Munk equation is usually used to relate signal intensity and zone concentration (weight per zone) for the reflectance (absorption) mode of densitometry:

$$(1-R)^2/2R = 2.303e(C/S)$$

where R is the light reflected from an infinitely thick opaque layer, e is the molar absorption coefficient of the analyte, C is the zone weight, and S is the layer scatter coefficient. Because layers are not infinitely thick, this equation is only an inexact model for TLC that leads to densitometry calibration plots (scan areas vs. zone weights for a series of standards) that are linear (pseudolinear) at lower weights and curve downward toward the weight (x) axis, and do not pass through the 0,0 point. For a wide weight range, better accuracy and precision are often obtained from a calibration plot based on second order polynomial regression. Samples are quantified by interpolation of sample weights from the calibration plot.

For fluorescence densitometry, the following equation describes emission at low-sample concentrations:

$$I = kI_0eaC$$

where I is the fluorescence intensity, k is a proportionality constant including the quantum yield, I_0 is the irradiation intensity of the excitation source, e is the molar absorption coefficient, a is layer thickness, and C is the analyte weight applied. The presence of the I_0 term in the equation means that more fluorescence is emitted with a more intense source, and lower amounts of analyte can be measured; this is why a xenon or mercury lamp, rather than deuterium, is used for fluorescence densitometry. Calibration plots are usually linear over two or three orders of magnitude for low analyte weights and pass through 0,0; for large weights, self-absorption causes the plot to curve towards the weight axis. Compared to absorbance, fluorescence measurements have greater selectivity because excitation and emission wavelengths can be chosen to "tune-out" interferences; sensitivity is 10–1000 times higher; and the emission signal is less dependent on zone shape or distribution. The advantages of fluorescence measurement may be realized for non-fluorescent compounds by pre- or post-chromatographic derivatization reactions with suitable fluorogenic reagents.

INSTRUMENTAL DESIGN AND SCANNING MODES

A commercial densitometer and a schematic diagram of the light path arrangement used in scanning are shown in Figs. 2 and 3, respectively.[3] The plate is mounted on a stage or platform that can be moved in the x- and y-directions, controlled by a stepping motor drive, to allow each chromatogram track to be scanned in, or opposite to, the direction of mobile phase development. A tungsten–halogen lamp is used as the source for scanning colored zones in the 400–800 nm range (visible absorption) and a deuterium lamp for scanning UV-absorbing zones directly or as quenched zones on phosphor-containing layers (F-layers) in the 190–450 nm range. The monochromator used with these continuous wavelength sources is a grating in modern instruments; some older instruments used a quartz prism, and low priced instruments designed for dedicated applications may have a monochromatic filter. The detector is a photomultiplier tube (PMT), photodiode, or photoresistor inclined above the layer at an angle (e.g., 30°) to measure diffusely reflected radiation. (Some scanners, e.g., Fig. 3, make use of a reference PMT in addition to the measuring PMT in the single beam mode. The reference PMT puts out a constant signal that is compared to the signal from the measuring PMT to produce a difference signal that is more accurate than a direct signal from a single measuring PMT because lamp aging and short-term fluctuations are

Fig. 2 TLC Scanner 3.

compensated for and warm-up time required for lamp stabilization is reduced.)

For normal fluorescence scanning, a high intensity xenon continuum source or a mercury vapor line source is used, and a cutoff or narrow-pass filter is placed between the plate and detector to block the exciting UV radiation and transmit the visible emitted fluorescence. For fluorescence measurement in the reversed beam mode, a monochromatic filter is placed between the source and plate and the monochromator between the plate and detector. In this mode, the monochromator selects the emission wavelength, rather than the excitation wavelength as in the normal mode.

Source: From Instrumental thin layer chromatography, in *Handbook of Thin Layer Chromatography*.[3]

Simultaneous measurement of reflection and transmission, or transmission alone, can be carried out by means of a detector positioned on the opposite side of the plate (Fig. 3). Ratio recording double beam densitometers, which can correct for background disturbances and drift caused by fluctuations in the source and detector, were designed earlier with two PMT detectors simultaneously recording the two beams (double beam in space), but later densitometers were equipped with a chopper and one detector (double beam in time). Dual wavelength, single beam scanning minimizes matrix interference and baseline problems if two similar wavelengths can be found, only one of which is absorbed by the analyte. For this method, a light beam is selected by a mirror and passes through two separate monochromators to isolate the two different wavelengths. The two beams are alternated by a chopper and recombined into a single beam representing a difference signal at the detector. Zigzag or meandering or flying-spot scanning with a small point or spot of light is possible with densitometers having two independent stepping motors to move the plate in the x- and y-axes (Shimadzu CS 9000 and Desaga CD 60). Computer algorithms integrate the maximum absorbance measurements from each swing to produce a distribution profile of zones having any shape (even distorted). The potential advantages of scanning zones with a moving light spot are offset by problems with lower spatial resolution and errors in data processing, and the method is not as widely used as conventional scanning of chromatographic tracks with a fixed slit. Some older densitometers had the ability to rotate the plate while scanning for measurement of circular and anticircular chromatograms.

Single-wavelength, single-beam, fixed-slit scanning is most often used and can produce excellent results when high quality plates and analytical techniques are employed. Positioning of the slit for scanning can be achieved manually or automatically. The slit length is chosen to be longer than the zone length (for bands) or zone diameter (for spots), or equal length (usually central) segments of homogeneous bands can be scanned (termed aliquot scanning). A small slit height improves the resolution of scan peaks for closely spaced zones.

SPECTRAL MEASUREMENT

Modern scanners have a computer-controlled, motor-driven monochromator that allows automatic recording of in situ absorption and fluorescence excitation spectra. Identification is aided by comparison of sample and standard zone spectra. Zone purity is determined by superimposition of spectra from different areas of a single

zone. The spectral maximum determined from the in situ spectrum is usually the optimal wavelength for scanning standard and sample areas for quantitative analysis. Because of possible sorbent effects, the in situ spectrum of a substance may not match its spectrum obtained in solution. For best results, comparison among spectra from different zones should be made for similar substance weights.

DATA HANDLING

The densitometer is connected to a recorder, integrator, or computer. A personal computer with software designed specifically for TLC is most common for data handling and automation of the scanning process in modern instruments. With a fully automated system, the computer can carry out the following functions: data acquisition by scanning a complete plate following a preselected geometric pattern with control of all scanning parameters; automated peak searching and optimization of scanning for each fraction located; multiple wavelength scanning to find, if possible, a common wavelength for all substances to be quantified, to optically resolve fractions incompletely separated by TLC, and to identify sample fractions by comparison using pattern recognition techniques of spectra with those of authentic standards cochromatographed on the same plate or stored in a spectrum library; baseline location and correction; setting of peak markers, computation of peak areas and/or heights of samples and codeveloped standards, and processing of the analog raw data to quantitative digital results, including calculation of calibration plots by linear or polynomial regression, interpolation of sample concentrations, statistical analysis of reproducibility, and presentation of a complete analysis report; and storage of raw data on disk for later reintegration, calibration, and evaluation with different parameters. For GMP and/or GLP applications, the report contains the date and time of the last change plus a unique system-generated identification number.

DIODE ARRAY SCANNER

The J&M TLC 2010 scanner (Fig. 4) contains a diode array detector rather than a PMT. Plates can be scanned rapidly with high spectral resolution and signal-to-noise ratio using tungsten (visible) and deuterium (UV) light sources. Each compound can be analyzed at its optimum wavelength for maximum sensitivity, and complete spectra of all substances on the plate can be acquired simultaneously in real time during the analysis to aid in zone identification and purity determination. Fiber-optics technology is used to separate the scanning and detection units, which allows performance similar to that found in HPLC diode array detectors. The solarization-free fiber

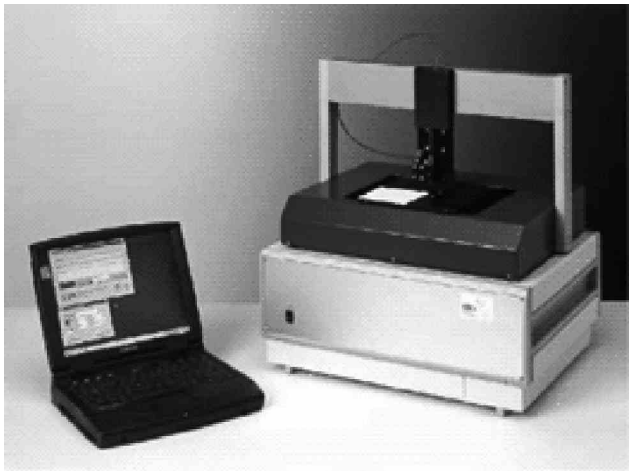

Fig. 4 J&M 2010 TLC Diode Array Scanner (TIDAS TLC 2010).
Source: Photo courtesy of SpectrAlliance, Inc., St. Louis, Missouri.

optics can operate from 1000 nm down to 190 nm without the use of a cutoff filter. A fiber-optic probe is used to scan plates containing up to 18 chromatograms at distances between 400 and 600 μm with an optical resolution of 160 μm. Software parameters are similar to those for HPLC diode array detection, including peak purity, resolution, identification by spectral library matching (Fig. 5), and quantification.

VIDEODENSITOMETRY

Video camera systems are available from several manufacturers for documentation and densitometric quantification of TLC plates. As an example, the Camag VideoScan (Fig. 6) consists of the VideoStore documentation system, which includes a lighting module with short- and long-wave UV and visible sources upon which the layer is placed, a CCD camera with zoom and long-time

integration capability, plus a PC under MS-Windows control with software for evaluation of images captured with a frame grabber, a monitor, and a printer. An image of all zones on the entire layer is obtained by the VideoStore camera simultaneously. The VideoScan software for quantitative evaluation allows display of the chromatogram tracks of the layer image acquired with the video camera as analog curves and calculation of their peak properties (R_f, height, area, height percent, and area percent). Quantification can be performed via peak areas or heights, with single or multilevel calibration (linear or polynomial regression).

Current video scanners can measure spots in the visible absorption, UV absorption, fluorescence, transmittance, and reflectance modes. They have potential advantages, including rapid data collection, simple design with virtually no moving parts, and ability to quantify two-dimensional chromatograms,[4] but they cannot perform spectral analysis. Current commercial instruments have not yet been shown to have the required capabilities, such as sensitivity, resolution, wavelength range, or the ability to illuminate the plate uniformly with monochromatic light of selected wavelength, to match the performance of slit scanning densitometers. However, videodensitometric analyses can often be validated at acceptable levels for many quantitative applications.[5]

DIGITAL CAMERA DENSITOMETERS

Instead of being based on computer analysis of a digitized signal from a video camera, a densitometer featuring a 3.3 mega pixel color digital camera, 3 × optical zoom lens, and overhead (reflected) 254 and 366 nm light and transmitted white light is available from Analtech (Fig. 7). The

Fig. 7 ChromaDoc-It TLC imaging system.

image analysis software, with a large selection of image capture and effects settings, generates quantitative data of lanes and bands as well as detailed, user-configured reports. Camag manufactures the DigiStore documentation system, which also uses a digital camera; images captured with the DigiStore can be quantified with VideoScan software.

DENSITOMETRY USING FLATBED SCANNERS

Zones on TLC plates can also be measured with a flatbed scanner. As with a CCD camera, chromatogram images are stored in digital form, and tracks and zones are detected and quantified with specialized software.[6,7] Commercial office scanners can be used for naturally colored zones or colored zones produced by postchromatographic derivatization.[8] Modified flatbed scanners have been described for use in quantification of fluorescent[9,10] and fluorescence-quenched[11] zones. As CCD cameras, flatbed scanners, and associated specialized software improve, quantification by image analysis will become increasingly competitive with slit scanners in the future.

APPLICATIONS AND PRACTICAL ASPECTS OF DENSITOMETRY

Densitometric quantification has been applied to virtually every type of analyte and sample. The greatest number of applications is for the analysis of drug and pharmaceutical compounds, most of which have structures including chromophores that cause strong UV absorption. These compounds are readily quantified by measuring the decrease in reflectance as a result of absorbance of radiation from a short-wave UV source on an F-layer.[12] The dark zones of

UV-absorbing compounds quantified by scanning at 254 nm (or a nearby wavelength of maximum analyte absorption) on fluorescent F-layers are commonly called "fluorescence-quenched zones" and the process "fluorescence quenching," even though use of these terms may not be technically correct in relation to the true measurement process occurring with the usual densitometer configuration (i.e., no cutoff filter blocking the excitation radiation from reaching the detector).

Lipids are compounds that are not easily analyzed by GC or HPLC because they lack volatility and the presence of a chromophore leading to UV absorption. The most successful way to quantify lipids is by densitometry after separation and detection on the layer with a chromogenic reagent, most notably phosphomolybdic acid.[13] The quantification of amino acids in biological samples[14] and dietary supplements[15] after detection with ninhydrin is another example of densitometry in the visible absorption mode. Fluorescence densitometry has been applied to the determination of naturally fluorescent compounds such as pyrene[16] and compounds derivatized with a fluorogenic reagent pre- or post-TLC (e.g., fumonisin B-1 reacted with fluorescamine).[17] HPTLC/densitometry is very widely used in pharmaceutical analysis, and inherent advantages compared to HPLC and full validation of procedures in accordance with international guidelines have been described.[18,19]

The steps in a typical densitometric quantitative analysis, regardless of analyte type, are the following:

1. Prepare a standard reference solution.
2. Prepare a sample solution in which the analyte is completely dissolved and impurities have been reduced to a level at which they will not produce chromatographic zones that interfere with scanning of the analyte.
3. Choose a layer and mobile phase combination that will separate the analyte as a compact zone with an R_f value in the range of 0.2–0.8.
4. Apply the standard and sample aliquots to the layer using an instrument (Fig. 1), or manually with a micropipet onto preadsorbent, laned plates. Generally, three or four standard zones are applied in constant volumes from a series of standard solutions with increasing concentrations, or in a series of increasing volumes from a single standard solution. The sample volume applied must provide an amount of analyte zone with a weight that is bracketed by the standard amounts.
5. Develop the plate in an appropriate chamber, and dry the mobile phase under a fumehood or in an oven.
6. Apply a detection reagent, if necessary, by spraying or dipping. The reagent should produce a stable colored, UV-absorbing, or fluorescent zone having high contrast with the layer background.
7. Scan the natural or induced absorption or fluorescence of the standard and sample zones on the plate using a densitometer with optimized parameters.
8. Generate a calibration plot by linear or polynomial regression of the scan areas and weights of the standards and interpolate the weights in the sample zones from the curve.
9. Calculate the concentration of analyte in the sample from the original weight of the sample, the original total volume of the sample test solution, the aliquot volume of the test solution that is spotted, the interpolated analyte weight in that spotted volume from the calibration curve, and any numerical factor required because of dilution or concentration steps needed for the test solution to produce a bracketed scan area for the analyte zone in the sample chromatogram.
10. Validate the precision of the TLC analysis by replicated determination of the sample and accuracy by comparison of the results to those obtained from analysis of the same sample by an established independent method or calculation of recovery from analysis of a spiked preanalyzed sample or spiked blank sample. Other validation parameters include specificity, detection limit, quantification limit, linearity, and range.[20]

ADVANTAGES OF TLC/DENSITOMETRY COMPARED TO HPLC

The following are some advantages of TLC/densitometry compared to the other major LC method, HPLC:

1. A wide range of mobile and stationary phases combined with capillary flow and forced flow one- and two-dimensional and multiple and gradient development modes lead to high separation selectivity.
2. The simultaneous analysis of multiple samples on a single plate leads to higher sample throughput (lower analysis time) and less cost per sample. Up to 36 tracks are available for samples and standards on a 10 cm × 20 cm HPTLC plate.
3. The ability to generate a unique calibration plot using standards developed under the same conditions as samples on each plate (in-system calibration) leads to statistical improvement in data handling and better analytical precision and accuracy and eliminates the need for an internal standard for most analyses.
4. Detection is versatile and flexible because the mobile phase is removed prior to detection. Because the detection process is static (the zones are stored on the layer), multiple, complementary sensitive, selective, or universal detection methods can be used. As

an example, niacinamide and γ-aminobutyric acid in dietary supplement capsules were quantified by HPTLC on a single plate using densitometry in the fluorescence-quenching mode for the former and the visible mode after spraying with ninhydrin for the latter.[21]

5. Storage of the chromatogram also allows scanning to be repeated with different parameters without time constraints and assures that the entire sample is available for detection and scanning.
6. Less sample cleanup can be tolerated because plates are not reused. Every sample is analyzed on a fresh layer without sample carryover or cross-contamination. Crude, complex, or dirty samples can be more easily analyzed.
7. Solvent use is very low for TLC, both on an absolute and per-sample basis, leading to reduced purchase and disposal costs and safety concerns.

CONCLUSIONS

The principles, procedures, and instrumentation for densitometric quantification of zones on TLC or HPTLC plates have been described briefly. The reading list below provides sources of more detailed information on these topics, as well as on applications to virtually all sample and analyte types. The results of TLC/densitometry are complementary with those from other analytical techniques, and the method has unique advantages for many analyses.

Optimization of TLC

Teresa Kowalska
Institute of Chemistry, Silesian University, Katowice, Poland

Wojciech Prus
School of Technology and the Arts in Bielsko-Biała, Bielsko-Biała, Poland

INTRODUCTION

The principal task of chromatography is the separation of mixtures of substances. By "optimization" of the chromatographic process, we mean enhancement of the quality of the separation by changing one or more parameters of the chromatographic system. An ability to foresee, correctly, the direction and scope of these changes is the most important goal of each optimization procedure.

Use of chemometrics to devise procedures suitable for the most crucial stage of optimization, optimization of selectivity, is generally performed in three steps:

1. Selection of the experimental method which best suits the analytical problem considered. At this stage, a chromatographic technique is chosen that ensures that the best possible range of retention parameters is obtained for each individual component of the separated mixture.
2. Establishing the experimental conditions that enable quantification of the influence of the optimized parameters of a chromatographic system on solute retention.
3. Fixing the experimental conditions at values that provide the optimum separation selectivity.

Chemometric optimization of the chromatographic system consists, in fact, in predicting local maxima in multiparametric space and, then, in further deciding which of these parameters is global with regard to the overall efficiency of a given chromatographic system.

QUALITY OF CHROMATOGRAPHIC SEPARATIONS

Elementary Criteria

The simplest way of quantifying the separation of two chromatographic bands, 1 and 2, is to calculate the difference between their respective retention parameters; that is, the difference between their R_F values,

$$\Delta R_F = R_{F_2} - R_{F_1} \tag{1}$$

or between their R_M values,

$$\Delta R_M = R_{M_1} - R_{M_2} = \log \frac{k_1}{k_2} = \log \alpha \tag{2}$$

where k_1 and k_2 are the capacity (retention) factors of the chromatographic bands and α is the separation factor.

The terms most frequently used to characterize the separation of two chromatographic bands are the separation factor, α,

$$\alpha = \frac{k_1}{k_2} \tag{3}$$

where $k_1 > k_2$, and the resolution, R_S,[1]

$$R_S = \frac{2(z_2 - z_1)}{w_1 + w_2} = \frac{2l\Delta R_F}{w_1 + w_2} \tag{4}$$

where z_1 and z_2 are the distances of the geometric centers of two chromatographic bands, 1 and 2, from the origin, l is the distance from the origin to the mobile phase front, and w_1 and w_2 are the diameters of the two chromatographic bands, measured in the direction of eluent flow.

Other elementary criteria include the separation factor, S,[2]

$$S = \frac{k_2 - k_1}{k_1 + k_2 + 2} \tag{5}$$

the peak-to-valley ratio of the bands, P,[3]

$$P = \frac{f}{g} \tag{6}$$

(where f and g are, respectively, the average peak height and valley depth, characteristic of a given pair of neighboring solutes on a chromatogram), the fractional peak overlap, FO,[4]

$$\mathrm{FO} = \frac{A_n - A_{n,n-1} - A_{n,n+1}}{A_n} \tag{7}$$

(where A_n is the surface area of the part of the band originating from the pure single compound, $A_{n,n-1}$ is the surface area of the fractional overlap of the nth and $(n-1)$th bands, and $A_{n,n+1}$ is the surface area of the fractional overlap of the nth and $(n+1)$th bands), and the selectivity parameter, R_R,[5]

$$R_R = \frac{R_{F_1}}{R_{F_2}} \tag{8}$$

where $R_{F_1} > R_{F_2}$.

Criteria for the Quality of Chromatograms

One method which can be used to establish the optimum conditions for the separation of a complex mixture (i.e., not only a pair) of compounds consists in searching for the maximum of a function denoted the chromatogram quality criterion. The evaluation of separation selectivity can be conducted with the aid of different criteria of chromatogram quality such as the sum of resolution, $\sum R_S$,[6] the sum of separation factors, $\sum S$,[2] and other sums and products of elementary criteria, selected examples of which are the resolution product, ΠR_S,[7] (Fig. 1)

$$\prod R_S = \exp\left(\sum \ln R_S\right), \tag{9}$$

the product of the separation factors, ΠS,[8] the product of the fractional peak overlap, Π FO,[9] and the product of the peak-to-valley ratio of the bands, ΠP.[10]

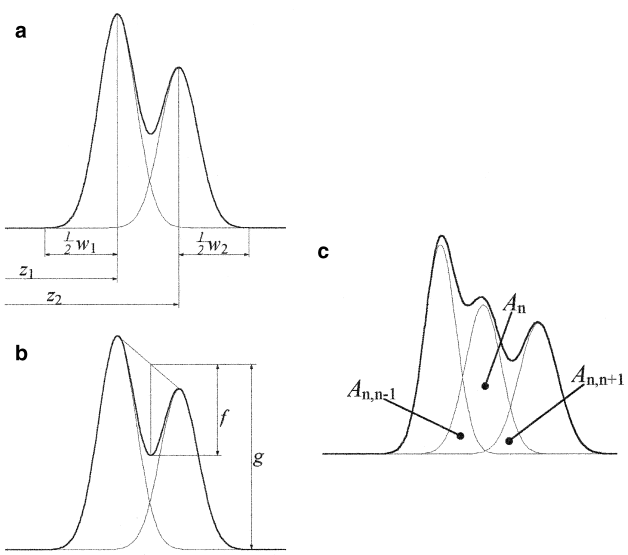

Fig. 1 Graphical interpretation of the selected elementary criteria: (a) resolution, R_s; (b) the peak-to-valley ratio, P; (c) the fractional peak overlap, FO.

There are also other, more complex criteria, including the normalized resolution product, r,[11]

$$r = \prod_{i=1}^{n-1} \frac{R_{S_{i,i+1}}}{R_S} = \prod_{i=1}^{n-1} \frac{S_{i,i+1}}{S} \tag{10}$$

where n is the number of the chromatographic bands,

$$\bar{R}_S = \frac{1}{n-1} \sum_{i=1}^{n-1} R_{S_{i,i+1}}$$

and

$$\bar{S} = \frac{1}{n-1} \sum_{i=1}^{n-1} S_{i,i+1}$$

and the minimum R_S,[8]

$$R_{S,\min} \geq x \text{ or } \max R_{S,\min} \tag{11}$$

The minimum of α is used as a criterion of the quality of chromatograms in liquid chromatography.[12]

Other criteria are the total peak overlap, φ,[13]

$$\varphi = \sum \exp(-2R_S), \tag{12}$$

the informing power, P_{inf},[14]

$$P_{\text{inf}} = \sum_{i=1}^{n} \log_2 S_i \tag{13}$$

and the chromatographic response function, CRF,[10]

$$\text{CRF} = \sum_{i=1}^{n} \ln P_i \tag{14}$$

(where P_i is the peak-to-valley ratio for the ith pair of chromatographic bands).

Performance of the Chromatographic System

One measure of the performance of a given chromatographic system is the number of the theoretical plates per chromatographic band (N). In its simplest form, this can be defined as

$$N = \frac{l}{H} \tag{15}$$

where l is the distance from the origin to the eluent front and H is the height equivalent to one theoretical plate (H is sometimes also denoted height equivalent to theoretical plate (HETP)).

The average height equivalent to one theoretical plate ($\bar{H}$) can be calculated from the relationship [15]

$$\bar{H} = \frac{(\sigma_i)^2}{(z_r - z_0)R_F} = \frac{(w_i)^2}{16 z_x} \tag{16}$$

where σ_i is the standard deviation, which characterizes the width of the chromatographic spot, or the band width on the densitogram, w_i is the spot width (or the width of the peak base on the densitogram), z_r–z_0 is the distance from the origin to the eluent front, and z_x is the distance from the origin to the geometric center of the chromatographic spot.

The relationship between the height equivalent to one theoretical plate (H) and the velocity of the mobile-phase flow is given by the simplified van Deemter equation [16]

$$H = A + \frac{B}{u} + Cu \tag{17}$$

where u is the linear velocity of the mobile phase, A is a constant characterizing eddy diffusion, B is a constant characterizing molecular diffusion, and C is a constant characterizing resistance to interphase mass transfer. This particular issue is of considerable significance in planar chromatographic separations, during the course of which the velocity of the mobile phase changes.

The concept of separation number (SN) in planar chromatography is a practical approach to the task of quantification of chromatographic system performance. According to this concept, such performance can simply be evaluated by calculating how many components of the separated mixture can be comfortably accommodated (i.e., without any overlap of adjacent components) along the direction of migration of the eluent. A convenient relationship proposed in Ref. [17] enables easy calculation of the numerical value of SN:

$$\mathrm{SN} = \left(\log\frac{b_0}{b_1}\right)\left(\log\frac{1 - b_1 + b_0}{1 + b_1 - b_0}\right)^{-1},$$

or, simplified,

$$\mathrm{SN} \approx \frac{1}{b_0 + b_1} \tag{18}$$

where b_0 is the width at half-height of a spot at the origin and b_1 is the width at half-height of a spot at R_F=1 (extrapolated) (b_0 and b_1 are in R_F units).

SEMIEMPIRICAL OPTIMIZATION STRATEGIES

Strategies used for optimization of selectivity can basically be divided into three separate groups: (a) the simultaneous strategy, (b) the sequential strategy, and (c) the interpretative strategy.

Simultaneous Strategy

In this strategy, one must accomplish all the experiments according to a plan devised earlier. All the results obtained must then be carefully evaluated, the optimum experimental conditions being chosen on this basis.

Sequential Strategy

In this strategy, the optimum experimental conditions are approached in a series of consecutive steps. The choice of any step results strictly from the outcome of all those accomplished previously. One example of a relevant algorithm is the simplex method[18]; the PRISMA[19] geometrical method is a suitable example of the overall optimization approach.

Interpretative Strategy

This method enables prediction of the quality of a separation on the basis of a relatively limited number of the experimental data, collected in previous experiments. According to this approach, the chromatographic results are interpreted in terms of the retention functions, valid for each individual solute separately. Some good examples of the interpretative strategy are the so-called "window diagrams" approach[20] and the search for the extremum of the multiparameter response function with the aid of the genetical algorithm.[21]

Organic Acids: TLC Analysis

Natasa Brajenovic
Institute for Medical Research and Occupational Health, Zagreb, Croatia

INTRODUCTION

A very large number of papers report new research works on analyses of organic acids by thin-layer chromatography (TLC), paper chromatography, high-performance liquid chromatography (HPLC), and other analytical techniques. One of the most popular and widely used separation techniques for qualitative and quantitative analyses in the laboratory is TLC.

The reason for using TLC is its wide applicability to a great number of different types of samples, high sensitivity, and speed of separation with relatively low cost. This technique is very fast, and many separations can be accomplished in less than an hour.

The development of different methods of analysis in TLC is a very important area of organic chemistry and biochemistry. Analysis of organic acids by TLC is widely applied in different fields of environmental, pharmaceutical, industry, industrial foods, organic chemistry, cosmetics, clinical, and biochemical assays.

OVERVIEW

Here, we present scientific activity in the analysis of organic acids by TLC in a period from 1993 to 2004. The review is based on a search of *Current Contents and Science Citation Index*, using different combinations of key words relevant for TLC, organic acids, and different kinds of organic acids, such as amino acids, carboxylic acids, humic acids, aromatic carboxylic acids, and fatty acids. In addition, the journals publishing papers covering specific topics related to the analysis of organic acids by TLC were searched directly: *Analytica Chimica Acta*, *Analytical Chemistry*, *Journal of Microbiological Methods*, *Journal of LC and Related Technologies*, *Journal of Chromatography (Parts A and B)*, *Chromatographia*, and *Journal of Pharmaceutical and Biochemical Analysis*.

GENERAL CONSIDERATIONS

Stationary Phase

Typical thin-layer separations are performed on flat glass or plastic plates that are coated with a thin and adherent layer of particles, which constitute the stationary phase.[1] Commercial plates come in two categories: conventional [thick layers (200–250 μm) of particles having sizes of 20 μm or greater] and high-performance plates (film thickness of 100 μm and particles whose diameters are 5 μm or less).

Silica gel is the most extensively used adsorbent in TLC because it leads to excellent, uncomplicated separations. It can be successfully employed for both qualitative and quantitative TLC analyses. It is usually used as a stationary phase in separations and analysis of alkaloids, various organic acids (especially amino acids and their derivatives), steroids, lipids, vitamins, plant pigments, pesticides, drugs, carbohydrates, phenolic substances, etc.

Besides silica gel, cellulose, and aluminum oxide, various other impregnated plates are also frequently used as stationary phases.[1]

Mobile Phase

Many different solvents and mixtures of solvents are used as mobile phases for the analysis of organic acids by TLC, such as chloroform, ethyl acetate, methanol, benzene, etc.

Identification

For identification in qualitative TLC, a great number of visualization reagents are used.[1] If compounds are not colored, a UV lamp may be used to visualize the plates. The quantitative determination of sample components is performed according to the following:

1. Extracting the stained spot with solvent and analyzing it spectrophotometrically; or
2. Scanning the plate densitometrically.[1]

APPLICATIONS

Pharmaceutical Industry, Medicine, Biochemistry, and Biology

TLC is used for the analysis of free amino acids from sanguine plasma in different progression states in maladies: diabetes, renal syndrome, and hepatic cirrhosis.[2] Elution was performed on cellulose plates and the densitometry was achieved with a photodensitometer (Shimadzu CS-9000) at 575 nm. In the case of hepatic cirrhosis, a better resolution was obtained. A mixture of *n*-butanol–acetone–acetic

acid–water (35 : 35 : 7 : 23 vol/vol/vol/vol) was used as the mobile phase.

A simple and fast method for identification of bifidobacteria using TLC analysis of short chain fatty acids in a culture broth is proposed (Table 1).[3] This approach has many advantages: the total time required to analyze organic acids is approximately 50 min; and the identification protocol is simpler, quicker, and more economical than conventional identification methods.

Mycolic acids analysis by TLC has been employed by several laboratories worldwide as a method for fast identification of *Mycobacterium*.[4] *Mycobacterium tuberculosis* strains identified by classical methods were confirmed by their mycolic acid content.

Using aminopropyl-modified silica gel plates in a normal phase system, the retention behavior of 12 acidic drugs and biologically active aromatic acids was investigated by high-performance TLC.[5]

The metabolism of aromatic amino acids (phenylalanine and tyrosine) can be studied following the excretion of their characteristic phenolic acid metabolites in urine using chromatographic methods. These apply acids to the investigations of amino acids themselves in diagnostics. Thin layers of cellulose or silica gel on aluminum foil were used as stationary phases.[6] The retention factor (R_f) of clinically important compounds in the three solvent systems is presented in Table 2.

TLC is also used for direct enantiomeric resolution of D,L-arginine, D,L-histidine, D,L-lysine, D,L-valine, and D,L-leucine on silica gel plates impregnated with optically pure (1*R*, 3*R*, 5*R*)-2-azabicyclo[3,3,0]octan-3-carboxylic acid, which serves as a chiral selector in the pharmaceutical industry.[7] To successfully resolve D,L-amino acids, various combinations of acetonitrile–methanol–water were proposed. The spot was detected by ninhydrin (0.2% in acetone).

TLC is often applied as an industrial control procedure in the synthesis of 2-hydroxy-3-naphthalenecarboxylic acids, on silica gel plates with chloroform–methanol–acetic acid (50:20:1) as developer.[8] 2-Hydroxy-3-naphthalenecarboxylic acid is an important intermediate in the synthesis of dyestuffs and drugs.

Separation of amino acids and their identification in different mixtures are frequent tasks encountered in biochemistry. TLC is a fast, simple, and inexpensive approach to attain this goal. Because some of the components are UV-inactive, other methods, such as vibrational spectroscopy, should be applied for detection and identification. Comparative study based on Raman spectroscopy of TLC spots of some weak Raman scatterers (essential amino acids) was carried out using four different visible and near-infrared laser radiation wavelengths: 532, 633, 785, and 1064 nm.[9] The best results were obtained with simple silica gel plates.

Table 1 Retention time (R_f) and detection color of standard organic acids.

Organic acids	R_f value	Methyl red + bromophenol blue
Lactic acid	0.53 (Upper spot)	Red
	0.37 (Lower spot)	Red
Acetic acid	0.44	Blue
Propionic acid	0.54	Blue
Butyric acid	0.61	Blue
Succinic acid	0.12	Yellow
Citric acid	0.03	Dark yellow
	0.52	Red

Environmental, Water, Plant, and Soil Applications

The occurrence of chlorinated organic compounds in fish from polluted waters is rather frequent.[10] Chlorinated carboxylic acids of fatty acid character have also been shown to account for up to 90% of the extractable organically bound chloride (EOCl) in fish. Purification by TLC of methyl esters of dichlorotetradecanoic, dichlorohexadecanoic, and dichlorooctadecanoic acids was used. They were detected at 1200 ppm of EOCl in fish.

Organic acid complexes with metal ions significantly affect the mobility of metal ions in plants and soils. Toxic metals also react with organic acids and have a harmful influence on the environment.

Many plants contain a variety of free acids such as acetic acid, citric acid, fumaric acid, malic acid, succinic acid, oxalic acid, glycolic acid, etc.[11–13] They are components

of citric cycle, whereas the others are intermediates in the pathway from carbohydrates to aromatic compounds.[11] Following extraction, organic acids can be separated and detected with a variety of techniques. TLC methods have been also employed to separate certain organic acids,[11,14,15] as presented in Table 3.

TLC of some plant phenolics, which play an important role in plant metabolism, was carried out on cellulose.[12] The solvents were: 2% formic acid, 20% potassium chloride, isopropyl alcohol–ammonium hydroxide–water (8 : 1 : 1), and 10% acetic acid. The plates were examined under UV light after development. The results of the chromatographic analysis of some phenolic acids are shown in Table 4.

The composition of lignin (an important component of plant cell walls) is very complex.[13] *p*-Coumaric acid, cinnamic acid, ferulic acid, and others are among the products of lignin biodegradation (Fig. 1). TLC is a very rapid method for their separation and is usually completed in a very short time. Six different solvents were used as developer (Table 5), with silica gel being used as a stationary phase.

Humic acids are also products of lignin biodegradation. The characterization of humic acids by TLC on Fe(III)-impregnated silica gel with tap water as developer has been presented.[14] During the chromatographic process, complexes between Fe(III) from the support group and the active functional group from humic acid are formed, causing successive attaching and detaching of Fe(III) from the support of Fe(III) hydroxy/oxide. These results could partially answer how the process of metal migration in soils and sediments progresses.

Some carboxy and benzene derivatives related to humic materials were also examined by TLC.[15] Aluminum oxide, silica gel, and Fe(III)-impregnated silica gel plates were used as supports, whereas the mobile phase was

water. The results are presented in Table 3. It was concluded that the hydroxy/oxide layer of iron and aluminum can affect the mobility of simple organic molecules in soil. On the other side, organic molecules having carboxy and hydroxy groups can improve the dissolution of hydroxy/oxides of iron or aluminum in soils and sediments.

Food Analysis, Agriculture, and Industry

There are several acids that are widely used in industries. For example, synthetic carboxylic acid esters are used in the perfume industry. Benzoic acids are used as sodium salts in the food industry as inhibitors of microorganism growth.[16]

Benzoic acid derivatives often contain amino, hydroxy, carboxy, and nitro groups. Analysis of substituted benzoic acids by TLC was performed on silica gel, polyamide, and cellulose containing UF_{254} fluorescent indicator.[17] For the mobile phase, different mixtures were used: hexane–acetic acid; hexane–ethyl acetate–formic acid; chloroform–methanol–phosphoric acid; cyclohexane–acetic acid; benzene–ethanol; etc. Because benzoic acid derivatives have similar retention parameters, their separation requires a thorough optimization of conditions (the nature of the stationary phase, the composition of the mobile phase, and the pH of the solutions).

For the separation of benzoic acids, planar electrochromatography was used.[18] In this approach, an electro-osmotic flow is used to drive the mobile phase in TLC. Planar electrochromatography has several advantages over classical TLC, especially substantially faster separation. For example, separation by planar electrochromatography can be 10 times faster than that using ordinary TLC.

TLC analysis of agricultural products, foods, beverages, and plant constituents is described by Sherma[19] in a review paper. In laboratories throughout the world, TLC is widely used for food analysis and qualitative control. Numerous applications of TLC have been reported in the area of food composition, involving determinations of compounds such as lipids, sugars, amines, vitamins, and organic acids such as amino acids and fatty acids.

Table 5 Different solvent systems used as developers for TLC separation for simple phenolic and related compounds such as cinnamic acid, *p*-coumaric acid, ferulic acid, and tannic acid.

1) Chloroform–methanol–acetic acid (90 : 10 : 1)
2) Petroleum ether (60–80°C)–ethyl acetate–formic acid (40 : 60 : 1)
3) Benzene–dioxane–acetic acid (85 : 15 : 1)
4) Chloroform–ethyl acetate–acetic acid (50 : 50 : 1)
5) Toluene–acetonitrile–formic acid (70 : 30 : 1)
6) Petroleum ether (60–80°C)–methanol–acetic acid (90 : 10 : 1)

Source: From Thin-layer chromatography of gallic acid, methyl gallate, pyrogallol, phloroglucinol, catechol, resorcinol, hydroquinone, catechin, epicatechin, cinnamic acid, *p*-coumaric acid, ferulic acid and tannic acid, in J. Chromatogr. A.[13]

VARIOUS ORGANIC COMPOUNDS

TLC analysis is also highly applicable to the determination of aromatic organic acids.[20] In human organisms, aromatic acids are synthesized as metabolites in intoxication by toluene, xylene, and ethyl benzene.[16] These

compounds are easily absorbed through the skin or respiratory system, and are oxidized to aromatic acids. The separation, identification, and quantitative analyses of aromatic acids are also necessary because they appear as semiproducts of the biosynthesis of aromatic amino acids in plants (phenolic acids), and metabolites of numerous toxic substances, drugs, and catecholamines. Polar adsorbents and polar-bonded stationary phases are also widely used in carboxylic separation by TLC, often coupled with densitometry.

Dansyl chloride (DNS-Cl; 5-dimethylaminonaphthalene-1-sulfonyl chloride) is used in analytical chemistry to fluorescently label substances. This process of dansylation creates fluorescent derivatives, which can be detected with great sensitivity. The method for the dansylation of hydroxyl (–OH) and carboxylic acid (–COOH) functional groups has been described.[21] Fluorescent labeling by dansyl chloride has applications in LC, HPLC, TLC, and MS. Fast TLC was accomplished using acetone as the resolving solvent, and resulted in good differentiation of analytes.

Many TLC systems for the separation of amino acids have been described.[22–24]

Copper sulphate and polyamide were tried as impregnants for improving the separation of 20 amino acids on silica gel layers. MeOH–BuOAc–AcOH–pyridine (20 : 20 : 10 : 5) was used as the solvent system.[22]

D-Enantiomers of amino acids have been frequently reported in various tissues of diverse organisms. A simple and rapid method of separating optical isomers of amino acids on a reverse-phase (RP) TLC plate is described.[23] Amino acids, derivatized with 1-fluoro-2,4-dinitrophenyl-5-L-alanine amide, were spotted onto a RP TLC plate. Acetonitrile in triethylamine–phosphate buffer was used as the developer.

For the evaluation of protein structure, identification of amino acids is extremely important. TLC is an appropriate method in this field. A variety of spray reagents are used, among which ninhydrin is the most popular one due to its high sensitivity.[24] Ninhydrin produces a purple/violet color with most amino acids. A typical experimental setup includes chromatographic plates prepared from silica gel; *n*-propanol–water (70 : 30) mixture was used as a mobile phase. For complex mixtures of substances, two-dimensional chromatography is preferred, using *n*-propanol–water (70 : 30) mixture and methanol–chloroform (3:1) mixture as the two developers.

CONCLUSIONS

TLC is a very widely used chromatographic technique in research activities of analytical chemists in many laboratories in the world. Many articles dealing with the development of new analytical methods for the analysis and separation of different organic acids in various fields have been published. There is a constant need for qualitative and quantitative analyses of organic acids in the pharmaceutical, cosmetic, and food industries; in medicine, biology, organic chemistry, and biochemical analysis; and in environmental studies. The important reasons for frequent applications of TLC in qualitative and quantitative analyses of organic acids are its high sensitivity, fast separation of components, and relatively low cost.

Organic Extractables from Packaging Materials: Identification and Quantification

Dennis R. Jenke
Technology Resources Division, Baxter Healthcare Corporation, Round Lake, Illinois, U.S.A.

INTRODUCTION

Plastic materials are widely used in medical items, such as solution containers, transfusion sets, transfer tubing, devices, and packaging systems. The physiochemical nature of these materials provides medical products with their necessary, desirable performance characteristics. While an important performance characteristic of plastics used in medical application is chemical inertness, interactions between a plastic material and a contacted pharmaceutical product are well documented. Such interactions may include sorption, the uptake of product components by the plastic material, or leaching, i.e., the release of plastic material components into the product. In the case of leaching, both the identities of the leached substances and their accumulation levels may impact the ultimate utility of the product.

A review, related to the chromatographic methods used to assess the accumulation of leachable substances from packaging materials used for pharmaceutical products, is provided. This considers methods used to identify and/or quantify such leachables in actual products or product-simulating solvent systems.

DISCUSSION

The assessment of the impact of the accumulation of leached substances in pharmaceutical products contacted by a plastic material during their manufacture, storage, and/or use is a multifaceted undertaking involving disciplines within the applied physical, chemical, and biological sciences. While numerous strategies can be envisioned, and have been utilized to perform such an assessment, considerations include the identification of the leached substances and the measurement of the actual or probable accumulation levels of the identified substances. The identification process is an extensive investigation that utilizes sensitive and information-rich scouting of analytical methods for the dual purposes of first revealing the leachables and then providing relevant information (e.g., formula and structure) that leads to their identification. In the worst-case scenario, such an analytical investigation is conducted blind; that is, the analytical team is faced with the unenviable challenge of finding an unknown number of unknown compounds, many of which accumulate in the product at levels much lower than its other constituents. These constituents may include both additives and non-material-related contaminants such as ingredient impurities and degradation products. This search for material-derived leachables in pharmaceutical products is greatly facilitated if it is conducted with information-rich analytical methodologies that exhibit a comprehensive ability to respond to a large population of analytes in both a universal, but very specific, manner. The dual performance requirements of universality and specificity are the primary reasons why chromatographic methods are almost exclusively used in investigations specifically associated with organic leachables.

Given the variety of packaging materials used in pharmaceutical applications, the population of potential primary and secondary organic leachables is large and compositionally diverse. While an analytical chemist has a multitude of chromatographic tools with which to perform a leachables assessment, some guidance in terms of successfully applied strategies and methods can greatly facilitate the assessment. Thus this entry contains a general compilation of published chromatographic methods and strategies that have been successfully applied to the identification and quantification of packaging material leachables. Examples are provided for each major separation strategy [e.g., high-performance liquid chromatograpy (HPLC), gas chromatography (GC), thin-layer chromatography (TLC), and supercritical fluid chromatography (SFC)] and for most commonly employed detection methods [e.g., ultraviolet (UV), mass spectrometry (MS), and flame ionization detection (FID)]. While the compilations in Tables 1–4 are by no means exhaustive, they are sufficiently broad in scope to provide the investigator with a general overview of the ways in which chromatography has been applied to meet the objectives of a leachables investigation.all

Tables 1–4 provide general method details, such as column type, elution and detection conditions, and other operating conditions. The materials investigated, as well as the specific leachables examined, are also indicated. General comments are provided in terms of sample preparation. Given the number of methods cited, it is not possible here to provide detailed chromatographic profiles, which are readily available in the cited references.

Table 1 Examples of HPLC methods used to identify and/or quantify packaging system extractables.

Material	Sample matrix	Sample preparation	Column	Mobile phase	λ (nm)	Other	Extractables	Refs.
PVC	Saline extracts	Extraction into hexane	Shandon ODS C_{18}, 200 × 4.6 mm, 200 × 2.1 mm	ACN/MeOH (9 : 1)	270	20 μl, 0.8 or 0.17 ml/min	Di-ethylhexyl-phthalate	[1][a]
PVC, PE, PS	Organic solvents	Direct injection	Spherisorb C_{18} ODS-2, 250 × 4.6 mm, 5 μm	MEOH/phosphate buffer, pH 5.5 (1 : 1)	225	20 μl, 1 ml/min	Monomers, caprolactam, aminocaproic acid	[2]
PVC, PE, PS	Organic solvents	Direct injection	Spherisorb C_{18} ODS-2, 250 × 4.6 mm, 5 μm	ACN/tetrahydrofuran (THF) (95 : 5)	280	20 μl, 1 ml/min	Antioxidants [Butylated hydroxy toluene (BHT), Irganox 1010, Irganox 1076]	[2]
PET	Oils	Solvent partitioning (ACN/hexane) with evaporative concentration	Microsorb C8, 250 × 4.6 mm, 5 μm	A = water/ACN (85 : 15), B = ACN/water (85 : 15)[b]	254	20 μl, 1.5 ml/min	PET oligomers (trimer-octamer), plasticizers (diethylene glycol dibenzoate)	[3]
PET	Oils	Solvent partitioning (ACN/hexane) with evaporative concentration	Microsorb C8, 250 × 4.6 mm, 5 μm	A = water/MEOH/AA (85 : 15 : 0.25), B = ACN/water (85 : 15)[c]	254	20 μl, 1.5 ml/min	PET oligomers, terephthalic acid, dimethylterephthalate, bis(2-hydroxyethyl) terephthalate	[4][a]
PP	Solvent extracts (hexane, ethyl acetate, diethyl ether)	Solvent evaporation, reconstituted in chloroform/MEOH	Spherisorb ODS-1, 50 × 4.6 mm, 5 μm	15–40% ethyl acetate gradient in 75 : 25 MEOH/water	271	35°C, 2 ml/min	Antioxidants (BHT, Irganox 1010, Irganox 1076, Irgafos 168)	[5][a]
HDPE	Dissolution with mobile phase	Direct injection	Spherisorb C_{18} ODS-2, 150 × 4.6 mm, 3 μm	MEOH/water/AA (66.5 : 32.5 : 1)	280	20 μl, 1 ml/min	Phenolic antioxidants[d]; propyl *p*-hydroxybenzoate	[6][a]
Laminated polyolefin	Drug product	SPE concentration, residue reconstituted in ethanol	LiChrosorb C18 ODS-2, 250 × 4.6 mm, 5 μm	MEOH/water (70 : 30)	280	20 μl	Caprolactam, butylhydroxytoluene, phthalic acid derivative	[7]

PC	Methylene chloride extract	Direct injection after polymer ppt with methanol	Restek RTx-5 FSOT, 30 m × 0.25 mm, 1.0 μm film	100°C, to 280°C at 10°C/min, hold for 3 min	MS *m/z* 213, $T = 290$°C	2 μl, split, $T = 280$°C	Bisphenol A	[9]
PVC	Pharmaceutical products	Solvent extraction, evaporative concentration	3% QF-1 or 3% SE-30 on Supelcoport	120°C for 1 min, to 225°C at 4°C/min	MS EI +, $T = 230$°C	$T = 230$°C	9,10-Epoxystearate ester	[20]
Rubber stoppers	Methylene chloride extracts	Direct injection	J&W DB-5MS, 30 m × 0.25 mm, 0.25 μm film	50°C for 5 min, to 275°C at 10°C/min, hold for 20 min	MS EI +, $T = 200$°C, 50–650 amu	1 μl, splitless, 200°C	Tributoxyethylphosphate BHT, diphenylamine 4-(2,2,3,3-tetramethylbutyl) phenol 2,2′-Methylenebis[6,(1,1 dimethylethyl)-4-ethyl] phenol	[21]

Laminated polyolefin[d]	Soxhlet and *n*-heptane extracts	Evaporative concentration with and without silylation	J&W DB-5, 30 m × 0.32 mm, 0.25 μl film	From 100°C to 280°C at 10°C/min	MS[e]	$T = 220$°C	Penta- to octa-decane Phthalic acid esters Mono- to hepta-cosane 13-diocosenoic acid	[22,23][f]
PET	Soxhlet extraction	Evaporative concentration, with and without silylation	J&W DB-1, 15 m × 0.53 mm, 1-μm film	50°C, hold for 10 min, to 280°C at 10°C/min	MS SIM mode, also FID	$T = 280$°C	Alkyl esters of nonanoic acid Ethylene glycol, BHT Phthalic acid esters Plamitic, stearic, oleic acid Terephthalic acid Alkyl terephthalic acid esters 2,6-bis-(1,1-methylethyl)-4-ethyl phenol Pyrogallol	[24][f]
Polyolefin	Solvent extraction	Evaporative concentration	TRB-5, 60 m × 0.25 mm, 0.5 μm film	40°C for 1 min, to 300°C at 20°C/min, hold for 26 min	MS EI +	1 μl, splitless, $T = 300$°C	Aliphatic hydrocarbons, straight-chained, branched and cyclic[f,g]	[25][h]
PE[i]	Solvent extraction	Direct injection	DB-1, 30 m × 0.25 mm, 0.32 μm film	50°C for 2 min, to 340°C at 5°C/min, hold for 10 min	MS EI +, 40–700 Da, $T = 270$°C	Splitless, $T = 250$°C	1,3-Di-*tert*-butyl benzene Oligomers 2,4-Di-*tert*-butylphenol Oxidized antioxidants Butanoic acid vinylester	[26][f,j]
Rubber[k]	Water extraction	Evaporative concentration	3% OV17 on Cas-Chrom Q, 1.5 m × 2 mm	140–200°C at 10°C/min	MS EI +, $T = 250$°C	2 μl, $T = 250$°C	Benzothiazole derivatives[l]	[27]

See legend of Table 1 for a list of material abbreviations.

[a]MS was used in compound identification.

[b]Method performance data are provided in this reference.

[c]This reference documents numerous extracted compounds in these general categories.

[d]Laminated film consisting of glycol-modified polyethylene terephthalate (PETG), polyvinylidene chloride (PVDG), and polyethylene (PE) with a polyurethane adhesive.

[e]GC/infrared spectroscopy analysis was also used under differing operating parameters to aid in compound identification.

[f]These cited references document numerous compounds in these and other general compound classes.

[g]Straight chained = C_{12}–C_{25}; branched = C_{19}–C_{30}; cyclic = C_{24}–C_{35}.

[h]Similar methods were used to identify compounds from polystyrene (styrene, styrene derivatives, glycolic esters of C16–C25 fatty acids, *trans*-1,2-diphenylcyclobutane).

[i]Material was gamma-irradiated prior to analysis.

[j]A similar method was used to identify compounds from PP, PVC, PS, PET, and polyamide.

[k]Components of disposable syringes.

[l]Identified compounds include 2-hydroxybenzothiazole, 2-mercaptobenzothiazole, 2-(methylmercapto)benzothiazole, 2-(2-hydroxyethoxy)benzothiazole, and 2-(2-hydroxyethylmercapto)benzothiazole.

Table 3 Examples of GC methods used to identify and/or quantify volatile packaging system extractables.

Material	Sample matrix	Sample preparation	Column	Oven program	Detection	Other	Extractables	Refs.
Paper and board	Extracts in water, ethanol, or chloroform	2.5 g sample per vial; 70°C for 30–60 min	Chrompack CP-Sil 8 CB, 50 m × 0.32 mm, 1.2 μm film	70°C for 2 min, ramp at 5°C/min to 110°C	MS	Also used diffusion trapping	Butanal, pentanal, hexanal Heptanal, 2-heptanal Ethyl acetate, chloroform Methyl acetate, nonanal *o*- and *p*-xylene, benzene, benzaldehyde, others	[28]
PVC bags	Portions of bags from actual products	1–5 mg sample per vial, 120°C for 5–20 min	SE-54, 20m × 0.2 mm	30°C for 2 min, ramp at 10°C/min to 280°C	MS	Evolved gas trapped in a container cooled with liquid nitrogen	Ethanol, pentane Acetic and formic acids Cyclohexanal, xylene Cyclohexanone, pentanal Heptanal, nonanal Phthalates, BHT Tetradecanoic acid Hexadecanoic acid	[12]
Polyolefin packaging material	7 cm^2 portion of the material	Investigated effect of temperature from 30°C to 125°C with a 3 min desorption	2% OV-7 on Aue 2 m × 2 mm	Start at 0°C, ramp at 10°C/min to 150°C	FID and MS	Also used purge and trap	Methanol, 1-propanol *t*-Butanol, toluene 2-Methyl-2-propanol 1-Ethoxy-2-propanol Methyl ethyl ketone 2-(2-Hydroxypropoxy-1 propanol	[29]

Drinking water in plastic bottles	Water solution	1 L of water stripped with N_2 at 600/ml/min for 8 hr, trapped on activated carbon	HP Ultra 2, 30 m × 0.53 mm, 1.5 μm film	40°C for 2 min, ramp at 10°C/min to 120°C, hold for 3 min.	MS	Analyte desorbed with CS_2 from activated carbon	2-Ethyl-1-hexanol Di-2-ethylhexyl phthalate	[30]
Irradiated poly-ethylene film	Pieces of film	Gas evolved at 80°C, transferred through trap with 3 L of N_2 at 50 ml/min Trapped volatiles desorbed at 200°C into N_2	Porapak Q, 3.1 m × 3.2 mm[a] or Ucon Oil HB2000 LB550X, 80 m × 0.2 mm[b]	60°C for 8 min, ramp to 230°C at 4°C/min[a] or 60°C for 16 min, ramp to 140°C at 4°C/min[b]	FID and MS	Tenax-GC 18 cm × 5 mm (60/80 mesh) rap used	Acetic acid, butyric acid Ethanol, isopropanol *n*-Propanol, *n*-butane 2-Pentanaone, 2-hexanone 3-Hexanaone, 3-heptanaone Toluene, butanal Acetaldehyde, propane Propionic acid	[31]

[a]Used for low-boiling compounds.
[b]Used for high-boiling compounds.

Table 4 Examples of miscellaneous chromatographic methods used to identify or quantify material extractables.

Material	Test sample	Method description	Extractables	Refs.
Polypropylene	Aqueous food-simulating solvents	Capillary SFC. Column: 10 m × 50 mm I.D. SB-Biphenyl-30, 0.25 μm film. Mobile phase = CO_2, linear flow rate ≈ 3 cm/sec. Pressure program, 100–400 bar; temperature program, 55–100°C. 1 μl injection using solvent venting with gas purging. Retention gap was 1.8 m × 100 μm deactivated fused silica. Detection by FID and MS.	Pentaerythrityl-tetrakis((3-(3,5-di-*tert*-butyl-4-hydroxy-phenyl) propionate) (*N*,*N*′-bis(2-hydroxyethyl)-C12.C14-amine) Tris-2,4-di-*tert*-butylphenyl)phosphite	[32]
Polyolefins, polypropylene, polyethylene	Soxhlet extracts	Capillary SFC. Column: 10 m × 50 μm I.D. fused silica capillary coated with cross-linked 5% phenyl-methypolysiloxane (0.4 μm film). Mobile phase = CO_2. Various temperature and pressure gradients used. Detection = FID at 300°C	Stearic acid, Irganox 1010 Irganox PS802, Atmos 150 Mono- and di-glycerides Alkenes, cycloalkanes	[33]
Polypropylene	Soxhlet extracts	Capillary SFC. Column: 10 m × 50 μm I.D. fused silica capillary coated with cross-linked methylpolysiloxane (SB-Methyl-100) or 50% octyl-substituted methylpolysiloxane (SB-Octyl-50), 0.25 μm film. Mobile phase = CO_2. Pressure program, 129–350 atm at 3 atm/min; temperature = 110°C. Detection = FID.	Additives including Topanol, Irgafos 168, Irganox 1076, Irganox 1330, Irganox 1010, ethylbenzoate, ethyl stearate	[34]
Polyolefin laminate	Drug product stored in plastic bags, SPE preparation	HPTLC. Plate = 10 × 20 cm silica gel. Mobile phase: acetone–chloroform–concentrated sodium hydroxide (20:80:0.2). Photodensitometric detection, at 200 and 234 nm before derivitization, 388 nm after derivitization with ninhydrin and 580 nm after derivitization with Bratton/Marshall reagent.	ε-Caprolactam Irganox 1010 Butylhydroxytoluene 4,4′-methylene dianiline	[7]
Polyethylene	Organic and water extracts	HPTLC. Plate = 10 × 10 cm Fertigplatten Kiselgel 40. Mobile phase: chloroform/cyclohexane (12:1). Densitometric detection.	Irganox 1076 3,5-di-*tert*-butyl-4-hydroxy-phenyl propionic acid	[35]

Preinjection sample preparation is not a chromatographic issue per se. Nevertheless, it is an important consideration in the successful application of a complete analytical process. Nerin et al.[36] reviewed sample treatment techniques applicable to polymer extract analysis, including headspace methods, supercritical fluid extraction, and solid phase microextraction.

Organic Polymer Additives: Identification and Quantification

Dennis R. Jenke
Technology Resources Division, Baxter Healthcare Corporation, Round Lake, Illinois, U.S.A.

INTRODUCTION

Plastic materials are widely used in numerous industries. The physiochemical nature of these materials provides a multitude of diverse products with their necessary, desirable performance characteristics. Commercial plastics are very complex materials. In addition to the various base polymers, commercially viable plastics contain a number of compounding ingredients (additives) whose purpose is to give the material its desired physical and/or chemical properties. Table 1 provides a brief summary of the types of additives typically encountered in commercial polymer systems.

Polymers and polymer systems are characterized for many reasons including the development of new materials or material sources, the end-use applications, the life test studies, the manufacturing control and troubleshooting, and the material or vendor identification. As it is typically the additive package that establishes the performance and processing properties of the commercial polymer, characterization of a polymer system for its additive package is essential in terms of material development, manufacturing, use, reuse, and, ultimately, disposal. A complete polymer characterization includes both the identities of the additives and their levels in the product. The identification and the quantification of additives in compounded polymers is generally a difficult task for the following reasons:

1. There is a wide variety of chemically diverse additive types. Literally, thousands of additives are commercially available, ranging from pure compounds, with molecular weights that vary from approximately 100 up to a few thousand mass units, to oligomers with up to 50 (or more) components.
2. Many additives are labile; thus, they are difficult to analyze without decomposition.
3. Complex mixtures of additives will normally be present in a commercial formulation.
4. Separation of the base polymer and the fillers from the organic additives are often required prior to additive analysis.
5. The levels of the organic additives in a commercial polymer may be quite low (and variable) compared to the base polymer and its associated fillers.

It is for these reasons that chromatographic methods of analysis have been widely employed in polymer characterization. In this entry, a review related to the chromatographic methods used to assess the identity and level of additives in polymer systems is provided.

DISCUSSION

Given the variety of additives used in commercial polymers, the task of characterizing such multicomponent systems for their additive packages can be daunting. While an analytical chemist has a multitude of chromatographic tools with which to perform an additive characterization, some guidance in terms of successfully applied strategies and methods can greatly facilitate the assessment. Thus this manuscript contains a general compilation of published chromatographic methods and strategies that have been successfully applied to the identification and the quantification of a large number of the more commonly encountered packaging material additives (Table 2 shows a listing of additives considered in this work's cited references). Examples are provided for each major separation strategy [e.g., high-performance liquid chromatography (HPLC), gas chromatography (GC), thin-layer chromatography (TLC), supercritical fluid chromatography (SFC)] and for most commonly employed detection methods [e.g., ulraviolet (UV), mass spectrometry (MS), flame ionization detector (FID)]. While the compilations in Tables (3–10) are by no means exhaustive or comprehensive, they are sufficiently broad in scope to provide the investigator with a general overview of the ways in which chromatography has been applied to meet the objectives of a polymer's characterization.

Tables (3–10) provide general method details, such as separation medium, elution, and detection conditions, and other operating conditions. The level of detail associated with each citation reflects the level of detail provided by the citation's author(s). The

Table 1 Common additives and fillers.

Classification	Purpose	Examples
Antioxidants	Prevent thermal and/or oxidative degradation during processing, handling, and use. Typically are radical scavengers which interrupt the chain propagation steps of polymer autooxidation	Irganox 1010, Irgafos 168, BHT
Light stabilizers	Absorb UV light to prevent photooxidation	Tinuvin 327, 328, 384, 440, etc. (derivatives of 2-hydroxy-benzophenone)
Heat stabilizers	Protect polymers during thermal processing	Metallic salts, especially of weak fatty acids (e.g., zinc stearate)
Plasticizers	Increase the workability, flexibility or distensibility of polymer	Derivatives of organic acids such as adipic, azelic, citric, phosphoric, phthalic, trimellitic acids
Lubricants (slip agent)	Reduce polymer adhesion to metal surfaces during processing	Derivatives of fatty acids (esters, amides, metal salts, Erucamide, silicones)
Viscosity improvers	Control the flow and the sagging of prepolymers	Ethoxylated fatty acids
Accelerators, activators	Compounds that control the rate or the nature of cure of elastomers	Zinc oxide, stearic acid, 2-2′-dithiobis-benzothiazole, zinc dialkyldithio-carbamate
Mold release agents	Prevent adhesion between two surfaces (e.g., sticking of polymer and metal mold)	Derivatives of fatty acids, Montan wax, silicones, diethylene glycol monostearate, ethylene bis (stearamide)
Fillers (extenders)	Finely dissolved solids added to polymer systems to improve properties or to reduce cost	Calcium carbonate, kaolin, talc, alumina trihydrate
Flame retardants	Decrease flammability	Alumina trihydrate, mixtures of halogenated organics and antimony oxide
Antistatic agents	Dissipate electrostatic surface charge on polymer surfaces	Quaternary ammonium compounds, long-chain derivatives of glycols and polyhydric compounds, Atmos 150, *N*,*N*-bis-(2-hydroxy-ethyl) alkyl-amine
Colorants	Improve the appearance of polymers, mask discoloration due to processing	Carbon black, titanium dioxide, azo-type dyes
Antimicrobial agents (biocides)	Reduce growth of microbes on polymer surfaces	Copper 8-hydroxyquinolate, *n*-(trichloromethylthio) phthalate
Cross-linking agents	Molecules that have two or more groups capable of reacting with the functional groups of polymer chains, where such a reaction connects or links the chains	2-Mercaptobenzothiazole, benzoyl peroxide, dicumyl peroxide, sulfur, toluene diisocyanate
Blowing agents	Gas-forming agents that facilitate the expansion of the polymer during processing	Nitrogen, toluenesufonyl semicarbazide, 1,1′-azobisforamide, phenyltetrazole

materials investigated, as well as the specific additives examined, are also indicated. General comments are provided in terms of sample preparation. Given the number of methods cited, it is not possible to provide chromatographic profiles which are readily available in the cited references.

In generating this review, the author balanced two objectives. The first objective was to summarize the most current technologies that are utilized for the task of polymer characterization, thus providing the researcher with the most relevant and state-of-the-art tools for the task at hand. Thus emerging automated and hyphenated techniques, coupled with online sample preparation, high-efficiency separations, and selective and sensitive detection [e.g., supercritical fluid extraction (SFE)/HPLC/MS], have a prominent place in this review. However, this author also notes that more historically relevant methods, such as GC and HPLC with UV detection, remain capable of providing

Table 2 Chemical names for the additives cited in this manuscript.

Trade name	Chemical name	CAS RN
AcraWax C	*N*,*N*′-ethylenebistearamide	110-30-5
Adkstab PEP-24G	Cyclinepentan tetrail bis (2,4-di-*tert*-butylphenyl) phosphite	29741-53-7
AM340		
ATBC	*O*-Acetyl-tri-*n*-butyl citrate (see Citroflex A-4)	—
Atmos 150	A mixture of glycerol mono- and distearate	11099-07-3
BAC-E	2,6-bis-[(Azidophenyl) methylene]-4-ethylcyclohexanone	
BBP	Benzyl *n*-butyl phthalate	85-68-7
Benzoflex-2860	A mixture of 19% di (2-ethylhexyl) adipate, 57% diethyleneglycol dibenzoate, 24% triethyleneglycol dibenzoate	400609-45-2
BEHB	Butylated hydroxyethylbenzene	
Behenamide	Docosanoic acid amide	3061-75-4
BHA	2-*tert*-Butyl-4-hydroxyanisole	25013-16-5
BHT	2,6-Di-*tert*-butyl-*p*-cresol	128-37-0
BHET	bis-(2-Hydroxyethyl) terephthalate	
Bis-A-bis azide	1,1′-(1-Methylethylidene)-bis-[4-(4-axidophenoxybenzene]	
Bisphenol A	2,2′-bis-(4-Hydroxyphenyl) propane	80-05-7
Brominated bisphenol A		
Brominated phenol		
Butyl oleate	9-Octadecanoic acid, butyl ester	142-77-8
Butyl palmitate	Hexadecanoic acid, butyl ester	111-06-8
Butyl stearate	Octadecanoic acid, butyl ester	123-95-5
Calcium stearate	Stearic acid, calcium salt	1592-23-0
Caprolactam	2-Oxohexamethyleneimine	105-60-2
Chimasorb 81	2-Hydroxy-4-*n*-octyloxybenzophenone	1843-05-6
Chimassorb 119 FL		
Chimassorb 944	Poly-[[6-[1,1,3,3,-tetramethylbutyl) amino]-1,3,5-triazine-2,4-diyl] [2.2.6.6-tetramethyl-4-piperidinyl) imino]-1,6-hexanediyl [2,2,6,6-tetramethly-4-piperidinyl) imino]]	71878-19-8
Citroflex A-4	2-Acetoxy-1,2,3-propanetricarboxylic acid tributyl ester	77-90-7
Cyanox 425	2,2′-Methylene-bis-(6-*tert*-butyl-4-ethylphenol)	88-24-4
Cyanox 1790	1,3,5-tris-(4-*tert*-Butyl-3-hydroxy-2,6-dimethylbenzyl)-1,3,5-triazine-(1*H*,3*H*,5*H*) trione	40601-76-1
Cyanox 2246	See Irganox 2246	—
Cyasorb UV 9		
Cyasorb UV-24	2,2′-Dihydroxy-4-methoxybenzophenone	131-53-3
Cyasorb UV 531	2-Hydroxy-4-(octyloxy) benzophenone	1843-05-6
Cyasorb UV 1084	2,2′-Thiobis-(4-*tert*-octylphenoxy) (nibutylamine) nickel	14516-71-3
Cyasorb UV 1164	2,4-bis-(2,4-Dimethylphenyl)-6-(2-hydroxy-4-octyloxyphenyl)-1,3,5-triazine	2725-22-6
Cyasorb 2908	3,5-Di-*tert*-butyl-4-hydroxybenzoate	67845-93-6

researchers with accurate, precise, and pertinent information. Thus this review attempts to maintain a historical perspective as well.

While it is not a chromatographic issue per se, pre-injection sample preparation, nevertheless, is an important consideration in the successful application of a complete analytical process. This fact is borne out in the observation that recent technological advances in polymer characterization focus not only on the analytical characterization of a test sample but also on the method of generation of that sample. Innovation in sample preparation is driven both by scientific considerations [the difficulty, but necessity, of isolating the analytes of interest (additives) from the sample matrix (bulk polymer) in such a way that the additives are not impacted by the process (e.g., Ref.[52])] and by practical considerations associated with all analytical chemistry (e.g., time and cost efficiency). While it is beyond the

Table 3 Examples of HPLC methods (UV detection) used to identify and/or quantify packaging system additives.

Material	Additive(s)	Sample preparation	Column	Mobile phase	λ (nm)	Other	Refs.
PE	Dicumyl peroxide, Santonox®	Extract with methanol, concentrate (evaporative)	Lichrosorb RP 18, 250 × 4.6 mm, 10 μm	Methanol/water, 80/20	254	1 ml/min	[1]
PVC	Di-(2-ethylhexyl) phthalate (DEHP), epoxidized linseed oil, tris (nonyphenyl) phosphite (TNPP)	Dissolve in tetrahydrofuran (THF), precipitate polymer with methanol, dry and dissolve residue	μPorasil C_{18}	Carbon tetrachloride-dicloromethane (65/35)	280	1 ml/min	[2]
LDPE, PP	BHT, Cyasorb 531, Tinuvin 327, Irganox 1076	Reflux with CCl_4 or THF, filter, concentrate	μBondapak C_{18}, 60 × 0.39 cm	Methanol/water/THF, 63/7/30	254	2 ml/min	[3]
LDPE, HDPE	Tinuvin P, BHT, BEHB, Oleamide, Cyasorb UV 531, Isonox 129, AM340, Irganox 1010, Irganox 3114, Erucamide	Soxhlet, ultrasonic or microwave extraction with various solvent systems	Nova-Pak C_{18}, 150 × 3.9 mm, 4 μm	A = water; B = acetonitrile; 3/2 initial, linear gradient to 100% B in 5 min	200	1.5 ml/min, $T = 50°C$	[4]
PP	Irgafos 168, Irganox 1076, Irganox 3114, Irganox 1010, Tinuvin P, Irgafos PEP-Q	Microwave extraction with 98/2 methylene chloride/2-propanol	Nova-Pak silica (150 × 3.9 mm, 4 μm) or resolve silica (150 × 3.9 mm, 5 μm)	70/30 *n*-butyl chloride/ methylene chloride	225	1.5 ml/min, $T = 30°C$	[4]
Polyolefin	Irganox (245, 259, 565, 1010, 1035, 3114); Tinuvin (P, 234, 320, 326, 327, 328)	N/A[a]	Capcell Pak C_{18}, 250 × 4.6 mm	Methanol/water mixtures (95/5, 90/10, 88/12, 85/15)	multiple	1 ml/min, $T = 45°C$, 20 μl	[5]
Polyolefin	BHT, BHA, Irganox 1010, Irganox 565, Tinuvin 327, Tinuvin P	N/A[a]	Licrosphere 100 RP 18, 250 × 4.6 mm, 5 μm	Various binary and tertiary mixtures of methanol, water, and acetonitrile	multiple	20 μl	[6]
General	BHT, Irganox antioxidants (245, 259, 565, 1010, 1035, 1076, 1098, 1222, 1330, etc.); UV absorbers (Tinuvin P, 312, 320, 327, 328, etc.)	N/A[a]	Ultrabase UB225, 250 × 4.6 mm, 5 μm; LiChrospher 100 RP 18e, 250 × 4.6 mm, 5 μm; Spheri 5-ODS, 250 × 4.6 mm, 5 μm	Quaternary gradient of THF, water, methanol, acetonitrile	Multiple wavelength UV and laser light-scattering[b]	1 ml/min, 20 μl, ambient temperature	[7][c]
General	BHT, BHA	N/A[a]	Whatman Partisil PXS 10/25 ODS-2	0.05 *M* $LiClO_4$ in 85% methanol	UV-electrochemical fluorescence	1 ml/min, 20 μl, $T = 40°C$	[8][d]

Table 3 Examples of HPLC methods (UV detection) used to identify and/or quantify packaging system additives. *(Continued)*

Material	Additive(s)	Sample preparation	Column	Mobile phase	λ (nm)	Other	Refs.
PP, ABS	Numerous[e]	Dissolve in $MeCl_2$, precipitate polymer with methanol	Spherisorb S30DS2, 150 × 4.6 mm, 3 μm	A = Acetonitrile; B = water; Initial = 40% A, ramped to 100% A in 15 min, maintained at 100% for 17 min	210, 280	1 ml/min (2 ml/min after 22 min); 10 μl	[9]
PE	Topanol OC; Cyasorb UV 531; Irganox 1010, 1076, 1330	SFE contrasted to Soxhlet extraction with dichloromethane	Kaseisorb ODS-5, 550 × 0.53 mm	Methanol	254 nm	Column pressure = 100 atm	[54]
PP	Irganox 1010, Irgafos 168	SFE	Licrosorb RP-18, 200 × 4.6 mm, 5 μm	Gradient from methanol/water (95/5) to 100% methanol in 17 min	280 nm	1.5 ml/min, 20 μl	[11]
Polyolefin	Irganox PS802, 1010, 1076, 1425; calcium stearate; sodium benzoate	Microwave-assisted solvent extraction	Various; e.g., Microsper C_{18}, 250 × 4.6 mm, 5 μm	Water/acetonitrile/*iso*-propanol; Start = 12/88/0; 0.1 min = 5/65/30; 10 min = 0/65/30; 18 min = 0/65/30	273 nm, light scattering	2 ml/min, 10 μl, $T = 50°C$	[12]
PMMA	Irganox 1010, 1076; Irgafos 168	SFE	Nova-Pak C_{18}, 5 μm	Acetonitrile/water gradient; start at 80/20, change to 100/0 in 5 min	254 nm	50 μl	[13]
Dielectric resins	BAC-E, bis-A-bis-azide	Dissolution in THF	Zorbax RX C8, 100 × 4.5 mm, 5 μm[f]	A = 50/50 acetonitrile/water; B = 90/10 mixture. Gradient was start ramp form 0% A to 100% B in 5 min, hold at 100% B for 5 min	254 nm (380 nm for internal standard)	3 ml/min	[14]

ABS = acrylonitrile–butadiene–styerene; HDPE = high-densitypolyethylene; LDPE = low-density polyethylene; PC = polycarbonate; PE = polyethylene; PMMA = polymethylmethacrylate; PP = polypropylene; PS = polystyrene; PVC = polyvinyl chloride.

[a]This reference examined the elution characteristics of the cited additives as a function of mobile phase and, thus, did not characterize actual polymers.

[b]These authors report that the UV response for the analytes is typically 5 to 50 times greater than the light-scattering response.

[c]Numerous other examples of separations provided.

[d]For BHA, the sensitivity was EC > UV (230 nm) > Fl. For BHT, the sensitivity was UV (280 nm) > EC > Fl.

[e]This study examined the elution characteristics, sensitivity, and analytical recoveries of over 25 additives.

[f]Preanalytical column sample cleanup was achieved online by SEC. This preanalytical processing was accomplished with a 25 cm × 250 μm I.D. fused silica capillary column (PL-Gel 50 Å, 5 μm) and a THF mobile phase at 1.3 μl/min.

Table 4 Examples of HPLC methods [infrared (IR) detection] used to identify and/or quantify packaging system additives.

Material	Additive(s)	Sample preparation	Column	Mobile phase	λ (nm)	Other	Refs.
Polyurethane	Irganox 1010	Extraction with *n*-hexane	μ-Porasil C_{18}	*n*-hexane/ dichloromethane, 80/20	254[a]	1 ml/min	[15]
PVC, PP, PE	Ionol 220, Irganox 1076, Tinuvin 327, Tinuvin 328, Cyasorb UV 531	Extraction with acetonitrile or methanol, evaporative concentration	RP: Spherisorb ODS-2, 100 × 1.0 mm, 3 μm; SEC: PL-Gel, 250 × 4.6 mm, 5 μm, 500 Å	RP = methanol/ water (95./5); SEC = Dicloromethane	280[b]	0.1–0.2 ml/min	[16]
PP	Irganox 1010, 3114; Tinuvin 326, 327	N/A[c]	Zorbax ODS, 250 × 4.6 mm		N/A[d]	0.5 ml/min, 20 μl	[17]
PP, PE	Irganox 245, 259, 1010, 1076, 1098, 3114; Irgafos 168; Tinuvin 234, 327, 328, 350; Sanowhite, Ethanox 330; Lowinox 22M46; Kemamide U; Naugard; BHT; Ultranox 626; Cyasorb 2908; Cyasorb UV 531	N/A[c]	Sperisorb ODS-2, 250 × 4.6 mm, 5 μm	Several cited[e]	280 nm and evaporative light scattering[f]	1 ml/min, 50 μl, ambient temperature	[18][g]

PE = polyethylene; PP = polypropylene; PVC = polyvinyl chloride.

[a]Peak collected on potassium bromide powder and an IR spectrum obtained off-line.

[b]Online Fourier transform infrared spectroscopy (FTIR) with spray-jet interface, deposition on a moving zinc selenide substrate. UV for quantitation, IR for identification.

[c]This reference examined the detection characteristics of the cited additives and, thus, did not characterize actual polymers.

[d]Used surface-enhanced infrared spectroscopy with effluent deposition on an Ag metal film (BaF_2 substrate). Reported a detection limit of 10 ng.

[e]Several separations are cited in this manuscript. A gradient using methanol and water was used for the separation of nine additives. Initial composition, 94/6 methanol/water for 7 min, change immediately to 100% methanol, hold for 14 min.

[f]Portion of column effluent deposited on a rotating germanium disk via drying nebulization.

[g]Detection limits by IR were generally near 0.2 μg, with quantities needed for accurate identification in the 0.5–1.0 μg range.

Table 5 Examples of HPLC methods (MS detection) used to identify and/or quantify packaging system additives.

Material	Additive(s)	Sample preparation	Column	Mobile phase	Detection	Other	Refs.
General(PP)	BHT, Irganox 1010, Irganox 1076, Irganox 1330, Santowhite	N/A[a]	ODS, 250 × 2.1 mm, 5 μm	A = 75/25 acetonitrile/water; B = 50/50 THF/ acetonitrile; 0 min = 100% A, 10 min = 60% A, 20 min = 100% B, 30 min = 100% B, 32 min = 100% A	UV, 280 nm. Moving belt MS interface, chemical ionization (CI) and electron input ionization (EI) spectra obtained	0.2 ml/ min, 10 μl	[19]
PVC	Mono-alkyl esters and di-alkyl phthalates	N/A[a]	Symmetry C-8, 150 × 3.9 mm, 5 μm	A = 0.1 *M* ammonium acetate in 10/90 methanol/ water; B = 0.1 *M* ammonium acetate in methanol 0% to 100% B over 25 min, hold for 5 min	UV, 277 nm. Thermospray MS, + ions	1 ml/ min	[20]
PP	NC-4, Naugard-XL, Irganox 1076	Extract with acetonitrile at 60°C for 72 hr	Symmetry C8, 150 × 3.9 mm, 3 μm	A = acetonitrile; B = water; 0 = 30% A, 10 min = 100% A, 30 min = 30% A, 40 min = 30% A	Multiple λ UV. MS = EI and atmospheric pressure chemical ionization (APCI) [positive ion, single ion monitoring (SIM)]		[21]
PP	Irganox 245, BHA, BHT, Bispenol A, Topanol CA	N/A	Hypersil H5ODS, 100 × 4.6 mm, 5 μm	80/20 deuterated acetonitile/water	UV, IR, MS, nuclear magnetic resonance (NMR)[b]	1 ml/ min	[21]

PP = polypropylene; PVC = polyvinyl chloride.

[a]This reference examined the elution characteristics of the cited additives as a function of mobile phase and thus did not characterize actual polymers.

[b]The column effluent was split after the column (95/5) between the FTIR flowcell [attenuated total reflection (ATR) used] and the MS detector (single quad, positive ions). The effluent from the FTIR cell was directed through the UV and ultimately nmR detectors.

Table 6 Examples of SFC methods used to identify and/or quantify packaging system additives.

Material	Additive(s)	Sample preparation	Column	Mobile phase	Detection	Other	Refs.
General (PE)	Numerous[a]	N/A[b]; SFE	C_{18}, 250 × 4.6 mm	CO_2 with methanol modifier; 2% methanol for 1 min, linear to 10% after 10 min, hold for 5 min	APCI-MS (+ and − ionization), UV	2 ml/min, 10 μl	[22][c]
PE	BHT, Tinuvin 326	SFE with various traps	Fused silica capillary (10 m × 0.1 mm I.D.) with octyl phase, 0.5 μm film	CO_2, pressure program (100 atm for 10 min, increased at 5 atm/min for 20 min)	FID	Column $T = 90°C$	[23]
Polyolefin (PP, PE)	BHT; Irganox PS800, PS802, 1010, 1076, 1330, 2246; Tinuvin P, 320, 326; Irgafos 168; Atmos 150	Soxhlet extraction with chloroform	Fused silica capillary (10 m × 0.05 mm I.D.) with 5% phenyl-polymethylsiloxane, 0.4 μm film	Various pressure and temperature programs with CO_2 were reported	MS, EI	1 μl injection	[5,24][d,e]
PP	Numerous[f]	Soxhlet extraction with diethyl ether for 15 hr, precipitate polymer with ethanol	Fused silica capillary (15 m × 0.1 mm I.D.) with 5% phenyl-polymethylsiloxane, 0.5 μm film	CO_2 at 140°C; pressure = 150 atm for 12 min, ramp to 350 atm at 3 atm/min	FID, FTIR microscope	2 μl split injection, $T = 150°C$	[26]
PE	BHT, Irganox 1010, Irgafos 168	SFE (contrasted to Soxhlet extraction)	Fused silica capillary (15 m × 0.1 mm I.D.) with SB-Biphenyl-30, 0.5 μm film	CO_2 at 140°C; pressure = 100 atm, ramp to 200 atm at 3 atm/min, ramp at 10 atm/min to 400 atm	IR (flow through cell)	—	[27]
General	Tinuvin P, 326, 234, 770; Chimasorb 81, Irganox 1010, 1076, 1330; Irgafos 168, Irgafos P-EPQ, *N*,*N*-bis (2-hydroxyethyl) alkyl-amine	N/A[b]	Fused silica capillary (20 m × 0.1 mm I.D.) with DB-5, 0.4 μm film	CO_2; pressure = 10.6 MPa for 10 min, ramp to 15 MPa in 3.5 min, hold for 5 min; ramp at 0.5 MPa/min to 35 MPa, hold for 10 min	FID and MS (EI, 70 eV)	2 ml/min, $T = 140°C$	[10]

(Continued)

Table 6 Examples of SFC methods used to identify and/or quantify packaging system additives. *(Continued)*

Material	Additive(s)	Sample preparation	Column	Mobile phase	Detection	Other	Refs.
LDPE	BHT, BHEB, Isonox 129, Irganox 1010, 1076	Online SFE	Deltabond cyano, 100 × 1.0 mm I.D., 5 μm	100 atm for 3 min, 100–330 atm for 7 min, 330–450 atm for 1.5 min	FID	Column $T = 100°C$	[28][g]
Polyurethane	BHT, Irganox 1010, Irganox 1076, dinonyl phthalate[h]	Online SFE	30% biphenyl polysiloxane, 10 m × 50 μm I.D., 0.25 μm film	CO_2; hold at 100 atm for 5 min, ramp at 5 atm/min to 300 atm, ramp at 20 atm/min to 400 atm	MS (EI)	Column $T = 100°C$	[29]
Nylon, polystyrene	Caprolactam and oligomers, stearic acid, Irganox 1076	Online SFE	Deltabond cyano, 100 cm × 1 mm, 5 μm	CO_2; hold at 100 atm for 2 min, ramp at 15 atm/min	FTIR	Column $T = 100°C$	[30]
PE, PP	BHT; Erucamide; Irgafos 168, Irganox 1010, 1076; Tinuvin 326, 770; Isonox 19; DLTDP	Online SFE	Deltabond 300 Octyl, 250 cm × 1 mm	CO_2; hold at 1500 psi for 6 min, ramp at 200 psi/min to 6000 psi	FID	FID $T = 350°C$; Column $T = 150°C$	[30]

LDPE = low-density polyethylene; PE = polyethylene; PP = polypropylene.
[a]Additives examined included: BHT; Irganox 245, 1010, 1035, 1076, 1330, 1425, PS802; Irgafos 168; Tinuvin 327, 328, 384 440, 622, 770, 1130; Topanol CA; Cyasorb UV1164; Oleamide; Erucamide; Synprolam; Chimassorb 944.
[b]This reference examined the elution characteristics of the cited additives as a function of mobile phase and, thus, did not characterize actual polymers.
[c]This reference provides elution characteristics and relative intensities for specific positive and negative ions.
[d]The performance of the SFC method was compared to that of an isocratic reversed-phase (RP)-HPLC method (UV detection).
[e]GC/MS was also used for compound identification.
[f]Additives included: Topanol OC; Tinuvin P, 292, 320, 326, 328, 770, 440, 144; Chimassorb 81; Erucamide; Irganox PS800, PS802, 245, 1010, 1035; MD1025, 1076, 1330, 3114.
[g]The SFE extraction was also coupled with HPLC separation and detection of the analytes.
[h]This method produced other additive peaks whose parent compound could not be identified.

Table 7 Examples of SEC/GPC methods used to identify and/or quantify packaging system additives.

Material	Additive(s)	Sample preparation	Column	Mobile phase	Detection	Other	Refs.
PP	General[a]	Extraction with THF	Porogel A-1 (slurry-packed)	THF	Refractive index (RI) (collected fraction tested via IR for identification)	2 ml/min, column $T = 30°C$	[32]
PS, PVC	Tinuvin P, TNPP, TETO	Solvent extraction	500, 100 and 50 Å PL-Gel (poly (styrene-divinylbenzene) 30 × 0.77 cm, 10 μm	THF	UV	2 ml/min, column $T = 30°C$	[33]
Polyolefin (PP, PE)	BHT; Cyasorb UV 9; Cyasorb UV 1084; Tinuvin 326, 327; Irganox 1076	General[b]	SEC (PL-Gel, 50 Å, 300 × 7.5 mm) coupled with normal phase (Nucleosil 100-7 OH, 250 × 4.6 mm, 7 μm)	*n*-hexane/ dichloromethane (73/27)	UV at 254 and 280 nm	0.9 ml/min, column $T = 35°C$	[34]
Polyolefin copolymers	Numerous[c]	Dissolution in THF	SEC (Uktrastyragel 10^4, 50 Å, 300 × 0.25 mm, 10 μm) coupled with GC (DB-1, 15 m × 0.32 mm I.D., 0.25 μm film)	SEC; THF mobile phase. GC; 100°C for 6 min, ramp at 16°C/min to 350°C	UV at 254 nm for SEC, MS (EI) for GC	For SEC: 3.0 μl/min, 0.2 ml injected	[35]

PE = polyethylene; PP = polypropylene; PS = polystyrene; PVC = polyvinyl chloride.

[a]This reference generated additive profiles for various test materials but did not specify the individual additives found.

[b]This reference examined the chromatographic characteristics of the cited additives as a function of mobile phase and, thus, did not characterize actual polymers.

[c]This reference documented chromatographic characteristics for many individual additives including plasticizers (phthalates, Citroflex A-4, TNPP); amides; Irganox and Irgafos antioxidants; UV absorbers (Tinuvin, Cyansorb); fatty acids (palmitic, stearic); Naugard XL-1; etc.

Table 8 Examples of TLC methods used to identify and/or quantify packaging system additives.

Material	Additive(s)	Sample preparation	Plate	Mobile phase	Detection	Other	Refs.
Rubber	Numerous[a]	N/A[b]	Silica gel G, thickness of 250–300 μm	Numerous solvent systems examined vs. compound class	Various UV and visible developing reagents	Sample size: 3–5 μl	[36]
Polyolefin	Tinuvin 144, 770; Hostavin TMN 20	Extraction with chloroform, polymer precipitation, evaporative concentration	Alumina F254, 20 × 20 cm plate, 0.25 mm thickness	88/12, *n*-hexane/ *iso*-propanol	Chlorination with chlorine gas, sprayed with potassium iodide starch solution	Sample size: 10 μl	[37]
Elastomers	BHT, Cyanox 2246, Cyanox 425, Permanax WSP, Naugawhite, Wingstay T, Naugard SP, Vulkanox CS	Soxhlet extraction with acetone, evaporative concentration	Merck 11845 silica gel	Benzene	Sprayed with 2.34% sodium tetraborate, 0.33% sodium hydroxide, and 0.1% methanolic solution of *N*-chlorodichloro-2,6-*p*-benzoquinone monoimine	Sample size: 20 μl	[38]
PP, PVC	Irganox 1010, Tinuvin 770, Chimassorb 119 FL, DEHP	N/A[b]	Silica gel 60 F254, 5 × 10 cm plate, 250 μm thickness	Toluene-diethyl ether (10/1) on first plate, acetone-formic acid (4/6) on second plate	UV for plate 1, plate 2 visualized by iodine vapor. Spots removed from plate 2 and analyzed by FTIR	Sample size: 2 μl	[39]

PP = polypropylene; PVC = polyvinyl chloride.
[a]This reference documents the chromatographic properties of over 100 rubber-related amine and phenolic antioxidants, antiozonants, guanidines, accelerators, and amine hydrochlorides.
[b]This reference examined the chromatographic characteristics of the cited additives and, thus, did not characterize actual polymers.

Table 9 Examples of GC methods used to identify and/or quantify packaging system additives.

Material	Additives	Sample preparation	Column	Oven program	Detection	Other	Refs.
PET	Diethylene glycol	High temperature and pressure extraction with water	Numerous[a]	Isothermal at 180°C	FID and thermal conductivity detector (TCD)	Injector $T = 260$°C; detector $T = 270$°C; He carrier at 50 ml/min	[40]
PET	BHET, EG, DEG, TA, MHET[b]	N/A;[c] samples TMS derivatized with BSFTA (80°C for 10 min)	3% OV101 on 80–100 mesh Chromosorb W, 6 ft, 0.125 in. o.d., 0.05 in. I.D.	80°C for 3 min, ramp at 15°C/min to 265°C	FID	Injector $T = 270$°C; detector $T = 280$°C; He carrier at 50 ml/min, 2 μl injection	[41]
Elastomers	Various antioxidants and additives	N/A[c]	3% SP2100 on 80–100 mesh Supelcoport	150°C for 2 min, ramp at 10°C/min to 250°C	MS	Injector $T = 270$°C; He carrier at 35 ml/min	[42]
Polyolefins	BHT; Irganox 1010, 1076, 2246; Irgafos 168, Santowhite	Refluxed in acetone for 2–3 hr, evaporated to dryness and dissolved in chloroform	PS264, 15 m × 0.32 mm I.D., 0.15 μm film	90°C to 280°C at 5°C/min	FID	Detector $T = 300$°C; He carrier at inlet pressure of 0.5 kg/cm^2	[43]
PVC	Benzoflex 2860, ATBC, DEHA[d]	SFE	SPB-5 fused silica capillary, 30 m × 0.25 mm I.D., 0.25 μm film	110°C to 260°C at 10°C/min	FID	Detector, injector $T = 300$°C; He carrier at 50 cm/sec, 1 μl splitless	[44]
Polyolefins	Numerous[e]	Reflux with chloroform, evaporative concentration	HR-1701 (14% cyanopropylphenylmethyl-siloxane) fused silica capillary, 15 m × 0.53 mm I.D., 1.0 μm film	100°C for 2 min, 20°C/min to 210°C, 1.5°C/min to 222°C 8°C/min to 350°C, hold for 10 min	FID	Injector and detector $T = 350$°C; He carrier at 5 ml/min, 1 μl splitless injection	[45]
Petroleum resin	Numerous[e]	Dissolve in *n*-hexane, cleanup with silica column	DB-1701 (14% cyanopropylphenylmethyl-siloxane) fused silica capillary, 15 m × 0.53 mm I.D., 1.0 μm film	150°C for 2 min, 20°C/min to 210°C, 1.5°C/min to 222°C, 8°C/min to 350°C, hold for 10 min	FID	Injector and detector $T = 300$°C; He carrier at 5 ml/min, 2 μl split injection (1:100 ratio)	[45]
PE	Numerous[f]	Dissolution	UA-1 HT (dimethylpolysiloxane) fused silica capillary, 30 m × 0.25 mm I.D., 0.1 μm film	Start at 50°C, ramp at 20°C/min to 300°C, hold for 10 min	MS, EI, 70 eV, 40–700 *m/z*	Injector $T = 250$°C; He carrier at 1 psi, 1 μl split injection (1/2 ratio)	[46]

PE = polyethylene; PET = polyethylene terephthalate; PVC = polyvinyl chloride.

[a]Columns used included: Carbowax 20M, Chromosorb W-HMDS, Aeropak Number 30, 10 ft × 1/8 in. × 0.055 in. I.D.

[b]BHET = bis (2-hydroxyethyl) terephthalate; EG = ethylene glycol; DEG = diethylene glycol; TA = terephthalic acid; MHET = mono-(2-hydroxyethyl)terephthalate.

[c]This reference examined the chromatographic characteristics of the cited additives and, thus, did not characterize actual polymers.

[d]ATBC = *O*-acetly-tri-*n*-butyl citrate; DEHA = di(ethylhexyl) adipate.

[e]Additives chromatographed included antioxidants (BHT; Irganox 1076, 1330; Yoshinow BB, SR, 2246 R; Irgafos 168; Ultranox 626; Topanol CA; DLTDP; DMTDP; DSTDP), light stabilizers (Sanol LS744, LS770; Tinuvin 120, 326, 327; UV 531), and slip agents (palmitic acid amide, oleic amide, stearic acid amide, erucic amide).

[f]This reference included the separation of 53 polymer additives including antioxidants, UV stabilizers, lubricants, and plasticizers. Performance details are provided.

Table 10 Examples of pyrolysis/GC methods used to identify and/or quantify packaging system additives.

Material	Additives	Pyrolysis conditions	Column	Oven program	Detection	Other	Refs.
Polyolefin, PMMA	Hostanox O3; Hostavin N 20; Irganox 3052 FF; Irganox 3114; Tinuvin 320, 329, 350	100 μg sample at 550°C	RTX-5 fused silica capillary, 60 m × 0.32 mm I.D., 0.5 μm film	60° to 300°C at 7°C/min	MS (EI, 45–700 mass range)	Injector $T = 260$°C; detector $T = 270$°C; He carrier at 50 ml/min	[47]
PVC Cellulose Copolymer[c] PS/PC blend PU	DEHP Dioctyl adipate Dibutyl sebacate, tributyl acetylcitrate TPP Mixture of didecyl phthalate esters	0.5 mg sample at 700°C	DB-5 fused silica capillary, 30 m × 0.25 mm I.D., 1.0 μm film	40°C for 4 min, ramp at 10°C/min to 320°C, hold for 18 min	MS (EI, 15–650 mass range)	Injector $T = 300$°C; detector $T = 300$°C; 30/1 injection split	[48][a,b]
Epoxy resin[d] Poly-(diallyl-phthalate) ABS	Brominated bisphenol A Dechlorane Plus Octabromodiphenyl oxide	0.5 mg sample at 950°C	DB-5 fused silica capillary, 30 m × 0.25 mm I.D., 1.0 μm film	40°C for 4 min, ramp at 10°C/min to 320°C, hold for 18 min	MS (EI, 15–650 mass range)	Injector $T = 300$°C; detector $T = 300$°C; 30/1 injection split	[49][a,e]
PC-ABS blend	Brominated phenol, triphenyl phosphate						
General	Various waxes, stearic acid, butyl stearate, zinc stearate, butyl oleate, butyl palmitate, stearamide, AcraWax C	0.5 mg sample at 950°C	DB-5 fused silica capillary, 30 m × 0.25 mm I.D., 1.0 μm film	40°C for 4 min, ramp at 10°C/min to 320°C, hold for 18 min	MS (EI, 15–650 mass range)	Injector $T = 300$°C; detector $T = 300$°C; 30/1 injection split	[50][a,f]
General	Irganox 565, 1010; MD1024, 1035, 1076, 1425, 3114; Irgafos 168	0.5 mg sample at 950°C	DB-5 fused silica capillary, 30 m × 0.25 mm I.D., 1.0 μm film	40°C for 4 min, ramp at 10°C/min to 320°C, hold for 18 min	MS (EI, 15–650 mass range)	Injector $T = 300$°C; detector $T = 300$°C; 30/1 injection split	[51][a,g]

ABS = acrylonitrile–butadiene–styerene; PC = polycarbonate; PMMA = polymethylmethacrylate; PS = polystyrene; PU = polyurethane; PVC = polyvinyl chloride.
[a]A more rapid oven program was also used to produce pyrograms via FID detection.
[b]This manuscript deals with plasticizers as a class of additives.
[c]Vinyl chloride–vinylidene chloride copolymer.
[d]Cross-linked epoxy resin (thermoset of bisphenol A diglycidyl ether).
[e]This manuscript deals with flame retardants as a class of additives.
[f]This manuscript deals with lubricants as a class of additives.
[g]This manuscript deals with antioxidants as a class of additives.

Table 11 Solubility of polymers.

Polymer	Soluble in
Alkyd resin	Chlorinated hydrocarbons, lower alcohols, esters
Acrylonitrile-butadiene-styrene terepolymer	Methylene chloride
Polyacrylamide	Water
Polyamides	Phenols, *m*-cresol, concentrated mineral acids, formic acid
Polycarbonate	Ethanolamine, dioxane, chlorinated hydrocarbons, cyclohexanone
Polyethylene	Dichlorobenzene, pentachloroethylene, dichloroethylene, tetralin
Poly (ethylene terephthalate)	Cresol, concentrated sulfuric acid, chlorophenol, trichloroacetic acid
Polyformaldehyde	Dichlorobenzene, DMF, chlorophenol, benzyl alcohol
Polystyrene	Aromatic and chlorinated hydrocarbons, pyridine, ethyl acetate, dioxane, chloroform, acetone
Polytetrafluoroethylene	Fluorocarbon oil
Polyurethanes	Dioxane, THF, DMF, dimethylsulfoxide (DMSO), *m*-cresol, formic acid, 60% sulfuric acid
Poly (vinyl chloride)	Cyclohexanone, THF, dimethylformamide (DMF), ethylene dichloride
Poly (vinylidene chloride)	THF, ketones, DMF, chlorobenzene
Vinyl chloride–vinyl acetate copolymers	Methylene chloride, THF, cyclohexanone

scope of this manuscript to exhaustively discuss sample preparation strategies for polymer characterization, this general information is provided to facilitate an important step of the overall analytical process. In terms of specific sample preparation methods, Nerin et al.[53] have recently provided a review of sample treatment techniques applicable to polymer extract analysis including headspace methods, supercritical fluid extraction, and solid-phase microextraction. In terms of general knowledge, Table 11 provides solubility information relevant to polymer dissolution.

Organic Solvents: Classification for CE

Ernst Kenndler
Institute for Analytical Chemistry, University of Vienna, Vienna, Austria

INTRODUCTION

In capillary electrophoresis (CE), several criteria can be applied to classify solvents [e.g., for practical purposes based on the solution ability for analytes, on ultraviolet (UV) absorbance (for suitability to the UV detector), toxicity, etc.]. Another parameter could be the viscosity of the solvent, a property that influences the mobilities of analytes and that of the electro-osmotic flow (EOF) and restricts handling of the background electrolyte (BGE). For more fundamental reasons, the dielectric constant (the relative permittivity) is a well-recognized parameter for classification. It was initially considered to interpret the change of ionization constants of acids and bases according to Born's approach. This approach has lost importance in this respect because it is based on too simple assumptions limited to electrostatic interactions. Indeed, a more appropriate concept reflects solvation effects, the ability for H-bonding, or the acido-base property of the solvent.

CLASSIFICATION OF SOLVENTS

A first classification, according to the dielectric constant ϵ (with a somewhat arbitrary value about 20 or 30 to distinguish the two main classes), is still useful, because the dielectric constant reflects the extent of ion association and ion-pairing. In solvents with a high dielectric constant, called polar solvents, ion-pairing is nearly negligible in dilute solutions. Acid strength can be assigned by a numerical value, independent of the base with which it undergoes reaction. Non-polar solvents, on the other hand (i.e., those with low dielectric constant), support ion-pairing, and the acidity is dependent on the choice of the reference base. Further grouping of the solvents is based on their ability for H-bond formation. Note that this scheme disregards the solvents' own acidity or basicity (this criterion is taken for the latter scheme).This is shown in Table 1. A typical H-bonded solvent, termed protic solvents, is water or methanol. Aprotic solvents (although containing H atoms or being able to accept H bonds) lack the ability to donate hydrogen bonds. The lower alcohols (except methanol) are grouped in the class with low ε. They are protic as well (they are able to donate hydrogen bonds), in contrast to the fourth group, where, for example, dioxane and tetrahydrofurane are found.

The solvents can be grouped according to another classification scheme introduced by Brønsted. It has significance for the evaluation of acido-basic equilibria in the particular solvents, especially for the interpretation of the changes of the pK values of weakly acidic (or basic) analytes and their degree of protolysis. Obviously, it is also of main importance for the evaluation of the pH scales in the different solvents or solvent mixtures. It differentiates, mainly, three groups: amphiprotic, dipolar aprotic, and inert solvents. As the first scheme, it also relates to the "polarity" of the solvent (expressible by the dielectric constant, too). *Amphiprotic* solvents have acidic and basic properties as well. These solvents, HS, are able to form lyonium ions, H_2S^+ with the proton, and stable lyate ions, S^-. Examples for *amphiprotic neutral* solvents (with high ε) are water and methanol. In the classification given in Table 1, they belong to the H-bonded solvents.

Amphiprotic protogenic solvents have higher acidic properties, but lower basic ones (always in comparison to

Table 1 Classification of solvents for potential use in CE, according to their dielectric constant, ε, and their ability for H-bond formation.

High ε		Low ε	
H-bonded	**Non-H-bonded**	**H-bonded**	**Non-H-bonded**
Water	Acetonitrile	Ethanol	Acetone
Methanol	*N*,*N*-Dimethylformamide	*n*-Propanol	Dioxane
Ethylene glycol	*N*,*N*-Dimethylacetamide	*i*-Propanol	Tetrahydrofuran
Formamide	Dimethyl sulfoxide	*n*-Butanol	
Acetamide		*tert*-Butanol	
N-Methylformamide			
N-Methylacetamide			

water). Examples are formic and acetic acid. *Amphiprotic protophilic* solvents have lower acidity and higher basicity than water, with formamide or ethanolamine as examples. *Aprotic dipolar* solvents have low acidity and (occasionally) basicity as well, with *N*,*N*-dimethylformamide and dimethylsulfoxide as examples for protophilic dipolar solvents and acetonitrile for a protophobic dipolar solvent.

Solvents with low ε and without the ability to form H bonds are also classified as dipolar aprotic solvents in some cases. Examples are dioxane and tetrahydrofuran, which have e values smaller than 7. They have reduced applicability in CE; however, their aqueous mixtures might be of some interest.

Inert solvents (according to the second classification scheme) have insignificant applicability for CE, as dissociation into free ions is reduced (and solubility of electrolytes is very low). Charged analytes form stable ion pairs there. Examples are the halogenated or aliphatic and aromatic hydrocarbons (e.g., octane, benzene).

Organic Solvents: Effect on Ion Mobility

Ernst Kenndler
Institute for Analytical Chemistry, University of Vienna, Vienna, Austria

INTRODUCTION

The ionic mobility, μ_i, of a species, i, is the velocity, v of a particle that moves under the influence of an electric field, E, of unit strength:

$$\mu_i = \frac{\nu_i}{E} \tag{1}$$

The dimension of the mobility is square meter per volt per second. The values of the mobilities range from more than 300 units for the proton in water to about 5 units for large organic ions in solvents with high viscosities. The mobility depends on the size and shape of the solvated ion, on its charge, and on the viscosity and temperature of the solution. Thus, it is clear that the mobility is a function of the solvent.

Three kinds of mobility can be distinguished: the absolute mobility, μ^0 in an infinitely diluted solution, the actual mobility of the fully charged ion at the ionic strength, I, of the solution, and the effective mobility, μ^{eff}, which depends on the degree of ionization, α.

IONIC MOBILITIES OF WEAK ELECTROLYTES

For higher ionic strengths, no quantitative theoretical description of the dependence of the mobility on the ionic strength exists. Even for lower ionic strengths, theory is directed, rather, to spherical ions of 1:1 electrolytes with low charge (Debye–Hückel–Onsager theory, see below) than to multiple charged ions with irregular geometry. An expression derived empirically relates the logarithm of the correction factor for the mobility on the square root of the ionic strength and the charge number of the analyte.

The degree of dissociation, on the other hand, depends, in a well-defined manner, on the pK of the analyte and the pH of the solution, according to the Henderson–Hasselbalch equation. α, is a function of pK_a and pH: for example, for monobasic neutral acids

$$\alpha = \frac{1}{1 + 10^{\text{p}K_a - \text{pH}}} \tag{2}$$

For this type of acid, the total mobility can be expressed as

$$\mu_i^{tot} = \mu_i^{eff} + \mu_{EOF} = \frac{\mu_i^0 f}{1 + 10^{\text{p}K_{a,i} - \text{pH}}} + \mu_{EOF} \tag{3}$$

Here, μ_i^0 is the absolute mobility, that of the ion at infinite dilution, f is the correction factor that takes into account the deviation from ideal behavior. It can be seen that an additional parameter occurs in this equation: the mobility of the electro-osmotic flow (EOF), μ_{EOF}, which occurs in many cases in the separation systems and leads to an additional velocity vector of the solutes.

INFLUENCE OF ORGANIC SOLVENTS

Eq. 3 is the key expression that enables understanding of the influence of the solvent on the mobility. From this expression, it follows that solvents may affect the following:

- the absolute mobility
- the correction factor, f
- the ionization constants, K_a, of the analytes and the buffering electrolytes
- the mobility of the EOF

Absolute Mobility

A first approach to take into account the solvent's effect on the absolute mobility of an ion was made by Walden. It is based on the Stokes' law of frictional resistance. Walden's rule states that the product of absolute mobility and solvent viscosity is constant. It is clear that the serious limitation of this model is that it does not consider specific solvation effects, because it is based on the *sphere-in-continuum* model. However, it delivers an appropriate explanation for the fact that, within a given solvent, the mobility depends on temperature to the same extent as the viscosity (in water, for example, the mobility increases by about 2.5% per degree Kelvin).The mobilities do not deviate too much from Walden's rule in some binary mixtures of water with organic solvents. This model is, on the other hand, not appropriate for forecasting or explaining the effect of the solvent on the mobility in a more general manner (see Table 1).

Table 1 Absolute mobilities and walden products of some anions in pure solvents.

	Water		Methanol		Acetonitrile	
Ion	μ_{abs}	$\eta\lambda^0$	μ_{abs}	$\eta\lambda^0$	μ_{abs}	$\eta\lambda^0$
Li^+	40.0	0.34	41.0	0.22	071.8	0.24
K^+	76.2	0.65	54.5	0.29	086.6	0.29
$(CH_3)_4N^+$	46.5	0.40	71.2	0.33	098.0	0.33
$(C_4H_9)_4N^+$	20.2	0.17	40.4	0.21	063.6	0.21
Cl^-	79.2	0.68	54.3	0.28	092.2	0.31
J^-	79.6	0.68	65.1	0.34	105.7	0.35
CH_3COO^-	42.4	0.36	40.8	0.21	110.9	0.37

Note: μ_{abs} is measured in 10^{-5} cm^2/Vs; $\eta\lambda^0$ is measured in $Pcm^2/\Omega mol$ where λ^0 is the single ion conductance at infinite dilution.

Taking specific solvation effects into account makes it clear that the hydrodynamic radius, r_h, of an ion depends on the solvent, due to the different solvation shell established:

$$r_{h,i} = \frac{z_i e_0}{6_{\pi\eta\mu_i}} \tag{4}$$

where e_0 is the electron charge and z_i is the charge number. This expression is valid for a spherical ion. It is obvious that by a simple geometrical argument, this radius changes for an ion with crystal radius, r_{cryst} according to solvation by n_h molecules of solvent, S, with radius, r_s, in the solvation shell:

$$r_h^3 = r_{cryst}^3 + n_h r_S^3 \tag{5}$$

Because n_h and r_S may change, the hydrodynamic radius and, therefore, the absolute mobility change as well.

Correction Factor

The correction factor, f, relates the actual mobility of a fully charged particle at the ionic strength under the experimental conditions to the absolute mobility. It takes ionic interactions into account and is derived for not-too-concentrated solutions by the theory of Debye–Hückel–Onsager using the model of an ionic cloud around a given central ion. It depends, in a complex way on the mean ionic activity coefficient. The resulting equation contains the solvent viscosity and dielectric constant in the denominator. In all cases, the factor is <1. The actual mobility is always smaller than the absolute mobility.

Ionization Constant

Organic solvents influence the ionization constants of weak acids or bases in several ways (note that they in-fluence the analytes and the buffer as well). Concerning ionization equilibria, an important solvent property is the basicity (in comparison to water), which reflects the interaction with the proton. From the most common solvents, the lower alcohols and acetonitrile are less basic than water. Dimethyl sulfoxide is clearly more basic. However, stabilization of all particles involved in the acido-basic equilibrium is decisive for the pK_a shift as well. For neutral acids of type HA, the particles are the free, molecular acid, and the anion, A^-. In the equilibrium of bases, B, stabilization of B and its conjugated acid, HB^+, takes place. As most solvents have a lower stabilization ability toward anions (compared to water), they shift the pK_a values of acids of type HA to higher values in general. No such clear direction of the change is found for the pK_a values of bases; however, they undergo less pronounced shifts.

Mobility of the EOF

According to the Smoluchowsky equation, the mobility of the EOF is

$$\mu_{EOF} = \frac{\varepsilon\varepsilon_o\zeta}{\eta} \tag{6}$$

where ε and ε_0 are the permittivity of the medium and the vacuum, respectively, η is the solvent viscosity, and ζ is the zeta potential of the electric double layer. Roughly, the mobility of the EOF should depend on the ratio of relative permittivity to viscosity of the solvent and on the conditions of the electric double layer of the surface of the capillary in capillary electrophoresis (CE). As in most cases, fused-silica capillaries are used in CE, and its ζ potential is a function of the buffer pH, because the silanol groups at the surface are weak acids, with pK values around 5–6. It follows that the solvent affects the pK of the silanol as well, in a manner similar to that for the ionization constants of the analytes and the buffers. Nearly all solvents shift the pK values of the silanol groups toward a higher, pure acetonitrile and to even to very high values.

Organic Solvents: Influence on pKa

Ernst Kenndler
Institute for Analytical Chemistry, University of Vienna, Vienna, Austria

INTRODUCTION

The influence of solvents on the ionization equilibrium is related to their electrostatic and their solvation properties. The value of the ionization constant of an analyte is closely determined, in practice, by the pH scale in the particular solvent. It is clear that it is most desirable to have a universal scale which is able to describe acidity (and basicity) in a way that is generally valid for all solvents. It is, in principle, not the definition of an acidity scale in theory which complicates the problem; it is the difficulty of approximating the measured values in practice to the specifications of the definition. The pH scale, as is common in water, is applicable only to some organic solvents (i.e., mainly those for which the solvated proton activity is compatible with the Brønsted theory of acidity). The applicability of an analog to the pH scale in water decreases with decreasing relative permittivity of the solvents and with their increasing aprotic character.

A scale that would enable us to compare the acidity in all solvents could be based on the transfer activity coefficient on the proton (see *CE in Nonaqueous Media*, p. 342). The effect of the solvent of any species can be expressed in the same way as for the proton by this concept and applied to all particles involved in the thermodynamic equilibrium.

MEDIUM EFFECT AND IONIZATION CONSTANTS OF WEAK ACIDS AND BASES

The ionization of a weak neutral acid, HA, is described according to

$$HA = H^+ + A^-$$

For the weak base, B, for formal reasons, it is favourably expressed for its conjugated cation acid:

$$HB^+, \text{by } HB^+ = H^+ + B$$

The corresponding changes of the ionization constants of these weak acids can be expressed by the particular transfer activity coefficients, ${}_m\gamma_i$, on the single species, i, according to

$$\Delta \mathrm{p}K_{a,\mathrm{HA}} = {}_{\mathrm{S}}\mathrm{p}K_{a,\mathrm{HA}} - {}_{\mathrm{W}}\mathrm{p}K_{a,\mathrm{HA}} = \log\left(\frac{{}_m\gamma_{\mathrm{H}^+}\,{}_m\gamma_{\mathrm{A}^-}}{{}_m\gamma_{\mathrm{HA}}}\right) \quad (1)$$

$$\Delta \mathrm{p}K_{a,\mathrm{HB}^+} = {}_{\mathrm{S}}\mathrm{p}K_{a,\mathrm{HB}^+} - {}_{\mathrm{W}}\mathrm{p}K_{a,\mathrm{HB}^+} = \log\left(\frac{{}_m\gamma_{\mathrm{H}^+}\,{}_m\gamma_{\mathrm{B}}}{{}_m\gamma_{\mathrm{HB}^-}}\right) \quad (2)$$

S and W indicate organic solvent and water, respectively. The transfer activity coefficients, ${}_m\gamma_i$, is the ratio of the activity coefficients in the particular solvents: ${}_m\gamma_i = {}_W\gamma_i / {}_S\gamma_i$.

Eqs. 1 and 2 enable the interpretation of the changes in pK_a values in the different organic solvents, compared to water. One must take into account not only the stabilization of the proton (this is given by the mutual basicity of the solvents) but also the different ability to stabilize the other individual particles. Besides the neutral particles HA and B, oppositely charged ions H^+ and A^- take part in the equilibrium in case of the neutral acids, and equally charged HB^+ and B^+ ions in case of the cation acid. This occurrence leads to a different change of the pK_a values for these two different types of weak electrolytes, depending on the ability of the solvent to stabilize anions or cations.

Nearly all organic solvents stabilize anions worse than water. For this reason, the pK_a values of neutral acids are larger in organic solvents (it is obvious that strongly basic solvents like amines may level out this effect). In lower alcohols, for example, the pK_a values increase by several units. In acetonitrile, which has generally even less cation stabilization ability in addition, the pK_a values may increase by 16 units. The effect of many solvents on weak bases (expressed by the pK_a of the corresponding cation acid) is much lower. pK_a values change only by few units. An exception is acetonitrile, due to the reason mentioned earlier.

It should be noted that traces of water have a great influence on the shift of pK_a values in all solvents, because there is a steep change of the pK_a with increasing water content of the organic solvent. It should be also pointed out that the pK_a of the silanol groups at the surface of the commonly used fused-silica material is affected by the choice of the solvent, too. It is also shifted to higher values (in water the pK_a is around 5–6).

Table 1 Ionization constants of neutral and cation acids of type HA and HB+, respectively, in water, amphiprotic, and dipolar aprotic solvents.

Organic Substances: Lipophilicity Determination by RP/TLC

Gabriela Cimpan
Sirius Analytical Instruments Ltd., East Sussex, U.K.

INTRODUCTION

Lipophilicity is an important physicochemical parameter for organic substances, related to their biological activity. According to 1993 International Union of Pure and Applied Chemistry (IUPAC) recommendations, the partition coefficient $P_{o/w}$ or $K_{o/w}$ is a "measure of lipophilicity by determination of the equilibrium distribution between octan-1-ol and water, as used in pharmacological studies and in the assessment of environmental fate and transport of organic chemicals":

$$P_{o/w} = \frac{C_o}{C_a} \quad (1)$$

where C_o and C_a are the equilibrium concentrations of the compound in the organic and the aqueous phase. The organic phase is usually *n*-octanol, alkane, or chloroform, and can be any other water-immiscible solvent. Qualitatively, the partition coefficient measures the preference of the compound for the non-polar phase, and from the thermodynamic perspective, it gives information about the intermolecular forces affecting a compound in solution.

DISCUSSION

The partition coefficient between *n*-octanol and water, $P_{o/w}$, can be measured experimentally using the "shake-flask" method, or can be calculated from structural fragments. The direct measurement of $P_{o/w}$ values by equilibration between *n*-octanol and water is difficult, time consuming, requires a fairly pure compound that must be available in an adequate quantity, and has a limited measurable lipophilicity range, not suitable for very lipophilic or very hydrophilic compounds. Measurable P (generic notation for the partition coefficient) values are usually in the range 10^{-2}–10^{7}. As these values extend over several orders of magnitude, they may be expressed logarithmically (as $\log_{10}$), and $\log P$ is often used instead of P for practical reasons.

Reversed-phase liquid chromatography (LC) has been widely used as an alternative method for $\log P_{o/w}$ determination, modeling the partition of a compound between the lipid layer and the biological membrane of a cell. The compound partitioning into a lipid layer rules the biological activity of substances, such as the absorption of drugs and their metabolites, the in vivo bioaccumulation of organic compounds, etc.

TLC was the first form of LC used for lipophilicity estimations. Reversed-phase TLC (RP-TLC) has distinct advantages compared to conventional methods for $\log P_{o/w}$ determination. It is a rapid and reliable method, having a good reproducibility, and it only needs a small amount of sample (μg/ml) that does not have to be pure. In an RP-TLC experiment, several samples can be run simultaneously, making the method an attractive option for high throughput screening of new organic compounds, especially in the pharmaceutical industry. In TLC, the retention parameter, R_F, is defined as the ratio between the migration distances of the compound and of the mobile phase, both measured from the sample application position (Eq. 2). The term R_M was introduced to facilitate a linear relationship with the $\log P$ values, and it is defined similar to the capacity factor, k, in HPLC (Eq. 3).

$$R_F = \frac{z_x}{z_f} \quad (2)$$

where z_x and z_f are the migration distances of the component and of the mobile phase between the start and the front line.

$$R_M = \log\left(\frac{1}{R_F} - 1\right) \quad (3)$$

The stationary phase in RP-TLC can be C8 or C18 chemically bonded silica gel, or a silica gel layer impregnated with paraffin or silicone oil. Better correlations are usually obtained for the R_M values vs. $\log P$ on C18 reversed phase, probably because the secondary interactions between the compound and the free silanol groups on the silica surface are stronger on C8 phases than on C18. The samples are usually detected by fluorescence quenching or by spraying the plate with specific derivatization reagents. The measurements of R_M values on silica layers impregnated with oils have lower reproducibility than those on silica C8 or C18 bonded phase.

The mobile phase used in the lipophilicity measurements by RP-TLC is usually a binary mixture of an organic solvent and water. The organic solvent can be methanol, acetonitrile, or acetone. The first two can also be used in reversed-phase high-performance liquid chromatography

(HPLC) (RP-HPLC) measurements, but acetone is restricted due to its absorption in low wavelength UV.

The correlations between log P and R_M are frequently linear for non-ionic and ionic compounds. When a compound contains one or more ionizable substituents, the pH and the ionic strength of the eluent modify the apparent lipophilicity according to the ratio of neutral and ionized species.

Extensive experimental results show the existence of a linear relationship between the retention parameter R_M and the concentration of organic modifier in the mobile phase, φ, in a similar way to the RP-HPLC experiments:

$$R_M = a_0 + a_1\varphi \tag{4}$$

where φ is the concentration of the organic modifier in the mobile phase, and a_0 and a_1 are the intercept and the slope of the linear relationship (4); a_0 corresponds to the R_{Mw} value obtained in the case when pure water (or aqueous buffer) is the mobile phase. Experimentally, the R_{Mw} value can be measured only for very hydrophilic compounds. Practically, the R_{Mw} value is extrapolated from the linear relationship (4) to 0% organic modifier in the mobile phase. The extrapolation method was confirmed by the good linear correlations obtained between the experimental and the extrapolated R_{Mw} values. In theory, the extrapolated R_{Mw} value should have the same value regardless of the nature of the organic modifier in the aqueous mobile phase. Practically, these values are slightly different, probably due to errors in the linear fit, and usually have little influence on the lipophilicity measurements. Sometimes, a positive or negative deviation of R_M values from the linear relationship (4) was observed, especially at low concentrations of organic modifier in the mobile phase (Fig. 1). In some cases, the deviation from the linearity can be significant; hence, the extrapolation method is not applicable.

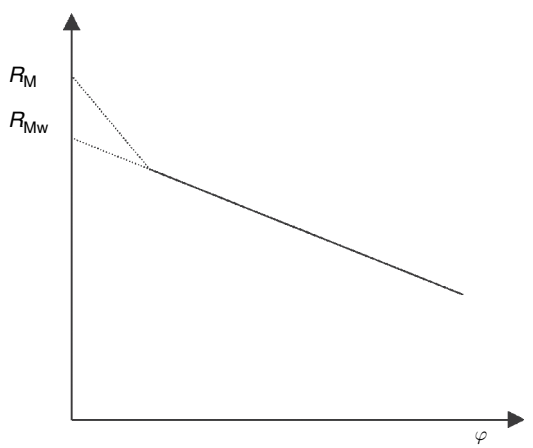

Fig. 1 The relationship between the R_M values and the organic modifier concentration (φ) in the aqueous mobile phase for RP-TLC lipophilicity measurements.

In practice, the R_{Mw} values correlate well with the log $P_{o/w}$ values, usually by a linear fit:

$$R_M = b_0 + b_1 \log P_{o/w} \tag{5}$$

where b_0 and b_1 are the coefficients, the intercept and the slope, respectively. Eq. 5 is similar to the linear relationships obtained in RP-HPLC between log k and log P values.

The extreme values for R_F are 0, obtained for very lipophilic compounds that remain at the start line, and 1, for very hydrophilic compounds that migrate to the mobile-phase front. As a consequence, the obtained R_M values can be situated between $-\infty$ and $+\infty$. Practically, the R_F values can be measured in the range 0.03–0.97, which means that R_M values can be measured in the range –1.5 to +1.5.

The R_{Mw} values for hydrophilic compounds can be obtained experimentally or by extrapolation. The relationship obtained between the experimental and the extrapolated R_{Mw} is linear, having an intercept value $m \cong 0$ and slope n approximately 1:

$$R_{Mw,experimental} = m + nR_{Mw,extrapolated} \tag{6}$$

Eq. 6 was verified experimentally for structurally different compounds and provided the validity of the extrapolation method for the R_{Mw} values, in the cases when direct measurement is not possible, e.g., for very lipophilic compounds.

Regardless of the nature of the organic modifier used in the aqueous mobile phase, a linear relationship can be obtained between the intercept and the slope of Eq. 4. This means that the intercept value, $a_0 = R_{Mw}$, is correlated with the slope a_1:

$$R_{Mw} = a + ba_1 \tag{7}$$

The linear correlation shown in Eq. 7 is not influenced by the value of the slope a_1. Considering a methanol–water mobile phase, an increase of methanol concentration will produce a more rapid decrease of R_M values for the lipophilic compounds than for the hydrophilic ones. This means that the lipophilic substances are more sensitive to variations in the mobile-phase composition.

The linear relationship between a_0 and a_1 values [Eq. 4] is an important relationship in the lipophilicity measurements. The intercept, $a_0 = R_{Mw}$, can be considered a measure of the partition of a compound between an aqueous, polar mobile phase and a non-polar stationary phase. The physicochemical significance of the slope, a_1, is not completely established. It was demonstrated experimentally that the slope shows the rate of increase in compound solubility in the mobile phase. The solubility increases as a consequence of the decrease of the mobile phase polarity.

The slope, a_1, depends on the non-polar surface of the organic compound; hence, it is the part of the compound that interacts with the non-polar stationary phase.

The correct measurement of the R_F values is very important because it affects the calculation of the R_{Mw} values and further correlations. Manual measurement of the R_F values includes an error of ± 1 mm, compared with the precision of a densitometer, which is ± 0.01 mm. The start and the front lines should also be exactly established, in order to reduce the measurement error. The "front line" in TLC is approximately equivalent with the "dead time/volume" concept in HPLC. The marker substance used in HPLC (such as inorganic salts) can be applied to estimate the exact front line in TLC. The measurement error for the front line is about 0.03 mm for a migration distance of 80 mm, for any concentration of the organic modifier in the aqueous mobile phase.

Overpressured Layer Chromatography

Jan K. Rozylo
Department of Adsorption Chromatography and Planar Chromatography, Marie Curie-Sklodowska University, Lublin, Poland

INTRODUCTION

Conventional thin-layer chromatography (TLC) in our experience, known under the name planar chromatography, uses horizontal or vertical glass or Teflon chambers for the development of chromatograms. As stationary phases, commonly known adsorbents or supports based on silica gel, aluminium oxide, magnesium silica, cellulose, and so forth are used; particle sizes are about 20 μm. The migration of the mobile phase is based on the phenomenon of capillary forces. This chromatographic method is described, in detail, in other sections of this volume.

This method is characterized by many limitations which either can cause unsatisfactory separation of a mixture of substances or lead to long development times (even up to several hours) or, sometimes, makes use of solvents of high viscosity impossible. The efficiencies of such chromatographic systems are also rather low.

DISCUSSION

In conventional TLC, the velocity of chromatogram development depends on the dimension of stationary-phase particles, viscosity of the mobile phase, distance from the start line of the mobile phase, and other parameters. Therefore, there is no possibility of regulation of resolution by change of migration velocity of mobile-phase flow; the distance between the solvent reservoir and the solvent front (z_f) varies with time (t) according to

$$z_f^2 = kt$$

where k is a constant that depends on the chromatographic system (mobile phase and adsorbent) and the size of sorbent particles constituting the layer and presents a parabolic relationship.

As the most popular planar liquid chromatographic technique, TLC uses a vapor phase of solvent above the sorbent layer, which has an important influence on the resolving power.

Many of the inconveniences of TLC are avoided in overpressured layer chromatography (OPLC), which is a logical extension of the theory and practice developed in HPLC which can now be used in the field of planar liquid chromatography. This extension offers some exceptional advantages to a chromatographer. OPLC is, in practical terms, a planar HPLC technique. OPLC integrates many of the benefits of TLC, high-performance TLC, and HPLC. This technique corresponds to an HPLC column having a relatively thin, wide cross section and using a pressurized ultramicrochamber with standard chromatoplates. Eluent is forced into the sorbent layer by the means of a pump which enables development of chromatograms with forced flow of the mobile phase (more precise penetration into micropores). The eluent migrates against the sorbent resistance imposed by external pressure on the sorbent surface, and the vapor phase is excluded. In the case of OPLC, there is a linear relationship between the distance (z_f) of the solvent front from the starting point and the migration time (t):

$$z_f = kt$$

where k is a constant that depends on the rate of solvent flow, on the externally applied pressure, and on the size of the particles constituting the layer. In principle, k is constant throughout the development and independent of the rate of solvent migration. In OPLC, R_F the parameter is also used to describe the position of the separated analyte and, in this case, the R_F values do not depend on the starting distance.

The parameters characterizing chromatographic systems in TLC, such as average plate height (H), reduced plate height (h), and theoretical plate number (N), are calculated in a similar way in OPLC, but, practically, they do not depend on either average particle diameter (d_p) or the start distance (s_0). In OPLC, the start distance has no influence on the efficiency of separation, and the average plate hight is nearly constant on a layer of exceptionally fine particles, even over a longer development distance. Thus, the major advantage of OPLC over other planar techniques lies in this fact. We can say that OPLC permits relatively large plate numbers to be obtained and can be applied more favorably in the case of smaller particles.

BASIC INSTRUMENTATION FOR OPLC

As far as OPLC is concerned, the method, in principle, differs from conventional TLC in the design of the

equipment that is used. The first attempts at construction of chromatographic pressure chambers were made in the beginnings of the 1960s. However, only at the end of the 1970s, Tyihák, Mincsovics, and Kalász were successful in construction of a well-operating OPLC chromatograph called Chrompress 10 (maximum pressure permitted in this chamber was 1.0 MPa) and, later, in the 1980s, Chrompress 25 (2.5 MPa) (Labor MIM, Hungary) and the most modern Personal OPLC BS-50 (OPLC-NIT, Budapest, Hungary) (5.0 MPa). In Poland, during 1980–1990, a pressure thin-layer chromatograph was constructed (Cobrabid, Warsaw); however, due to its narrow range of operating pressures (0.8 MPa), it was not widely used.

We will describe only the most up-to-date OPLC system. This fully automatic OPLC system allows separation of mixtures on an analytical and on a semipreparative scale. The fundamental separation process occurs on a chromatographic plate (constructed of glass or aluminum foil) with sorbent (Fig. 1) covered and compressed by a special polyethylene or Teflon foil, pressured by water. In this way, a flat, thin chromatographic column is created. This technique also requires a special chromatoplate which is sealed at the edges, which prevents the eluent from flowing off the chromatoplate in an unwanted direction. According to the technique of chromatogram development used (unidirectional, bidirectional, circular, online, off-line, parallel coupled multilayer, serial coupled multilayer), all four margins of a plate, three margins, two opposite margins can be impregnated, or they can be left uncoated.

In linear development of a chromatogram, unidirectional or bidirectional developments of the chromatogram are possible. Similarly, as in liquid column chromatography, there are possible, in this case, either online or off-line techniques of sample application, separation, and detection, as well as various modifications (e.g., partly offline method). Bidirectional development can also be vertical. Using vertical bidimensional development, applying different eluents, components of complex, difficult mixtures can be separated. The separation of such mixtures is also possible by means of this technique using multiple automatic development of chromatogram.

In OPLC, the changes in composition of the eluent give good possibilities for special separation techniques such as isocratic and gradient separation. The choice of mobile phase can be effectively and quickly determined using the optimization model Prisma according to Nyiredy. This is a three-dimensional model that correlates the solvent strength and the proportion of eluent constituent, which determines the selectivity of the mobile phases according to Snyder's solvent classification.

The newest apparatus for overpressured layer chromatography, "Personal OPLC BS-50" manufactured in Hungary, is shown in Fig. 2. Generally speaking, it consists

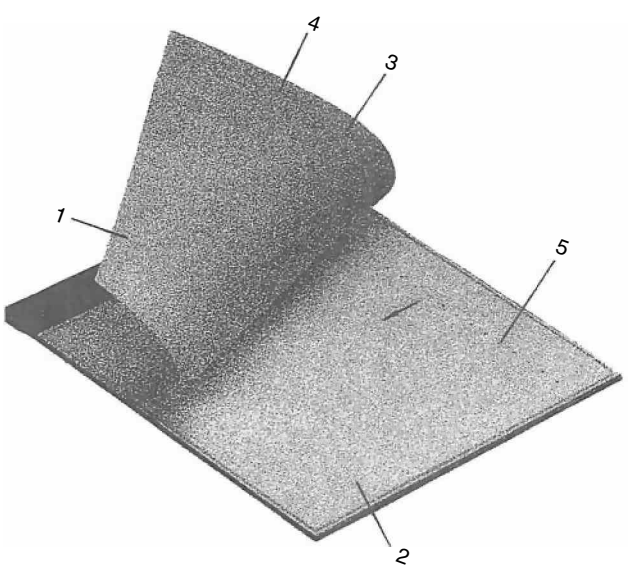

Fig. 1 Cassette of foil-backed layer for linear development: 1 = cover sheet, 2 = sorbent layer, 3 = eluent puncture, 4 = eluent trough, 5 = sample application site.

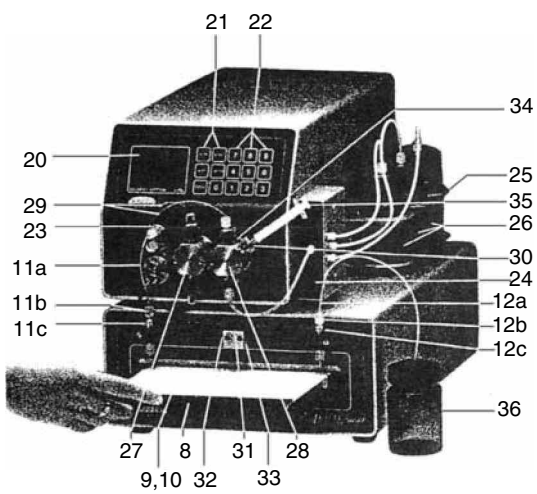

Fig. 2 Personal OPLC BS-50 apparatus: 9,10 = Teflon cover sheet of cassette, upper and lower, respectively; 11a = tube driving eluent from pressure gauge to chamber inlet connector; 11b = end connector for tube 11a; 11c = chamber–eluent– inlet connector; 12a = tube for eluent outlet of the chamber; 12b = end connector for tube 12a; 12c = chamber–eluent–outlet connector; 20 = display; 21 = function keys; 22 = numeric keys; 23 = pressure gauge for eluent; 24 = eluent switching valve; 25 = tank holder; 26 = eluent tanks A, B, and C; 27 = pump head for hydraulic liquid delivery; 28 = pump head foreluent delivery; 29 = hydraulic liquid and eluent connecting tubes; 30 = connecting stub for syringe to fill up eluent pump; 31 = middle hole of T distributor for fitting tubes in case of two-directional development; 32 = left hole of T distributor for fitting tubes in case of two-directional development; 33 = right hole of T distributor for fitting tubes in case of two-directional development; 34 = hole for piston rinsing against deposition; 35 = syringe.

of the separation chamber and a liquid delivery system. The separation chamber contains the following units: (a) holding unit, (b) hydraulic unit, (c) troy layer cassette, and (d) drain valve. The apparatus also has a pumping system for eluent delivery and for the hydraulic liquid delivery. The entire apparatus and the total chromatogram development process are controlled by a computer system. The apparatus and the method of chromatogram development is characterized by high reproducibility of results and chromatographic parameters. External pressure (5 MPa), eluent flow rate and its volume, and development time can be automatically programmed. The OPLC-BS-50 chamber works in off-line and online systems. Using this equipment, it is possible to separate 70–100 or even more samples at the same time, depending, of course, on the chosen technique of the OPLC process.

This OPLC method is charaterized by high precision for determination of retention parameters and reproducibility of results.

ADVANTAGES

- Separation of components which the former TLC techniques failed to achieve
- Smaller attainable plate height over longer migration distances
- Rapid separation and high resolution for industrial control
- Optimization of resolution as a function of solvent velocity, development distance, and temperature
- Possibility of using high-viscosity eluents and poorly wettable stationary phases
- Possibility of both quantitative evaluation and preparative applications
- Efficient separation of multicomponent samples
- Different development modes: unidirectional, bidimensional, continuous online, and off-line Long migration distances on fine-particle layers with short development times
- No air interactions
- Minute consumption of developing solvent
- Programmable operating system.

Some applications include analytical and preparative analyses in all types of biological, biochemical, pharmaceutical, clinical, forensic, food, and environmental laboratories.

Oxolinic Acids: HPLC Analysis

Abdul Rahman
Assessment Service Unit, Airlangga University, Surabaya, Indonesia

Mochammad Yuwono

Faculty of Pharmacy, Airlangga University, Surabaya, Indonesia

INTRODUCTION

Oxolinic acid (OA) (5-ethyl-5,8-dihydro-8-oxo-1,3-dioxolo[4,5-*g*]quinoline-7-carboxylic acid) is an antibacterial agent that belongs to the class of quinolone derivatives (Fig. 1). Quinolone antibiotics are active against a variety of gram-positive and gram-negative bacteria; they act by inhibiting DNA gyrase (topoisomerase II), a bacterial enzyme involved in DNA replication, recombination, and repair, leading to bacterial cell damage.

Oxolinic acid is widely used in farming, including shrimp, fish, chicken, and swine farming.[1–4] Compared to other drugs, quinolone antibiotics have a rapid bactericidal effect against most susceptible organisms.[5] Another advantage of OA in farming is its shorter half-life, which means it can be eliminated faster from the animal tissues, hence minimizing its residual effects. Excessive use of these antibacterial agents may cause residual effects in the animal tissues intended for human consumption. Therefore, to ensure human food safety, the European Union has set maximum residue limits (MRL) for these compounds; for OA, the limit in fish muscle is 300 μg/kg.[6,7]

Various analytical methods have been developed for the analysis of OA in pharmaceutical preparations, plasma, urine, and animal tissues. Other authors also developed methods for analyzing OA as a pollutant in aquatic plants and sediments.[8–10] Methods commonly used for the analysis of OA are bioassay, thin-layer chromatography (TLC) fluorescence, high-performance liquid chromatography (HPLC) with ultraviolet or fluorescence detection, HPLC–mass spectrometry (HPLC–MS), HPLC-ES–MS, gas chromatography–mass spectrometry (GC–MS), and capillary electrophoresis.[4,11–13] Capitan-Vallvey et al.[14] developed a phosphorimetric sensor method for detecting OA in human urine and cow's milk. Among these methods, HPLC is preferred.

SAMPLE PREPARATION

Analysis of OA in biological matrices is quite complicated, owing to the very complex nature of the sample, which may lead to difficulties in extraction procedures. Furthermore, the very low concentration of these agents has become the second obstacle. Generally, two methods of extraction are being used, i.e., liquid–liquid extraction (LLE) and solid-phase extraction (SPE). In general, SPE is generally preferred, because of its simplicity.

Liquid–Liquid Extraction Methods

For LLE, the acid–base solubility property of OA (soluble in organic solvent in acidic condition and soluble in basic aqueous solution) was utilized.[8] The lower cost of chemicals used in liquid–liquid separation makes this method more cost effective. The only disadvantage is that it is time consuming and tedious. Some authors found that the recovery of OA by LLE was higher than that by SPE.[1,2,8] Solvents commonly used for LLE methods are summarized in Table 1.

Solid-Phase Extraction Methods

For solid-phase extraction, the offline procedure, based on sample pretreatment on disposable SPE cartridges, and a totally automated online procedure, based on column switching, have been developed. The column switching procedure involves the use of a polystyrene-divinylbenzene column for sample concentration and cleanup.[16]

The principle of SPE is based on selective retention of the analyte on a bonded silica material. Frequently used solid-phase materials include C_2-, C_8-, C_{18}-, CN-, and

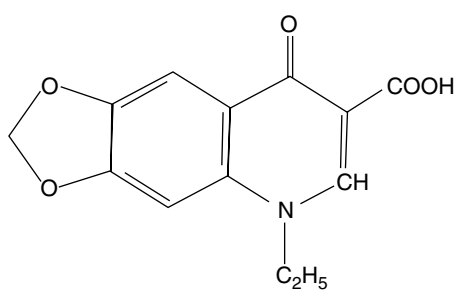

Fig. 1 Chemical structure of OA.

Table 1 Solvents frequently used for traditional liquid–liquid extraction methods for OA.

Matrices	Solvents	Recovery (%)	Refs.
Fish serum and muscles	ACN–THF (95 : 5)	95.1 (serum) 92.0 (muscle)	[15]
Fish tissues	NaOH–acetone; re-extracted by $CHCl_3$–H_3PO_4	97	[1]
Feces and urine of *Scophthalmus maximus*	Feces: aqueous $ZnSO_4$, NaOH 0.1 *M*, and ACN; Urine: NaOH, chlorhydric acid, and chloroform	102 (feces) 91.6 (urine)	[2]
Fish muscle	Buffer solution, pH 9, and acetonitrile; then washed with *n*-hexane	69	[6]
Aquatic plants	1 *M* NaOH aqueous solution then re-extracted with $CHCl_3$ in acidic condition	68.3	[8]
Meat	Na_2SO_4 and ACN; washed twice with *n*-hexane	85 ± 7	[13]

phenyl-bonded phases. An idealized SPE protocol involves trapping the analyte on a solid phase, washing off interferences that are less attracted to the sorbent, then eluting analyte(s) and leaving interferences with greater attraction bound to the sorbent.[17] For OA, C_2-, C_8-, and CN-bonded phases gave excellent recovery and, by using C_2-bonded phase, up to 100.1% recovery may be achieved.[16]

The SPE cartridge must be conditioned prior to use. Usually, the solvents used for preconditioning are MeOH and water;[18,19] MeOH, water, and 0.05 *M* phosphate buffer at pH 7;[7] MeOH and 5% MeOH in 0.001 *M* phosphoric acid;[1] MeOH, acetate buffer, pH 3–4, and 0.5 m*M* OCN;[11] and MeOH and 1.0 *M* orthophosphoric acid.[16] The common methods used for sample preparation using SPE are given in Table 2.

HPLC CONDITIONS

Among the methods for analyzing OA, HPLC combined with UV, fluorescence, or diode array detection is the most used. The applied HPLC conditions are summarized in Table 3, and a typical chromatogram and UV-spectrum of OA is presented in Fig. 2.

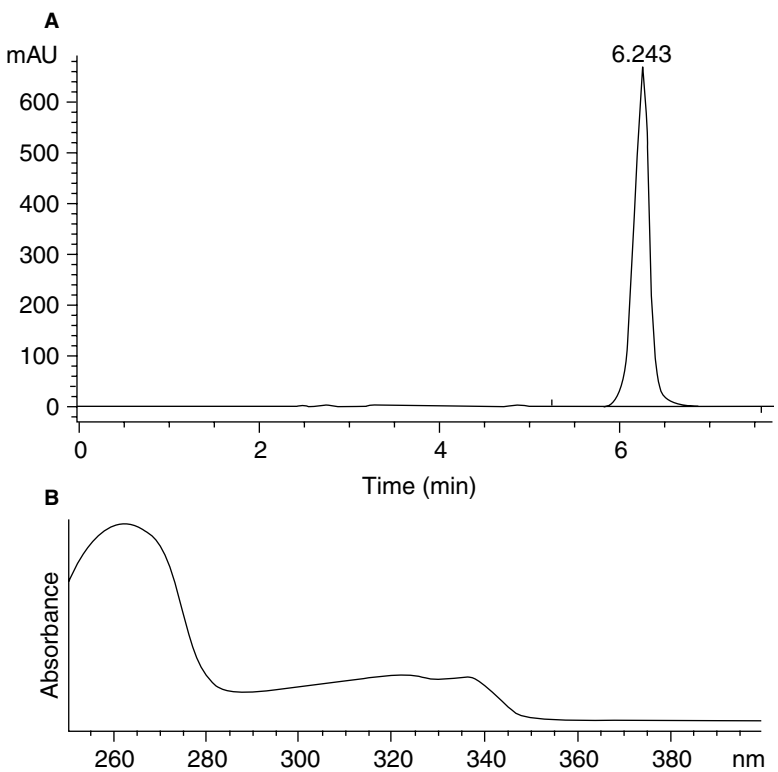

Fig. 2 A, HPLC chromatogram of standard OA at 261 nm (Sigma, Cat. No. 14698-29-4); column: Hypersil BDS C-18®; eluent: H_3PO_4 (pH 3): ACN (70 : 30 v/v); and B, UV-Spectrum of OA peak.

CONCLUSIONS

Various HPLC methods have been developed and used to analyze oxolinic acid in various matrices. The suitable methods for sample preparation and extraction largely depend on the nature of samples. Extraction using SPE methods have not always given better results when compared to traditional liquid–liquid extraction methods. The most used HPLC column for analyzing OA is a C_{18} column combined with UV or fluorescence detectors.

Packed Capillary LC

Fernando M. Lanças
Institute of Chemistry of São Carlos (USP), University of São Paulo, São Carlos, Brazil

INTRODUCTION

Liquid chromatography (LC) was the first chromatographic mode to be developed in the beginning of the twentieth century. For almost 70 years, it was employed without major modifications until the end of the 1960s when an instrumental version of LC was finally produced. Before this milestone, LC was performed mainly in large-bore glass tubing packed with large-diameter solid particles. To differentiate the instrumental version developed in the late 1960s from the non-instrumental, usually referred as the "classical" version, the former was named high pressure liquid chromatography and, later, high-performance liquid chromatography (HPLC). Because HPLC used smaller particles as the stationary phase, the columns had to be packed at higher pressures in order to obtain a more stable bed required by the higher pressures used in these techniques. Altogether, HPLC offered a much higher efficiency (number of plates) than "conventional LC" and, as a consequence, higher resolution (separation power) as well. The standard HPLC columns used in the 1970s consisted of particles of 5–10 μm packed in stainless-steel tubing of 4.0–4.6 mm inner diameter (I.D.) and 15–25 cm long. Typical flow rates under these conditions are ~1–2 ml/min. In a typical quality control laboratory (8 hr a day; 5 days a week, 20 days a month; 12 months a year), more than 100 L of chromatographic solvent are generated in a 1 year period. Most of these solvents are highly toxic to man and the environment, requiring special waste storage, transportation, and final disposal. As a consequence, a miniaturization of the HPLC techniques using less solvent became important immediately after its development.

A major step in the miniaturization of HPLC columns was done early in 1967 by Horváth and coworkers,[1,2] when investigating the parameters that influence the separation of nucleotides in a 1 mm I.D. column. These columns were then named microbore columns. A further step in the miniaturization process was done in 1973, by Ishii and coworkers, by separating polynuclear aromatic hydrocarbons (PAHs) in a 0.5 mm I.D. polytetrafluoroethylene (PTFE) column. The term micro-LC was then introduced to differentiate this technique from HPLC, which uses larger-bore columns.[3–5] Shortly after, Scott and Kucera published several articles dealing with microbore (1 mm I.D. columns) LC.[6,7] In spite of the fast development in its early days (late 1960s and early 1970s), the miniaturization of HPLC followed a slow progress until recently, with the development of LC/mass spectrometry (MS) using electrospray-type interfaces.

CAPILLARY LC

Capillary liquid chromatography (CLC) is a mode of HPLC that deals with columns having internal diameters equal to, or smaller than, 0.5 mm. This number is limited by the internal diameter of the fused-silica tubing commercially available, which is the most popular tubing used in this area. The CLC columns are usually 15–60 cm long, having internal diameters <0.5 mm and being either coated or packed with the stationary phase. Due to the small inner diameter of the CLC columns, this technique is more demanding in instrumentation than HPLC, particularly with respect to the solvent delivery, sample introduction, and detection systems.

Sample Introduction

Because the column inner diameter is small, the amount of stationary phase is also very small and, as a consequence, the amount of sample that can be introduced into the column without overloading is very small (typically a few nanoliters). In most cases, the preferred sample introduction system consists of an injection valve containing an internal loop smaller than 0.1 ml.

Pumping System

Because the eluent flow rate is relatively small (typically a few microliters per minute), the pump used to deliver it to the column is critical. There are two major approaches being used: pumps capable of delivering flow rates in the range of few microliters per minute (usually syringe-type pumps) or reciprocating pumps using a flow splitter. In both cases, reproducible flow rates are hard to obtain using commercially available pumps.

Detectors

Almost all detectors currently used in HPLC have been evaluated to be used in CLC. The major modification required, in most cases, is a decrease in the detector cell volume in order to accommodate the small sample volume without considerable peak broadening. Ultraviolet–visible

(UV–Vis), fluorescence, electrochemical, mass spectrometric, and several other detectors have been successfully used with CLC.

Columns

Capillary LC columns can be generally made in two different ways: wall-coated open tubular (WCOT) or packed columns. Coating the internal wall of the tubing (usually fused silica) with a thin film of a solvent-resistant polymer makes WCOT columns and is the same technology as used for capillary gas chromatography (GC) columns. Usually, cross-linked or immobilized phases are preferred in order to avoid stationary-phase removal by the eluent. The major drawback of these columns is that they have to be made with an internal diameter smaller than 20 mm in order to be highly efficient for complex separations, thus justifying their use instead of the packed capillary columns.[8] This places great demands on the instrumentation, the eluent quality, the sample preparation step, and so forth, thus making it impractical at this moment. As an alternative, the packed capillary columns using the technology already available to prepare HPLC columns is less instrument demanding and have been gaining more acceptance, every day becoming the preferred form of CLC.

ADVANTAGES OF CAPILLARY LC

The advantages of CLC are consequences of its miniaturization.[9] Due to its miniaturized size, it requires much less stationary phase than does ordinary HPLC and, as a consequence, more expensive phases can be used to prepare the columns. This includes chiral phases, experimental new materials, expensive biocompounds, and so forth. In the same way, the amount of mobile phase is very small, thus leading to a savings in buying, storing, and discarding the solvent, allowing the use of expensive eluents such as deuterated solvents and chiral modifiers such as cyclodextrins, transition metals, and so forth. In many cases, the total amount of mobile phase in one separation is just 10 ml (1 μml/min; 10 min run); this explains why this technique is sometimes referred to as "one-drop chromatography." The amount of sample injected is also very small, so it becomes an important technique when the sample size is critical, such as in biomedical studies (brain, spine liquid, newborn tests, etc.), forensic chemistry (fire debris, explosives, blood residues), environmental analysis, and several other application fields.

Other advantages of CLC, when compared to HPLC, includes its higher permeability,[10] chemical inertia, easier coupling to other separation and identification systems such as MS, GC, and nuclear magnetic resonance, and the possibility of making longer columns, thus achieving more plates (efficiency) and resolution.

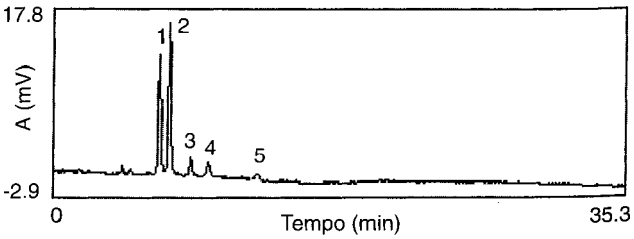

Fig. 1 Capillary LC chromatogram of a river water solidphase extract containing PAHs. Column: fused silica (20 cm × 0.25 mm) H2O home-packed with RP-18 (5 mm). Mobile phase: ACN/H2O (75 : 25), flow rate 4 ml/min, UVdetection at 254 nm. Compound identity: 1 = fenanthrene, 2 = anthracene, 3 = fluoranthene, 4 = pyrene, 5 = crysene.

Fig. 1 shows a chromatogram of a separation of PAHs using a packed capillary column. As can be verified, a good separation is obtained with minute amounts of stationary phase, mobile phase, and sample.

LIMITATIONS OF CAPILLARY LC

In spite of the several advantages over HPLC, CLC has not yet achieved its maturity as a separation technique to be used worldwide, particularly as a routine technique for quality control laboratories. Among the limitations still hindering the further development of CLC, one of the most critical ones is the very limited availability of commercial equipment dedicated to this technique. Even so, most systems are simple adaptations of parts already used for HPLC, by just decreasing their sizes and volumes without specifically having CLC in consideration. Therefore, in order to become a routine technique as its counterpart in GC, capillary LC still has to have a broader interest for the instrument manufacturing companies in the technique before it will spread out beyond the academic environment. Those who have worked with packed columns in GC in the 1960s have already seen this same history.

Particle Separation: Acoustic FFF

Niem Tri
Ronald Beckett
Water Studies Centre, Monash University, Melbourne, Victoria, Australia

INTRODUCTION

Field-flow fractionation (FFF) is a suite of elution methods suitable for the separation and sizing of macromolecules and particles.[1] It relies on the combined effects of an applied force interacting with sample components and the parabolic velocity profile of carrier fluid in the channel. For this to be effective, the channel is unpacked and the flow must be under laminar conditions. Field or gradients that are commonly used in generating the applied force are gravity, centrifugation, fluid flow, temperature gradient, and electrical and magnetic fields. Each field or gradient produces a different subtechnique of FFF, which separates samples on the basis of a particular property of the molecules or particles.

RESEARCH AND DEVELOPMENTS

The potential for using acoustic radiation forces generated by ultrasonic waves to extend the versatility of FFF seems very promising. Although only very preliminary experiments have been performed so far, the possibility of using such a gentle force would appear to have huge potential in biology, medicine, and environmental studies.

Acoustic radiation or ultrasonic waves are currently being exploited as a non-contact particle micromanipulation technique.[2] The main drive to develop such techniques comes from the desire to manipulate biological cells and blood constituents in biotechnology and fine powders in material engineering.

In a propagating wave, the acoustic force, F_{ac}, acting on a particle is a function of size given by[1]

$$F_{ac} = \pi r^2 E Y_p \tag{1}$$

where r is the particle radius, E is the sound energy density, and Y_p is a complicated function depending on the characteristics of the particle which approaches unity if the wavelength used is much smaller than the particle. Particles in a solution subjected to a propagating sound wave will be pushed in the direction of sound propagation. Therefore, sized-based separations may be possible if this force is applied to generate selective transport of different components in a mixture. In a FFF channel, it is likely that the receiving wall will reflect at least some of the emitted wave. If the channel thickness corresponds exactly to one-half wavelength, then a single standing wave will be created (see Fig. 1). For a single standing wave, it is interesting to note that three pressure (force) nodes are generated, one at each wall and one in the center of the channel.

Yasuda and Kamakura[3] and Mandralis and coworkers[4] have demonstrated that it is possible to generate standing-wave fields between a transducer and a reflecting wall, although of much larger dimensions (1–20 cm) than across a FFF channel. Sound travels at a velocity of 1500 m/sec through water, which translates to a wave of frequency of approximately 6 MHz for a 120 μm thick FFF channel.

The force experienced by a particle in a stationary acoustic wave was reported by Yosioka and Kawasima[5] to be

$$F_{ac} = 4\pi r^3 \kappa E_{ac} A \sin(2\kappa x) \tag{2}$$

where r is the particle radius, κ is the wave number, E_{ac} is the time-averaged acoustic energy density, and A is the acoustic contrast factor given by

$$A = \frac{1}{3}\left(\frac{5\rho_p - 2\rho_l}{\rho_l + 2\rho_p} - \frac{\gamma_p}{\gamma_l}\right) \tag{3}$$

where ρ_p and γ_p are the particle density and compressibility, respectively, and ρ_l and γ_l are the liquid density and compressibility, respectively. Thus, in a propagating wave, the force on a particle has a second-order dependence, and in a standing wave, the force is third order. This should give rise to increased selectivity for separations being carried out in a standing wave.[6]

Due to the nature of the acoustic fields, the distribution of the particles will depend on the particle size and the compressibility and density of the particle relative to the fluid medium. Closer examination of the acoustic contrast factor shows that is may be negative (usually applicable to biological cells which are more compressible and less dense relative to the surrounding medium) or positive (as is in many inorganic and polymer colloids). Therefore, acoustic FFF (AcFFF) has tremendous potential in very clean separations of cells from other particles. One

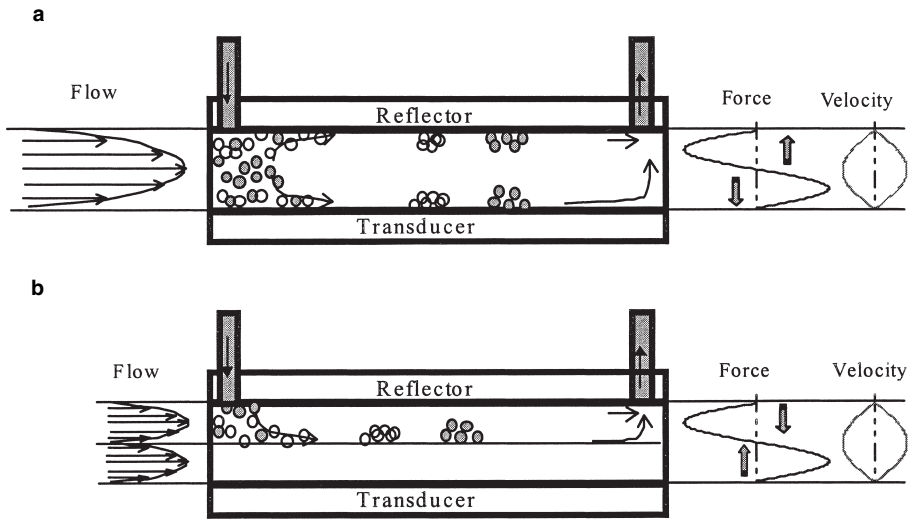

Fig. 1 Acoustic FFF channels suitable for particles with (a) A , 0 and (b) A . 0, utilizing a divided acoustic FFF channel.

important application may be for the separation of bacterial and algal cells in soils and sediments.

If the acoustic contrast factor A , 0, then a conventional FFF channel will enable normal and steric mode FFF separations to be carried out (Fig. 1a).

However, if A . 0, then the particles will migrate toward the center of the channel. In this case, a divided FFF cell could be used as shown in Fig. 1b. This ensures that particles are driven to an accumulation wall rather than the center of the channel where the velocity profile is quite flat and selectivity would be minimal.

Johnson and Feke[7] effectively demonstrated that latex spheres migrate to the nodes (center of the cell) and Hawkes and coworkers[8] showed that yeast cells migrate to the antinodes (walls of the cell). These authors used a method similar to split-flow thin-cell (SPLITT), which is another technique closely related to FFF, also originally developed by Giddings.[9] Semyonov and Maslow[10] demonstrated that acoustic fields in a FFF channel affected the retention time of a sphere of 3.8 μm diameter when subjected to varying acoustic fields. However, the high resolution inherent in FFF has not yet been exploited.

Naturally, with some design modifications to the FFF channel, SPLITT cells could be used for sample concentration or fluid clarification.

Particle Size: Gravitational FFF Determination

Pierluigi Reschiglian
Department of Chemistry "G. Ciamician", University of Bologna, Bologna, Italy

INTRODUCTION

Particle size distribution analysis was considered, in one of the latest Pittsburgh Conferences, as one of the most outstanding trends in analytical science. This is not an overstatement, as most of the real samples of analytical interest occur either in dispersed form or in dispersed matrices. Just for argument's sake, in industrial applications the characterization of the size of sample particles is routine and is an essential part of the overall quality control procedures. In the medical field, for particles used to carrier drugs, the size is a critical performance factor (e.g., liposomes). In the food industry, the alcoholic yield from fermentation of starch, and even the taste of chocolate, depends on the size of particles of which these samples are composed.

BACKGROUND

Before discussing our method for determining particle size, it is necessary to briefly review the definition of size distribution. If all particles of a given system were spherical in shape, the only size parameter would be the diameter. In most real cases of irregular particles, however, the size is usually expressed in terms of a sphere *equivalent* to the particle with regard to some property. Particles of a dispersed system are never of either perfectly identical size or shape: A spread around the mean (*distribution*) is found. Such a spread is often described in terms of standard deviation. However, a frequency function, or its integrated (cumulative) distribution function, more properly defines not only the spread but also the shape of such a spread around the mean value. This is commonly referred to as the *particle size distribution* (PSD) profile of the dispersed sample.

An examination of technical literature and trade publications indicates that a wide variety of instruments are commercially available for PSD analysis.[1] The classical methods are based on either electrical properties (e.g., the Coulter Counter® principle) or optical properties (e.g., laser scattering) of the analyte. However, none of these techniques are separation methods. Because particulate dispersions are often highly complex in terms of the polydispersity index, multimodal size distribution, and density, it is hardly possible, without the use of separative methods, to obtain an accurate determination of their size distribution. Among separative chromatography-like methods, one can consider hydrodynamic chromatography and field-flow fractionation (FFF). The application to PSD of a subset of the latter family of methods is the topic of this entry.

PSD by FFF

Field-flow fractionation is a broad family of liquid chromatographic-like techniques which have been shown, over more than 20 years, to be able to fractionate and characterize high-molecular-weight species in a size range spanning five orders of magnitude, from macromolecules to micron-size particles.[2] FFF has been demonstrated to be a rapid method for the determination of the mean diameters and polydispersities of particulate samples. When compared to standard methods for PSD analysis, the main advantage of FFF lies in the fact that FFF is a separation method which has some common features with liquid chromatography. The output from an FFF experiment is a function of the detector signal vs. the retention time of the analyte. Whereas, in liquid chromatography, such an analytical response is referred to as the *chromatogram*, in FFF it is commonly defined as the *fractogram*. However, when it is compared to classical liquid chromatography, the existence of a direct relationship between retention and some physical properties of the analyte, such as the size, is a fundamental feature of most FFF techniques. The theory of FFF retention has been fully explained elsewhere,[2] and references therein] as well as in other entries of this encyclopedia. What is important to focus on here is that, in FFF, particle size determination of the analyte can be obtained by means of a direct numerical conversion of the retention scale, whereas the relative amount of separated analyte is, as in the case of chromatograms, in some way proportional to the signal intensity. The basic procedures for the two conversions is the topic of this entry.

Gravitational FFF: An Economical Device for PSD Analysis of Micron-Size Dispersions

Here, we treat the case of PSD analysis of particulate systems of micron-size range (i.e., with a size distribution extending above 1 μm). Since 1994, in our laboratories, this topic has been dealt with by means of a low-costsubset of sedimentation FFF (SdFFF), the gravitational field-flow fractionation (GrFFF) technique.[3] GrFFF had already

been applied to the fractionation of a variety of micron-size dispersion, either inorganic as commercial chromatographic supports[4] or biological, as cells and parasites.[5] In no cases, however, had PSD been performed through GrFFF. As an SdFFF subset, GrFFF requires the application of a sedimentation field that, in this case, is simply Earth's gravity applied perpendicularly to a very thin, empty channel with a rectangular cross section. The big advantage of GrFFF, compared to other techniques for the characterization of particulate matter, lies in its very low cost (~$50 for a homemade channel) and easy implementation in a standard high-pressure liquid chromatography (HPLC) system (the channel can simply replace the standard HPLC column). The GrFFF channel employed here can be easily built as described elsewhere.[3–9] It is basically a ribbonlike capillary channel which consists of two mirror-polished plates, of either glass or plastic material (e.g., polycarbonate) which are clamped together over a thin sheet of either Teflon or Mylar from which the channel volume has been removed. Simplicity and economy of use make it possible for laboratories that are not specialized in PSD analysis to perform dimensional characterization of supermicron particles dispersions with limited effort and cost.

We shall show here that GrFFF is capable of performing reliable, quantitative PSD analysis of particulate matter. Some basics of the overall procedure will be overviewed and the relevant questions presented. In fact, in order to obtain a PSD by means of GrFFF, the conversion of the retention time axis into the analyte size axis is necessary. For the same reason, the detector signal axis must be converted into mass (or concentration) of the fractionated analyte.

PROCEDURE AND DISCUSSION

From a GrFFF Fractogram to a PSD

The diameter scale can be obtained from retention coordinates (i.e., the retention time axis) by applying to the fractogram the well-known, approximate expression that is valid for highly retained samples in GrFFF:[3]

$$d_i = \frac{wV_0}{3\gamma}\frac{1}{V_{r,i}} \tag{1}$$

where d_i (cm) is the diameter value corresponding to the ith data point of the fractogram, the retention volume of which is $V_{r,i}$ (cm^3). V_0 (cm^3) is the void volume of the GrFFF channel, w (cm) is the channel thickness and γ is the so-called hydrodynamic correction factor, the knowledge of which is, therefore, required for PSD analysis.

In practice, PSD curves can be obtained directly from the experimental, digitized peak (fractogram), $y_i(V_{r,i})$ once it is converted to a function of particle diameter with the use of Eq. 1. The frequency function of particle size is expressed as[3]

$$f_{m,i} = \frac{\delta m_i}{\delta d_i} = \frac{\delta m_i}{\delta V_{r,i}}\frac{\delta V_{r,i}}{\delta d_i} \tag{2}$$

where $\delta m_i / \delta V_{r,i}$ (g/cm^3) is the mass concentration of the analyte at the ith digitized point and $\delta V_{r,i}$ and δd_i are the differences in retention volume and particle diameter between the ith and the $(i-1)$th digitized points, respectively. The incremental quantity δd_i can be calculated for any given $\delta V_{r,i}$ by Eq. 1.

As far as the conversion of the analytical response y_i is concerned, the most used detectors in GrFFF have been, until now, conventional ultraviolet (UV) detectors commonly used for HPLC. With this type of detector, the amount of particles with diameter d_i is proportional to the detector response at the ith point. With particulate samples, in fact, because of UV detector optics, the response is a *turbidity* signal read within an angle between the incident light and the photosensor (i.e., usually smaller than ~10°) rather than the *absorbance*. This turbidity signal can be assumed to be directly proportional to the sum of all cross-sectional areas of the particulate sample components at any time. The validity of the above assumption, in the case of particles which are about 10-fold larger than the incident wavelength, is discussed elsewhere.[6] The mass frequency function can thus be expressed as[7]

$$f_{m,i} \propto (\text{UV signal})_i(d_i)\frac{\delta V_{r,i}}{\delta d_i} \tag{3}$$

For the reader's convenience, a scheme of the required conversion is represented in Fig. 1. It is evident that it is rather straightforward to derive a PSD from a GrFFF experiment.[3] An example of GrFFF–PSD analysis for a sample of silica particles commonly used as the stationary phase in HPLC (5 μm LiChrospher, Merck) is reported in Fig. 2a. For the sake of comparison, the PSD of the same

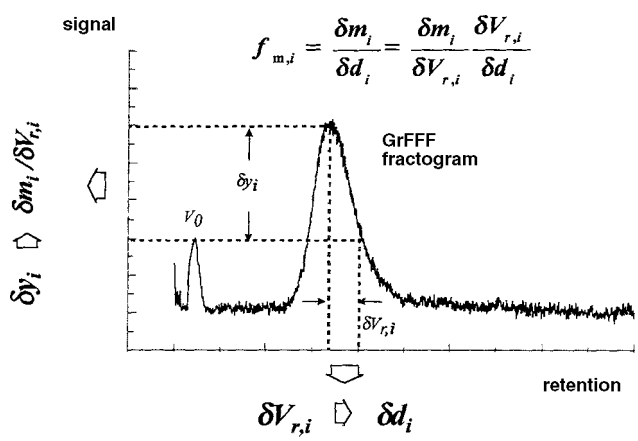

Fig. 1 Scheme for the conversion from a fractogram to a frequency function of particle size.

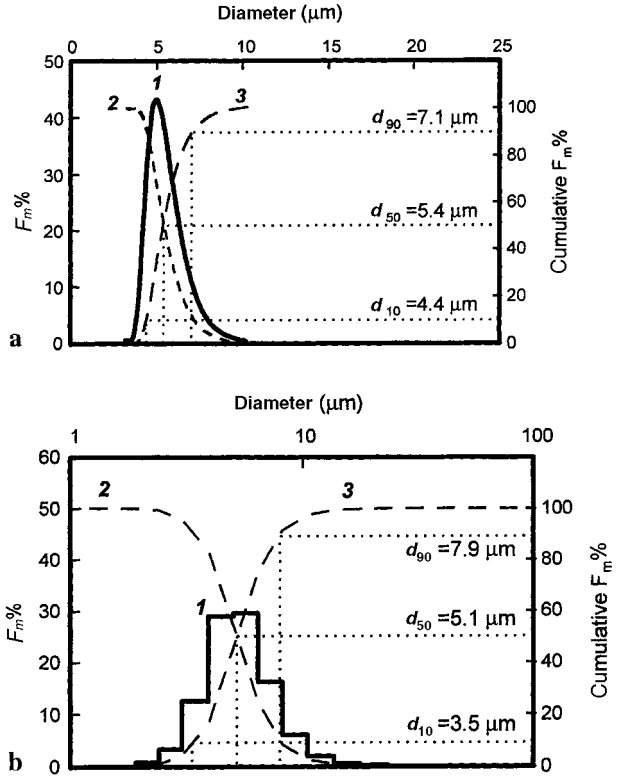

Fig. 2 Comparison between normalized, frequency functions of size (F_m %) of silica particles for HPLC packing (5 μm; Li-Chrospher, Merck, Darmstad); nominal distribution percentiles: $d_{10} = 3.7$ μm, $d_{50} = 5.0$ μm, $d_{90} = 6.8$ μm); curve 1 (full line): F_m %; curve 2 (dashed line): F_{cum} %; curve 3 (dashed line): $100 - F_{cum}$ %. (a) GrFFF/PSD: Sample load: 100 μg; channel: $90 \times 2 \times 0.020$ cm; mobile phase: Milli-Q water/Triton X-100, 0.1% (v/v)/NaN_3 0.02% (w/v); flow rate: 1.010 ± 0.004 cm^3/min; UV detection: 330 nm; experimental $\gamma = 0.70$. (b) Laser diffraction PSD (Malvern MASTERSIZER®, Malvern Instruments Ltd., UK).

sample obtained by laser diffraction is reported in Fig. 2b. We can observe that PSD resolution is higher in GrFFF than in laser diffraction, where just a histogram is obtained. On the other hand, accuracy is comparable when the experimental distribution moments (i.e., the percentiles indicated as d_{10}, d_{50}, d_{90}) are compared to the nominal values given by the manufacturer. We must point out that differences in distribution moment values as high as 10% are commonly reported when different, uncorrelated techniques for PSD studies are compared.[1]

Quantitative Particle Size and Sample Amount Distribution in GrFFF

We have derived an original method by which quantitative particle size and sample amount distribution (PSAD) in GrFFF can be obtained by applying to Eq. 2 a derivation of the Lambert–Beer law in flowthrough systems.[7] If compared to standard PSD, a PSAD thus represents a distribution of the *real* mass of the analyte as a function of size, rather than a functional expression only *proportional* to mass.

For particle dispersions in the micron-size interval, which is the typical application range of GrFFF, it has been demonstrated that the sample amount exiting the detector cell, N_0 (g), can be expressed as

$$\frac{AF}{Kb} = N_0 \tag{4}$$

where A (min) is the peak area, F (cm^3/min) is the flow rate, b (cm) is the cell thickness, and K (cm^2/g) is the total extinction coefficient of the particulate sample. If the extinction coefficient can be assumed to be approximately constant, as in the case of particles whose size is at least 10 times higher than the incident wavelength,[6] the detector reading, expressed as "absorbance" at the ith point is related to the real turbidity signal from the detector (τ_i) by the equation[7]

$$A_i = Kc_i b = \frac{\tau_i}{2.303} b \tag{5}$$

where c_i (g/cm^3) is the analyte concentration at the ith point of the fractogram; that is,

$$c_i = \frac{\delta m_i}{\delta V_{r,i}}$$

Therefore, the turbidity signal can be expressed as

$$\tau_i = 2.303K \frac{\delta m_i}{\delta V_{r,i}} \tag{6}$$

and the PSD expression for the frequency function, which is, in Eq. 3, just proportional to particle mass, can be transformed into a real function in mass directly from Eq. 6, thus giving[7]

$$f_{m,i} = \frac{\delta m_i}{\delta d_i} = \frac{\tau_i}{2.303K} \frac{\delta V_{r,i}}{\delta d_i} \tag{7}$$

Integration of Eq. 7 yields the cumulative distribution which gives, plotted as percent distribution, the size distribution percentiles (d_{10}, d_{50}, d_{90}). Moreover, once it is related to the injected sample amount, it gives the cumulative distribution of analyte mass as a function of size, with its asymptotic value giving the total sample recovery. Some examples of GrFFF/PSAD of silica samples used as HPLC column packing are reported in Ref.[7]

Direct Conversion of Retention to Size; Secondary Effects

As shown earlier, the direct conversion from retention time to particle diameter values (Eq. 1) requires that the correction factor γ is predicted or experimentally estimated. It is known that, in GrFFF, γ can be influenced by either hydrodynamic or other effects as those due to the mobile phase[8] and the channel walls' nature.[9] All of these effects can influence particle size determination by GrFFF.

We have been developing an approach to the evaluation of the second-order effects, which act on GrFFF retention, and to the prediction of the correction factor γ. Among these effects, prominent are those due to hydrodynamic forces which lift the analyte particles away from the accumulation wall during their elution. GrFFF really shows a significant dependence of retention (and, thus, of the parameter γ) on the flow rate: The higher the flow rate, the higher the lift and, therefore, the lower the retention. In order to evaluate particle lift and, thus, particle retention, the semiempirical model given by Williams et al. has been applied.[10–12] This model is known to predict particle elevation from the accumulation wall in sedimentation field-flow fractionation (SdFFF), of which GrFFF it is just a subset, as noted earlier. A description of the hydrodynamic and other secondary effects on GrFFF retention is far above the introductory nature of this entry. However, just to introduce the reader to the possibility of obtaining a direct conversion of retention to size by predicting γ, the above-mentioned model can be used for relating retention volume to particle mean elevation during elution as follows:[10]

$$V_{r,i} = V_0 \left[6f\left(\frac{2\delta}{d_i}\right)\frac{x_i}{w}\left(1-\frac{x_i}{w}\right)\right]^{-1} \tag{8}$$

where x_i (cm) is the distance of the center of the particles from the accumulation wall ($x_i = \delta + d_i/2$) and $f(2\delta/di)$ is an empirical function. It was shown that under optimized experimental conditions, in a properly designed GrFFF system, a balance between secondary effects of forces other than hydrodynamic forces can give negligible effects.[9] In this way, particle elevation is predictable. In this case, also, the value of γ can be estimated, thus allowing for the direct conversion of retention time to analyte size without previous calibrations (*standardless*). This possibility of calculating γ is a task still in progress and it will open more promising uses of GrFFF for dimensional analysis of suspended particulate matter, because PSD can be obtained in the "single-run" mode (i.e., without previous calibration). This could be a significant enhancement in the future evolution of GrFFF/PSD. In fact, in the GrFFF/PSD example in Fig. 2a, the conversion from retention to size was performed only by means of an experimental evaluation of the parameter γ, with a calibration plot formerly obtained with standards.[3]

Particles and Macromolecules: Focusing FFF

Josef Janca
Department of Chemistry, University of La Rochelle, La Rochelle, France

INTRODUCTION

The original idea of focusing field-flow fractionation (focusing FFF)[1] was introduced in 1982. Giddings[2] proposed the same principle in 1983 under the name hyperlayer FFF. A more detailed methodology of focusing FFF was developed later by the exploitation of various separation mechanisms.[3] The emerging discipline of isoperichoric focusing FFF represents a generalization of the original concept.[4]

The principle of focusing FFF is different from that of the polarization FFF. The crucial difference between the focusing and polarization mechanisms is that the intensity and direction of the driving field force must be dependent on the position across the channel and converging in focusing FFF, whereas it is position independent in polarization FFF. The sample components are focused at different altitudes across the channel and, consequently, eluted at different velocities corresponding to their positions within the flow velocity profile in focusing FFF, as shown in Fig. 1A. Although focusing FFF is as yet in a stage of fundamental investigation, some applications concerning the fractionation of macromolecular and particulate species have been published.

METHODS AND TECHNIQUES

Focusing can take place only if a gradient of the effective forces exists and the magnitude of these converging forces is position dependent and is zero at the focusing point. Various combinations of fields and gradients determining the focusing FFF methods and techniques can be exploited, as demonstrated in the following subsections.

Effective Property Gradient of the Carrier Liquid Combined with a Field Action

The gradient of an effective property of the carrier liquid combined with the action of a field can lead to the focusing of macromolecules or particles. For example, a density gradient combined with a gravitational or centrifugal field leads to focusing of the species at their isopycnic positions, amphoteric species focus at their isoelectric points in a pH gradient combined with an electrical field, and so forth. All these phenomena are known under the general term *isoperichoric focusing*, introduced by Kolin.[5]

Usually, the same primary field forces as those that produce the effective property gradient, are used to generate the focusing. However, the use of secondary field forces of a different nature to generate the focusing phenomenon within the corresponding gradient established by the primary field is possible; for example, isopycnic focusing of large-sized uncharged particles due to a weak gravitational field force was found effective under dynamic focusing FFF conditions, where the density gradient was generated by an electrical field acting on small charged colloidal particles suspended in the carrier liquid.[6] The construction of the fractionation channel is extremely simple, as shown in Fig. 1B. This principle, applied under static or dynamic FFF conditions, is promising for high-performance analytical and micropreparative separations.

Although focusing under static conditions, without the action of perpendicularly (with respect to the focusing axis) applied bulk flow, can lead to good separation of the focused species, theoretical calculations, as well as experimental tests, have shown increase in resolution under the dynamic conditions of focusing FFF.

Cross-Flow Velocity Gradient Combined with a Field Action

The velocity gradient of the carrier liquid across the fractionation channel, generated by transversal flow through semipermeable walls, which opposes the action of an external field, can produce the focusing phenomenon. A longitudinal flow is applied simultaneously. This method is called elutriation focusing FFF and has been used to separate model mixtures of polystyrene latex particles and silica particles in a trapezoidal cross-section channel.[7] The principle of this fractionation channel is shown in Fig. 1c. A similar focusing FFF principle can be utilized in a rectangular cross-section channel with two opposite semipermeable walls if the flow rates through the walls are different.[8]

Lift Forces Combined with a Field Action

The hydrodynamic lift forces appearing at high flow rates of the carrier liquid, combined with field forces, are able to concentrate suspended particles into focused layers. While the field forces in polarization and steric FFF concentrate the retained species at the accumulation wall, the lift

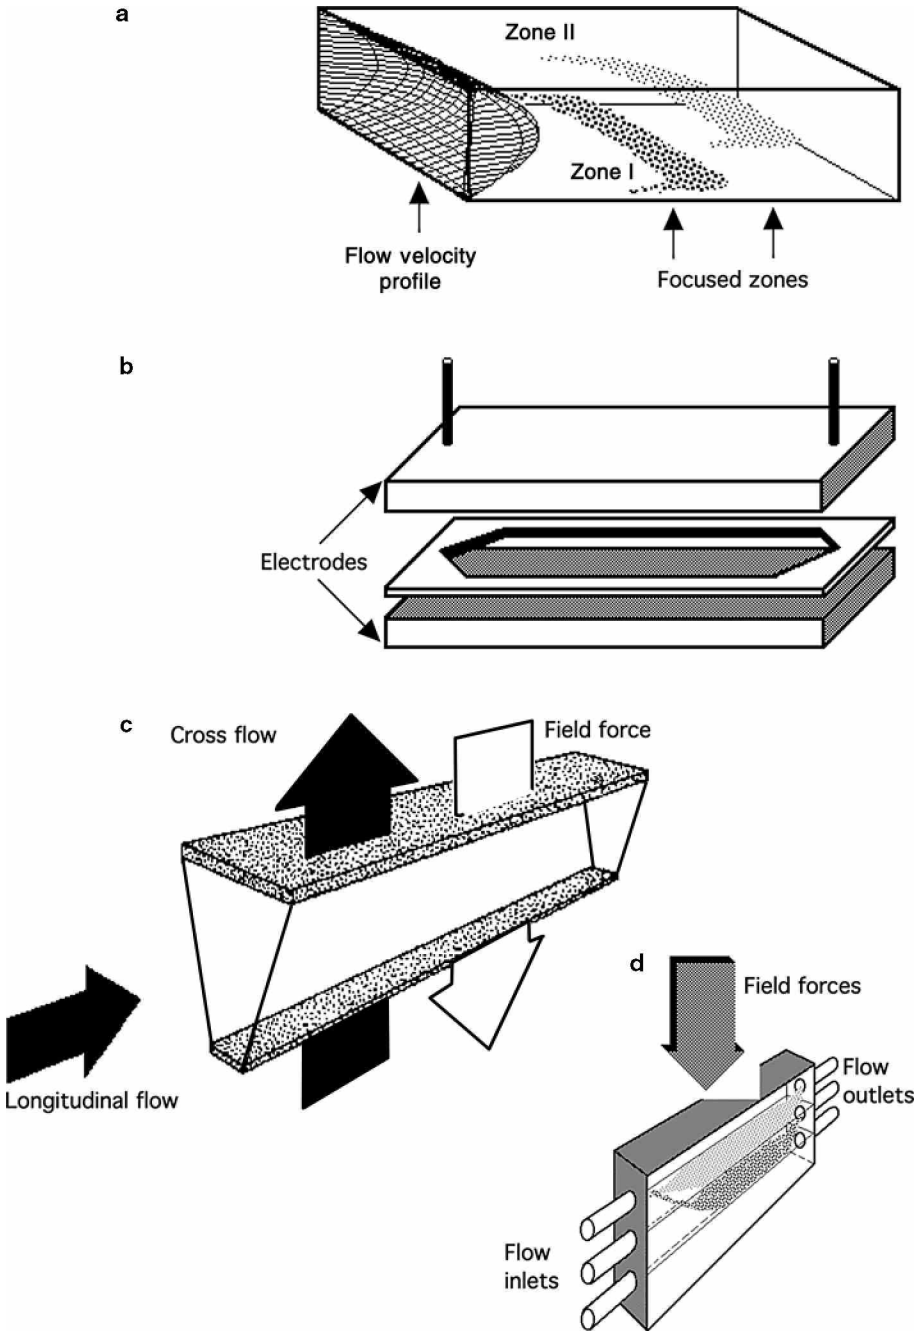

Fig. 1 Principle of focusing field-flow fractionation. a, Section of the channel demonstrating the principle of focusing FFF with two distinct zones focused at different positions and the parabolic flow velocity profile; b, Design of the channel for dynamic focusing FFF in coupled electrical and gravitational fields; c, Schematic representation of the trapezoidal cross-section channel for elutriation focusing FFF; and d, Separation channel for continuous preparative focusing FFF operating in natural gravitational field with three inlet capillaries allowing one to preform the step density gradient by pumping three liquids of different densities and with three outlet capillaries to collect the separated fractions.

forces, becoming operational at high flow rates, pull the particles away from this wall. As a result, the transition from polarization or steric to focusing FFF appears first, followed by the proper focusing effect. In most published works, the appearance of the lift forces generating the focusing effect has been observed in sedimentation and flow FFF. For example, Wahlund and Litzen[9] observed the interference of the lift forces in polarization flow FFF carried out in an asymmetrical channel with one semi-permeable wall. Such interference perturbs the separation. However, in some cases, the lift forces have been exploited under optimized operational conditions and, as a result, high-speed and high-performance separations have been achieved. Two examples of such spectacular separations have been published for sedimentation FFF[10] and very recently for microthermal focusing FFF.[11] Although this focusing FFF method is just beginning to be used in real applications, its main advantages, high speed and high performance, seem to make it very promising.

Shear Stress Combined with a Field Action

A high-shear gradient can lead to the deformation of macromolecular coils. The entropy gradient thus

generated produces the driving forces that displace the macromolecules into a low-shear zone. The reversed elution order of high-molecular-weight polystyrenes in thermal FFF at high flow rates could be attributed to this phenomenon,[12] but another possibility to explain the reversed elution order cannot be neglected.[13]

Gradient of a Non-homogeneous Field Action

The use of a high-gradient magnetic field has been proposed to separate paramagnetic and diamagnetic species by a mechanism of focusing FFF.[14] Various aspects of focusing FFF carried out under these conditions have been discussed, but no experimental results have been published until now.

Preparative Fractionation

No principal difference distinguishes the analytical and preparative uses of focusing FFF. Both types of fractionation can be carried out under conditions of continuous operation,[15] which represents the high-performance experimental arrangement for preparative FFF. The fractionation channel, equipped with several outlet capillaries at various positions (and occasionally with several inlets to preform a stepwise gradient in the direction of the focusing), allows one to fractionate the sample, which is introduced continuously into the channel, and to collect the focused layers eluted at the individual outlets. A schematic representation of such a fractionation channel is shown in Fig. 1.

The experimental implementation of this technique has been demonstrated by the fractionation of various samples of silica particles by applying natural gravitation and a counteracting cross-flow gradient. The silica particles were separated according to size. Isopycnic or isoelectric focusing FFF, already performed on an analytical scale, can easily be transformed into such continuous large-scale separation.

APPLICATIONS

Focusing FFF represents an important contribution to the science and technology of separation and analysis of macromolecules of synthetic or natural origin. The range of molar masses and sizes of particles in submicron and micron ranges, supramolecular structures, organized biological species such as the cells and microorganisms, and so forth that can be fractionated by focusing FFF is very large.

Molecules that do not interact sufficiently with the imposed fields, such as low-molar-mass species, and that, consequently, do not exhibit the focusing effect can still be separated. The condition is that an equilibrium between them and the effectively focused species should be established. As a result, species that originally do not undergo the separation processes can be transported and thus fractionated with the "carrier" focused species.

The most important field of potential applications of focusing FFF is in research and technologies related to the life sciences and macromolecular chemistry. Problems related to trace analysis, which have enormous importance in the protection of the environment and many other scientific and technological activities, have already stimulated the development of new analytical separation methods. Focusing FFF is one of them, representing an alternative choice whenever macromolecular or particulate species are concerned.

The newest achievements in focusing FFF clearly indicate that most of the experimental implementations have been with model systems. Practical applications for daily laboratory use, elaborated to the minutest details, have rarely been described. However, the most significant advantages of these methods, already mentioned earlier, are evident. Some of these advantages are inherently related to the separation principle of focusing FFF, such as the absence of a large surface area inside the separation channel, which is of crucial importance for sensitive biological materials, which can be denatured by contact with active surfaces.

The operational variables, such as the strength of the field, the flow rate, and so forth, can be manipulated continuously in a very wide range. Another advantage is that although specific FFF apparatuses are already in production, the instruments commercially available for liquid chromatography (LC) can easily be adapted for use with focusing FFF methodology. All specific components of the complete focusing FFF apparatuses are identical to those for LC, except the separation channel, which, in most cases, is not difficult to construct in the laboratory. Certainly, focusing FFF represents a large field of challenges, soliciting creativity and inventiveness in theory, methodology, and practical applications.

PCR Products: CE Analysis

Mark P. Richards
Livestock and Poultry Sciences Institute (LPSI), Agricultural Research Service, U.S. Department of Agriculture (USDA-ARS), Beltsville, Maryland, U.S.A.

INTRODUCTION

It is now possible to routinely analyze very small amounts of DNA using a procedure known as the polymerase chain reaction (PCR).[1] PCR involves repeatedly subjecting a buffered salt solution containing deoxyribonucleotide triphosphates (dNTPs), two strand-specific oligonucleotide primers, a thermalstable DNA polymerase enzyme (Taq), and a small amount of the DNA to be analyzed to a three-step temperature cycle. Using PCR, discrete regions of the source DNA molecules are copied and amplified by the repetitive cycling to readily detectable levels. It is also possible to analyze RNA sequences with PCR after an initial DNA strand (cDNA) and one complementary to it are produced from the original RNA template by the reverse transcription (RT) reaction.[2] The combined process, RT–PCR (also referred to as RNA–PCR), has been effectively used to study small amounts of RNA, such as individual messenger RNAs (mRNAs) or viral RNA, present in tissues and physiological fluids. Both PCR and RT–PCR produce double-stranded DNA (dsDNA) fragments of various sizes which are subsequently isolated and characterized by a number of qualitative and quantitative methodologies.

DISCUSSION

The most common method of analyzing PCR and RT–PCR products involves separating a portion of the reaction mixture by agarose slab gel electrophoresis with ethidium bromide staining to detect the presence of the amplified dsDNA fragments.[3] There are several disadvantages associated with slab-gel techniques, including the following:

1. Gel casting and handling are costly, labor intensive, and not readily automated.
2. A significant portion of the PCR or RT–PCR sample is typically consumed by this mode of analysis.
3. Buffer and reagent consumption, and hazardous waste generated from the use of radioactive probes and ethidium bromide stain, can be considerable.
4. Quantitation requires additional steps and instrumentation for gel imaging and analysis.

During the past decade, capillary electrophoresis (CE)-based techniques have been developed and refined for the analysis of dsDNA products of PCR and RT–PCR.[4–7] CE has several advantages over conventional slab-gel separation techniques, including the following:

1. Capillary electrophoresis instrumentation is fully automated with respect to sample injection, separation, on-capillary detection, and postrun data analysis.
2. Because the separation is conducted in a narrow-bore capillary that facilitates Joule heat dissipation, higher field strengths can be used, resulting in enhanced resolution and shorter run times.
3. Very small amounts (nl) of sample are required for the analysis, thus preserving more of the original sample for subsequent procedures, such as cloning or sequencing.

Considering the expanding base of CE applications, it is becoming clear that the majority, if not all, of conventional slab-gel separation techniques can be readily adapted to capillary format. Analysis of PCR products by CE is becoming more routine and it will likely become one of the primary applications of CE in the area of DNA separations.[6] This entry describes the use of CE-based techniques for the analysis of dsDNA products from PCR and RT–PCR.

Table 1 summarizes selected parameters that are important for establishing a robust and reproducible technique for the separation and quantification of dsDNA products of PCR and RT–PCR using CE. Important advances have been made in a number of areas, including capillary coatings, sieving gel matrices, and high-sensitivity detection methods. Because of a

Table 1 Analysis of PCR products by CE: selected technique parameters.

Capillaries
Untreated (bare-fused silica): not frequently used
Coated: polyacrylamide, polysiloxane (e.g., DB-1, DB-17), polyvinyl alcohol
Separation matrix
Buffer: 89–100 m*M* Tris-boric acid, 2 m*M* EDTA, pH 8.2–8.5 (1X TBE)
Sieving gel
Chemical (fixed) gels: cross-linked polyacrylamide, bonded to capillary wall
Replaceable Gels (entangled polymer networks): linear polyacrylamide, methyl cellulose, hydroxypropylmethyl cellulose, hydroxyethylcellulose, polyethylene oxide, polyvinyl alcohol, agarose
Intercalating dyes: 9-aminoacridine (non-fluorescent), ethidium bromide, TOTO, YOYO, YO-PRO-1, TO-PRO-1, TO-PRO-3, SYBR Green I, EnhanCE™
Sample injection
Hydrodynamic: high reproducibility; useful for quantitative analyses; direct injection of untreated samples possible
Electrokinetic: affected by sample salt concentration (i.e., prior dialysis or dilution of the sample required)
Detectors
Ultraviolet (UV): 254–260 nm, least sensitive
Laser-induced fluorescence (LIF): up to 1000 × more sensitive than ultraviolet
Data analysis
Qualitative: optimization of PCR conditions and product characterization
Quantitative:
Relative: ratio of product (target) to "housekeeping" gene or other heterologous dsDNA internal standard
Competitive: ratio of product (target) to homologous, modified internal standard (competitor); most accurate estimate
Applications
Clinical/diagnostic: screening for genetic abnormalities and diseases
Forensic: human identity testing
Biotechnology: genetic analysis, gene expression, genotyping

nearly identical linear negative charge density at neutral pH and above, dsDNA molecules exhibit an electrophoretic mobility in free solution that is independent of molecular size.[3] Therefore, a gel or sieving matrix is required to effect a separation based on molecular size and, for that reason, capillary gel electrophoresis (CGE) has become the specific separation mode most often used for PCR product analysis. Because of the negative charge on DNA molecules, uncoated (bare fused silica) capillaries, which above pH 7 exhibit a strong electro-osmotic flow (EOF) in the direction of the cathode, are rarely if ever used. Instead, capillaries treated with a specific interior surface coating to greatly reduce or completely eliminate EOF are routinely employed in the separation of DNA, a process that is conducted in reversed polarity mode (i.e., cathode at the capillary inlet side). Capillary surface coatings can either be covalently bound to the surface or dynamically adsorbed to the wall. Examples of typical surface coatings include polyacrylamide, polysiloxanes (dimethyl and phenyl–methyl), cellulose derivatives, and polyvinyl alcohol.[4–7]

Early CGE separations of dsDNA made use of capillaries in which a polyacrylamide gel was polymerized in and linked to the wall of the capillary, producing what has been referred to as a fixed or chemical gel.[4–7] Although such gels are capable of extremely high resolution due to a well-controlled pore size, they are not commonly used for PCR product analysis because of the problems related to air bubble formation and limited useful lifetime.[5] The development of replaceable sieving gels (also referred to as entangled polymer networks) that can be flushed from the capillary after the separation is complete has been one of the major factors in establishing CGE as a routine method for PCR product analysis. With this system of replaceable gels, a "new" gel is used for each separation. Some of the most widely used replaceable gel compounds include linear polyacrylamide, alkylcelluloses, polyethylene oxide, agarose, and polyvinyl alcohol.[4–7] These polymer compounds are employed to produce viscous buffered solutions that enable the separation of dsDNA in a capillary based on molecular size.[5] In general, the pore size and, hence, the resolving capacity for dsDNA molecules are controlled by simply manipulating the gel concentration.

One factor that initially hampered the direct analysis of PCR samples by CGE was the presence of high levels of salt, especially chloride ions, in the samples injected into the capillary. Electrokinetic injection, which is the requisite loading method when using fixed gels, is severely affected by the presence of high salt concentration because it impairs the loading of dsDNA into the capillary. Although PCR samples can be injected directly into capillaries using replaceable gels, the presence of salts adversely affects the quality of the results obtained. Also, the presence of other components in the PCR sample (dNTPs, primer oligonucleotides, etc.) not only affect the separation, but they can also obscure peaks when ultraviolet (UV) detection is employed. Fortunately, two relatively simple cleanup methods have been devised to counteract the effects of the PCR sample matrix. The two most common methods are sample microdialysis (float dialysis) and dilution of the sample (20–100-fold) with deionized water prior to CGE.[6] Both methods are effective in reducing the adverse effects of salts, but sample dilution necessitates the use of high-sensitivity detection to compensate for the reduction in the dsDNA concentration.

An important development in CE technology that has helped to promote the analysis of PCR products by CGE is the introduction of laser-induced fluorescence (LIF) detection.[4–7] Because LIF can increase the sensitivity of detection for dsDNA by more than 400-fold over UV detection, it has become the method of choice for the vast majority of dsDNA separations.[5] A practical illustration of the advantage of LIF detection is that typical separations of PCR products by slab-gel electrophoresis with ethidium bromide staining require approximately 5 ng of DNA per band for adequate detection, whereas, with CGE–LIF, subpicogram levels of DNA are readily detected.[6]

In order to employ LIF detection, it is necessary to label the dsDNA molecules with a fluorescent compound prior to and/or during their separation by CGE. Two approaches have been employed. The first, and most common, involves the incorporation of an intercalating dye into the separation gel buffer (and, in some cases, into the sample loading buffer), which is highly fluorescent only when bound to dsDNA. Table 1 lists a number of commonly used intercalating dyes. Both monomeric and dimeric dyes have been developed and used to detect PCR products.[8] They offer unique advantages in that they enhance detection sensitivity two to three orders of magnitude over UV detection, and separation resolution and selectivity are often improved with their inclusion.[4] A second approach involves labeling of the primers used in PCR with a fluorophore, such as fluorescein, to produce 5′-end-labeled dsDNA products that can be separated and detected by CGE–LIF. The former approach offers the highest sensitivity with the amount of intercalating dye bound proportional to the size of the dsDNA fragment (i.e., the larger the fragment, the more dye will be bound). Not only do intercalating dyes label the dsDNA for detection, but they also can enhance the selectivity and resolution of dsDNA fragments of similar size.[4,6] Intercalating dyes can also produce anomalous effects on peak shape, depending on such factors as their concentration in the separation or sample buffer and certain sequence-dependent properties of the dsDNA (e.g., %GC composition). These effects result from the binding and retention of differing amounts of dye molecules by the dsDNA fragments during CGE. Therefore, care must be taken to carefully evaluate the use of a specific intercalating dye with a particular PCR product in order to generate reproducible results.

Capillary gel electrophoresis–LIF analysis of PCR and RT–PCR products has been applied to the areas of clinical diagnostics, forensics, and biotechnology. Screening of patients for genetic and infectious diseases, human identity testing using PCR-amplified DNA fragments from specific polymorphic genomic regions (loci) defined by a variable number of tandem repeats (VNTRs) or short tandem repeats (STRs), analysis of mitochondrial DNA, genotyping, and gene expression studies are only a few examples of these applications.[4–7] The types of results that can be gained from CGE analysis of PCR products are twofold. First, CGE is useful in a qualitative evaluation of PCR by separating target DNA from non-specific products and demonstrating that a single dsDNA fragment resulted from the amplification. CGE is also a rapid method of evaluating various PCR parameters (e.g., cycle number, temperature, $[Mg^{2+}]$, [dNTPs], etc.) for optimizing the efficiency of the reaction. Another use for CGE is to accurately determine the size of the PCR products. This approach has been applied to DNA profiling in human subjects by an assessment of PCR amplified alleles resulting from VNTRs and STRs.[6]

The ability to do on-capillary detection and to calculate integrated peak areas from the collected data makes CGE–LIF very useful for the quantification of PCR- and RT–PCR-generated dsDNA products. The quantity of the amplified product can be indicative of the efficiency of PCR and this information can be used to optimize the reaction. Such information is also useful in determining the amount of a specific DNA or RNA present in the analyzed sample. Quantitation can be achieved by relative or absolute estimates. A ratio of target DNA peak area to the peak area of an added dsDNA internal standard gives an estimate of the relative amount of target DNA generated by PCR. Internal-standard dsDNAs can derive from genes that remain at constant levels in the sample (are unaffected by experimental treatments), such as the so-called "housekeeping" genes or they can be added amounts of a known quantity of a purified and well-characterized dsDNA, such as restriction enzyme digest fragments of genomic DNA. For example, the digestion of ϕX174 bacteriophage DNA with *Hae*III produces 11 distinct dsDNA

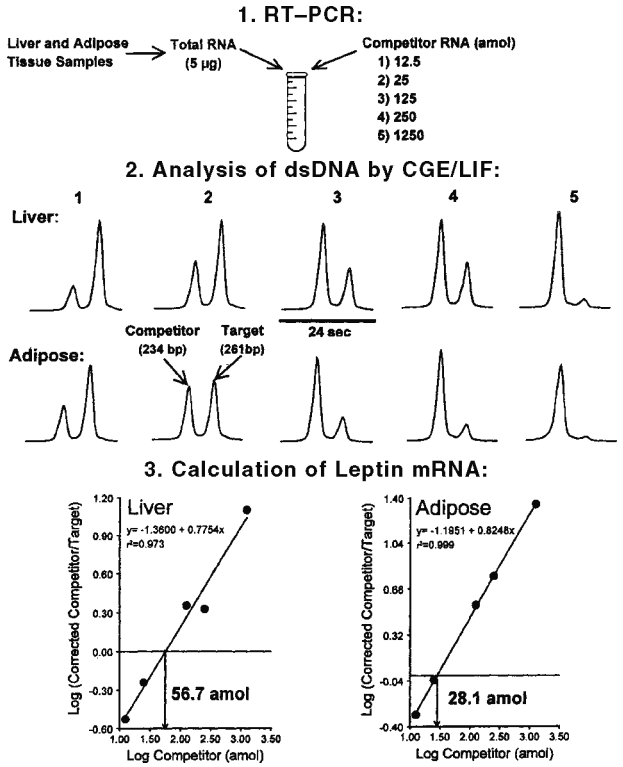

Fig. 1 Analysis of leptin gene expression in chicken liver and adipose tissue by QC–RT–PCR using capillary gel electrophoresis with laser-induced fluorescence detection (CGE–LIF). Target (261 bp) and competitor (234 bp) dsDNA amplicons were separated on a DB-1-coated capillary (27 cm × 100 mm inner diameter) at a field strength of 300 V/cm in a replaceable sieving matrix consisting of 0.5% HPMC in 1XTBE buffer with 0.5 µg/ml EnhanCE™ intercalating dye. RT–PCR samples (1–2 µl) were diluted 1:100 with deionized water and introduced into the capillary by electrokinetic injection. Separations were completed in under 5 min. A portion (4.4–4.8 min) of each separation shows the changes in the competitor and target peaks. CGE–LIF was more sensitive in detecting both amplicons than agarose slab gel electrophoresis with ethidium bromide staining. The integrated peak area ratio of competitor/target for a series of five individual samples (to which increasing amounts of a synthetic competitor RNA were added prior to RT–PCR) is used to calculate the amount of leptin mRNA (amol) in total RNA isolated from liver and adipose tissue by linear regression analysis.

fragments ranging in size from 72 to 1353 bp.[6] The latter type of standardization also affords the opportunity to accurately determine the size of the PCR product in addition to estimating its quantity when appropriate standards are chosen. Such standards can be obtained from commercial sources.

The most accurate means for quantitation of PCR products, especially those of low copy number, involves a method known as competitive PCR. In quantitative-competitive PCR (QC–PCR), known amounts of an internal standard (competitor) are co-amplified along with an unknown amount of target DNA. The competitor's sequence is chosen to be nearly identical to that of the target except for a small addition or deletion of sequence. The competitor is designed to use the same set of primers as the target so that a competition for them develops. Because the target and competitor are exposed to identical PCR conditions, the ratio of the two products should remain constant even after the reaction has reached its plateau phase. Thus, by plotting the different competitor/target peak area ratios against the amount of added competitor and extrapolating from the point at which the ratio is equal to 1, the amount of target DNA in the original sample can be determined in absolute terms. For RT–PCR, a competitor RNA is used to correct for variable conditions in both the RT and PCR steps.[9,10]

Fig. 1 depicts a scheme for the estimation of leptin mRNA (encoded by the obese gene, *ob*) contained in total RNA samples isolated from liver and adipose tissues of chickens. Using QC–RT–PCR with CGE–LIF, it was possible to derive absolute estimates (in attomoles) of leptin mRNA. Others have demonstrated a further extension of QC–RT–PCR with CGE–LIF called multiplexing, in which more than one competitor–target pair is subjected to co-amplification and subsequent analysis by CGE–LIF.[9,11] With multitarget QC–RT–PCR, it is possible to monitor PCR-amplified dsDNA corresponding to several genes simultaneously in a single sample assuming PCR conditions have been optimized for each product formed.[11]

Future applications of CE to PCR product analysis will arise from improvements in CE instrumentation. Advances in miniaturization of CE devices by producing glass chips with etched channels of <1 cm in length have already been demonstrated as a feasible method for ultrafast (<45 sec) separations of dsDNA.[4–7] The use of multiple capillaries or capillary arrays has proven to be useful in dedicated devices for DNA sequencing.[4–7] Recently, it has been possible to integrate PCR amplification and CE separation in a single device using an array of eight capillaries for high sample throughput.[12] This technology will undoubtedly produce dedicated CE instruments for PCR product analysis that will feature rapid run time and high throughput. New detection methods such as mass spectrometry offer the promise of increases in selectivity, detection sensitivity, and more accurate quantification of PCR products. It is now clear that, in the future, CEbased analyses of PCR products will continue to get faster and more reliable while achieving wider acceptance by biomedical and biotechnology laboratories.

Peak Skimming for Overlapping Peaks

Wes Schafer
Merck Research Laboratories, Rahway, New Jersey, U.S.A.

INTRODUCTION

Any discussion of quantitating overlapped peaks should be prefaced by stating that baseline resolution of peaks is the only means of absolutely assuring the accuracy of their integration. All deconvolution methods involve assumptions that can affect accuracy. These methods are particularly inaccurate in cases of small peaks eluting on the tails of much larger peaks where percent errors are measured by two to three orders of magnitude.[1,2] In any case, the accuracy of all baseline methods generally increases with increasing resolution between the overlapping pair of peaks.

DISCUSSION

This discussion is confined to single-channel chromatographic analyses such as high-performance liquid chromatography (HPLC) with single-wavelength ultraviolet (UV) detection or gas chromatography with flame ionization or thermal conductivity detection. Three-dimensional (multichannel) techniques such as photodiode-array, multiwavelength detection may allow deconvolution based on component characteristics such as absorptivity at multiple wavelengths rather than peak shape. These techniques and/or the required information about the components are not always available, however, and many routine analyses are still conducted with single-channel detection because of their lower cost and relative simplicity.

In the overlap region between two unresolved chromatographic peaks, the detector response is a function of the response due to the first peak and the response due to the second peak. For a single-channel detector, this is mathematically equivalent to a single equation with two unknowns, which is impossible to solve. Detection and integration schemes, in such cases, must make assumptions regarding the shapes of the chromatographic peaks in order to attribute the response in the overlap region to one peak or the other. In some cases, the assumption is based on the ease of determining the baseline and, in other cases, on theoretical models of chromatographic peaks such as Gaussian or exponentially modified Gaussian (EMG) distributions.

Chromatographic data analysis systems generally employ three methods for determining baselines in overlapping peaks: *perpendicular drop*, *linear tangential skim*, and *exponential skim* (see Fig. 1). In order to choose the most appropriate method, the analyst must understand the assumptions and weaknesses of the three methods.

The perpendicular drop method produces accurate peak areas for symmetrical overlapped peaks of similar height and width. In this case, the portion of the second peak attributed to the first peak is offset by the portion of the first peak attributed to the second peak and vice versa. For overlapped peaks of significantly different size, the perpendicular drop method always overestimates the peak area of the smaller peak as the smaller peak gains more area from the larger peak than it "loses" to the larger peak. Quantitation errors are further exacerbated in the case of a smaller peak imposed on the tail of a much larger tailing peak. This method tends to show little injection-to-injection variability because of its simplicity.

Linear tangential skimming, on the other hand, consistently underestimates the area of the smaller peak by neglecting that portion of the peak area under the tangential baseline. As seen in Fig. 1, it is easy to visually underestimate the size of a peak that is unresolved from a significantly larger one, giving the appearance that the linear tangential skim method is much more accurate than it is. The relative simplicity of this method makes it rugged as well.

Many commercial software packages offer a non-linear exponential skimming method as well. As it has been estimated that 90% of all chromatographic peaks can be modeled by an exponentially modified Gaussian function,[3] this method should be the most accurate for tailing overlapped peaks. The algorithms for calculating such baselines are considerably more complicated, however, and the reproducibility of the technique may be problematic for some separations. The calculation of necessary parameters may limit its usefulness in extreme cases of tailing and peak width. In addition, the ability of exponential skimming to mimic symmetrical (Gaussian) peaks may also be an issue in some software. Examination of the constructed baselines is crucial in determining the proper use of this technique.

The peak area errors for the two most studied deconvolution methods (i.e., perpendicular drop and linear tangential skim) are dependent on a complex combination of resolution, relative peak width, relative peak height, and asymmetry ratio.[1] Exponential skimming assumes that the tailing of the first peak can be described by an exponential decay and that the peaks are sufficiently resolved to

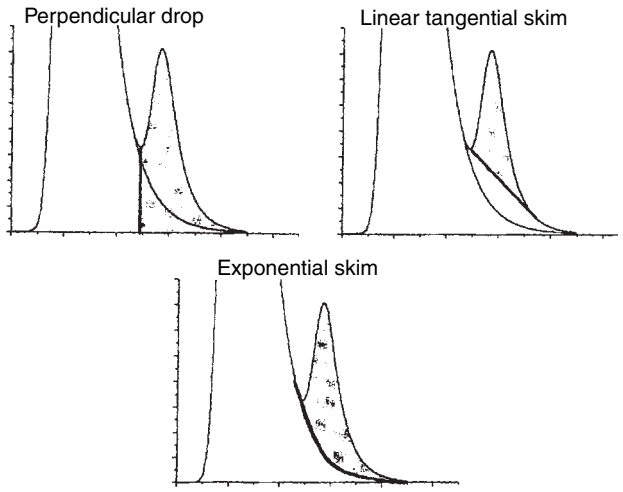

Fig. 1 Common methods for determining the baselines of overlapping peaks.

determine the decay parameters. Nonetheless, some broad generalizations can be made:

1. For symmetrical overlapped peaks of equal size and width, the perpendicular drop method provides accurate peak areas. Peak heights may still be overestimated.
2. In general, exponential skimming should be used when the first peak tails significantly or when the peak widths are significantly different. Care should be given that the area calculated by this method does not exceed the area by the perpendicular drop method, which already overestimates peak area.
3. For cases when exponential skimming is not possible or appropriate, due to extremely poor resolution or tailing, the tangential skim method should be used when the peak widths of the unresolved peaks vary significantly (>2:1).[2]
4. Quantitation by peak height should also be considered. It has been shown that peak height is more accurate in cases where the sizes of the overlapping peaks vary widely (>100:1). Quantitation is also generally more accurate for peak pairs of disparate size if the smaller peak elutes first.[1]

Although only doublets have been considered here, the arguments can be extended to multiplets by considering the effects on the front and tail of surrounded peaks.

Pellicular Supports for HPLC

Danilo Corradini
Institute of Chromatography, Rome, Italy

INTRODUCTION

In current practice, high-performance liquid chromatography (HPLC) supports consist of siliceous or polymer-based materials having pore sizes in the range of 80–120 Å for chromatography of small molecules and of 300–1000 Å for large biological molecules. Diffusional resistances in the stagnant mobile phase in the retentive material can have a significant influence on the efficiency of separation, particularly for large molecules of biological origin. Furthermore, pore size distribution of many mesoporous particles is rather wide and poor mass recovery is frequently encountered due to entrapment of macromolecules in the porous interior.

DISCUSSION

One approach to minimize mass-transfer resistance in a stagnant mobile phase employs specially designed particles with a bimodal network of pores. The larger pores (1000 Å) facilitate convective transport of the mobile phase inside the particles, whereas the small pores (500 Å) are explored by the sample components by diffusion only and provide the necessary surface area for adequate sorption capacity.

Another approach consists in eliminating the pore structure, using pellicular column packing materials. These HPLC supports are mechanically stable, fluidimpervious microspheres with a thin retentive layer on the surface.[1,2] Such a stationary-phase configuration facilitates the interactions of the analytes with the active moieties of the stationary phase, which are completely exposed to the mobile-phase steam in the interstitial space of the column packing material. Because the diffusional path length in the retentive surface layer of the pellicular stationary phase is very short, the plate height contribution to the *C* term in the van Deemter equation is relatively small. It should be recalled that the *C* term in the van Deemter equation estimates the contribution to the plate height of the resistance to mass transfer. As a result, the absence of intraparticulate diffusional resistance and the fast mass transfer between the stationary and the mobile phases due to the small particle size allows high column efficiency, even at relatively high flow rates. In addition, the lack of internal pore structure eliminates the undesirable steric effects encountered in HPLC of large biological molecules with mesoporous stationary phases, resulting in good sample recovery.

With porous materials, the largest contribution to the total surface area is due to the area contained within particles; it is related to the pore volume, surface area, and pore diameter. As a result, there is little variation in the total surface area of packing materials with different diameters, but identical pore size. On the other hand, with pellicular particles, the total surface area within a column is a function of particle size. Consequently, stationary phases having the pellicular configuration have an adsorption capacity lower than the conventional mesoporous particles. This appears to be particularly so with micropellicular materials in HPLC of small molecules. With large molecules such as proteins, the loading capacity of columns packed with traditional mesoporous particles may be only three or four times higher than that of columns packed with the micropellicular stationary phases.[3] However, this somewhat low loading capacity is still adequate in the analytical mode and is more than compensated for by the high analytical speed and efficiency obtained with pellicular stationary phases.

Conventionally, the phase ratio is the volume of the active moieties of the stationary phase divided by the volume of the mobile phase in the column. From the particular configuration of pellicular stationary phases described earlier, it follows that they have a relatively low phase ratio with respect to that of the conventional packing materials employed in HPLC.

A variety of micropellicular packing materials has been developed for the analysis of both small and large molecules by various HPLC modes, including ion exchange (IEC), metal interaction (MIC), reversed-phase (RPC),[4] and affinity chromatography (AC).[5] Besides analytical applications, other possible utilization of micropellicular stationary phases includes fundamental kinetic and thermodynamic studies of the retention mechanisms on a well-defined surface. Nevertheless, a relatively limited variety of micropellicular columns are commercially available. They are mainly restricted to ion-exchange and reversed-phase stationary phases. This may reflect certain practical disadvantages of micropellicular sorbents.

Columns packed with pellicular stationary phases of small particle size have low permeability and, therefore, cannot be operated at relatively high flow rates due to the pressure limitation of commercial HPLC instruments. However, due to the non-porous structure, micropellicular particles are generally more stable at higher temperature than conventional porous materials. Consequently, in the

absence of limitation due to the thermal stability of either the sample or the bonded stationary phase, a column packed with non-porous materials can be operated at elevated temperatures with practical advantages from column permeability and sorption kinetics. This appears to be particularly so with several micropellicular materials employed in reversed-phase HPLC. By increasing the column temperature, the viscosity of the mobile phase decreases with concomitant increases in column permeability, which allows operating the column at high flow rates. In addition, with increasing temperature, sample diffusivity also increases and, in many cases, the sorption kinetic improves.

The elevated mechanical and thermal stabilities of pellicular stationary phases having a solid, fluid-impervious core have favored the development of non-porous particles tailored for the rapid HPLC analysis of peptides, proteins, and other biopolymers. Most of these applications are in RPC.

Although governed by the same separation mechanism, RPC of proteins differs significantly from that of small molecules because of high molecular weight and complex tertiary structure of these macromolecules. A large molecular size is associated with low diffusivity and molecular complexity is associated with multipoint interactions of proteins with the hydrophobic stationary phase, which complicate the dynamics of the separation process. In addition, the elution of certain proteins may be further complicated by conformational changes associated with the retention mechanism. Hence, RPC of proteins and other complex macromolecules is generally performed under the gradient elution mode, which reduces analysis time and improves the performance of separation. In the reversed-phase gradient elution mode, proteins are believed to be retained at the column inlet until, at some point in the gradient, corresponding to the proper mobile-phase composition, they are desorbed completely. Proteins then move through the column without apparent further interaction with the hydrophobic stationary phase.

In most cases, RPC of peptides and proteins are performed under denaturing conditions using hydro-organic mobile phases containing acidic additives such as trifluoroacetic or phosphoric acid. Because the elution strength of the mobile phase increases by decreasing its polarity, the appropriate gradient is produced by increasing the concentration of the organic solvent in the hydro-organic mobile phase during the chromatographic run. The variation of the eluent composition as a function of time gives the gradient shape, which is steep in the case of fast analysis performed with micropellicular reversed phase (i.e., high rate of change of mobile-phase composition during gradient elution).

Steep gradients require high flow rates in order to maintain satisfactory differences in retention of the analytes. According to Snyder and Standalius,[6] the influence of the gradient parameters on retention is given by

$$k = \frac{t_g F}{1.15 \Delta\phi V_m S} \quad (1)$$

where k is the effective capacity factor for gradient elution, which is the value of the corresponding capacity factor under isocratic conditions (k') for the peak when it reaches the column midpoint, t_g is the gradient time (time from the beginning to the end of the gradient), F is the flow rate, $\Delta\phi$ is the variation of the fraction of organic solvent in the mobile phase during gradient, is the column void volume, and S is the slope of the plot of the logarithmic retention factor (k') against mobile-phase composition under isocratic conditions. The value of the parameter S is related to the magnitude of the hydrophobic contact area and the number of the interaction sites established between the solutes and the stationary phase during the separation process. In comparison to small molecules, biopolymers have a larger contact area with the stationaryphase surface and, as a result, the retention is very sensitive to the content of the organic solvent in the hydro-organic mobile phase (i.e., the value of the parameter S is relatively large).

Eq. 1 clearly shows that in order to maintain K constant while decreasing t_g, the flow rate must be proportionally increased. Because of the favorable mass-transfer properties of pellicular stationary phases, columns packed with such material can be employed at a high flow rate without loss in resolution. Moreover, pellicular column packings have a negligible intraparticulate void volume and, after the gradient, can be rapidly reequilibrated to the starting conditions. Finally, the thermal stability generally exhibited by these stationary phases allows running the gradient at relatively elevated temperature with the beneficial effect of reducing the viscosity of the mobile phase, which reflects on reducing the column inlet pressure. In addition, temperature influences the retention behavior of the analytes. Generally, the chromatographic retention decreases with increasing temperature, with concomitant improvement in column efficiency due to increased solute diffusivity and faster mass transfer. However, with proteins, the retention may increase and efficiency decrease when temperature promotes further unfolding of the protein.

Pellicular packings may also consist of a fully functionalized layer encapsulating solid particles, where there is no physical attachment of the active layer to the core particles[7] or as colloidal particles bearing charged moieties (latex) electrostatically bound to a solid core functionalized with groups of opposite charge (Fig. 1).[8] Most of the anion-exchange columns in use today for either carbohydrate or ion chromatography are packed with electrostatically latexcoated pellicular ion exchangers. These sorbents consist of three parts: (a) a highly cross-linked polymeric non-porous core, (b) a sulfonated layer at the outer surface of the solid core, and (c) a monolayer coating of anion-exchange latex particles functionalized with quaternary

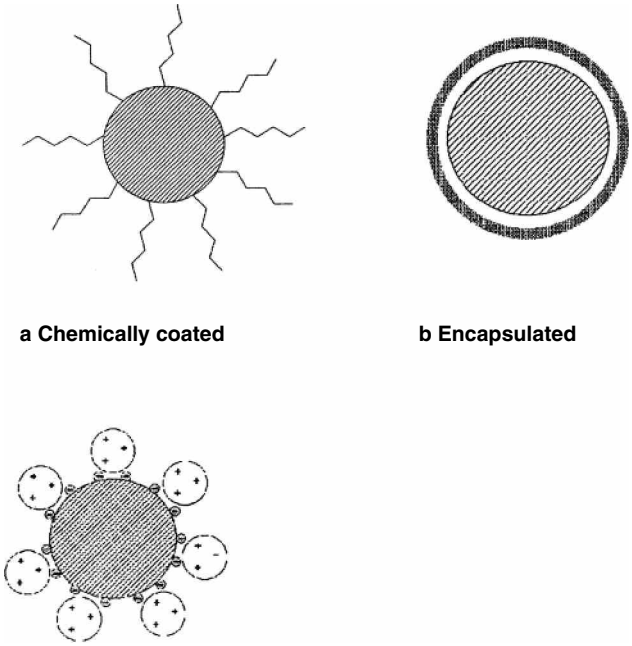

Fig. 1 Shematic representation of pellicular stationary phases consisting of covanlently bonded functional groups at the surface (a) funtionalized layer-encapsulating solid particles (b) and functionalized particles electrostatistically bound to a solid core groups of opposite charge (c).

ammonium compounds. The solid support and the latex particles are manufactured separately and brought together after independent quality control performed to remove particle agglomerates. This allows easy control of phase thickness, which results from the monodisperse latex particles, attached to the solid core by electrostatic forces. As a result, loading capacity increases with increasing the diameter of the latex particles, which generally ranges from 50 to 500 μm. For a 250 mm × 4 mm I.D. column, the corresponding loading capacity ranges from 5 to 150 μmEq/column.

The highly cross-linked polymeric non-porous core may consist of either a polystyrene-divinylbenzene or an ethylvinylbenzene-divinylbenzene substrate. The latex coatings are generally made from vinylbenzenylchloride polymer cross linked with divinylbenzene and fully functionalized with an appropriate quaternary amine for introducing anion-exchange properties.

Pellicular anion-exchange sorbents may also consist of quaternized latex hydrophobically coated onto the surface of an unsulfonated polystyrene solid core. However, using hydro-organic mobile phases can easily wash off the latex particles held onto the particle surface by hydrophobic interactions.

Peptides and Proteins: TLC Analysis

C. Marutoiu
Department of Chemistry, Lucian Blaga University of Sibiu, Sibiu, Romania

M.L. Soran
National Institute of Research and Development for Isotopic and Molecular Technology, Cluj-Napoca, Romania

INTRODUCTION

Thin-layer chromatography (TLC) and the more modern technique—high-performance thin-layer chromatography (HPTLC)—have numerous applications in proteins chemistry. These techniques are used for the quantitative determinations of peptides (nanograms), identification of peptides in partially hydrolyzed proteins, correlation of chromatographic properties for peptides and their constituent amino acids, as well as identification and characterization of proteins present in small quantities.

Various mixtures of peptides and proteins can be separated and identified using different stationary phases, such as silica gel, cellulose, mixtures of cellulose and silica gel, hydroxylapatite, ion exchangers, and other chemically modified stationary phases.

SEPARATION OF PEPTIDES

Various types of peptides can be separated on cellulose plates using various mobile phases, e.g.,

- *n*-butanol–acetic acid–pyridine–water (15:3:10:12, v/v);
- *n*-butanol–acetic acid–5% NH_4OH (11:6:3, v/v);
- chloroform–34% NH_4OH–ethanol (2:1:2, v/v);
- ethanol–pyridine–water–acetic acid (5:5:3:1, v/v);
- *n*-butanol–acetic anhydride–water (4:1:1, v/v);
- *n*-butanol–acetic acid–water (4:1:1, v/v);
- chloroform–methanol (3:1, v/v);
- chloroform–methanol–acetic acid (45:4:1, v/v);
- phenol–water (3:1, v/v);
- *n*-butanol–pyridine–water (15:10:3, v/v);
- *n*-butanol–pyridine–acetic acid–water (130:20:6:24, v/v);
- chloroform–methanol–water (68:25:4, v/v);
- chloroform–acetone (5:1, v/v; 8:2, v/v; 9:1, v/v);
- propanol–acetic acid–water (3:3:2, v/v);
- chloroform–methanol–17% NH_4OH (2:2:1, v/v);
- isoamyl alcohol–ethanol–acetic anhydride–pyridine–water (175:50:13:175:150, v/v);
- *iso*-propyl alcohol–ethanol–NH_3 (4:4:3, v/v);
- *iso*-propyl alcohol–1 N HCl (3:3, v/v);
- 0.1 N HCl–96% ethanol (1:1, v/v);
- 0.5 N HCl–ethanol–acetone (5:3:0.5, v/v);
- *iso*-butanol–pyridine–water (7:7:6, v/v);
- isoamyl alcohol–pyridine–water (7:7:6, v/v).

The following mobile phases have been used for separations on silica gel plates:

- *n*-butanol–acetone–water–pyridine (15:3:10:12 or 30:6:30:24 or 60:20:6:11, v/v);
- *n*-butanol–acetone–water (5:2:3, v/v);
- chloroform–methanol (7:3 or 9:1 or 1:9, v/v);
- *n*-butanol–acetic acid–water–ethyl acetate (1:1:1:1, v/v);
- *n*-butanol–pyridine–acetic acid–water (12:4:1:4 or 15:10:3:12 or 15:10:6:12, v/v);
- water–ethyl acetate–propanol (2:5:3, v/v);
- *n*-butanol–acetic acid–water (4:1:1, v/v);
- ethyl acetate–pyridine–acetic acid–water (56:20:6:11, v/v);
- dichloromethane–methanol–acetone (19:3:1 or 40:1:2 or 19:2:1 or 20:1:1 or 20:2:1, v/v);
- hexane–ethyl acetate–acetone (11:7:1, v/v);
- *n*-butanol–acetone–ethyl acetate–water (1:1:1:1, v/v);
- dichloromethane–methanol–10% NH_3 (10:1:0.1 or 10:3:0.1, v/v);
- *n*-butanol–dioxane–water (4:5:1, v/v).

Silica gel impregnated with 5% liquid paraffin in petroleum ether is another stationary phase, which is sometimes used for the separation of peptides. The separations are performed using the mixture methanol–water (1:4, v/v) as mobile phase.

The separation of this class of substances on silica gel C-18 is performed with dichloromethane–hexane (5:95, v/v) and methanol–water (1:1, v/v).

DETECTION OF PEPTIDES ON CHROMATOGRAPHIC PLATES

The detection of peptides is performed using various visualizing reagents. The hexa- and penta-peptides are visualized either in UV light after spraying with Pauly's reagent (4-sulfo-benzenediazonium hydroxide in 2 N Na_2CO_3), by the Reindel–Hoppe procedure, or by spraying with ninhydrin. The peptides of type Ac-Pro-Val-Val-Ser-Gly-NH_2,

Ac-Pro-Glu-Val-Ala-Gly-NH_2 can be visualized with chlorine–toluidine reagent. The cyclic peptides can be visualized by immersion of the developed chromatographic plates in 20% trichloracetic acid for 10 min and 5 min in 0.3% Serwa Blue W aqueous solution. In the case of peptides with a poly-[Lys(X_i-DL-Ala_m)] formula, the detection is performed with 0.3% ninhydrin solution in acetone and starch–KI reagent.

The tri- and tetra-peptides, in various mixtures, separated on silica gel plates, are identified in UV light or by spraying with ninhydrin, t-BuOCl/starch–KI, or Sakaguchi reagent.

The method of the iodine-starch reagent consists of the introduction of the developed plate into an iodine vapor atmosphere for 5 min, followed by spraying with 1% aqueous starch solution. The peptides produce blue spots.

Morin reagent is also used for the detection of peptides. The developed plates are dried and sprayed with 0.05% morin (3,5,7,2′,4′-pentahydroxyflavone) solution in methanol and activated for 2 min at 100°C. In this case, the peptides produce yellowish-green fluorescent spots on a green fluorescent background or dark absorption spots under UV light. The detection limit is just about 2 μg/spot. Detection of ^{32}P-labelled opioid peptides is done by autoradiography.

SEPARATION OF PROTEINS

A mixture of 14 proteins (cytochrome C, ribonuclease, lysozyme, myoglobin, α-chymotrypsin, trypsin, ovomucoid pepsin, ovalbumin, hemoglobin, bovine serum albumin, bovine γ-globulin, thyroglobulin, and macroglobulin) was separated on Sephadex G-100 and Sephadex G-200 plates, using 0.5 *M* NaCl solution as mobile phase.

The neoglycoproteins were separated on silica gel using dichloromethane–methanol (9:1, v/v), dichloromethane–acetone (8:2, v/v), or acetone–25% NH_3 (6:4, v/v) as mobile phase. Using DEAE-cellulose on chromatographic plates and a mobile phase containing 0.01 *M* sodium phosphate solution, bicine, or sodium chloride, proteins such as albumin, transferrine, lactoferrine, and lysozyme are separated as reference compounds. The optimum pH-value for the separation is 8.5.

The composition of protein and lipid in chemically modified keratin fibers was analyzed on silica with chloroform–methanol (80:2, v/v). A rapid immunochromatographic method for the analysis of protein antigens, based on a "sandwich" assay format, uses monoclonal antibodies of two distinct specificities, one covalently immobilized to a defined detection zone on a porous membrane, while the other serves as a label. The sample is mixed, and is then passed along the porous membrane by capillary action, giving a blue color with the antibodies in the detection zone. The detection limit can be below the nanomolar range for the antigen, as in the case of the human chorionic gonadotropin.

Two-dimensional TLC separations of 4-*N*,*N*-dimethylaminoazobenzene 4′-isothiocyanate protein derivatives were performed on polyamide using an acetic acid–water (1:2, v/v) mixture for development in one direction and toluene–hexane–acetic acid (2:1:1, v/v) mixture for the second direction.

TLC of HBsAG segments (HBsAG = hepatitis B-virus) was done on silica with solvent systems obtained by mixing ethyl acetate with a stock solution of pyridine–acetic acid–water (20:6:11, v/v). TLC separation of high-density lipoprotein and oxidized high-density lipoprotein were performed on silica gel with chloroform–NH_3–methanol–water (180:11:108:11, v/v) systems.

DETECTION OF PROTEINS

The neoglycoproteins were identified by spraying the plates with sulfuric acid. A series of proteins and lipids separated from the mixture were visualized by exposure to iodine vapors. HBsAG segments were visualized by spraying with tolidine–KI after chlorination.

The proteins separated on gel layers are transferred onto filter paper (Whatman 0.3 mm) and are visualized by the usual methods of paper chromatography, i.e., the dried paper is introduced, for 15 min, into Amido Black 10B (0.6 g) dissolved in methanol/ethanol (750 ml), water (450 ml) and glacial acetic acid (100 ml) mixture and treated three times with 1% acetic acid for 30 min each time. Alternatively, the paper is stained in a 1% solution of bromophenol blue saturated with mercuric chloride for 5 min and then treated five times with 0.5% acetic acid for 30 min each time.

CONCLUSION

Separation of peptides and proteins has been described with many examples being included. Effective visualization techniques are also discussed.

Peptides, Proteins, and Antibodies: Capillary Isoelectric Focusing

Anders Palm
Cell and Molecular Biology, Astra Zeneca, Lund, Sweden

INTRODUCTION

Capillary isoelectric focusing (CIEF) is a high-resolution technique for protein and peptide separation performed at academic sites and in the biotechnology and pharmaceutical industries for the analysis and characterization of, for example, recombinant antibodies and other recombinant proteins, isoforms of glycoproteins, point mutations in hemoglobin, and peptide mapping. Also, hyphenation to mass spectrometry and chipbased CIEF (microfabrication) have shown promise. CIEF kits and specific recipes/application notes are available from vendors of capillary electrophoresis (CE) equipment, as are a vast amount of publications and handbooks of CE published over recent years.

Capillary isoelectric focusing is a rapid analysis technique with typical run times of 5-30 in, fully automated with online detection and real-time data acquisition, and minute sample consumption (a few microliters is enough for repetitive injections). A linear dynamic range over one order of magnitude is achievable, and a detectability down to 5-10 μg/ml. A resolution of ΔpI-0.01 is possible under optimized conditions. Reproducibility of p*I* determination is typically $<0.5\%$ (RSD) using internal standards.

SAMPLE SALT CONTENT

For high-performance analysis, it is important that the sample applied has a low salt content.[1] Salt concentrations below 10 m*M* is preferable; concentrations above 40–50 m*M* should be desalted. The salt will compress the pH gradient so that it will occupy only some part of the capillary. Hereby, the resolution will decrease and the risk for protein precipitation will increase (see the section on Focusing, below). Also, focusing time will have to be increased as well as focusing/mobilization time being less reproducible.

AMPHOLYTES

Several commercial ampholytes are available covering broad-range (pH 3–10) and narrow-range pH gradients (e.g., pH 6–8). Broad-range gradients are suitable for analysis of proteins covering a wide spectrum of isolectric points, whereas narrow-range gradients are preferable for high-resolution separations where only minor differences in protein p*I*'s are expected.[2] Tailor-made gradients can easily be made by mixing ampholytes of different pH ranges or by adding ampholyte spacers.[3] It is preferable, also, to mix ampholytes (with a similar pH interval) from different suppliers so as to create a smoother gradient. Typical concentrations of ampholytes used are 1–5% (v/v); the concentration employed will affect, for example, the protein load, resolution, and focusing/mobilization voltage and time.

ADDITIVES

Additives are used in the sample-ampholyte solution either: (a) to suppress protein aggregation/precipitation or (b) to decrease the electro-osmotic flow (EOF) velocity and/or protein adsorption to the capillary surface. Protein precipitation is often a major problem in CIEF due to a highly concentrated protein band, and because electrostatic repulsion is minimal at the p*I*, proteins interact strongly by hydrophobic interactions (also hydrogen-bonding) causing irreproducible migration time and peak area quantification, and sometimes capillary clogging.[1,2] Precipitates are often seen as "spikes" in the electropherogram. Strategies to minimize precipitation include reducing the protein concentration and focusing time, applying a lower field strength, and/or using various additives. Because as high a resolution and detection sensitivity as possible are strived for, additives are often the first choice. Many such additives are used to enhance the solubility of proteins like (a) non-ionic detergents (e.g., reduced Triton X-100 and Brij-35), (b) zwitterions (e.g., CAPS and sulfobetain), (c) carbohydrates (e.g., sucrose, sorbitol, and cellulose derivatives), (d) urea, and (e) organic modifiers (e.g., ethylene glycol and glycerol). It is also common to mix different additives.[3] There seems to be no universal solubilization recipe covering all sorts of proteins. Instead, tailor-made recipes often must be worked out whenever precipitates are encountered. The commonly used mixture of 8 *M* urea and 2% detergents, as employed in the first dimension in two-dimensional gel electrophoresis, often performs well, although attention must be paid to protein modification causing artifacts in the electropherogram.[1]

Because urea also denatures proteins (in contrast to the other, more mildly, solubilizers), a shift in p*I* might be expected. See Ref.[3] for new types of solubilizers used in CIEF.

Additives used for decreasing the EOF and/or protein adsorption are often cellulose derivatives [e.g., hydroxypropylmethylcellulose (HPMC)]. The cellulose adsorbs to the capillary surface. Hereby, the viscosity will increase at the capillary surface (more than in bulk solution), causing a reduction in EOF as well as a decrease in protein adsorption to the capillary wall. The tendency for protein precipitation will also decrease by addition of cellulose derivatives.

FOCUSING

Focusing is the process where ampholytes and proteins migrate to their respective p*I* positions in the capillary. During focusing, current will decrease, as the current carrier ampholytes cease to migrate, and finally reach a constant value when the pH gradient is fully developed and the steady state has been attained (certain gradient drifts are often observed in CIEF whose presence will affect performance and reproducibility)[2] Normally, focusing is considered complete when current has decreased to 10% of its original value; a longer focusing time increases the risk for protein precipitation.

Resolution in CIEF is described by the following formula:

$$\Delta \mathrm{p}I = 3\left(\frac{D(d\mathrm{pH}/dx)}{E(d\mu/d\mathrm{pH})}\right)^{1/2}$$

where D is the diffusion coefficient, dpH/dx is the change of pH with distance x, E is the electric field strength, and $d\mu/d$pH is the change of mobility with pH.[2] The importance of the applied voltage is clearly seen, as a higher field strength gives a better resolution and shorter focusing time. Field strengths between 300 and 700 V/cm are normally used. The optimal voltage may be determined experimentally from a series of runs with different voltages. The formula also reveals that proteins attain a higher resolution than peptides because their D values are lower and $d\mu/d$pH is higher.

MOBILIZATION

Single-Step CIEF

In single-step (electro-osmotic displacement) CIEF, focusing and mobilization take place simultaneously.[1,2] Here, a dynamically coated (or static coated with reasonably high EOF) capillary is used where the EOF is fast enough to sweep all proteins by the detector in a reasonable time frame and slow enough to simultaneously allow the protein zones to focus. Additives are used to manipulate the velocity of the EOF as well as to decrease protein adsorption. The single-step method benefits from short analysis times and an extended capillary lifetime but suffers from lower detectability (due to lower protein load), compromised resolution, and non-linearity of the p*I* calibration curve.[4] A variant of the single-step CIEF is to use whole-column imaging detection where all the focused bands in the capillary are detected simultaneously without any need for mobilization.[5]

Two-Step CIEF

Two-step CIEF is used when EOF in the capillary is strongly reduced. After focusing is complete, a separate mobilization step is applied where the protein bands are transported past the fixed detector. Mobilization can be achieved either by chemical means [for cathodic (anodic) mobilization, the composition of the catholyte (anolyte) is changed; thereby the pH gradient will change], or by applying a positive/negative pressure, or by a mixture of both.[1,2] A pressure will induce zone broadening due to the parabolic flow profile; a modest pressure in combination with highvoltage will preserve the high-resolution pattern 4. Pressure mobilization offers good reproducibility (migration times and p*I* values) and a linear p*I* calibration curve. Chemical mobilization shows the same performance and also exhibits the highest resolution, at the expense of longer migration times. Anodic mobilization affords a better resolution of the acidic region, whereas cathodic mobilization is preferable for the basic region.[4]

DETECTION

Absorbance detection at 280 nm is mostly used. Below 220 nm is preferable for sensitive protein/peptide detection but is not possible because of background-absorbing ampholytes.[2] Proteins with chromophores (e.g., hemoglobins) can be detected at visual wavelengths. However, because CIEF is a concentrating technique (the protein bands will be concentrated about 100-fold during focusing), a fairly good sensitivity for most proteins is still attainable at 280 nm. For high-sensitivity analysis, laser-induced fluorescence detection might be an alternative, but it requires a labeling procedure.[5,6] By labeling, a change in intrinsic p*I* might occur and the same analyte might be subjected to multiple labeling sites showing several peaks in the electropherogram (especially proteins). This might, however, be the only choice for peptides lacking tyrosine and tryptophan. Whole-column imaging detection (no mobilization step needed) with different detection schemes is also possible for proteins and peptides.[5]

Capillary isoelectric focusing coupled to mass spectrometry has gained popularity in recent years (by analogy to two-dimensional gel electrophoresis). Additional information obtained from mass spectrometry includes not only precise molecular-weight determination but also the possiblity for peptide sequencing. Analysis of hemoglobin variants, recombinant proteins, and monoclonal antibodies have been demonstrated.[1,7,8]

APPLICATION OF CIEF TO PEPTIDES, PROTEINS, AND ANTIBODIES

Peptides

Peptides are not as commonly analyzed by CIEF as are proteins; one reason is their lower resolution, another their lower (or lack of) detectability at 280 nm (the wavelength mostly used). The separation of tryptic digests (peptide mapping) of proteins have been performed by using absorption detection at 280 nm and refractive index gradient imaging detection; no exact correlations were observed between measured and calculated p*I* values.[1,5] Refractive index detection is a universal detection method (i.e., independent of chromophores like tyrosine and tryptophan) but suffers from low sensitivity. Assays of trypsin activity have also been performed with laser-induced fluorescence detection for enhanced sensitivity, with detectability down to picomolal concentrations.[5,6]

Hemoglobins

Analysis of hemoglobin (Hb) variants are of major clinical importance. Many hematological disorders exist where the globin chains have been subjected to alterations (e.g., point mutations or deletion of gene sequence). Four hemoglobin, variants (A, F, S, and C) having very close p*I* values (from 7 to 7.40) are often employed as standards to demonstrate the high resolving power of CIEF.[2] Several other variants are possible to resolve (e.g., the separation of Hb A from its glycated form whose p*I*'s differ only by 0.01 or less).[1,3] Quantitative determination of is routinely used for assessing the degree of diabetes. To improve the resolution between Hb A and spacers, β-alanine and 6-aminocaproic acid were added to a mixture of pH 3–10 and pH 6–8 ampholytes in a coated capillary.[3] The spacers flatten the pH gradient in the p*I* region of the Hb's, thus allowing full separation.

Antibodies

Analysis of microheterogeneity in natural and recombinant monoclonal antibodies is a challenge where CIEF seems to be particularly well suited (see Fig. 1).[4] Minor modifications (e.g., deamidation, improper folding, and a change in glycosylation pattern) arising from protein synthesis or posttranslational modifications are often detected by CIEF.[1,2,9] The use of CIEF and comparison to flat-bed IEF for routine analysis of recombinant immunoglobins have been demonstrated with a coated capillary, methylcellulose, and a two-step mobilization procedure. The performance of the analysis and coating stability were constant for over 150 analyses with qualitatively and quantitatively equivalent immunoglobulin focusing profiles obtained via CIEF and IEF. Intra-assay reproducibility was less than 2% RSD for peak areas and 1% RSD for migration time. Interassay (72 hr) reproduciblity was less than 8% RSD for peak areas and 3% for migration time.[10]

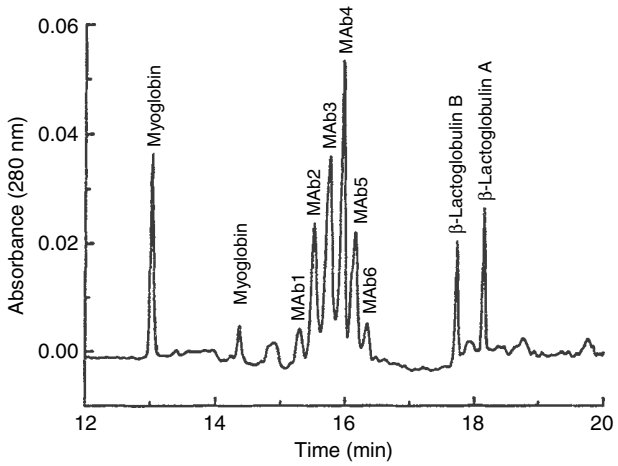

Fig. 1 CIEF of a mouse monoclonal antibody (MAb). Antibody concentration: 0.5 mg/ml; concentration of the marker proteins (myoglobin and β-lactoglobulin): 0.05 mg/ml; capillary: μ-SIL DB-1, 27 cm total length (20 cm to detector); carrier ampholytes: 4% Pharmalyte pH 3–10 including 1% TEMED and 0.8% methylcellulose (MC); anolyte: 10 m*M* H_3PO_4 in 0.4% MC; catholyte: 20 m*M* NaOH. Focusing for 2 min at 20 kV, followed by obilization at low pressure (0.5 psi) at 20 kV.
Source: From Capillary isoelectric focusing: A routine method for protein analysis?, in Electrophoresis.[4]

GLYCOPROTEINS

Applications of CIEF for the separation of isoforms of transferrin have been reported by several groups.[1,2,5] Transferrin contains different number of sialic acid residues, with an additional −1 charge added per residue. Also, transferrin bound to different amount of iron atoms has been separated by CIEF.[1,2,5] Glycoforms of recombinant tissue-type plasminogen activator (rtPA) is another sialic acid containing protein which has been the subject of analysis by CIEF.[1,2,11] A rapid (<10 min) one-step method was developed using a coated capillary, HPMC, and urea in a mixture of pH 3–10 and pH 5–8 ampholytes. Ten species could be detected. Intra-assay precision was less than 5% for peak migration times and 10% for normalized peak areas.[11]

Peptides: CCC Separation

Ying Ma
Yoichiro Ito
National Heart, Lung, and Blood Institute (NHLBI), National Institutes of Health (NIH), Bethesda, Maryland, U.S.A.

INTRODUCTION

Countercurrent chromatography (CCC),[1–4] because it uses no solid support in the separation column, is particularly suitable for the separation and purification of peptides which often present a problem of irreversible adsorption onto solid supports. Since the 1970s, the horizontal flow-through coil planet centrifuge (CPC) has been used for the separation of a variety of natural and synthetic peptides.[5] High-speed CCC,[6,7] which was developed in the 1980s, has improved partition efficiency in terms of resolution and separation times, yielding up to a few thousand theoretical plates in a few hours. During the last decade, a preparative scheme called pH-zone-refining CCC was developed. This method yields multigram quantities of pure fractions at an extremely high concentration.[8,9] More recently, a new column, called spiral disk assembly, was designed for high-speed CCC to separate peptides and proteins using polar two-phase solvent systems.[10]

The performance of these CCC instruments has been examined using butanol-based solvent systems and a set of dipeptide samples containing a tyrosine and/or a tryptophan moiety, which allows monitoring of the effluent at 280 nm.

HORIZONTAL FLOW-THROUGH CPC

Fig. 1A shows the original prototype of the horizontal flow-through CPC (HCPC), which can be operated without rotary seals.[5] A set of coiled tubes is arranged around the rotary shaft, which undergoes a specific planetary motion (type-J): The column assembly rotates about its own axis and revolves around the centrifuge axis at the same angular velocity, in the same direction. This planetary motion allows each helical turn of the column to retain the stationary phase of either the organic or the aqueous phase while vigorously mixing the two phases at each rotation cycle.

The system provides a stable retention for polar solvent systems up to 40% of the total column capacity. A typical separation of a set of dipeptides is illustrated in Fig. 1B. Using a two-phase solvent system composed of 1-butanol/acetic acid/water (4:1:5, vol/vol/vol), seven components were well resolved in 70 hr.

Before the advent of high-speed CCC, the method was utilized for the purification of various samples such as synthetic peptides, cholecystokinin analogs, and their fragments (HCPC; Table 1).

HIGH-SPEED CCC USING TYPE-J PLANETARY MOTION

High-speed CCC is considered to be the most advanced form of CCC in terms of partition efficiency and separation times. The design of the apparatus is similar to that of the HCPC, except that the coiled column is mounted coaxially onto the column holder. Since the early 1980s, the method has been widely used for the separation and purification of a variety of natural and synthetic products, including peptides and their derivatives.[6,7] Except for hydrophobic ring peptides such as gramicidin and bacitracin, most of the peptides are separated using polar butanol solvent systems, including 1-butanol/acetic acid/water (4:1:5), 1-butanol/aqueous trifluoroacetic acid (TFA; 1 : 1), and so on—typical examples of which are shown in Fig. 2A and B. Occasionally, one encounters a problem of carryover loss of the stationary phase from the multilayer coil separation column of the high-speed CCC centrifuge. To alleviate this problem, a new column, called spiral disk assembly, has recently been designed.[10] When mounted on the type-J high-speed CCC rotor, it enhances the retention of the stationary phase because of its radially acting centrifugal force gradient through the spiral channel. Thus the method enables the use of highly polar solvent systems with low interfacial tension, such as aqueous–aqueous polymer phase systems used for protein separation.

HIGH-SPEED CCC USING CROSS-AXIS CPC

This CCC scheme produces a unique pattern of planetary motion: The axes of the rotation and the revolution are perpendicular to each other. This planetary motion produces a centrifugal force vector acting across the diameter of the multilayer coil to enhance the retention of the

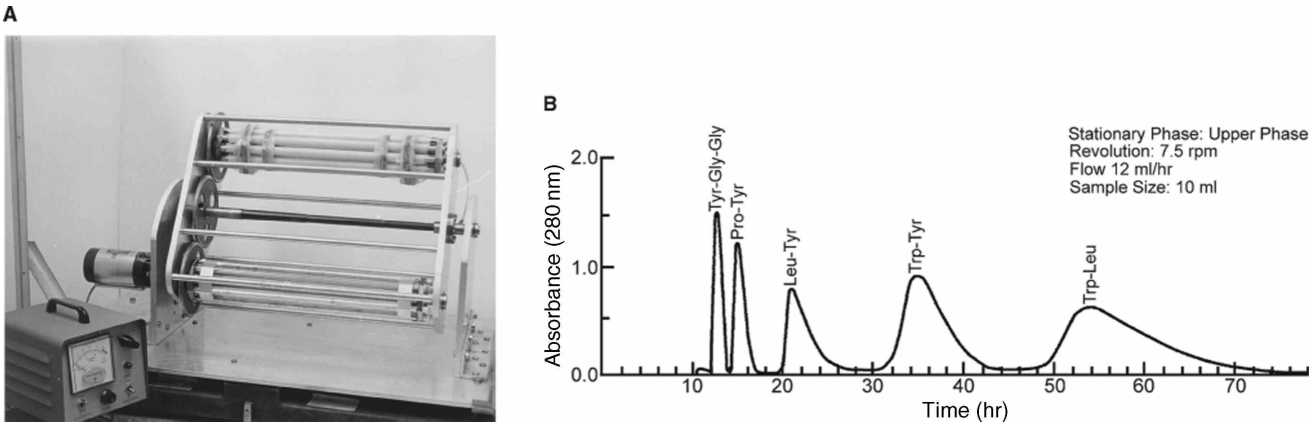

Fig. 1 Photograph of the horizontal flow-through coil planet centrifuge (A) and the chromatogram of dipeptide separation (B).

Table 1 Peptide samples and two-phase solvent systems for standard CCC techniques.

Peptide sample	Solvent system[a]	CCC instrument[b]
Dipeptides	1-BuOH/AcOH/H_2O (4 : 1 : 5)	TCC, HCPC, mLCPC ICPC, SDA
Dipeptides	1-BuOH/DCA/NH_4OAc (100 : 1 → 2 : 100)	ICPC, ACPC
Synthetic peptide	1-BuOH/AcOH/H_2O (4 : 1 : 5)	HCPC (6, 5, 9, and 15 mers)
Des-enkephalin γ-endorphin (12 mers)	1-BuOH/0.1% TFA (1 : 1)	HCPC
Cholecystokinin fragments (four to eight mers)	1-BuOH/AcOH/H_2O (4 : 1 : 5)	HCPC
	1-BuOH/0.2–0.5 *M* NH_4OAc (1 : 1)	HCPC
	1-BuOH/0.1% TFA (1 : 1)	HCPC
Cholecystokinin fragments sulfonated	1-BuOH/0.2–0.5 *M* NH_4OAc (1 : 1)	HCPC
	1-BuOH/EtOH/Hex/AcOH/H_2O (3 : 1 : 2 : 1 : 5)	HCPC
	1-BuOH/AcOH/H_2O (4 : 1 : 5)	HCPC
Cholecystokinin analog	$CHCl_3$/AcOH/H_2O (2 : 2 : 1)	MLCPC
Bacitracins	$CHCl_3$/95% EtOH/H_2O (4 : 3 : 2)	HCPC, MLCPC, XCPC
Gramicidins	$CHCl_3$/C_6H_6/MeOH/H_2O (15/15/23/7)	HCPC, MLCPC, XCPC DCCC
WAP-8294A	1-BuOH/EtOH/0.005 TFA (pH 2.5) (1 : 3 : 4)	MLCPC
Tyrocidines	$CHCl_3$/MeOH/0.1 m HCl (19 : 19 : 12)	DCCC
Colistins A and B	1-BuOH/0.04 m TFA (1 : 1)	MLCPC
Kangdisu/colistin E	1-BuOH/2% DCA + 5% NaCl (1 : 1)	MLCPC
Bombesin	1-BuOH/1% DCA (1 : 1) at 50°C	MLCPC
Bovine insulin	2-BuOH/3% DCA (1 : 1)	ICPC, ACPC
	1-BuOH/0.5% DCA (1 : 1) at 50°C	MLCPC

[a]ACN = acetonitrile; AcOH = acetic acid; BuOH = butanol; DCA = dichloroacetic acid; EtOH = ethanol; NH_4OAc = ammonium acetate; Hex = hexane; MeOH = methanol; TFA = trifluoroacetic acid.
[b]CPC = coil planet centrifuge; ACPC = type-I L-angle rotor CPC; DCCC = droplet CCC; HCPC = horizontal flow-through CPC; MLCPC = type-J multilayer CPC; SDA = spiral disk assembly; TCC = toroidal coil centrifuge; ICPC = type-I CPC; XCPC = cross-axis CPC.

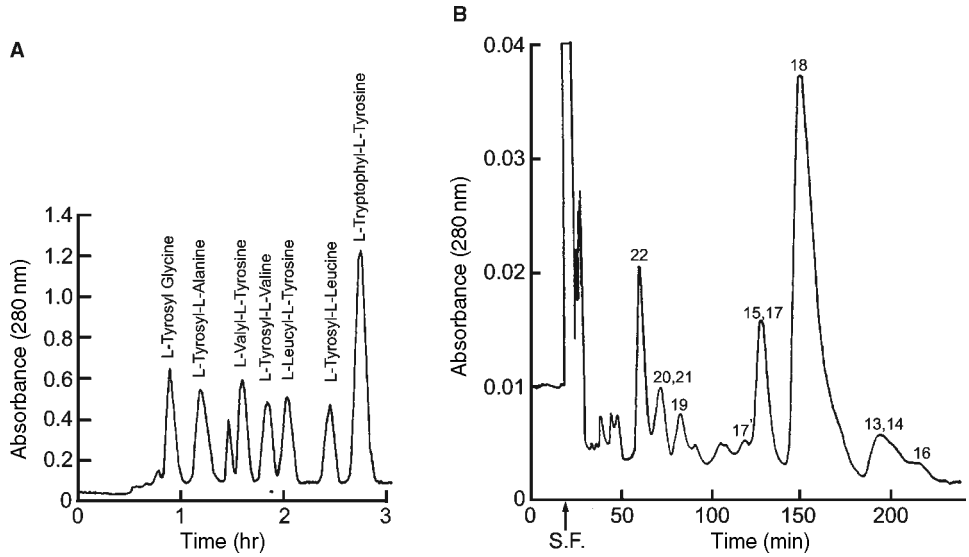

Fig. 2 Chromatograms obtained by high-speed CCC. (A) Separation of a set of dipeptides by gradient elution. Experimental conditions are as follows: apparatus: type-J multilayer CPC prototype with a 10 cm revolution radius; column: multilayer coil, 1.6 mm I.D., 130 m length, 285 ml total capacity; sample: dipeptide mixture 70 mg; solvent system: linear gradient between the starting medium of 1-butanol/dichloroacetic acid/0.1 *M* ammonium formate (1 : 0.01 : 1) and the ending medium of 1-butanol/0.1 *M* ammonium formate (1 : 1); mobile phase for 4 hr: lower aqueous phase; flow rate—214 ml/hr; revolution: 800 rpm; detection: 280 nm; retention of stationary phase: 55% of the total column capacity. (B) Separation of bacitracins by high-speed CCC. Bacitracins A and F are separated in peaks 18 and 22, respectively. Separation conditions are as follows: apparatus: Shimadzu type-J multilayer CPC (model HSCCC-1A; Shimadzu Corporation, Kyoto, Japan) with a 10 cm revolution radius; column: multilayer coil, 1.6 mm I.D., 325 ml capacity; sample: 50 mg; solvent system: chloroform/ethanol/methanol/water (5 : 3 : 3 : 4); mobile phase: lower organic phase; flow rate: 3 ml/min; detection: 254 nm.

Table 2 Peptide samples and solvent systems for pH-zone-refining CCC.

Peptide[a] (weight; g)	Solvent system[b]	Key reagents[c] Retainer	Eluter	Ligand
CBZ dipeptides (0.8 g)	MBE/ACN/H_2O (2 : 2 : 3)	TFA (16 m*M*/SP)	NH_3 (5.5 m*M*/MP)	—
CBZ dipeptides (3 g)	MBE/ACN/H_2O (2 : 2 : 3)	TFA (16 m*M*/SP)	NH_3 (5.5 m*M*/MP)	—
CBZ tripeptides (0.8 g)	1-BuOH/MBE/ACN/H_2O (2 : 2 : 1 : 5)	TFA (16 m*M*/SP)	NH_3 (2.7 m*M*/MP)	—
Dipeptide βNA (0.3 g)	MBE/ACN/H_2O (2 : 2 : 3)	TEA (5 m*M*/SP)	HCl (5 m*M*/MP)	—
Dipeptides (1 g)	MBE/ACN/50 m*M* HCl (4 : 1 : 5) (SP)	TEA (20 m*M*/SP)		DEHPA (30%/SP)
	MBE/1-BuOH/ACN/H_2O (2 : 2 : 5 : 1) (MP)		HCl (20 m*M*/MP)	
Bacitracins (5 g)	MBE/50 m*M* HCl (SP)	TEA (40 m*M*/SP)		DEHPA (10% SP)
	MBE/H_2O (MP)		HCl (20 m*M*/MP)	

[a]CBZ = carbobenzoyl; βNA = naphthyl amide.
[b]ACN = acetonitrile; BuOH = butanol; MBE = methyl *tert*-butyl ether; MP = mobile phase; SP = stationary phase.
[c]DEHPA = di-[2-ethylhexyl]phosphoric acid; TFA = trifluoroacetic acid; MP = mobile phase; SP = stationary phase.

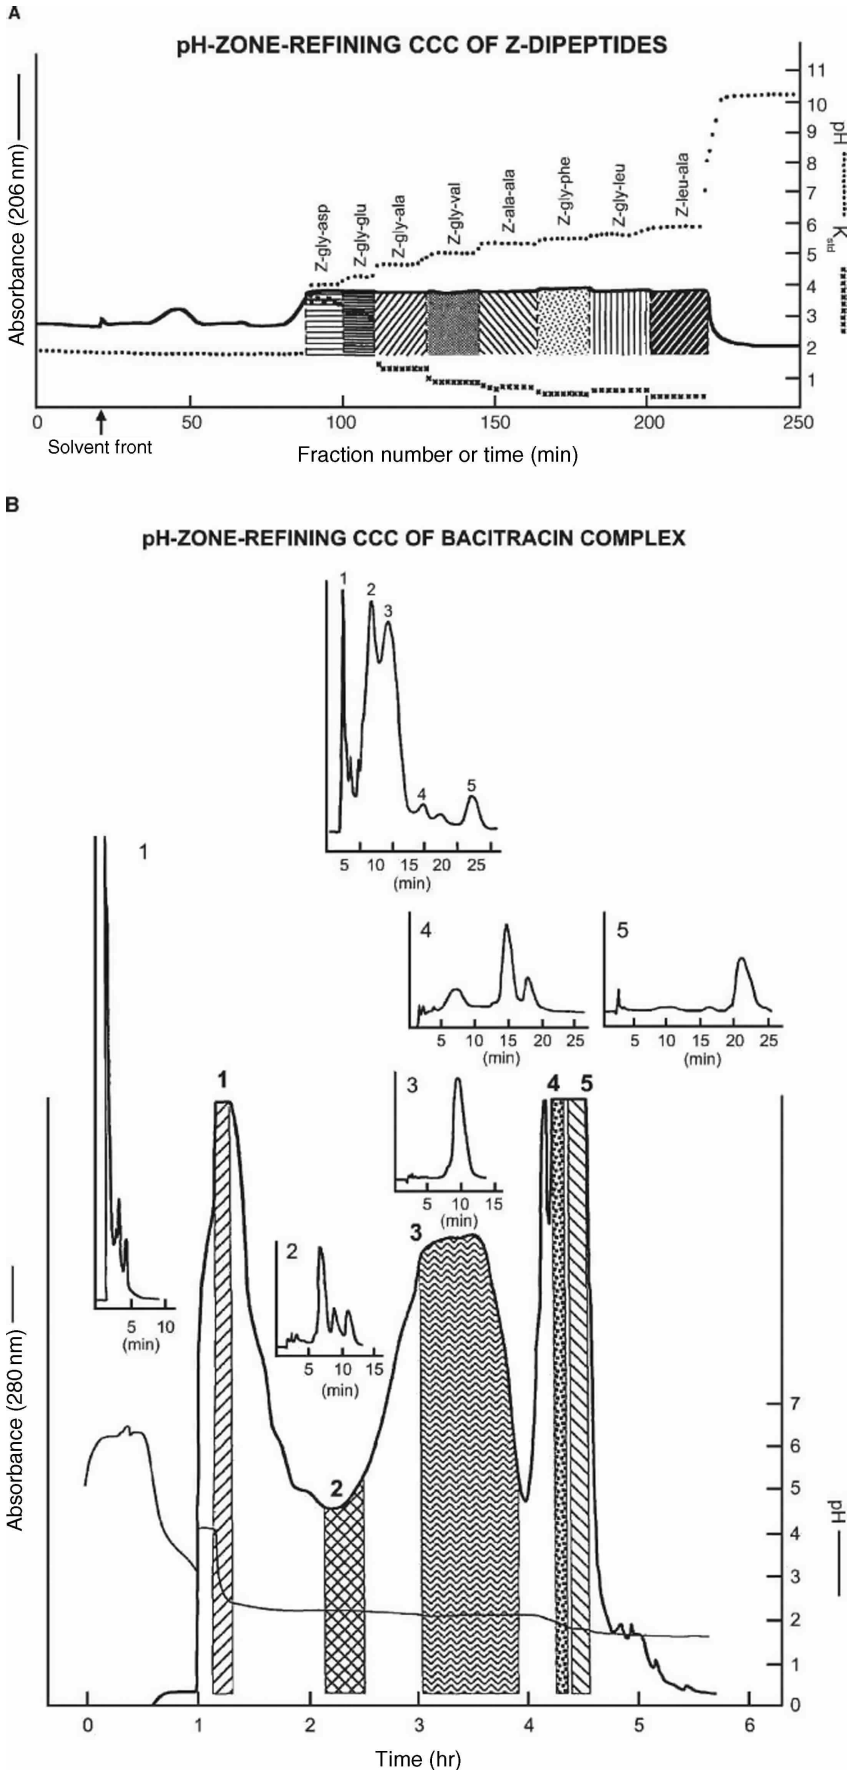

Fig. 3 Chromatograms obtained by pH zone-refining CCC. A, Separation of CBZ(Z) dipeptides. Experimental conditions are as follows: apparatus: type-J multilayer CPC (PC Inc., Potomac, Maryland, U.S.A.) with a 10 cm revolution radius; column: multilayer coil, 1.6 mm I.D., 325 ml capacity; solvent system: methyl *tert*-butyl ether/acetonitrile/water (2 : 2 : 3), 16 m*M* TFA in organic phase (pH 1.83), and 5.5 m*M* NH_3 in aqueous phase (pH 10.62); sample: eight CBZ(carbobenzyloxy) dipeptides as indicated in the chromatogram, each 100 mg in 50 ml of solvent (25 ml in each phase): flow rate: 3.3 ml/hr in head-to-tail elution mode; detection: 206 nm; revolution: 800 rpm; retention of stationary phase: 65.1%. (B) Separation of bacitracin complex. HPLC analysis indicated that two major components, bacitracins A and B, were isolated in peaks 3 and 5, respectively. Experimental conditions are as follows: apparatus and column: same as above; solvent system: methyl *tert*-butyl ether/acetonitrile/water (4 : 1 : 5), 40 m*M* triethylamine, 10% DEHPA in the organic stationary phase, and 20 m*M* HCl in aqueous mobile phase; flow rate: 3 ml/min; sample: 5 g of bacitracin dissolved in 40 ml of solvent (20 ml in each phase); revolution: 800 rpm; detection: 280 nm.

stationary phase, whereas the system yields less efficient resolution than the type-J high-speed CCC. Although the system was successfully utilized for the separation of bacitracin and gramicidin having a potential for a large-scale preparative separation of more polar peptides, the method is currently used almost exclusively for the separation of proteins with aqueous–aqueous polymer phase system.[11]

pH Zone-Refining CCC

In addition to the standard high-speed CCC technique described above, peptides can be purified by using a large-scale preparative method, called pH zone-refining CCC, in which analytes form a train of highly concentrated rectangular peaks with minimum overlapping.[8,9] The solvent system and the separation procedure of this technique are quite different from the standard high-speed CCC. The method requires a pair of special agents called "retainer" and "eluter." As suggested by their names, the retainer serves to retain the analyte in the stationary phase and the eluter serves to elute the analyte with the mobile phase. The separation of free peptides requires another agent, called an affinity ligand, such as di-[2-ethylhexyl]phosphoric acid (DEHPA), which is introduced into the stationary phase to enhance the retention of the analyte in the column. The typical retainers, eluters, and affinity ligands, together with the two-phase solvent systems, are listed in Table 2. Usually, the separation is performed with a two-phase solvent system containing *tert*-butyl methyl ether (MBE) as a major organic solvent (Table 2), which, because of its less viscous nature, gives higher stationary phase retention and partition efficiency than the butanol solvent systems.

Fig. 3A and B illustrates typical chromatograms. obtained by pH-zone-refining CCC (Table 2).

CONCLUSIONS

The CCC technique is well suited for the separation of peptides and related compounds because it eliminates sample loss and denaturation caused by the solid support used in conventional LC. The method separates multigram quantities of peptide samples using pH zone-refining CCC.

Peptides: HPLC Analysis

Karen M.Gooding
Eli Lilly and Company, Indianapolis, Indiana, U.S.A.

INTRODUCTION

The rapid advancement in peptide research over the past 25 years must be attributed, in part, to the effectiveness of high-performance liquid chromatography (HPLC), particularly reversed-phase chromatography, in the separation and analysis of peptides. The resolution and selectivity of this technique allows peptides to be effectively isolated and purified from closely related substances. It also separates most or all of the components of complex biological mixtures such as tryptic digests of proteins.

MODES OF HPLC

Peptides, which are composed of amino acids linked by amide bonds, are often found in random coil to semi-defined conformations, depending on their lengths and structures. As such, most of the composite amino acids are available to interact with the bonded phase of an HPLC support. Although the variety of amino acid characteristics, such as charge, polarity, and hydrophobicity, would suggest that multiple modes of HPLC would be effective for separation, reversed-phase chromatography has shown the ultimate success in selectivity and resolution of peptides. Hydrophilic interaction chromatography (HICIC) is a good alternative for hydrophilic peptides or other mixtures that are not separated well by reversed-phase chromatography (RPC), whereas cation-exchange chromatography can be effective for highly cationic species. Size-exclusion chromatography (SEC) is a difficult technique for analysis of peptides, due to their varying solubilities and high degrees of hydrophobicity and charge; however, it is invaluable for resolution from dimers and aggregates.

REVERSED-PHASE CHROMATOGRAPHY

Reversed-phase chromatography is a method in which molecules are bound hydrophobically to non-polar ligands in the presence of a polar solvent. Solutes are generally bound in an acidic mobile phase with elution occurring during a gradient to an organic solvent. Molecules will tend to be unfolded due to the combination of acidic and organic mobile phases and the hydrophobic bonded phase. Consequently, binding involves most of the amino acids, depending on the conformation. RPC can differentiate peptides which vary in the positions of their amino acids, as well as in their identities, thus making it a powerful analysis tool. Very high selectivity is attained even for complex biological mixtures, such as the tryptic digest of human growth hormone shown in Fig. 1.[1]

There are many ligands used for RPC, but the most popular for peptide analysis are octadecyl (C_{18}) and octyl (C_8) chains. Little difference in selectivity for peptides is observed with ligand chain-length variation; however, mass recovery of very hydrophobic species may be enhanced on the shorter chains. Many RPC bonded phases are synthesized by silane bonding, with or without endcapping, which results in a hydrophobic layer on a silanol surface. Recently, more hydrophilic–hydrophobic phases have been developed whereby amide linkages are embedded in the non-polar layer to provide a wettable area which may be more compatible with some biological molecules. Due to their higher efficiencies, silica-based supports are generally used for peptide analysis; however, polymeric supports are effective for operation at high pH. The silica matrix is sometimes a factor in retention because silanols on reversed-phase supports are rarely totally eliminated. Most peptide analyses use supports with pore diameters of at least 300 Å to allow access to the bonded phase; non-porous supports offer a high-resolution option with significantly lower capacities. Dynamic loading capacities of peptides on porous analytical reversed-phase columns (250×4.6 mm I.D.) are usually 100–500 μg.

Due to the multiple functional groups found in peptides, selectivity can be vastly changed by operational factors. Variable mobile-phase parameters include organic modifiers, pH, ion-pair agents, and gradient rates. Acetonitrile is the most popular organic solvent for RPC of peptides due to its transparency at low wavelengths ($<$210 nm) and its tendency to yield narrow peak widths. The strength of the organic solvent which causes elution increases from methanol to acetonitrile to isopropanol. Acidic pH is generally utilized to minimize silanol interactions; however, distinct pH conditions yield different selectivities. Ion-pairing agents, such as trifluoroacetic acid, are often added to the mobile phase to change the ionic or hydrophobic properties of either or both of the solute and the bonded phase. Amounts of 0.1% added to both the aqueous and the organic mobile phases are usually adequate, but optimal concentrations can be determined experimentally. Trifluoroacetic acid (TFA) is the most popular ion-pairing agent for peptides, imparting some

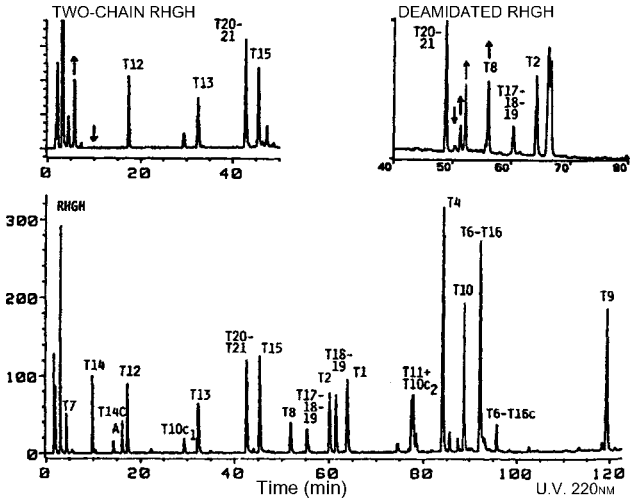

Fig. 1 Tryptic maps of the intact and (insets) degraded forms of recombinant human growth hormone (RHGH). The separation was achieved on a Nucleosil C-18 column (150 × 3.9 mm inner diameter) with a 120 min mobile-phase gradient from 10 m*M* potassium phosphate (pH 2.85) to 60% acetonitrile in the starting buffer. The flow rate was 1 ml/min and detection was at 214 nm.

additional hydrophobicity to amine groups and neutralizing cationic charges.

Most RPC peptide separations utilize gradient rather than isocratic conditions. Small peptides may be resolved well isocratically; however, due to multipoint interactions, larger ones yield broad peaks and tailing unless gradients are used. Shallow gradients generally improve resolution in an analytical mode or purity in preparative applications. For complex mixtures, 0.5–1% organic/min is usually a satisfactory rate. Increased temperatures can be implemented to reduce both retention times and the pressure generated by small-particle-diameter supports.

HYDROPHILIC INTERACTION CHROMATOGRAPHY

Hydrophilic interaction chromatography is a variation of normal-phase chromatography in which solutes are retained on a polar bonded phase under high concentrations (80–90%) of organic solvent and released during a gradient to a more aqueous solvent. If the polar bonded phase contains a charge, a salt gradient can also be implemented, yielding separation by both charge and polarity. HILIC is most effective for polar peptides which are often poorly retained by RPC. Fig. 2 compares the differences in selectivity and resolution of a cation-exchange (CEX) procedure on a HILIC column with that of RPC for a peptide mixture.

The HILIC - bonded phases are hydrophilic, consisting of amide and/or polyhydroxy functionalities. Pore diameters are at least 300 Å to allow penetration of peptides. Supports can be based on either silica or polymer because the matrix is not exposed to the solutes.

Mobile-phase manipulation causes variations in selectivity in HILIC. Although a buffer is used for pH control, it may also serve to change the hydrophobicity of the solutes by ion-pairing. More hydrophobic ions such as acetate will decrease retention. The pH is a less important factor than the identity of the salt in HILIC selectivity. The organic modifier and its initial concentration directly affect retention and resolution. At least 80–90% organic is usually required to achieve adequate retention of hydrophilic peptides. For HILIC/cation exchange (HILIC/CEX), a

salt gradient is implemented to separate the hydrophilic peptides by charge, as can be seen in Fig. 2.[2]

ION-EXCHANGE CHROMATOGRAPHY

Ion-exchange chromatography (IEC) separates peptides by ionic attraction of their composite amino acids to charges on the stationary phase. Selectivity is dependent on the number and the identity of the amino acids, as well as their spatial arrangement. A peptide with charges grouped together will bind differently than one whose charges are dispersed. IEC has been most successful for cationic peptides that cannot always be analyzed effectively by RPC.

Supports for IEC possess either anion- or cation-exchange functionalities which are positively or negatively charged, respectively. They are also classified as weak or strong to correspond to their titration curves, similar to acid and base designations. Generally, strong cation-exchange supports are used for peptide analysis. The pore diameter is important in that it must be large enough to allow access of the peptides so that they are effectively retained and have optimum loading capacities.

In IEC, solutes are bound in a low-ionic-strength buffer (0.02–0.05 *M*) at an appropriate pH (often 1–2 pH units from the p*I*). Elution occurs when the ionic strength is increased during a concentration gradient of a salt in the same buffer. Isocratic elution may successfully separate small peptides with one or two charged groups, but larger peptides with more charged groups will require gradients for good peak shapes, resolution, and reproducibility. The nature of the salt in IEC has a major effect on selectivity due to interaction of the composite ions with either the stationary phase or the solutes. The hydrophobicity of many peptides may necessitate the addition of 5–10% organic solvent to improve peak shape. This can usually be included in the mobile phase without deleterious effects on the separation.

SIZE-EXCLUSION CHROMATOGRAPHY

Size-exclusion chromatography is a method in which molecules are separated by size due to differential permeation into a porous support. It requires complete solubility of the analytes in the mobile phase and elimination of all interactions with the bonded phase. In these respects, SEC is not as useful for the separation of peptides as it is for proteins because peptides vary drastically in solubility, charge, and hydrophobicity. Peak capacity in SEC is fairly low compared to other HPLC methods because all separations must occur in the internal volume (V_i) of the support, which is generally less than half the volume of mobile phase in the column. Despite these deficiencies, SEC can be very effective for separating peptides from dimers, aggregates, small molecules, proteins, and other molecules which differ by size.

Supports for SEC of proteins are designed to be neutral and very hydrophilic to avoid interaction of the solutes with the support by ionic or hydrophobic mechanisms. The base matrix can be either silica or polymer; efforts are made to totally mask its properties with a carbohydrate-like stationary phase. The pore structure is critical to successful SEC. Not only must the total pore volume (V_i) be adequate for separation, the pore diameter must be consistent and nearly homogeneous for attainment of maximum resolution between molecules with relatively small differences in molecular size (radius of gyration or molecular weight). A twofold difference in size is usually required for separation by SEC. Retention in SEC is directly related to the logarithm of the radius of gyration or the molecular weight. Because peptides do not all have the same shapes, their molecular volumes may not correspond uniformly to their molecular weights unless they are in the presence of sodium dodecyl sulfate (SDS) or another denaturing agent.

The mobile phase is a critical factor in SEC because it must eliminate all solute–support interactions. This may require adjustment to low pH or to an ionic strength which eliminates ionic interactions (0.05–0.2 *M*) and/or the addition of 5–10% organic solvent to remove hydrophobic binding. Due to their variations in physical properties, it is sometimes difficult to eliminate all the ionic and hydrophobic interactions of a mixture of peptides using a single mobile phase.

DETECTION

The detectability of peptides varies greatly, depending on their amino acid composition. The aromatic amino acids (tyrosine, tryptophan, and phenylalanine) offer selective detection by ultraviolet (UV) light at 280 or 254 nm or by fluorescence detection. In the absence of these amino acids, low wavelengths (<220 nm), which also detect many other substances, including components of the mobile phase, must be used. TFA and acetonitrile are compatible with low wavelengths, making this system a popular one for peptide analysis by RPC. Alternatively, the amine functionalities of peptides can be derivatized using precolumn or postcolumn techniques with compounds such as fluorescamine. In this way, selective and sensitive detection methods like fluorescence can be implemented. Mass spectrometry also provides a viable, albeit, expensive means of detection of peptides.

CONCLUSIONS

High-performance liquid chromatography provides a rapid and effective means for the analysis and purification of peptides. RPC is the primary and most universally

successful mode, with HILIC and IEC offering alternative methods for hydrophilic peptides or others where RPC is ineffective. HILIC and IEC are also orthogonal modes to RPC for preparative or identification purposes. The ability to change selectivity using the mobile phase in HPLC methods makes them versatile techniques which can be rapidly optimized and implemented.

Peptides: Purification with Immobilized Enzymes

Jamel S. Hamada
Southern Regional Research Center, Agricultural Research Service, U.S. Department of Agriculture (USDA-ARS), New Orleans, Louisiana, U.S.A.

INTRODUCTION

Affinity chromatography is a powerful separation technique that exploits specific binding properties among biomolecules. For protein purification, the enrichment obtainable in single-step affinity chromatography sometimes exceeds 1000-fold. This high selectivity is due to the vast variety of specific interactions that characterize the functional properties of protein molecules. Like any other affinity chromatography technique, purification of peptides by immobilized enzymes captures the unique interactions between biomolecules (see Refs.[1–3]). For example, many enzymes reversibly bind to their organic cofactor molecules and inhibitors. The separation of such enzymes from other proteins can be easily achieved by using a chromatography column containing immobilized inhibitors. Inversely, the enzyme inhibitors can be isolated and purified to a high degree of purity by affinity chromatography using immobilized enzymes. Because affinity chromatography is a most selective technique, it may be used alone as a single chromatography step for peptide purification. However, as many input-material contaminants as possible must be removed prior to using affinity chromatography (e.g., before the affinity chromatography step). For instance, ultrafiltration or gel permeation chromatography (GPC) is sometimes used concurrently to separate the high- and low-molecular-weight forms while exchanging buffers. In this entry, the focus will be on the use of affinity chromatography to purify peptides when the immobilized ligand is an enzyme.

GENERAL PRINCIPLES OF PEPTIDE PURIFICATION BY IMMOBILIZED ENZYMES

The first step in this type of chromatography is the preparation of the column by enzyme immobilization on activated support. Enzymes are immobilized by covalent bonding to a packing of a chromatography column (i.e., a support solid matrix such as a cross-linked agarose bead). A mixture of components containing the peptide of interest is applied to the column. Peptides are bound with a high degree of specificity to the immobilized enzyme that functions as an ionic, hydrophobic, aromatic, or stoically active binding site, depending on the particular circumstances. The unbound contaminants, which have no affinity for the ligand, are washed through the column, leaving the desired peptide bound to the matrix. Bound peptides are released by manipulating the composition of the eluant buffers. Generally, the elution of the peptide is accomplished by changing the pH and/or salt concentration or by applying organic solvents or a molecule that competes for the bound ligand (Fig. 1).

EXAMPLES OF PURIFICATION OF PEPTIDES BY IMMOBILIZED ENZYMES

Purification of Protein Hydrolysates

Proteases possess special characters, including their ability to cleave at certain amino acid sites such as at the hydrophobic or neutral residues. This cleavage specificity produces protein hydrolysates that vary significantly in their molecular weights, charge characteristics, functional profiles, and, thus, their potential specific interactions. Using immobilized proteases for peptide purification is a typical application of this type of affinity chromatography. Trypsin is a serine protease; that is, it contains an essential serine at its active site and cleaves the peptide bond next to a basic amino acid residue. Anhydrotrypsin is an inert derivative of trypsin and, thus, has no catalytic activity. It contains dehydroalaninein in place of the active serine residue site. The modified enzyme has 20-fold more affinity for product peptides produced by tryptic cleavage than substrate peptides. C-Terminal arginine peptides adhere more tightly than COOH-terminal lysine peptides. Accordingly, immobilized anhydrotrypsin has been used as an affinity ligand for the purification of these peptides. Because of widely varied peptide structure, further specificity may be obtained during elution, which usually involves decreasing pH gradients.

Purification of Pawpaw Glutamine Cyclotransferase

Pawpaw glutamine cyclotransferase (PQC) was purified 279-fold to near homogeneity by a combination of ion-exchange chromatography on SP-Sepharose, hydrophobic interaction chromatography on Fractogel TSK Butyl-650, and affinity chromatography on immobilized trypsin.[4] Trypsin was immobilized on Affigel-10 (Bio

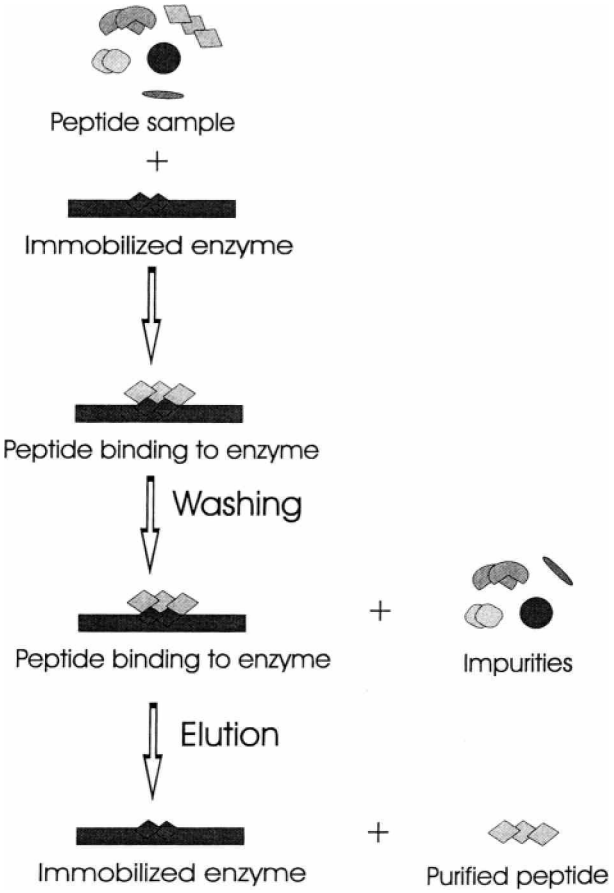

Fig. 1 Schematic illustration of purification of a peptide by affinity chromatography on an immobilized enzyme.

Rad Laboratories) according to procedures recommended by the manufacturer. After the concentration of pooled fractions from the last purification step (Fractogel column) by ultrafiltration, affinity chromatography was used. Partially purified PQC was injected into a 12.5 × 1.6 cm inner diamater column of immobilized trypsin gel preequilibrated in the eluting buffer (20 m*M* in 50 m*M* Tris-HCl buffer, pH 8.2). Affinity purification was accomplished because PQC contains a unique and highly basic polypeptide chain containing covalently attached phosphate groups without any disulfide bonds.

Purification of Enzyme Inhibitors

Enzyme inhibition may be reversible or irreversible with different inhibitors. Irreversible inhibitors usually form covalent bonds and, thus, are not useful for this type of affinity chromatography. Reversible inhibitors work by a variety of mechanisms, but usually competitive inhibitors structurally resemble the peptide substrates and bind the active center. *Trichosanthes kirilowii* trypsin inhibitor analog (Ala-6-TTI) is a trypsin inhibitor in which methionine at position 6 is replaced by alanine. Affinity chromatography was used to purify expressed fusion protein containing large proteins and (Ala-6)-TTI, with methionine as a connecting residue.[5] After cyanogen bromide cleavage and reduction of the fusion protein, followed by affinity chromatography separation on trypsin-Sepharose 4B as a matrix and on the immobilized trypsin, the fully active (Ala-6)-TTI was obtained in a high purity and high yield. The trypsin inhibitory activity and amino acid composition of the recombinant (Ala-6-TTI) were consistent with those of the natural one.

An essentially pure extracellular glycoprotein proteinase inhibitor was isolated from the latex of green fruits of papaya by a single affinity chromatography purification step.[6] An immobilized trypsin-Sepharose CL 4B column was prepared according to the manufacturer (Amersham Pharmacia Biotech), which provided elaborated bulletins for the preparation procedures and applications of these affinity gel columns. Latex extract was applied to the column after equilibration with 20 m*M* Tris-HCl, pH 8.0, containing 0.5 *M* NaCl and 0.05 *M* $CaCl_2$. The column was extensively washed with the same buffer until ultraviolet (UV) absorbance became undetectible. The bound trypsin inhibitor was eluted with 0.02 *M* HCl and recovered by lyophilization after dialysis against water.

Purification of Dipeptidyl Peptidase IV

Dipeptidyl peptidase IV (E.C. 3.4.14.5) cleaves off N-terminal dipeptides from peptides when a proline or alanine is at the penultimate position. The enzyme was purified from human seminal plasma and prostasomes by a two-step scheme of ion-exchange chromatography on DEAE–Sepharose, followed by affinity chromatography on adenosine deaminase (E.C. 3.5.4.4)–Sepharose.[7] This scheme resulted in a pure, native protein with an overall yield ranging from 35% to 55%. The preparation obtained was free of contaminating aminopeptidase activity.

Purification of Recombinant Proteins via Peptide Accession

Purification of peptides by immobilized enzymes is a relatively recent approach that may have a potential use in the purification of genetically engineered proteins. Purification of recombinant proteins is often difficult and involves many purification steps for a very low yield. Smith et al.[8] found that a specific metal-chelating peptide on the NH_2 terminus of a protein can be used to purify that protein with immobilized ion affinity chromatography. The nucleotide sequence that codes for the expressed protein is extended to include codons for the chelating peptide. This concept of amino acid addition to recombinant proteins can also be beneficial in protein purification by affinity chromatography with immobilized enzymes.

This will have an impact on the cloning, expression, and the purification of proteins.

CONCLUSIONS

Affinity purification of peptides by immobilized enzymes relies on the highly specific interaction of an ionic, hydrophobic, aromatic, or stoically active binding site on the desired peptide to the immobilized enzyme. The unbound contaminants are washed through and the desired peptide is released by buffer elution. This technique is beneficial in the purification of many peptides and can also be used for affinity chromatography of recombinant proteins after cloning and expression.

Pesticides: GC Analysis

Fernando M. Lanças
Institute of Chemistry of São Carlos (USP), University of São Paulo, São Carlos, Brazil

M.A. Barbirato
Chromatography Laboratory, University of São Paulo, São Carlos, Brazil

INTRODUCTION

In spite of the worldwide controversy which has surrounded the use of pesticides for many years, there can be little doubt that they provide one of the most effective contributions to increasing crop production and they have helped the farmer to improve the quality and variety of our foodstuffs. However, even when used correctly, these compounds can cause ecological consequences, public health problems, and the occurrence of toxic residues in foodstuffs. These problems make necessary the development of analytical methodologies that allow the appropriate monitoring of pesticides residues.

One of the most important analytical techniques used today is high-resolution gas chromatography (HRGC). The pesticide residues can be analyzed by specific or multiresidue methods. When crops are treated with several pesticides, the use of a multiresidue method is preferable due the reduced cost and time of analysis. The methods of pesticides residue analysis usually present an initial step of extraction with a solvent which is not miscible with water, followed by a cleanup step and the analyte determination by gas chromatography (GC).

EXTRACTION METHODS

Sample preparation represents a formidable challenge in the chemical analysis of the "real-world" samples. Not only is the majority of total analysis time spent in sample preparation, but also it is the most error-prone, least glamorous, and the most labor-intensive task in the laboratory. The components to be separated from the matrix are usually taken up with an auxiliary substance such as a carrier gas, an organic solvent, or an adsorbent. These separation processes can be regarded as extraction procedures [i.e., liquid–liquid extraction (LLE), liquid–solid extraction (LSE), Soxhlet extraction (SE), solid-phase extraction (SPE), supercritical fluid extraction (SFE), solid-phase microextraction (SPME), etc.].

Soxhlet extraction has been the standard extraction method of the analyst for nearly 90 years. The complete extraction produces a high-volume diluted solution that usually needs to be concentrated prior to analysis. The choice of solvent determines the solvating power as well as the temperature of the extraction. Perhaps the greatest disadvantage of using the Soxhlet method is the utilization of expensive, high-purity organic solvents such as acetone and methylene chloride.

Liquid–liquid extraction uses two immiscible liquids as the two phases. The sample is dissolved in one of the liquids (refinate) which comes in contact with the other liquid (extractant) into a separatory funnel, under agitation, to increase the contact area among the phases. Some mixing time is usually necessary for efficient phase exchange. Multiple extractions are also mandatory if quantitative extraction is desired. Sample transfer can become a problem, especially if phase emulsions are produced.

Solid–liquid extraction, normally performed at room temperature, is a simpler version of Soxhlet extraction (Fig. 1). The extraction of sample components is performed by blending the sample with a solvent. The choice of the extraction solvent can be determined by the analyst's experience, the equipment available in the laboratory, the type of sample to be analyzed, and the range of target analytes. Ethyl acetate is usually more powerful than acetone for extraction of more polar compounds. As regards selectivity, acetone is preferable because the amount of polar coextracted matrix interference will be less.

Solid-phase extraction is based on low-pressure LC, where a short column is filled with an adsorbent. The separation mechanisms are based on the intermolecular interactions among analyte molecules and functional groups of sorbent. The choice of eluent is made by the relationship between the eleutropic value (Σ°) and the analyte polarity. SPE is fast, selective, and economical if compared with the extraction methods described previously. It can be applicable to both non-polar and polar analytes, but both matrix and analyte must be in the liquid state.

Supercritical fluid extraction provides, for the first time, a viable alternative to other traditional sample preparation techniques which are slow, composed of several steps, and make use of organic solvents. A supercritical fluid can be defined as any substance that is above its critical temperature and critical pressure. A supercritical fluid exhibits physicochemical properties intermediate between those of liquids and gases. Specifically, its relatively high (liquid-like) density gives good solvating

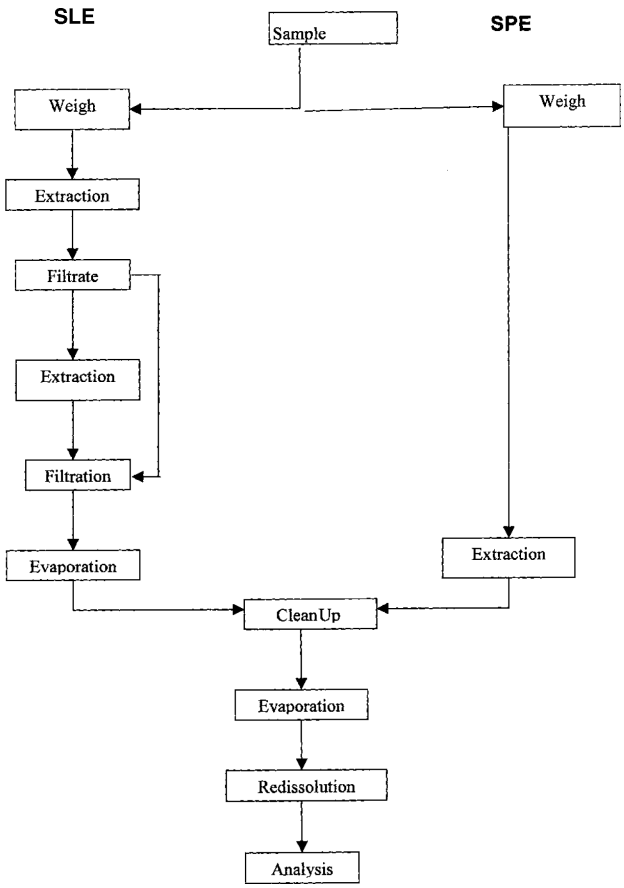

Fig. 1 Schematic diagram of the main steps of the solid–liquid extraction and supercritical fluid extraction methodologies for pesticide residue analysis.

power, whereas its relatively low viscosity and high diffusivity (gas-like) values provide appreciable penetrating power into the matrix. These latter two properties have been shown to give rise to higher rates of solute mass transfer into a supercritical fluid than into a liquid.

Supercritical CO_2 is the fluid with more applications at the present time, due to its readily amenable critical conditions ($T_c = 31.3°C$; $P_c = 72.9$ atm) and high volatility and diffusivity, and it also is inert, inexpensive, non-flammable, nontoxic, and miscible with most solvents. It has been used to extract compounds ranging from low polarity to moderate polarity. The extraction of polar compounds can be performed by supercritical CO_2 modified by the addition of a small volume of a polar liquid solvent.

The major parameters that influence the supercritical fluid extraction are temperature, pressure/density, fluid composition, particle size, matrix type, and extract collection system.

Solid-phase microextraction is based on the adsorption of an analyte in a fused-silica fiber externally coated with a stationary phase and following a thermal desorption in the injector of a GC. The fiber is introduced into the aqueous sample. In SPME, usually equilibrium among the aqueous samples and the stationary organic phase occurs instead of an exhaustive extraction. The pH, ionic strength, temperature, time, and agitation of the sample can exert an influence on the quality of the extract. The SPME process can integrate sampling, extraction, concentration, and sample introduction in just one step.

CLEANUP PROCEDURES

No single cleanup method is able to cover the entire matrix range. The need for a cleanup procedure prior to GC analysis is largely dependent on the complexity of the matrix and the range of analytes to be analyzed.

The most important cleanup procedures are liquid–liquid partition, LC in a column of silica, florisil, and/or alumina, gel permeation chromatography, and solid-phase extraction. Gel permeation chromatography (GPC) is the most universally applicable cleanup method for the removal of high-molecular-weight compounds. It is most favorable towards the multimatrix aspect and includes most pesticides. GPC has its limitations in the analyses of samples with a high load of coextractives and does not offer selectivity with respect to interference with low molecular weights. A selectivity gain can be obtained by the application of an additional cleanup using a small-scale chromatographic separation on silica, florisil, or alumina.

GC ANALYSIS

For the set up a GC-based multiresidue method for a specific pesticide–matrix combination, information is needed on GC retention and detectability of the analytes; also, the need for a cleanup procedure must be evaluated.

In general, the nature of the analyte determines the choice of stationary phase. For example, for the separation of organochlorine and pyrethroid pesticides, a non-polar stationary phase such as DB-1 (or OV-1) is recommended. For the separation of somewhat more polar compounds, such as organophosphorus compounds, OV-17 (or DB-1701) can be applied. In addition, for confirmation purposes, the use of two columns with distinct stationary-phase polarities (e.g., DB-1 and DB-1701) is certainly required. A polar stationary phase (e.g., DB-wax) is suitable for the more polar compounds such as methamidofos, but its application to some detection modes is limited due to stationaryphase bleeding.

Due its robustness, particularly toward uncleaned samples, on-column, splitless injection is the most widely applied technique for sample introduction.

The conventional sensitive and specific GC detection such as electron-capture detector (ECD) (see Fig. 2), flame thermionic detector (FTD), and flame photometric detector (FPD) are still widely used in pesticide residue analysis. In recent years, mass spectrometric detection is becoming

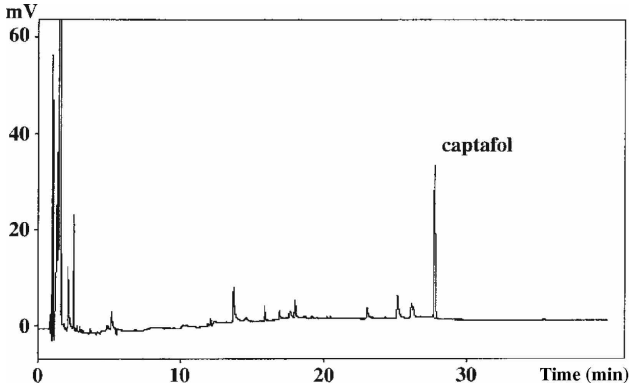

Fig. 2 Gas chromatogram (ECD) resultant from the analysis of captafol residues in tomato, after supercritical fluid extraction with neat CO_2 without further cleanup.

more and more important. Although other types of mass analyzers are commercially available, the equipment used in modern residue laboratories is based on two major types: the classical quadrupole mass analyzers and those based on the ion trap (also called tridimensional quadrupole).

For most compounds, the information on the *m/z* fragments were obtained with a quadrupole instrument. It should be mentioned, however, that the sensitivity of quadrupole detectors must be enhanced by means of limited mass range scanning or by selected ion monitoring, whereas ion-trap-based instruments offer a fair sensitivity with simultaneous monitoring of the complete *m/z* range.

ACKNOWLEDGMENTS

Professor Lanças wishes to express his appreciation to the Brazilian Agencies FAPESP (Fundação de Amparo à Pesquisa do Estado de São Paulo) and CNPq (Conselho Nacional de Desenvolvimento Científico e Tecnológico) for their financial support for our research programs.

Pesticides: TLC Analysis

Joseph Sherma
Department of Chemistry, Lafayette College, Easton, Pennsylvania, U.S.A.

INTRODUCTION

Thin-layer chromatography (TLC) is complementary to gas chromatography (GC), high-performance liquid chromatography (HPLC), capillary electrophoresis (CE), and immunochemical methods for the determination of single and multiple residues of many classes of pesticides (e.g., insecticides, herbicides, and fungicides) in a variety of food, feed, biological, and environmental samples. The increasing use of TLC for pesticide analysis is due to the wide variety of available stationary phases, optimization of mobile phases, and modern instruments for separation and quantification. The off-line development arrangement of TLC allows significant advantages in many pesticide analyses, including high sample throughput, because many samples can be chromatographed simultaneously on a single plate. This entry reviews the steps of pesticide analysis by TLC and offers selected examples of applications to a variety of pesticides and sample matrices.

MATERIALS AND TECHNIQUES

This section contains an overview of the materials and techniques most widely used in TLC pesticide analysis at the current time. Additional information on specific layers and mobile phases and methods for sample preparation, development, detection, and quantification for a number of particular pesticides and samples are given in the "Example Applications" at the end of this entry.

Sample Preparation

Trace pesticide analysis involves extraction and cleanup steps prior to TLC. Extraction is carried out with a solvent of appropriate polarity by Soxhlet, homogenization, or shaking, followed by liquid/liquid partitioning and/or column adsorption or GPC cleanup. Because each plate is used only once, another advantage of TLC is the possibility of analyzing cruder samples than could be injected into a GC or HPLC column without ruining the analysis, thereby reducing the number of sample preparation steps. These conventional procedures, which are slow and consume large volumes of solvents, have been largely superseded. Simple dissolving procedures are used for sample preparation in pesticide formulation analysis.

A number of modern methods for pesticide residue extraction and cleanup are being applied more frequently. Solid-phase extraction (SPE) using small, disposable cartridges, columns, or disks is employed for isolation and cleanup of pesticides from water and other samples prior to TLC analysis, especially using reversed-phase (RP) octadecyl (C-18) bonded silica gel phases. Microwave-assisted extraction (MAE) is a time- and solvent-saving method for removing residues from samples such as soils. Supercritical fluid extraction (SFE) has been used for sample preparation in the screening of pesticide-contaminated soil by conventional TLC and automated multiple development (AMD). Ultrasonic solvent extraction (USE) and videodensitometry have been combined for quantification of pesticides in soil. Matrix solid-phase dispersion (MSPD) with TLC and GC has been used to determine diazinon and ethion in nuts.

Stationary and Mobile Phases

Most pesticide analyses have been performed by normal- or straight-phase (NP) TLC using commercial plates precoated with silica gel. Lipophilic-bonded phase silica gel layers, mainly C-18, have been used for RPTLC. Other precoated layers used less often for pesticide analysis include aluminum oxide, magnesium silicate (Florisil), polyamide, inorganic ion exchangers, cellulose, acetylated cellulose (reversed phase), and polar modified silica gel layers containing bonded amino, cyano, diol, and thiol groups. Treatment with mixtures of sorbents or impregnation with various reagents has been used to prepare layers with special selectivity properties. High-performance TLC (HPTLC) plates with smaller particles of sorbent provide improved resolution, shorter analysis time, higher detection sensitivity, and more precise and accurate in situ quantification compared to conventional TLC plates. Plates with a preadsorbent or concentrating zone may provide cleanup by retaining some interfering substances from impure samples, and they allow application of larger sample amounts for quantification of very low pesticide concentrations without loss of zone resolution. Plates with a silica gel layer adjacent to a C-18 strip (Whatman Multi-K CS5) have been shown to separate complex mixtures of pesticides by two-dimensional (2-D) TLC with different separation mechanisms in each direction (Fig. 1). Soil TLC is a technique in which the studied soil serves as the stationary phase; it is used for investigation of pesticide mobility and adsorption in soils, which can have serious influence on the pollution of groundwater.

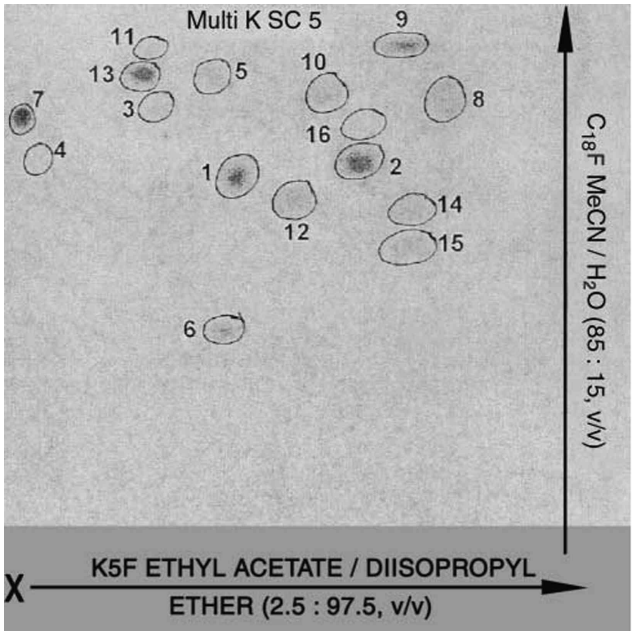

Fig. 1 Photograph taken with a videodensitometer of a Whatman Multi-K SC5 plate showing the 2-D separation of a 16-component mixture of pesticides. The fluorescence-quenched zones are outlined for clarity. Direction 1: ethyl acetate–diisopropyl ether (2.5 : 97.5) mobile phase on the 20 cm × 3 cm K5F silica gel strip (normal phase TLC); direction 2: acetonitrile–water (85 : 15) on the adjacent 20 cm × 17 cm C-18F bonded silica gel layer (RPTLC). X: Origin. Pesticides: 1, propaquizafop; 2, quizalofop-P; 3, triadimefon; 4, triadimenol; 5, fenoxycarb; 6, quinoxyfen; 7, cyromazine; 8, oxyfluorfen; 9, fluoroglycofen; 10, acetochlor; 11, metazachlor; 12, piperonyl butoxide; 13, furalaxyl; 14, pyriproxyfen; 15, buprofezin; 16, clofentezine.
Source: From Separation of a mixture of pesticides by 2D-TLC on two-adsorbentlayer Multi-K SC5 plate, in J. Liq. Chromatogr. Relat. Technol.[1] with permission of Marcel Dekker, Inc.

The mobile phase for a particular separation is usually selected empirically using prior personal experience and literature reports of similar separations as a guide. Typical mobile phases that have been used for separations of many classes of pesticides on silica gel have been mixtures of hexane–acetone, toluene–acetone, chloroform–diethyl ether, and toluene–methanol, while mobile phases for RPTLC analyses on C-18 layers are usually methanol–water and acetonitrile–water mixtures. Computer-assisted, systematic mobile-phase optimization schemes are being used more frequently, especially the PRISMA model.

Application of Samples and Standards

Initial zones in the form of round spots are applied manually to the origins of the layer using a glass micropipet such as a 10 or 25 μl digital microdispenser. In addition, partly or fully automated instruments are available for application of solutions as spots or bands in the microliter to nanoliter range. Compact bands are also produced when samples are applied manually with a micropipet as diffuse vertical streaks to plates containing a preadsorbent zone. Band application is advantageous for obtaining tighter zones, high resolution separations, and accurate and precise quantitative results by densitometry.

Chromatogram Development Techniques

Pesticide analyses have usually been carried out in paper-lined, vapor-saturated glass N-chambers using a single ascending development with the mobile phase. Increased resolution is obtained by 2-D development, overpressured layer chromatography (OPLC), and AMD with gradient elution. An AMD separation of a complex pesticide mixture, with multiple wavelength scanning to provide confirmation of identity, is shown in Fig. 2.

Zone Detection

Pesticides are detected after development as colored, ultraviolet (UV)-absorbing, or fluorescent zones after reaction with a more or less selective derivatization reagent applied to the layer by spraying or dipping. Silver nitrate with UV irradiation is an example of a chromogenic detection reagent used to visualize chlorinated pesticides, while arsenic trichloride–sulfuric acid has been used to detect various pesticide classes. Phenolic pesticides and metabolites are detected as fluorescent zones under 366 nm UV light by use of 7-chloronitrobenzo-2-oxa-1,3-diazole to produce fluorescent 4-nitrobenzofuran derivatives, or by means of Pauly's reagent (sulfanilic acid + KNO_2 + NaOH) for compounds that can form intensely colored azo dyes.

Pesticides that absorb shortwave (254 nm) UV light, particularly those with aromatic rings and/or conjugated double bonds, can be detected by fluorescence quenching on a layer containing a fluorescent indicator (phosphor).

Biological methods of detection have included enzyme inhibition for organophosphorus (OP) pesticides. After mobile-phase development, the layer is sprayed with esterase-1 (*Bacillus subtilis*), followed by 1-thionaphthyl acetate substrate, and finally [2,2′-azo(1-naphthol-8-chloro-3,6-disulfonic acid) 4,4′-diphenyl disulfide] indicator to produce pink zones on a blue background with 0.05–5 ng minimum detection limits. Herbicides have been detected by inhibition of the Hill photosynthesis reaction.

Another important advantage of the off-line operation of TLC is the versatility achieved by use of multiple detection methods. For example, the layer can be viewed under longwave (366 nm) and shortwave UV light, followed by one or more chromogenic, fluorogenic, or biological detection methods; if more than one derivatization reagent is used, only the final one can be destructive.

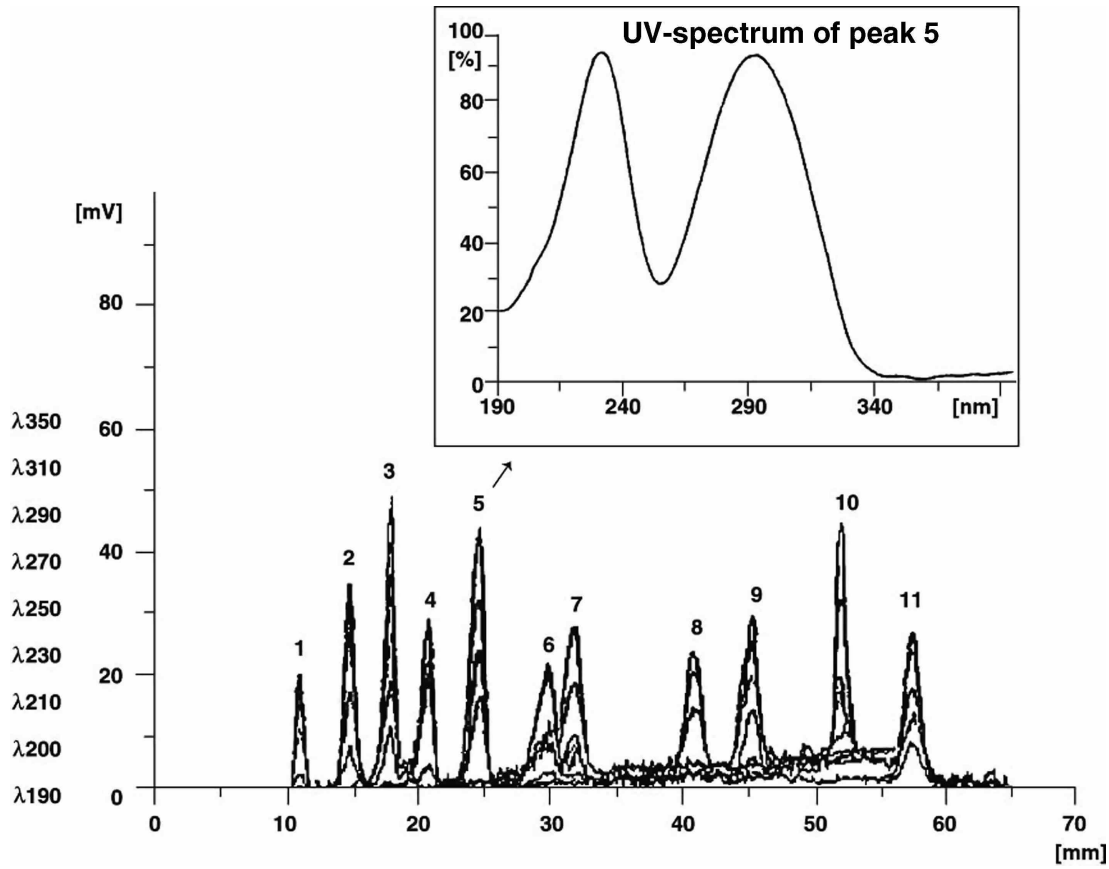

Fig. 2 Multiwave chromatogram of a mixture of 11 pesticides (50 ng/compound) and in situ UV spectrum of peak 5. Compounds represented by peaks: 1, clopyralid acid; 2, triclopyr acid; 3, bitertanol; 4, atraton; 5, chloridazon; 6, sethoxydim; 7, atrazine; 8, iprodione; 9, desmedipham; 10, ethofumesate; 11, pendimethalin.

Quantitative Analysis

Quantitative pesticide analyses are performed by measuring the areas of sample and standard zones on an HPTLC plate using a slit-scanning densitometer or videodensitometer (CCD camera). Calibration plots are prepared for each analyte (scan areas vs. weights of a series of standards), and sample weights are interpolated from the plots. Validation protocols must be applied to evaluate factors such as linearity, detection limit, accuracy, precision, and ruggedness of the analysis. Excellent accuracy and precision can be obtained because samples and standards are chromatographed and measured in parallel under the same conditions on a single TLC plate.

When a videodensitometer (CCD camera) is used, the image of the layer is first recorded and stored (useful for qualitative documentation purposes), and quantitative software transforms the image into chromatographic data by measuring the pixels comprising the sample zones (unknown analyte weights) vs. corresponding standard zones (known weights) through calibration plots.

Identification and Confirmation of Zones: TLC Combined with Spectrometry

The identification of unknown pesticide zones is initially based on comparison of the migration of sample zones relative to standards developed on the same layer (R_f values) and colors obtained with selective chromogenic and fluorogenic detection reagents. Many densitometers can record in situ UV and visible absorption and fluorescence excitation spectra to confirm compound identification by comparison of unknown spectra with stored standard spectra obtained under identical conditions or spectra of standards measured on the same plate. Additional confirmation methods include off-line and online (coupled, hyphenated) combination of TLC with infrared, Raman, photoacoustic, or mass spectrometry (MS); MS/MS; GC; or HPLC. Identification of pesticides by multiwavelength UV scanning is demonstrated in Fig. 1.

Special Techniques

Thin-layer radiochromatography (radio-TLC) is widely applied for a variety of environmental studies involving

radiolabeled pesticides, such as plant uptake from soil; bioaccumulation in fish; dissipation from soil; metabolism in soil, plants, and fish; and environmental fate. Techniques employed for detection, identification, and quantification of radioactive zones include contact autoradiography, liquid scintillation counting, electronic autoradiography, and storage phosphor screen imaging.

The determination of the lipophilicity of pesticides is important because their bioaccumulation and tendency for degradation and biotransformation are related to lipid solubility. TLC has advantages for lipophilicity studies compared to traditional partition coefficient measurement in an octanol–water system.

EXAMPLES OF PESTICIDE TLC ANALYSIS APPLICATIONS

Separation of 16 Pesticide Standards

- Sample preparation: Standard mixture was applied as a 0.5% solution.
- Layer: Whatman Multi-K SC5 plate described in Fig. 1.
- Mobile phase: 2-D development with the mobile phases given in Fig. 1.
- Detection: Fluorescence quenching under 245 nm UV light.[1]

Screening of 265 Pesticides in Water

- Sample preparation: SPE on a C-18 column or liquid/liquid extraction with dichloromethane.
- Layer: HPTLC silica gel.
- Mobile phase: Universal gradient based on dichloromethane.
- Detection: UV absorption densitometry (see Fig. 2).[2]

Determination of Carbaryl and Propoxur in Water

- Sample preparation: Chloroform extraction; grain samples were also analyzed.
- Layer: Silica gel G.
- Mobile phase: Acetone–hexane (1 : 4) or butanol–acetic acid–water (3 : 1 : 6, butanol layer).
- Detection: Spray with diazotized *p*-nitroaniline followed by aqueous NaOH to produce blue and purple spots, respectively.
- Quantification: Colored sample and standard zones were scraped and eluted with 6 *M* NaOH and the solutions measured by spectrometry.
- Validation: Recovery of 25–100 ng of the pesticides added to water ranged from 98% to 100%.[3]

Determination of 24 Pesticides in Water

- Sample preparation: Samples (1000 ml) of ground, surface, and drinking water were extracted using a C-18 SPE cartridge; the cartridge was eluted with 3 ml of acetonitrile, and the eluate was used directly for TLC or cleaned up on a silica column eluted with acetonitrile.
- Layer: HPTLC silica gel 60F-254; samples applied by the spray-on technique using a Linomat IV.
- Mobile phase: AMD with 20-step universal gradients based on dichloromethane containing 0.1% acetic acid, methanol, and hexane (screening gradient) and *t*-butyl methyl ether containing 0.1% acetic acid, acetonitrile, and hexane (confirmatory gradient).
- Detection and identification: Comparison of sample and standard chromatograms scanned at six different wavelengths with a densitometer.[4]

Determination of Carbamate Insecticides in Water

- Sample preparation: Pesticides recovered from pond water by SPE on a C-18 column eluted with ethyl acetate.
- Layer: Channeled preadsorbent HPTLC silica gel.
- Mobile phase: Toluene–acetone (4 : 1) (carbaryl, carbofuran, methiocarb) or hexane–acetone–chloroform (75 : 15 : 10) (propoxur).
- Detection: Plate dipped into *p*-nitrobenzenediazonium fluoborate chromogenic reagent.
- Quantification: Densitometric scanning of sample and standard zones at 610 nm (carbaryl), 550 nm (carbofuran, propoxur), or 510 nm (methiocarb).
- Validation: Recovery averaged 97% for analysis of water spiked with pesticides at 0.5–5 ppm.[5]

Determination of Atrazine and Its Major Metabolites in Soils

- Sample preparation: Soil was extracted with methanol, the suspension was filtered, and the filtrate was concentrated by evaporation.
- Layer: HPTLC reversed phase plates; samples were applied with a Nanomat III.
- Mobile phase: Methanol–water (7 : 3); development in a horizontal chamber.
- Quantification: Zones were scanned at 222 nm with a dual-wavelength flying-spot densitometer; standard curves were prepared by quadratic regression analysis, which gave a higher correlation coefficient than linear regression.

– Validation: Recovery of atrazine from fortified samples ranged from 87% to 97%; the detection limit of the method was 20 ng.[6]

Determination of Cymiazole and Pentachlorophenol (PCP) in River Water and Honey

– Sample preparation: The pesticides were extracted from water and honey using C-18 SPE.
– Layer: Channeled preadsorbent high performance silica gel.
– Mobile phase: Toluene–methanol (9:1) for PCP; hexane–acetone–methanol–glacial acetic acid (35:10:5:0.1) for cymiazole; paper-lined twin trough chamber.
– Detection: Fluorescence quenching under 254 nm UV light; 200 ng sensitivity.
– Quantification: Scanning densitometry at 215 nm for PCP and 265 nm for cymiazole.
– Validation: Recoveries from water at concentrations of 0.25–5 ppm ranged from 97.7% to 100% for PCP and from 89.5% to 94.9% for cymiazole. Recoveries from honey at 10 and 50 ppm ranged from 94.0% to 96.1% for PCP and from 91.9% to 93.7% for cymiazole.[7]

Determination of Diflubenzuron in Water

– Sample preparation: Extraction on a C-18 SPE column eluted with acetonitrile.
– Layer: Channeled preadsorbent high performance silica gel.
– Mobile phase: Ethyl acetate–toluene (1:3); paper-lined glass HPTLC chamber.
– Detection: Spraying with 6 *M* HCl, heating for 10 min at 180 °C, and spraying with Bratton–Marshall reagent [sodium nitrite and *N*-(1-naphthyl) ethylenediamine dihydrochloride]; purple-blue band, 100 ng sensitivity.
– Quantification: Scanning densitometry at 550 nm.
– Validation: Sensitivity was 0.1 μg, recoveries at 50 μg/L 95–97% with relative standard deviations (RSDs) of 2–3%; semiquantitative limit of determination 125 ng/L.[8]

Determination of OP Insecticides in Water

– Sample preparation: C-18 SPE.
– Layer: Preadsorbent silica gel.
– Mobile phase: Hexane–acetone (4:1).
– Detection: 5% $MgCl_2$, 0.3% *N*,2,6-trichlorobenzoquinoneimine; 100 ng limit of detection (LOD).
– Quantification: Scanning densitometry.[9]

Separation of Organochlorine and OP Insecticides

– Sample preparation: Standard solutions (0.1%) in benzene; 5 μl applied.
– Layer: Silica gel 100F.
– Mobile phase: Heptane–acetone (4:1).
– Detection: Zones viewed under 254 and 366 nm UV light.[10]

Determination of Metribuzin and Its De-ethyl, Deisopropyl, and Hydroxy Metabolites in Soil and Water

– Sample preparation: Soil was extracted with methanol–0.01 *M* calcium chloride dihydrate (4:1), and the extract was filtered and cleaned up on a C-18 cartridge; water samples were eluted directly through the cartridge.
– Layer: Hydrocarbon-impregnated RPTLC plates; zones applied with a Nanomat III.
– Mobile phase: Methanol–water (45:55).
– Quantification: Scanning at 290 nm with a dual-wavelength flying-spot densitometer; standard curves produced by linear regression.
– Validation: Recoveries of metribuzin from water samples fortified at 10 and 100 μg/L ranged from 85% to 92%, and from 73% to 86% from soils fortified at 2 mg/kg; the LOD for metribuzin was 30 ng.[11]

Determination of Alachlor, Atrazine, and α-Cypermethrin in Water

– Sample preparation: SPE on Empore C-18 disks eluted with dichloromethane or hexane.
– Layer: RP-$18F_{254}$; samples applied as bands with a Linomat IV.
– Mobile phase: 2-Propanol–water mixtures optimized by the window diagrams method.
– Detection and quantification: Videodensitometry of fluorescence-quenched zones at 254 nm.
– Validation: Recoveries were 94.7–104.2% for 250–1000 ml water samples.[12]

Determination of Phenylurea Herbicides in Drinking Water

– Sample preparation: SPE on C-18 cartridges eluted with acetonitrile.
– Layer: (I) Bonded diol-F, (II) bonded amino-F, and (III) silica gel-F.
– Mobile phase: (I) Water–acetone–methanol (6:1:3), (II) chloroform–toluene (8:2), and (III) benzene–triethylamine–acetone (75:15:10).

- Detection: Viewing under 254 and 366 nm UV light.
- Quantification: UV absorption scanning densitometry; a fluorodensitometric screening method involving thermal hydrolysis and subsequent derivatization of the corresponding anilines with fluorescamine was also developed.
- Validation: Recoveries were 87–102% for 1 L of water spiked with 1 μg of pesticide; the LOD was improved 25-fold by derivatization.[13]

Analysis of Formulations of Pyrethrins

- Sample preparation: Formulations were dissolved in ethyl acetate, standard pyrethroids in cyclohexanone–Tween 80 (9:0.1 w/w).
- Layer: Aluminum-backed silica gel $60F_{254}$; solutions applied with a Linomat IV.
- Mobile phase: Hexane–toluene (1:1); development in a twin-trough chamber.
- Quantification: Scanning densitometry at 220 nm.
- Validation: Recoveries of laboratory-prepared test formulations ranged from 95% to 99%.[14]

Screening of Pesticides in Tomatoes

- Sample preparation: Atrazine, carbaryl, carbofuran, chloroxuron, diuron, dimethoate, imazalil, oxamyl, and methamidophos were extracted from tomatoes with ethyl acetate–$NaHCO_3$ and the extract cleaned up by semiautomatic GPC.
- Layer: Silica gel 60F.
- Mobile phase: Ethyl acetate or dichloromethane.
- Detection: *O*-Toluidine–potassium iodide (*O*-TKI) and *p*-nitrobenzenediazonium fluoborate (NBFB) chromogenic reagents. Minimum detection quantities were 12–125 ng for *O*-TKI and 60–70 ng for NBFB.[15]

Fate of ^{14}C-Diazinon in Compost, Soil, and Worms

- Sample preparation: Sequential acetone extraction.
- Layer: Silica gel $60F_{254}$ HPTLC and silica gel GF TLC.
- Mobile phase: Chloroform–acetone (8:1) or ethyl acetate–benzene–chloroform–propanol (2:2:1:1).
- Detection and quantification: Autoradiography.[16]

Chlorpyrifos Degradation in Soil

- Sample preparation: Surface and subsurface clay loam soils were incubated with radiolabeled chlorpyrifos, and samples were extracted with methanol by ambient shaking and SFE.
- Layer: Silica gel F.
- Mobile phase: Toluene–methanol–hexane (18:1:1).
- Detection: Chlorpyrifos and its metabolite 3,5,6 trichloropyridinol (TCP) were detected as fluorescence-quenched zones under 254 nm UV light. Bands were scraped and radioactivity measured by liquid scintillation counting.[17]

CONCLUSIONS

The determination of pesticides is important because of the serious and growing concerns about their possible detrimental effects on human and animal health, the food supply, and the environment. TLC, along with GC, HPLC, and immunoassay, are the major methods for analyzing water, soil, food, biological, and other sample types for pesticides and their residues having a great variety of structures and modes of action. The following lists of References and Bibliography contain sources of detailed information on the procedures and instrumentation of TLC and applications to pesticide analysis, which will augment the material presented in this entry.

pH: Effect on MEKC Separation

Koji Otsuka
Shigeru Terabe
Department of Material Science, Himeji Institute of Technology, Hyogo, Japan

INTRODUCTION

In micellar electrokinetic chromatography (MEKC), the effect of the constituents of the buffer is not significant, whereas the pH is critical, especially for ionizable analytes, as well as to the electrokinetic velocities. The change in the buffer pH, especially in the lower-pH region, causes a significant change in the velocity of the electro-osmotic flow (EOF).

ELECTROKINETIC VELOCITIES

When sodium dodecyl sulfate (SDS) is employed as an ionic micelle or pseudo-stationary-phase in MEKC, the relationship between the velocity of the EOF, v_{EOF}, and the migration velocity of the SDS micelle, v_{mc}, is given as

$$v_{mc} = v_{EOF} + v_{cp} \tag{1}$$

where v_{cp} is the electrophoretic velocity of the SDS micelle. The sign of each velocity is defined as plus when the migration is toward the cathode and as minus when toward the anode.

The dependence of these electrokinetic velocities on pH is shown in Fig. 1.[1] In the case of capillary zone electrophoresis (CZE), with a bare fused-silica capillary, the pH greatly affects the EOF velocity (i.e., significantly decreases with the decrease in pH from 8 to 3). In MEKC, however, the dependence on pH is different from that in CZE, especially under weakly acidic conditions (pH 7.0–5.5). In the range of pH between 7.0 and 5.5, v_{EOF} slightly decreases with the decrease in pH, due to the adsorption of the SDS molecule or monomer on the inside wall of the capillary. On the other hand, v_{EOF} rapidly decreases with the decrease in the pH below 5.5. The decrease of v_{EOF} is mainly caused by the decrease in the zeta-potential of the inside wall of the capillary, because the dissociation of silanol groups on the capillary wall is more suppressed as the solution becomes more acidic.

The electrophoretic velocity of the SDS micelle (v_{cp}) (i.e., $v_{mc} - v_{EOF}$) is almost constant over the pH range in Fig. 1; that is, the charge of the SDS micelle is almost constant in this pH range.

The migration velocity of the SDS micelle (v_{mc}) changes from positive to negative at a pH below 5.0, which means that the SDS micelle migrates toward the anode; thus, the migrating direction of the SDS micelle is opposite that of the EOF. One should note that the reproducibility of retention times was low in acidic solutions, especially below pH 5.0, compared with that in neutral SDS solutions.

MIGRATION TIME

The migration time, t_R of a neutral solute in MEKC is represented by

$$t_R = \left(\frac{1+k}{1+(t_0/t_{mc})k}\right)t_0 \tag{2}$$

where t_0 is the migration time of an unretained solute or insolubilized solute by the micelle at all, t_{mc} is that of the micelle, and k is the retention factor of the solute. Here, we define the sign of the migration time as positive when the solute migrates toward the cathode or the velocity of the solute, v_s is positive, and vice versa. When neutral SDS solutions are employed, the t_{mc} is positive and of any neutral solute is always positive and limited to between t_0 and t_{mc}. Under acidic condition, or typically pH below 5.0, the neutral solute totally solubilized by the SDS micelle, such as Sudan III, migrates toward the anode and, hence, t_{mc} becomes negative, whereas the solute insolubilized by the micelle (e.g., methanol) migrates toward the cathode. By considering Eq. 2, it is apparent that the migration time of the solute whose capacity factor is equal to $-(t_{mc}/t_0)$ becomes infinity when $t_{mc} < 0$ and the solute never migrates in the column, whereas the solute of $k > -(t_{mc}/t_0)$ migrates toward the same directions as the micelle.

RESOLUTION

In MEKC, the resolution, of two peaks of which the retention factors are and is described as (see *Retention Factor: MEKC Separation*, p. 2033):

$$R_s = \frac{N^{1/2}}{4}\left(\frac{\alpha-1}{\alpha}\right)\left(\frac{k_2}{1+k_2}\right)\left(\frac{1-t_0/t_{mc}}{1+(t_0/t_{mc})k_1}\right) \tag{3}$$

For the closely migrating peaks, we can assume that $k_1 = k_2 = k$. Then, the fourth term of the right-hand

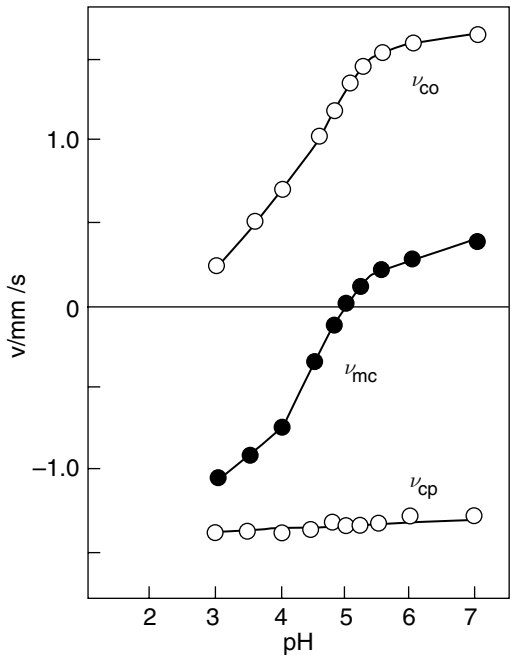

Fig. 1 Dependence of electrokinetic velocities on pH: v_{co} = velocity of the EOF, v_{mc} = migration velocity of the micelle, v_{cp} = electrophoretic velocity of the micelle.
Source: From Effects of pH on electrokinetic velocities in micellar electrokinetic chromatography, in J. Microcol. Separ.[1]

side of Eq. 3 will become infinity when k is equal to $-t_{mc}/t_0$ thus, the resolution will become maximum or infinity. The function $f(k)$, the product of the last two terms in Eq. 3, is written as

$$f(k) = \left(\frac{k_2}{1+k_2}\right)\left(\frac{1 - t_0/t_{mc}}{1 + (t_0/t_{mc})k_1}\right) \quad (4)$$

The value of $f(k)$ approaches infinity, as in the case of t_R as k becomes close to $-t_{mc}/t_0$ and, consequently, R_s becomes quite large. Hence, a considerably large R_s will be obtained for a solute having k close to $-t_{mc}/t_0$, although a quite long t_R is required for such a solute.

MIGRATION WINDOW

The parameter t_0/t_{mc} is related to the migration window. As long as t_{mc} is positive, a smaller value of t_0/t_{mc} gives a wider migration window. Some attempts to extend the migration window have been made by (a) the addition of organic modifiers (e.g., methanol, acetonitrile, and 2-propanol) to the micellar solution and (b) the use of capillaries of which the inside walls were chemically modified to reduce the silanol-group concentration. In each case, the extension was mainly achieved through decreasing the EOF owing to a decrease of the zeta-potential of capillaries. As mentioned earlier, the migration window is no longer limited when acidic micellar solutions (i.e., pH below 5.0) are employed. The value of zero for t_0/t_{mc} corresponds to the case of conventional chromatography, in which the elution range is infinity; in other words, the solute of $k = \infty$ (e.g., Sudan III) never comes out from the capillary. The case also causes the infinite migration window.

IONIZABLE SOLUTES

If the ionized form of the solute has the same charge as the micelle, it will be incorporated into the micelle less than with its neutral form. By contrast, the ionized form of the solute will be bound to the micelle more strongly than its neutral form if the ionized solute has the opposite charge to that of the micelle. The dependence of the apparent retention factor, on the buffer pH for chlorinated phenols has been investigated in an SDS/MEKC, where both the ionizable solutes or chlorinated phenols and SDS have negative charge. The apparent retention factor was calculated by the usual equation for the retention factor in MEKC:

$$k_{app} = \frac{t_R - t_0}{[1 - (t_R/t_{mc})]t_0} \quad (5)$$

regardless of whether the solutes were ionized or not. For acidic compounds, the increase in pH will promote ionization; then, the distribution coefficient to the SDS or an anionic micelle will be decreased. For example, the apparent retention factor for 2,3,4,5-tetrachlorophenol ($pK_a = 5.6$) was dramatically changed from ~100 at pH 6.0 to 4 at pH 9.0.

It is often essential to find the optimum pH for the separation of ionizable solutes, where closely spaced peaks are obtained.

Phenolic Acids in Natural Plants: HPLC Analysis

E. Brandsteterova
A. Ziakova-Caniova
Department of Analytical Chemistry, Slovak Technical University, Bratislava, Slovakia

INTRODUCTION

Many medicinal and food plants contain large amounts of antioxidants other than vitamin C, vitamin E, and carotenoids. The antioxidative effects are mainly due to phenolic compounds: phenolic acids, flavonoids, and phenolic diterpenes. These natural antioxidants can exert considerable protection, in humans, against aging and cancer caused by free radicals, and can replace synthetic antioxidants such as butylated hydroxyanisole (BHA) and butylated hydroxytoluene (BHT), which are suspected to have toxic and carcinogenic effects on humans.

Phenolic acids constitute a large group of naturally occurring organic compounds with a broad spectrum of pharmacological activities. It was found that they possess not only antioxidant but also antiviral and antibacterial properties. The antioxidant activity of phenolics is generally combined with hydroxyl groups on their molecules. Phenolic acids are widely distributed in natural plants, e.g., fruits, vegetables, various medicinal and other plants. Phenolic acids occur in plants in different concentrations and, of course, each plant sample could be specific enough for the presence of different phenolic acids and their derivatives in combination with the other groups of phenolic compounds. Very often, all important phenolics present in plant samples are analyzed simultaneously.

Phenolic acids include the benzoic acids (C_6–C_1), e.g., gallic, vanillic, syringic, protocatechuic, *p*-hydroxybenzoic acid, as well as cinnamic acids (C_6–C_3), e.g., caffeic, *p*-coumaric, ferulic, sinapic acids, and their depsides and derivates, e.g., rosmarinic acid and lithospermic acid (Fig. 1).[1] Phenolic acids and flavonoids in plants may occur in the free form, but they are often glycosylated with various sugars, especially glucose. Phenolic acids may also be present in the esterified as well as bound forms. Free phenolic acids are found especially in herbs and spices and, very often, in compounds responsible for antioxidant activity (benzoic and cinnamic acids and some of their derivatives). The bound forms are more common for the fruits, vegetables, and other plant materials. Therefore, in some cases, it is necessary to combine the analysis of their free and bound forms.

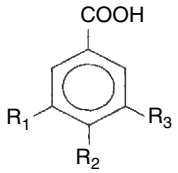
HPLC OF PHENOLIC ACIDS

The content of various phenolic acids in plants can be determined using various analytical instrumental methods gas chromatography, thin-layer chromatography, and capillary electrophoroesis (GC, TLC, CE), but high-performance liquid chromatography (HPLC), with a broad range of detection possibilities, is the best method of choice for routine analysis. HPLC techniques offer a real chance to separate simultaneously all analyzed components together with their possible derivatives or degradation products. In many cases, this method enables the determination of low concentrations of analytes in the presence of many other interfering and coeluting components. There are many advantages influencing the increased popularity of the HPLC technique in plant material analysis, such as the large choice of commercially available columns with very desirable properties; the application of all chromatographic separation principles, including the use of new generation sorbents; and the possibility of combining two or more columns in a switching mode.[2]

HPLC Columns

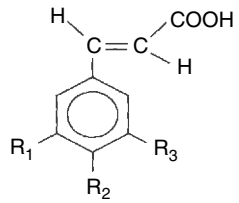
The columns used for the separation of phenolic acids are mainly reversed-phase (RP), other silica-based chemically bound phases, and non-silica polymers or mixed inorganic–organic phases. Special silica sorbents with reduced metallic residue contents and minimum residual silanol groups on the surface could positively influence peak symmetry without the strict demands for the successful separation of acidic analytes. Almost exclusively, RP C_{18} phases ranging from 100 to 250 mm in length and usually with an internal diameter of 3.9 to 4.6 mm are recommended. Particle sizes are in the range of 3–10 μm. Short 50–100 mm columns with 3 μm particles have also been tested for fast phenolic acid separations. Narrow bore columns (internal diameter 2 mm) are recommended especially for HPLC/MS applications.[3,4] Some problems could arise with the applications of narrow or microbore columns in the direct injections of plant extracts; there is the possibility of plugging the column after repeated injections. In these cases, an additional clean-up step has to be applied instead of just the simple extraction assay. Moreover, in the case when columns with lower diameters and particle sizes are used, the adaptation of HPLC equipment is often necessary, e.g., ultra violet (UV) detection cells with reduced

Benzonic acid derivates:

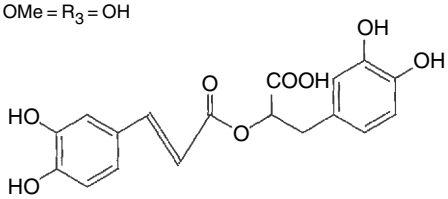


Gallic acid, $R_1 = R_2 = R_3 = OH$
p-Hydroxybenzoic acid, $R_1 = R_3 = H$, $R_2 = OH$
Protocatechuic acid, $R_1 = R_2 = OH$, $R_3 = H$
Vanillic acid, $R_1 = OMe$, $R_2 = OH$, $R_3 = H$
Syringic acid, $R_1 = R_3$, $OMe = R_2 = OH$

Cinnamic acid derivates:



Caffeic acid, $R_1 = R_2 = R_3 = OH$
p-Coumaric acid, $R_1 = R_3 = H$, $R_2 = OH$
Ferulic acid, $R_1 = OMe$, $R_2 = OH$, $R_3 = H$
Sinapic acid, $R_1 = R_2$, $OMe = R_3 = OH$



Rosmarinic acid

volume, low injection volumes, pumps with well-controlled low flow-rate, and low diameter capillary connections.[1]

Some published results have confirmed the fact that the quality of sorbent (purity, end-capping) and the particle size does not have a very significant influence on the peak symmetry of the analyzed phenolic acids,[5] but the chromatographic resolution and the efficiency of the column (number of theoretical plates) are better for columns with very good free silanol group covering, end-capping, or embedding. Maybe, it is the main reason for the use of good quality commercially available columns for most phenolic acid analyses in plant materials during the last years.[6] Especially, if a great number of analytes are required to be separated simultaneously, the column with the best separation properties is applied. The choice of columns depends also on the developed sample preparation technique, because the less clean extracts could decrease the lifetime of or cause damage to the column.

Most HPLC analyses of phenolic acids are performed at ambient column temperature, but moderately higher temperatures between 30° and 40°C have also been recommended in the analysis of fruits, vegetables, and other plants.

HPLC Mobile Phases

Both isocratic and gradient elution are applied for phenolic acid analyses. The choice depends on the number and type of analytes and the nature of plant matrix. Methanol, acetonitrile, and tetrahydrofurane are the most commonly used organic modifiers, as well as aqueous acidified solvents such aqueous acetic acid, formic acid, phosphoric acid, or perchloric acid. In some cases, acetonitrile leads to better resolution in a shorter analysis time than methanol and, generally, acetonitrile gives sharper peak shapes, resulting in a higher plate number. However, methanol is often preferable to acetonitrile because of its non-toxic properties and the possibility of using higher percentages in the mobile phase (lower solvent elution strength) which could protect the HPLC column. Also, tetrahydrofurane, with its high elution strength, could be applied to phenolic acid separations.[1] As most phenolic acids have p*K*s of about 4, the recommended pH range for the HPLC assay is pH = 2–4. It is important to avoid the ionization of analytes during analysis to improve the resolution and reproducibility of the retention characteristics. The most available columns allow the application of mobile phases with pH of about 2. The pH value is controlled by adding small amounts of acids to the water–organic mixture. Some authors also recommend the use of aqueous buffers (citrate buffer, phosphate buffer, ammonium acetate buffer) instead of the addition of acid. The buffer concentration can vary from 5 to 50 m*M*. The next alternative for controlling analyte retention may be the application of ion-pairing reagents, added to the aqueous mobile phases. However, the new generation of sorbents recommended for simultaneous separation of acids and bases can be applied without ion-pairing agents. An additional advantage of these new sorbents is the possibility of working with aqueous mobile phases with very low organic solvent content or without any organic modifier at all. The isocratic mode has been recommended for extracts containing components with very similar properties, especially with similar polarities in the purified extracts, with a small number of impurities or for coeluting compounds. Free phenolic acids (chlorogenic, protocatechuic, *p*-hydroxybenzoic, caffeic, vanillic, syringic, *p*-coumaric, and ferulic) could be isolated from some samples of medicinal plants or pharmaceutical preparations using a simple isocratic mobile phase (methanol–water–acetic acid).[7,8] Simple isocratic elutions have also been used for the analysis of phenolic acids in fruit products.[9] The same isocratic mobile phases were applied in the HPLC separations of simple phenolic acids using two columns of different properties. Chromatograms are illustrated in Fig. 2A and B. It is obvious from both chromatograms that the quality of the column, e.g., good end-capping of free silanol groups on the silica surface and low content of metal ions in silica material, can significantly influence the separation of analytes. Chromatographic resolution values are better

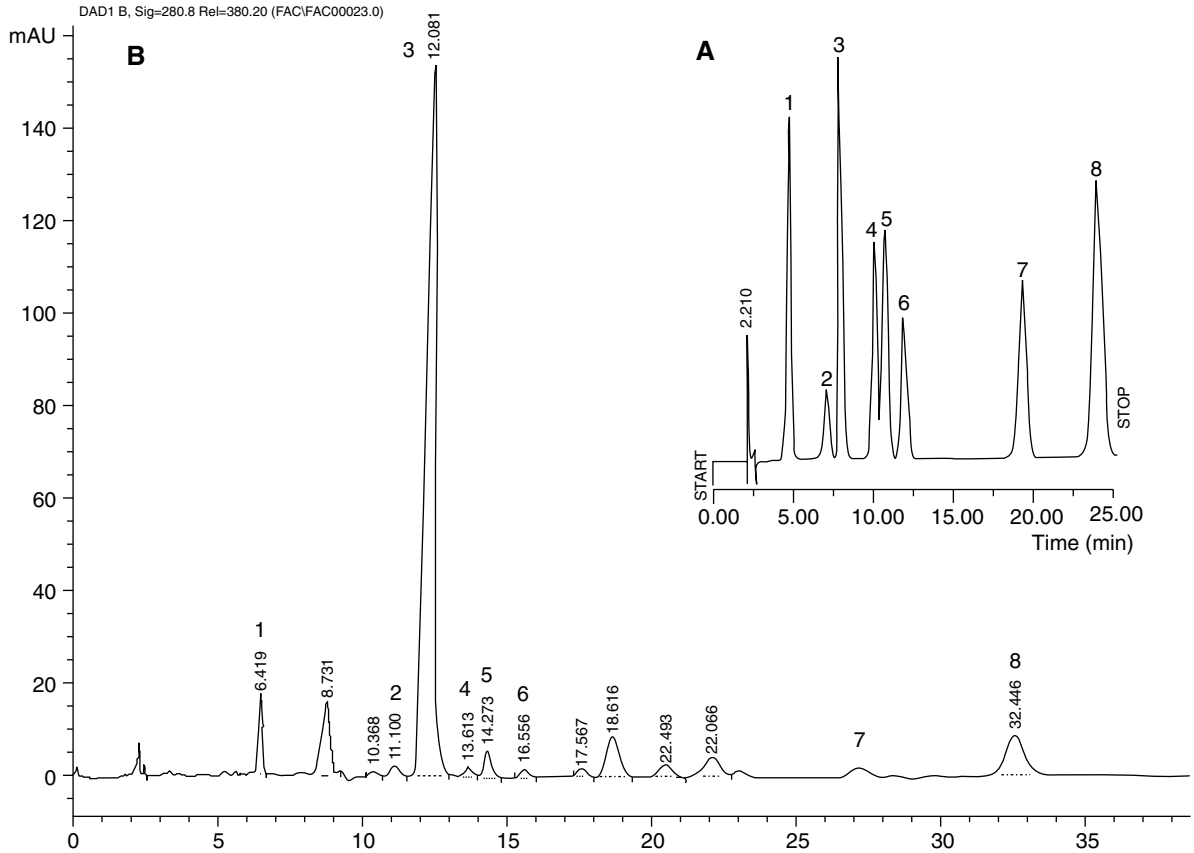

Fig. 2 HPLC chromatogram of phenolic acids using (A) ODS Hypersil column, (B) Symmetry C_{18} column and isocratic elution. Conditions: (A) column: ODS Hypersil (200 × 4.6 mm, 5 μm), mobile phase: methanol–water–acetic acid (25 : 75 : 1), flow-rate 1 ml/min; (B) column: Symmetry C_{18} (250 × 4.6 mm, 5 μm), mobile phase: methanol–0.001 *M* phosphoric acid (23 : 77), flow-rate 1 ml/min. Peaks: 1) protocatechuic acid; 2) chlorogenic acid; 3) *p*-hydroxybenzoic acid; 4) vanillic acid; 5) caffeic acid; 6) syringic acid; 7) *p*-coumaric acid; 8) ferulic acid.
Adapted from Glowniak, Zgorka, & Kozyra[7] and Zgorka & Kawka.[8]

for the Symmetry™ column, which makes quantitative analysis much simpler and reproducible. In the case when phenolic acids of different chemical structures and different polarities have to be analyzed simultaneously, gradient elution is necessary. Of course, in this case also, the choice of column is also a very important consideration. HPLC separation of phenolic acids of different polarities (e.g., protocatechic, caffeic, rosmarinic acids) using different quality columns often requires gradient elution.[5,10] This separation is illustrated in Fig. 3A and B. It can be seen from the chromatograms that there is no significant difference in the asymmetry values for all analytes, but the efficiencies of the two columns and the possibility of more compounds being separated at the same time are much higher for the Symmetry™ column. The same situation occurs if phenolic acids of different polarities, as well as other groups of phenolic compounds (flavonoids, diterpenes), have to be determined in a single analytical run. In this case, the separation of more analytes of different chemical structures has not been realized using a column without special properties. The simultaneous HPLC separation of different phenolic acids and flavonoids that could be present in some medicinal plants is demonstrated in Fig. 4.[10] The Symmetry C_{18} column and gradient elution were used. All analytes were separated in about 30 min, with the sufficient resolution. The same choice of mobile phase components is used for the gradient mode as was mentioned for the isocratic elution. This means using organic–water mixtures with controlled pH, or organic–buffer compositions. The binary linear or step gradients are mostly used. Concerning the elution order of separated phenolic acids, it is obvious that individual compound retention depends on their polarities and, of course, on the character of the stationary phase that is used. Generally, phenolic acids are eluted from RP columns according to decreasing polarities. Loss of polar hydroxy groups and the presence of the methoxy groups or ethylenic side chains could decrease the polarity and increase the retention time. Of course, the derivatives of common phenolic acids with two or more aromatic rings

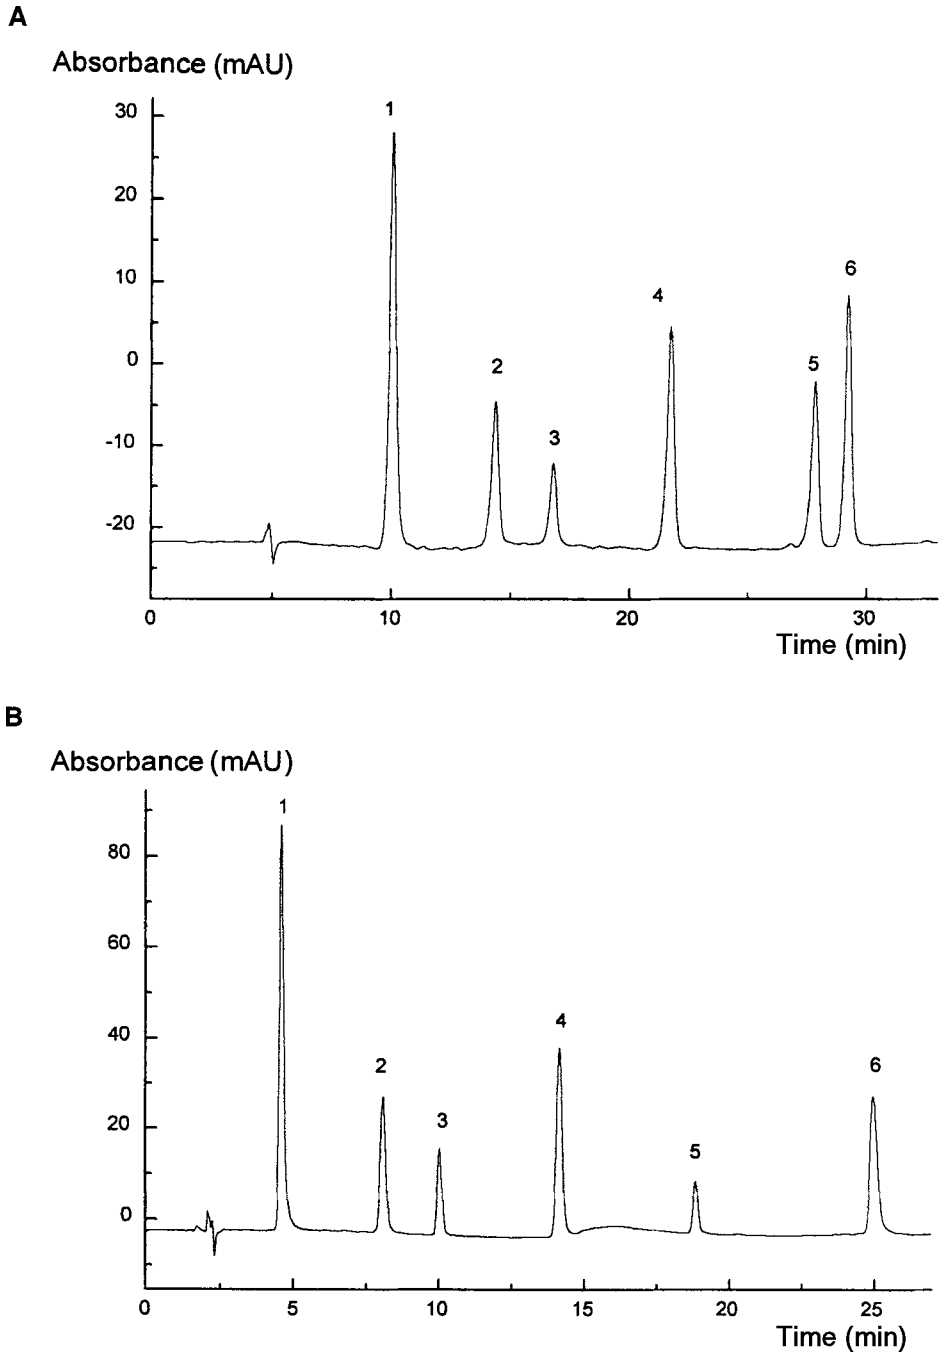

Fig. 3 HPLC analysis of phenolic acids using (a) Separon SGX C_{18} column and (b) Symmetry C_{18} column and gradient elution. Conditions: (A) column: Separon SGX C_{18} (250 × 4.6 mm, 7 μm), mobile phase: methanol–water (pH = 2.5, adjusted with formic acid), linear gradient from 15% methanol to 75% methanol in 40 min, flow-rate 0.5 ml/min; (B) column: Symmetry C_{18} (150 × 3.9 nm, 5 μm), mobile phase and flow-rate same as in (a). Peaks: 1) gallic acid, 2) protocatechuic acid, 3) catechin, 4) caffeic acid, 5) sinapic acid, 6) rosmarinic acid.

are less polar and are eluted much later than others. So, the gradient scheme has to be managed individually, according to the number and chemical properties of the analyzed compounds. Some phenolic acids could be present in natural plants as geometric isomers. Their simultaneous separation is usually possible using RP stationary phases. The greatest number of phenolic acids occurs in nature as *trans*-isomers, but on exposure to UV radiation or daylight they are gradually transformed to *cis*-isomers, which elute, usually, before *trans*-isomers.[1,5] For this reason, the stability studies of analyzed compounds are valuable and the results have to be taken into consideration during the sample preparation method development. UV radiation and elevated temperature could decrease the extraction recoveries and lower the reproducibility of the assay.

HPLC Detection

Phenolic acids absorb well in the UV range, but no single wavelength is sufficient for their simultaneous monitoring

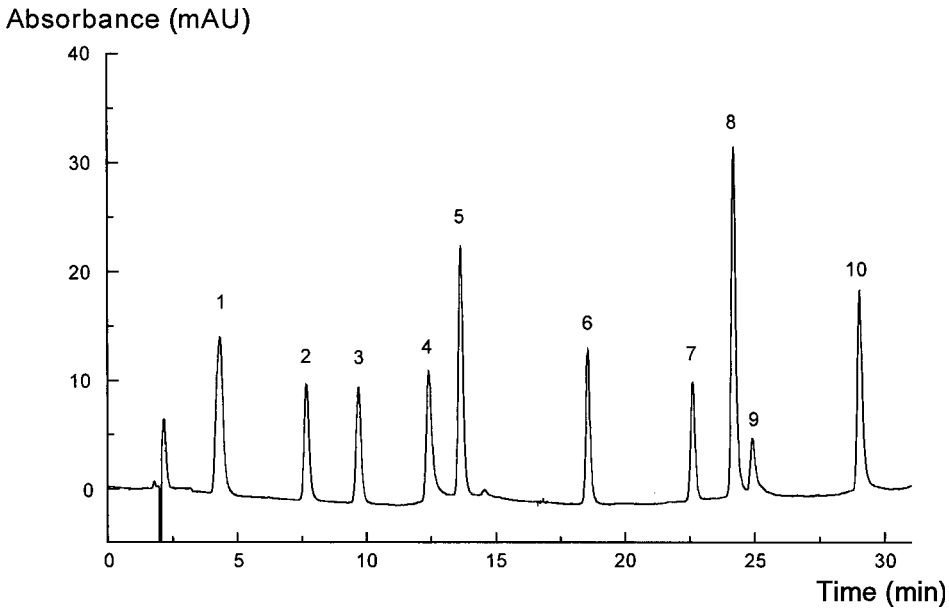

Fig. 4 HPLC analysis of phenolic acids and flavonoids using Symmetry C_{18} column and gradient elution. Conditions: column: Symmetry C_{18} (150 × 3.9 nm, 5 μm), mobile phase the same as in Fig. 3B, flow-rate 0.6 ml/min. Peaks: 1) gallic acid, 2) protocatechic acid, 3) catechin, 4) epigallocatechin gallate, 5) caffeic acid, 6) ferulic acid, 7) rutin, 8) rosmarinic acid, 9) myricetin, 10) quercetin.

in extracts of various natural plant extracts. Therefore, variable-wavelength UV or diode-array (DA) detectors are the most commonly used in the HPLC analyses of phenolic acids. Most of the benzoic acid derivatives have absorption maxima at 246–262 nm, with a shoulder at 290–315 nm, except for gallic and syringic acids with absorption maxima at 271 and 275 nm, respectively. The cinnamic acids absorb in two ranges: 225–235 and 290–330 nm. As was mentioned previously, the maxima of the UV spectra differ significantly for the individual phenolic acids; the range of wavelengths for their detection is wide (210–370 nm). Systematic studies of the absorbance spectra recommended for their simultaneous separation require the following single wavelengths: 254, 280, and 320 nm; for dual monitoring: 254 and 280 nm, or 280 and 320 nm. However, detection at 280 nm is the most generally used wavelength for the simultaneous separation of mixtures of phenolic acids.[1] Of course, DAD is the best detection choice, as it enables scanning of the UV spectra of all solutes passing through the detector; it could help in the identification of individual compounds in the extracts of complex mixtures, such as extracts of natural plants. Moreover, DAD also gives important information about the purities of all analytes.

Fluorescence detection is not very often used in phenolic acid analysis, but, in cases when very low concentrations of some analytes or many interfering compounds are present in extracts, the combination of UV and DAD with fluorescence detector could be valuable. However, the same problems could arise as in the UV detection, i.e., establishing the correct excitation and emission wavelengths, as large differences for several phenolic acids were observed. In this case, the rapid scanning fluorescence detector, in combination with DAD, is available for applying multiple excitation and emission wavelengths.[8]

Electrochemical detection is very sensitive for the compounds that can be oxidized or reduced at low-voltage potentials. Therefore, it could also be applied in the HPLC analysis of phenolic acids that are present in natural samples at very low concentrations. With the recent advances in electrochemical detection, multi-electrode array detection is becoming a powerful tool for detecting phenolic acids and flavonoids in a wide range of samples. The multi-channel coulometric detection system may serve as a highly sensitive way for the overall characterization of antioxidants; the coulometric efficiency of each element of the array allows a complete voltametric resolution of analytes as a function of their reaction (redox) potential. Some peaks may be resolved by the detector, even if they are unresolved when they leave the HPLC column.[11]

The detection and identification of phenolic compounds, including phenolic acids, have also been simplified using mass spectrometry (MS) techniques online, coupled to the HPLC equipment. The electrospray ionization (ESI) and atmospheric pressure chemical ionization (APCI) interfaces dominate the analysis of phenolics in herbs, fruits, vegetables, peels, seeds, and other plants. In some cases, HPLC, with different sensitivity detectors (UV, electrochemical, fluorescence), and HPLC/MS are simultaneously used for the identification and determination of phenolic acids in natural plants and related food products.[4,12,13] In some papers, other spectroscopic instrumental techniques (IR, ^{1}H NMR, and ^{13}C NMR) have also been applied for the identification of isolated phenolic compounds.[3]

SAMPLE PREPARATION

Sample handling is a very important part of the method development for HPLC determination of phenolic acids in

natural plants. Because of the great variability of phenolic acids (different polarity, acidity, number of hydroxyl groups, and aromatic rings), the various concentration levels of individual analytes, and the very complex natural matrix with many interfering components, the choice of the technique for their isolation and quantification differs from one described HPLC assay to the next. In some cases, only a one-step extraction and simple clean-up procedure are sufficient before the HPLC analysis, but the most often described HPLC assays include two or more steps of sample preparation, especially in the case of fruits and vegetable samples. It is obvious that each step contributes, on one hand, to the higher sensitivity and selectivity, but, on the other hand, it could increase the number of errors and decrease the recovery of the method. Therefore, it is very important to choose the optimal preparation of plant material according to the chemical structures and properties of analyzed compounds.

Liquid Extraction (LE)

Liquid extraction is the most commonly used procedure prior to HPLC analysis of phenolic acids in natural plants. Most of these samples are not of liquid consistency, and they cannot be injected directly into the HPLC column. Therefore, the analytes have to be isolated from the matrices in which they exist naturally before HPLC analysis. Of course, as the first steps of the preparation procedure, there are sample handling, milling, grinding, and homogenization. These steps can also influence the results of the complete HPLC assay. In many cases, the analyst has the possibility to control all preparation steps and to evaluate their influence on the analytical results. Commonly used extraction solvents are alcohols (methanol, ethanol), acetone, diethyl-ether, and ethyl acetate. However, very polar phenolic acids (benzoic, cinnamic acids) could not be extracted completely with pure organic solvents, and the mixtures of alcohol–water or acetone–water are recommended. On the other hand, the less polar analytes (phenolic acid derivatives) are not isolated quantitatively from plant matrices using only pure water as the extraction solvent. Less polar solvents (dichlormethane, chloroform, hexane, benzene) are suitable for the extraction of non-polar extraneous compounds (waxes, oils, sterols, chlorophyll) from the plant matrix. Of course, other factors (e.g., the choice of pH, temperature, sample-to-solvent volume ratio, and the number and time intervals of individual extraction steps) also play an important role in the extraction procedure. All these factors influence recovery values and, of course, the validation parameters of the complete assay. Therefore, it is necessary to optimize the extraction conditions.[5] The analysis of free phenolic acids, especially in fruits and vegetables, also often requires a hydrolysis step, as the phenolic acids could be found, in these sources, in the conjugated form and rarely in the free state. The assays could employ either acidic, alkaline, or enzymatic hydrolysis. An alkaline hydrolysis is used to break ester complexes (the most common form of phenolic acids) and acidic hydrolysis is used to disrupt glycoside linkages. Alkaline hydrolysis can be accomplished using 2N NaOH for some hours, at ambient or lower temperatures, often under nitrogen stream. Acidic hydrolysis is performed often at higher temperatures (100°C) with 2N HCl for some hours. But not all extracts are clean enough to be injected directly into the HPLC column. So, it is necessary sometimes to use additional clean-up step(s).

Extraction and clean-up procedures also apply column LC, solid-phase extraction (SPE), super critical fluid extraction (SFE), or matrix solid-phase dispersion (MSPD). The preferred approach is determined according to the nature of the plant matrix and the number and chemical properties of analyzed phenolic acids.

Solid-Phase Extraction

SPE is a good choice for the clean-up procedure for crude plant extracts. This technique, which applies all separation principles, has become very popular in the past decade. The advantage of SPE over LE is that SPE is faster and more reproducible, and fairly clean extracts are obtainable, emulsion creation is avoided, and smaller volumes are applied. From the environmental point of view, a lower consumption of toxic solvents is the reality of this technique. In some cases, more than one single-functional group SPE cartridge is used, or two or more SPE cartridges with different sorbents could be combined.[7–9] New generation sorbents are now also commercially available with hydrophilic–lipophilic properties which enable the simultaneous separation of both polar and less polar compounds. Very simple SPE assay is required for all acidic and basic analyte isolation from the "crude" plant extract and high recoveries are common for this simple procedure. The great advantage of SPE is the possibility of combining the SPE procedure, online, with the HPLC equipment and realizing the so-called direct sample analysis (DSA). This means that the "crude" extract of plant material is injected directly into this SPE/HPLC system.

Matrix Solid-Phase Dispersion

MSPD is the next alternative for sample preparation of fruits, vegetables, herbs, cereals, and other plants. It is convenient for liquid and semi-liquid samples. This technique is a multi-residual assay which consists of matrix homogenization with a solid silica phase placed into a short column, as in SPE. Analytes and matrix interferences are retained on the mixed solid-phase material with completely new separation characteristics. Specific elution allows one to obtain analytes after the elimination of matrix compounds via washing steps. This

technique combines homogenization, cellular disruption, extraction, fractionation, and purification in a single process. MSPD has many advantages: the sample is dispersed over a large surface area, the volumes of extraction solvents are low in comparison with liquid extraction, and so, as is the case with SPE, it can be automated. The application of MSPD as the preparation step before HPLC analysis of various analytes in plants, fruits, and vegetables has been reviewed.[14] This technique has also been tested for phenolic acids in herb materials.[10]

Supercritical Fluid Extraction

Supercritical fluids are attractive extraction agents, as the solvent power (density) can be manipulated over a wide range of temperatures and pressures. The solvating power of a supercritical fluid is varied by controlling the pressure or by adding organic modifiers such as methanol. SFE provides relatively clean extracts because the degradation of certain compounds by lengthy exposure to high temperatures and oxygen is avoided, and chlorophyll and other non-polar compounds are insoluble in supercritical CO_2. This technique is amenable to medicinal or other plant samples[15] and it can be combined also with other preparation techniques such as LE or SPE. Some problems could arise if SFE is used for some fruit and vegetable samples with high percentages of water. All samples are usually dried before the SFE assay. For some phenolic compounds, the extraction recoveries are not very high, as the content of organic modifier is, in many cases, not sufficient for their complete isolation, especially in the case of very polar phenolic acids.

APPLICATIONS

Herbs and Other Plants

Most papers dealing with phenolic acid HPLC analysis in herbs describe only simple liquid extraction without the hydrolysis step. Acetone, methanol, or alcoholic–water or acetone–water mixtures are applied.[16] Very rarely, pure water is used as the extraction solvent.[11] It was found that the extraction recoveries for water extracts are often lower in comparison to alcoholic–water mixtures, especially when the simultaneous separation of polar and less polar phenolic acids has been performed. Sometimes, the control of pH can improve the recovery.[5] If necessary, *n*-hexane, chloroform, diethyl ether, benzene–acetone, petroleum ether, or other less polar solvents are recommended for removing interfering compounds. The extraction is usually performed by refluxing the samples for a specific time in a Soxhlet apparatus, with simple mechanical or magnetic stirring of the sample with the extraction solvent, or by plant sample maceration. The application of an ultrasonic bath for the liquid extraction has also become popular in recent years. The hydrolysis steps have also been recommended for medicinal species preparation, especially when other phenolic compounds are also analyzed simultaneously with phenolic acids in herbs.[17]

Other plants (cereals, seeds, rye, nuts, barley, malt) can also be extracted with organic solvents or their mixtures with water, but, in many cases, less polar solvents are also used for the elimination of pigments, oils, non-polar and macromolecular compounds. Many of these assays have also included acidic and/or alkaline hydrolysis steps, column liquid clean-up procedures, or SPE. The simultaneous separation of phenolic acids and other phenolic compounds in these samples also complicates the preparation step. Very often, multi-step liquid extraction and sample clean-up assays are recommended. It is necessary to select extraction solvents according to the polarities of the analytes and the form of their bonding to the sample matrix. Very often, both free and bound phenolic acids are separated in plant samples, and hydrolyzed and non-hydrolyzed materials are analyzed separately. In some cases, two or more hydrolysis methods are applied for the analyses of cereals and nuts.[18,19]

Fruits and Vegetables

In the sample preparation step for fruits and vegetables, liquid extraction is performed combined with optimized hydrolysis before the HPLC analysis of phenolic acids.[20,21] A high quality column (e.g., Symmetry C_{18}) with simple gradient elution was used for the HPLC separation of phenolics expected to be present in vegetable samples before and after the hydrolysis steps.[21] In the cases when not only phenolic acids but also other phenolic compounds are determined in these samples, the extraction procedure consists, in many cases, of multi-step extractions and clean-up procedures. Column liquid chromatography or SPE is also recommended.[4] But sometimes the simple water extraction assay has been recommended for more fruits (strawberry, orange, grape, apple, banana, pear, etc.) and vegetable samples (carrot, potato, tomato, cucumber, leaf lettuce, eggplant, cauliflower, cabbage, garlic, onion, spinach).[11] It depends on the character of the sample matrix and the detection mode of the HPLC assay. The use of fluorescence, EC, or MS detectors also makes the sample preparation procedure much simpler by comparison with the common generally used detectors (e.g., UV), where more interfering components could be eluted simultaneously with phenolic acids and, for this reason, they have to be removed effectively in the preparation step.

More knowledge about the separation conditions for the HPLC analysis of phenolic acids in plant materials is available in the cited references. Some of them represent chapters in books with abundant additional information

about the above topic,[1,2] or review article,[6] with details from more than 60 papers published in the last 5 years, dealing with the choice of stationary phases, mobile phases, detection, sample preparation of plants prior to phenolic acid HPLC analyses, etc.

CONCLUSIONS

HPLC is a preferred technique for routine monitoring of phenolic acids in natural plants. With various detection possibilities, or their combinations, and completed with effective sample preparation procedures, HPLC enables the determination of phenolic acids occurring in herbs, fruits, vegetables, and other plants, in both free and bound forms; very often, phenolic acids are analyzed simultaneously with the other phenolics. Chromatographic conditions for these analyses are not complicated when efficient, commercially available, reversed-phase columns are applied. A new generation of sorbents can improve the separation parameters and, with their high separation power, can influence the number of analyzed compounds within a given relatively short separation time. The mobile phases used are also very simple (organic–water mixtures with controlled pH) and both isocratic and gradient modes are recommended. In the case of the simultaneous separation of many phenolic compounds, gradient elution is more suitable. Because of the complexity of some natural plant samples, the sample preparation procedure is the most important step of the entire assay. But today, many techniques offer the real possibility of preparing the sample before the HPLC analysis with sufficient specificity. Liquid extraction has to be, in many cases, the first step of the preparation stage. SFE or MSPD could also be suitable alternatives. Attention should be devoted to effective clean-up methods for plant extracts, such as simple column chromatography or SPE in off-line or online modes. The combined techniques, such as HPLC–MS, are very valuable for the possible identification of all analyzed compounds. The column-switching technique, with online connected columns (one as preparation and the second as the analytical column), enables the direct injection of the crude plant extract into the HPLC system, without special complicated clean-up procedures.[10] It is obvious that all these prospective methods, which today are commonly applied in the HPLC analyses of other analytes, will also find importance and practical use in the analysis of phenolic acids in plant materials.

Abstract
In this entry, the main parameters related to phenolics chemistry and analysis by chromatography are discussed. The most used extractive techniques, such as solid-phase extraction (SPE) and matrix solid-phase dispersion (MSPD), will be referred and compared. In addition, the most relevant analytical approaches, including high-performance liquid chromatography–diode-array detector (HPLC–DAD), LC–mass spectrometry (LC–MS), and LC–nuclear magnetic resonance (LC–NMR), will be presented, focusing on the advantages and disadvantages of each method.

INTRODUCTION

Phenolic compounds are secondary metabolites quite widespread in nature. They play several physiological roles in the plants where they occur, but many of them are also favorable to human health because of their biological activities. Recently, these compounds have been recognized as important in chemical fingerprints in metabolomic studies of several matrices.[1]

The characteristics of high-performance liquid chromatography (HPLC) make it the method of choice for the separation of these compounds. Many improvements have been achieved in this field; however, it was in the area of devices for detection and identification coupled to HPLC that more advances were made in recent years. In this entry, an overview of the chemistry of phenolics and their extraction, purification, and analysis procedures by HPLC is provided.

CHEMISTRY

According to Metcalf,[2] there are expected to be about 50,000–100,000 products resulting from secondary metabolism. It is estimated that about 20% of all carbon fixed by photosynthesis is channeled to the phenylpropanoid pathway, thus generating most of the phenolics found in nature.

Among phenolic compounds, flavonoids are of exceptional interest, as they represent one of the most ubiquitous and widely spread groups of natural products present in a majority of plants.

Flavonoids can be described as compounds that include carbon in an arrangement C_6–C_3–C_6 or, more accurately, that possess the phenylbenzopyran function. Therefore, according to the degree of oxidation and saturation of the heterocyclic ring, flavonoids can be classified into different classes (Fig. 1). Additionally, flavonoids may be modified by hydroxylation, methoxylation, or *O*-glycosylation of hydroxyl groups, as well as direct *C*-glycosylation of carbon atoms in the flavonoid skeleton. In *O*-glycosides sugar substituents are bound to a hydroxyl group of the aglycone, usually located at position 3 or 7, whereas *C*-glycosides have sugar groups bound to a carbon of the aglycone, usually C_6 or C_8. Flavonoid glycosides can also be acylated with aliphatic or acidic aromatic molecules.[3]

With a basic skeleton of C_6, there are simple phenols and benzoquinones; with C_6–C_1 structure, there are hydroxybenzoic acids such as gallic acid; C_6–C_2 corresponds to phenylacetic acids; and with C_6–C_3 skeleton there is a larger class including hydroxycinnamic acids, coumarines, and chromones. Sometimes these structures appear duplicated, giving rise to lignoids. Naphthoquinones have a C_6–C_4 structure, while xanthones exhibit a C_6–C_1–C_6 one. Stilbenes and anthraquinones are C_6–C_2–C_6 compounds.

EXTRACTION AND PURIFICATION

Sample preparation is fundamental for the analysis of phenolics in natural matrices, namely, medicinal plants, and is far more critical for quantification than for identification. The suitable procedure for extraction of phenolics from a plant material depends on the nature of the sample, particularly its physical state, and on the type of phenols to be extracted. The conditions employed should be as mild as possible to avoid chemical artifacts arising from hydrolysis, oxidation, and isomerization.[4]

This assumes that compounds are not covalently bound to the matrix, which is generally accurate in the case of flavonoids but not for phenolic acids. Some of these interferences may be avoided, at least partially, by the addition of an antioxidant, such as *tert*-butyl-4-hydroxyanisole, *tert*-butylhydroquinone, or sodium fluoride, which acts as a polyphenol oxidase inhibitor.

Depending on the aim of the work, hydrolysis of the extracts may be a useful approach, as this step decreases the number of compounds to be identified/quantified, thus

resulting in a better resolution and better characterization of the matrix. Acid hydrolysis is used to remove the sugar moiety, yielding the aglycones. Alkaline hydrolysis is applied when the objective is deacylation of sugars and the break of the covalent bond that phenolic acids may have with the matrix. For an example, please see the work by Ferreres et al.[5] However, when the aim of the work is profiling the endogenous phenolics in an extract, hydrolysis is usually not used, as it drastically changes the identity of compounds.

Although there are several extraction procedures at present, classical extraction with aqueous methanol and solid-phase extraction (SPE) are the most commonly used.[6] Some interfering compounds such as lipids, carotenoids, and chlorophylls can be removed from the water–alcohol extracts with hexane, chloroform, or petroleum ether. The defatted extracts may be analyzed directly or after partitioning of the phenolics with ethyl acetate. The suitable extraction conditions are dependent on the compound(s) and on the matrix of origin. For instance, extraction of flavonoids from biological fluids is one of the fastest tasks. This happens as a consequence of the simple manipulation of relatively small amounts of samples, in addition to good analytical characteristics, namely, limit of detection and relative standard deviation.[6]

Solid samples involve, in a general way, the most tedious and time-consuming procedures, particularly when isolating compounds in pure form and considerable amounts.

For some years, SPE, an adsorption–desorption technique, has been widely used in procedures of purification, trace enrichment, and class fractionation of phenolics. The SPE extraction of phenolics is usually performed using C_{18}-bonded silica reversed-phase (RP) sorbents, styrene–divinylbenzene copolymers, or graphitized carbon black, but other new polymeric sorbents such as RP105 and Oasis HLB are successfully used in the separation and preconcentration of phenolic acids.[7]

In C_{18}-bonded silica RP sorbents, the separation of phenolic acids is greatly affected by the number of free silanol groups. Silva et al.[8] showed that C_{18} non-end-capped columns are more suitable for the recovery of several phenolic acids and flavonoids than C_{18} end-capped ones. An enhanced recovery was obtained when 1% of methanol, serving as wetting agent, was added to the samples.

An alternative to official methods involving classical extraction and/or SPE techniques is matrix solid-phase dispersion (MSPD), a technique that has been widely used in the past years for the isolation of a range of drugs, pesticides, naturally occurring constituents, and other compounds from different complex plant and animal tissues, providing, in many cases, equivalent or superior results.[9,10] The main advantage of MSPD is the elimination of the several steps necessary for the analysis of solid, semisolid, and/or highly viscous biological samples, namely, preparation, extraction, and fractionation.[11] In this technique, all these steps are combined in just one, once the entire sample is homogeneously dispersed in a solid support, usually a C_{18}- or C_8-bonded silica, creating a unique chromatographic phase that is used as the stationary phase of a column. Extraction of analytes and cleanup are carried out simultaneously, with generally good analytical parameters such as recovery and precision.

In MSPD, sample is completely disrupted and dispersed into particles of very small size, which enhances a surface area required for subsequent extraction of the compounds, whereas in solid–liquid (SL)-SPE, sample disruption must be carried out separately and several compounds must be discarded before an extractive solution is found suitable for application on SPE column. While in SPE the extracted compounds are usually absorbed onto the top of the column packing material, in MSPD they are absorbed throughout the column. Physical and chemical interactions among the components of the system are greater in MSPD than those occurring in classical SPE or other forms of liquid chromatography (LC).

Despite the advantages present, namely, simplicity, speed, and requirement of much less solvent than in classical methods, MSPD is very rarely used in the extraction of phenolics. Only a few studies on MSPD can be referred to, such as the study of phenolic acids[12] or isoflavonoids.[13] Additionally, these studies do not show clearly that the complete extraction of phenolics can be accomplished by MSPD.

Xiao et al.[13] compared the efficiency of MSPD with ultrasonic and Soxhlet methods to extract isoflavonoids from radix astragali, the dried root of a Chinese medicinal plant. Four main isoflavonoids were identified, two aglycones and two glycosides, but while the amounts of the two aglycones were higher when using MSPD, the efficiency of extracting the glycosides was better if conventional techniques, ultrasonic or Soxhlet (especially the last one), were applied. Rijke et al.[14] used MSPD to extract and isolate isoflavone glucoside malonates from leaves of leguminous plants. However, when compared to solid–liquid extraction, the efficiency of extracting the glycosides was found to be lower. In the work of Ziaková et al.,[12] the extraction of phenolic acids from a medicinal plant (*Melissa officinalis*) was tried by MSPD, but the results obtained were not quantitatively compared with any other conventional techniques.

Dopico-García et al.[11] tested the ability of MSPD to extract phenolic compounds from white grapes in just one step, simplifying the SL-SPE analytical procedure. Phenolic compounds under study were determined using HPLC coupled to a diode-array detector (DAD). The recoveries obtained for phenolics were, in general, lower using MSPD than using SL-SPE. In some MSPD assays, only the recoveries obtained for the pair quercetin-3-*O*-glucoside/quercetin-3-*O*-rutinoside and for epicatechin were similar to those obtained using SL-SPE. So, for the pair quercetin-3-*O*-glucoside/quercetin-3-*O*-rutinoside, the

signal obtained with the assay 6-MSPD was similar to the one obtained with SL-SPE (101%), but a very high volume of solvent (150 ml of ethanol), not usual in MSPD, was required. The best results for epicatechin were obtained with the experiment 5-MSPD when a sorbent obtained by mixing 50% non-end-capped C_{18} and 50% end-capped C_{18} was used. The amount of epicatechin obtained corresponded to 90% of that found with SL-SPE. For the rest of the phenolics the recoveries obtained using MSPD were very poor in comparison to those obtained using SL-SPE. The pair kaempferol-3-*O*-glucoside/kaempferol-3-*O*-rutinoside was not recovered at all in the experiment 6-MSPD, even though the highest elution volumes were used. This indicates that probably these compounds were eluted with the first solvent [aqueous HCl (pH 2)] instead of ethanol. Recoveries of quercetin and kaempferol, in all the assays carried out by MSPD, were always much lower than those obtained using SL-SPE, with the best recoveries being around only 30%. So, comparing MSPD and SL-SPE for extracting phenolic compounds from white grapes, MSPD was found to be a simpler and faster technique, but a complete extraction of all compounds studied could not be achieved. Although MSPD could be a useful tool to identify the phenolic composition of white grapes, for this matrix SL-SPE was preferred to get quantitative recoveries of these compounds.

The main problem in the analysis of phenolics in plant-derived foods such as honey, fruit juices, and jam, is the high content of sugars and other polar compounds which cause interphasing when liquid–liquid partitions are chosen as a method of extraction.

The use of the non-ionic polymeric resin Amberlite XAD, by an adsorption–desorption technique, solved this problem. Tomás-Barbéran et al.[15] demonstrated that the polystyrene resins (XAD-2, XAD-4, and XAD-16) were more useful for the fractionation of flavonoids into aglycones and glycosides compared to the polyacrylic resins (XAD-7 and XAD-8). Amberlite XAD-2 was the more suitable non-ionic polymeric resin for the recovery and further fractionation of flavonoids from sugar-rich foods.

Apart from these techniques, supercritical fluids extraction (SFE) is the preferred technique in many areas of active compounds extraction. However, in what concerns to flavonoids, its utility is highly influenced by the matrix's composition. For example, in the case of isolation of non-polar flavonoid aglycones by SFE, when compared with classical techniques, SFE provided identical or sometimes better results. Nevertheless, when water-soluble glycosides are considered, the use of SFE results in considerably different yields.[16,17] Still, the use of aqueous methanol constitutes a useful and balanced extraction solvent that allows the extraction of both aglycones and flavonoid glycosides, depending on the conditions used, such as time and temperature, among others. Other reported solvents used for extraction are acetone, ethanol, and dimethyl sulfoxide (DMSO), with the water-to-solvent ratios being adjusted in accordance to the properties of the compounds to be extracted. Although DMSO presents properties that make it an excellent solvent, like the fact that it dissolves both polar and non-polar compounds and is miscible with a wide range of organic solvents as well as with water, one of the problems associated with the use of this solvent is due to its low volatility. Therefore, enhanced extraction can be achieved by using methanol or ethanol with 5–10% DMSO, which has a lower boiling point and allows an easier evaporation in subsequent stages of extraction.

DETECTION AND IDENTIFICATION

LC-UV/LC-DAD

All flavonoid aglycones contain at least one aromatic ring and therefore efficiently absorb UV light. The A-ring is responsible for the first maximum, found in the 240–285 nm range, and the second maximum, observed at 300–550 nm, is due to the substitution pattern and conjugation of the C-ring.[18]

When a UV detector works at a fixed wavelength, the obtained information is still very limited. In this case, to identify a compound using different experimental conditions, cochromatography is necessary with authentic reference compounds. DADs are much more useful, because they yield the full record of the UV–Vis spectrum of each compound. Because each class of phenolic compounds has a characteristic spectrum, identification is facilitated, although a safe characterization still requires a standard to compare retention time and UV spectra (see Fig. 2 for an example).

When two compounds with very close, or even superimposable, retention times and identical UV spectra are found in a chromatogram, it is necessary to use more sophisticated detectors that can yield much more structural information without requiring the isolation of the compounds. LC–mass spectrometry (LC–MS) and LC–nuclear magnetic resonance (LC–NMR) are often used, as it will be presented later.

HPLC-DAD is still the main technique used for phenolics quantification, a parameter not usually determined by other techniques such as LC–MS, given its poor sensibility.

Because of the great number of different flavonoid glycosides in nature, one cannot proceed with their quantification using authentic standards, as most of them are not commercially available. However, because sugar moieties are poor chromophores, their influence on UV absorption behavior of glycosides is smallest when compared with that of the aglycones. So, it is a common practice to quantify glycosides using standards of the corresponding aglycone, or a similar one.

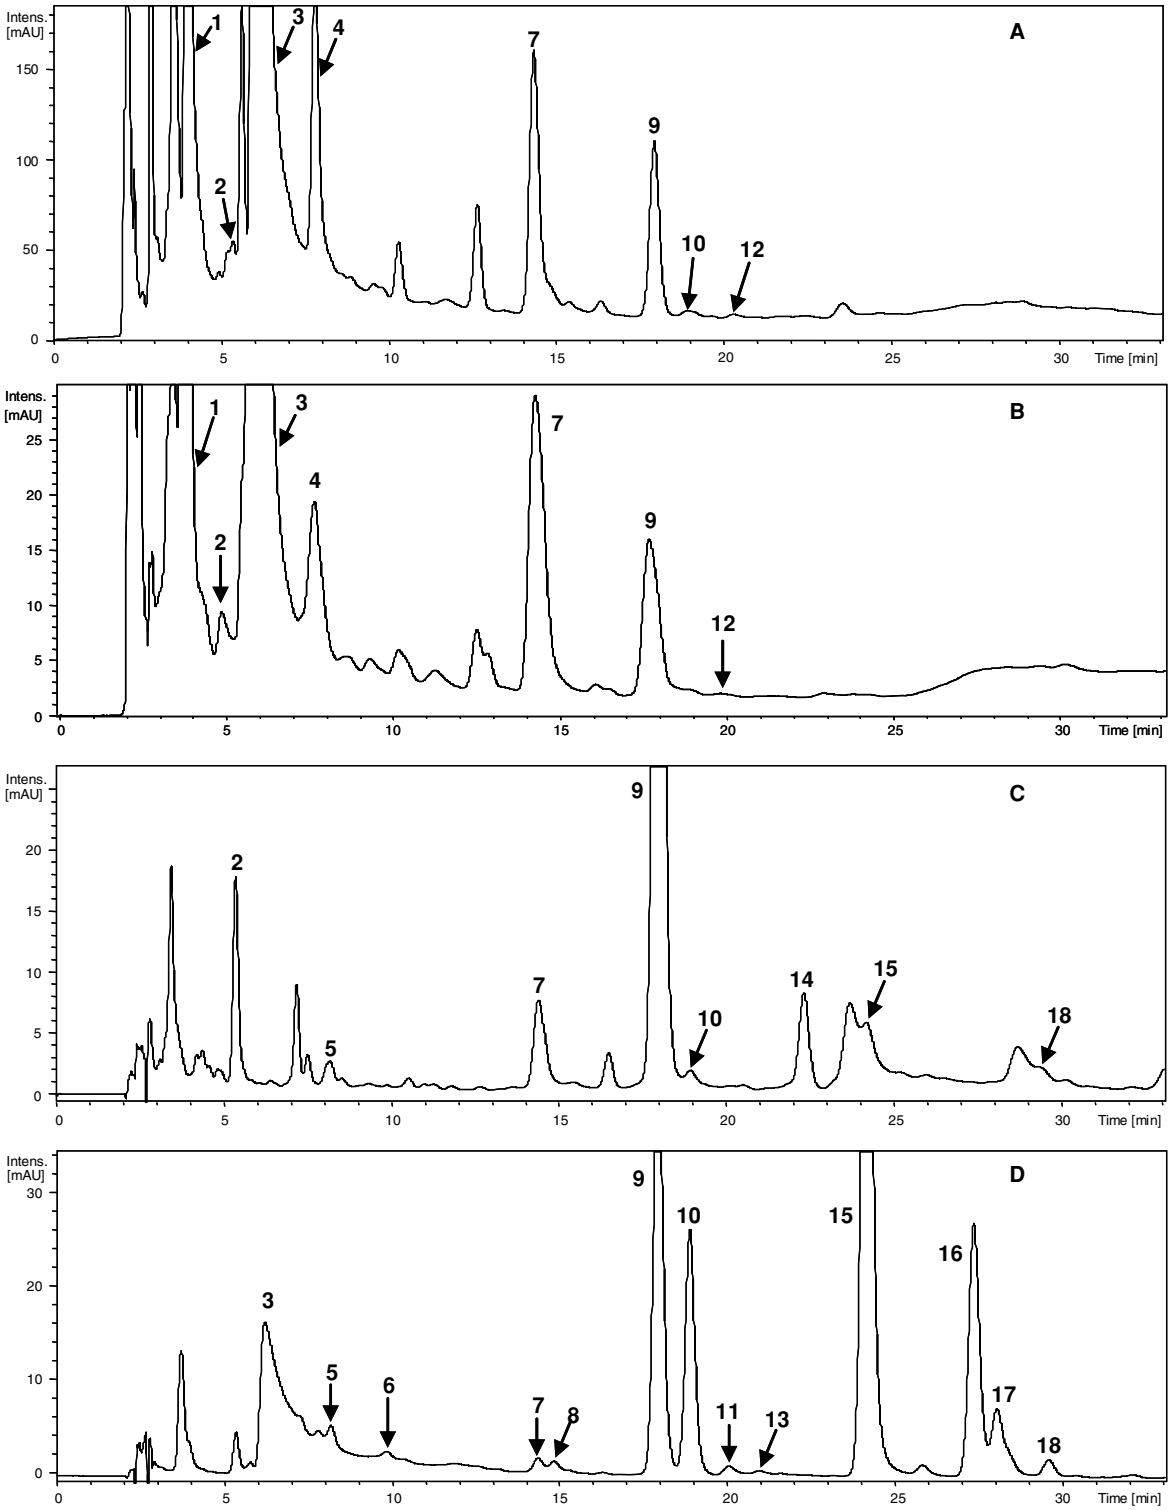

Fig. 2 HPLC-DAD chromatograms of *Catharanthus roseus* extracts: (A) stems, (B) leaves, (C) seeds, and (D) petals. Detection at 340 nm. (1) 3-*O*-caffeoylquinic acid; (2) kaempferol-3-*O*-(2,6-di-*O*-rhamnosyl-galactoside)-7-*O*-hexoside; (3) 4-*O*-caffeoylquinic acid; (4) 5-*O*-caffeoylquinic acid; (5) kaempferol-3-*O*-(6-*O*-rhamnosyl-galactoside)-7-*O*-galactoside; (6) kaempferol-3-*O*-(6-*O*-rhamnosyl-galactoside)-7-*O*-glucoside; (7) quercetin-3-*O*-(2,6-di-*O*-rhamnosyl-galactoside); (8) quercetin-3-*O*-(2,6-di-*O*-rhamnosyl-glucoside); (9) kaempferol-3-*O*-(2,6-di-*O*-rhamnosyl-galactoside); (10) kaempferol-3-*O*-(2,6-di-*O*-rhamnosyl-glucoside); (11) quercetin-3-*O*-(6-*O*-rhamnosyl-galactoside); (12) isorhamnetin-3-*O*-(2,6-di-*O*-rhamnosyl-galactoside); (13) quercetin-3-*O*-(6-*O*-rhamnosyl-glucoside); (14) isorhamnetin-3-*O*-(2,6-di-*O*-rhamnosyl-glucoside); (15) kaempferol-3-*O*-(6-*O*-rhamnosyl-galactoside); (16) kaempferol-3-*O*-(6-*O*-rhamnosyl-glucoside); (17) isorhamnetin-3-*O*-(6-*O*-rhamnosyl-galactoside); (18) isorhamnetin-3-*O*-(6-*O*-rhamnosyl-glucoside).
Adapted from New phenolic compounds and antioxidant potential of *Catharanthus roseus,* in J. Agric. Food Chem.[19]

In contrast to flavonoids, standards of most of the phenolic acids are commercially available and their positive identification can be performed by comparison of the retention time and characteristic UV absorbance with those of authentic reference compounds.

As regards hydroxycinnamic acids, they absorb at two regions of the UV spectrum, presenting a maximum at 225–235 nm and two other, very near of each other, by 290–330 nm. The double absorption in this region arises from the presence of *cis* and *trans* isomers, and the ratio between these two forms contributes to the final spectrum. In alkaline medium, all three maxima suffer a bathochromic shift. The different esters of the same acid present similar spectrum, regardless of the molecule presenting the alcohol function (quinic acid, sugar, or tartaric acid).[20]

In what concerns benzoic acids, the UV spectrum is more influenced by the hydroxylation degree of benzenic moieties than that of hydroxycinnamic acids. Methylation of hydroxyl groups has almost no effect on the UV spectrum. Only dihydroxylated benzoic acids present two maxima.[20]

LC–MS

MS has proved to be a very powerful technique in the analysis of flavonoids and phenolic acids mainly due to its high sensitivity and the possibility of coupling with different chromatographic techniques such as gas chromatography (GC–MS), capillary electrophoresis (CE–MS), and especially LC–MS. Nowadays, techniques such as LC-DAD–MS, and particularly LC-DAD–electrospray ionization (ESI)/MS, are regarded as necessary tools for the analysis of phenolics in natural matrices.[21,22]

The amount of information obtained by multisignal MS or MS–MS renders two levels for identification of compounds: positive and provisional. Positive identification can be achieved when reference compounds are available, thus allowing comparison of both retention time and UV spectra. However, when no standards are available, generally provisional identification takes place. In this case, although the identity of subunits such as aglycones, sugars, and acyl moieties is elucidated, the positions of glycosidic and acyl linkages remain unknown, with the exception of some fragmentation patterns that allow a positive identification of the glycosidic bonds (Fig. 3).[22] In many cases, a taxonomic approach may help in identification (e.g., most flavonoid glycosides present a 7-*O* linkage); however, NMR analysis is usually necessary. Nevertheless, the level of identification required in food and botanical analysis is a question worth postulating . For example, in the analysis of beverages (such as wines) and oils, most of the time, profile analysis yielding provisional identification is enough for quality control and detection of adulteration.

Spectroscopy by UV–Vis and MS, when in total ion count mode, yields comparable detection limits for flavonoids, in the range of 10 ng. When single ion monitoring (SIM) mode is used, MS analysis provides better detection limits, usually below 1 ng.[21] SIM mode, however, causes loss of valuable information concerning fragmentation pattern, which is very important for the identification of many compounds.

With the advent of atmospheric pressure ionization (API) sources, LC–MS coupling has become more efficient and accessible, causing this technique to be one of the most used for online flavonoid analysis nowadays.

Comparison of different API sources such as ESI, atmospheric pressure photoionization (APPI), and atmospheric pressure chemical ionization (APCI), is available in literature.[23] ESI is more frequently used in flavonoid analysis; however, APCI is gaining popularity and in some cases better responses are obtained in this mode.

The highest sensitivity can be obtained by the use of ESI in negative ion mode, usually involving an eluent consisting of an acidic ammonium acetate buffer. When using positive ion mode, the lowest detection limits involve the use of 0.5% formic acid. Also, negative ion mode results in limited fragmentation, which is particularly suited for molecular mass determination, especially when the concentration of compounds is low.[22]

In the formation of adducts, or even molecular complexes, with solvent or acid molecules, the peak at the highest *m/z* ratio may not correspond to the molecular ion species ($[M + H]^+$ in positive mode and $[M - H]^-$ in negative mode). Instead, $[2M + H]^+$ or $[2M - H]^-$ may be formed. This issue may be corrected by an increase in cone voltage, which diminishes formation of both adducts and complexes.[21]

While negative ion mode is very useful to identify known compounds, the first-order mass spectrum yielded by positive ion mode can provide more structural information. So, the combined use of both ionization modes can give additional accuracy to the molecular mass determination, which is particularly relevant when noise levels are high.[21]

Besides spectroscopic data, chromatographic retention times can also add further knowledge to the compounds' chemistry. In general, on C_{18}- or C_8-RP columns, more polar compounds are eluted first. Thus, increase in glycosylation results in decrease in retention times. In contrast, acylation, methylation, or prenylation have a distinct effect—rising retention time, although the position where this occurs may play a significant role in chromatographic behavior. In what concerns aglycones, flavanones precede flavonols, which in turn precede flavones, for compounds with an equivalent substitution pattern.[24]

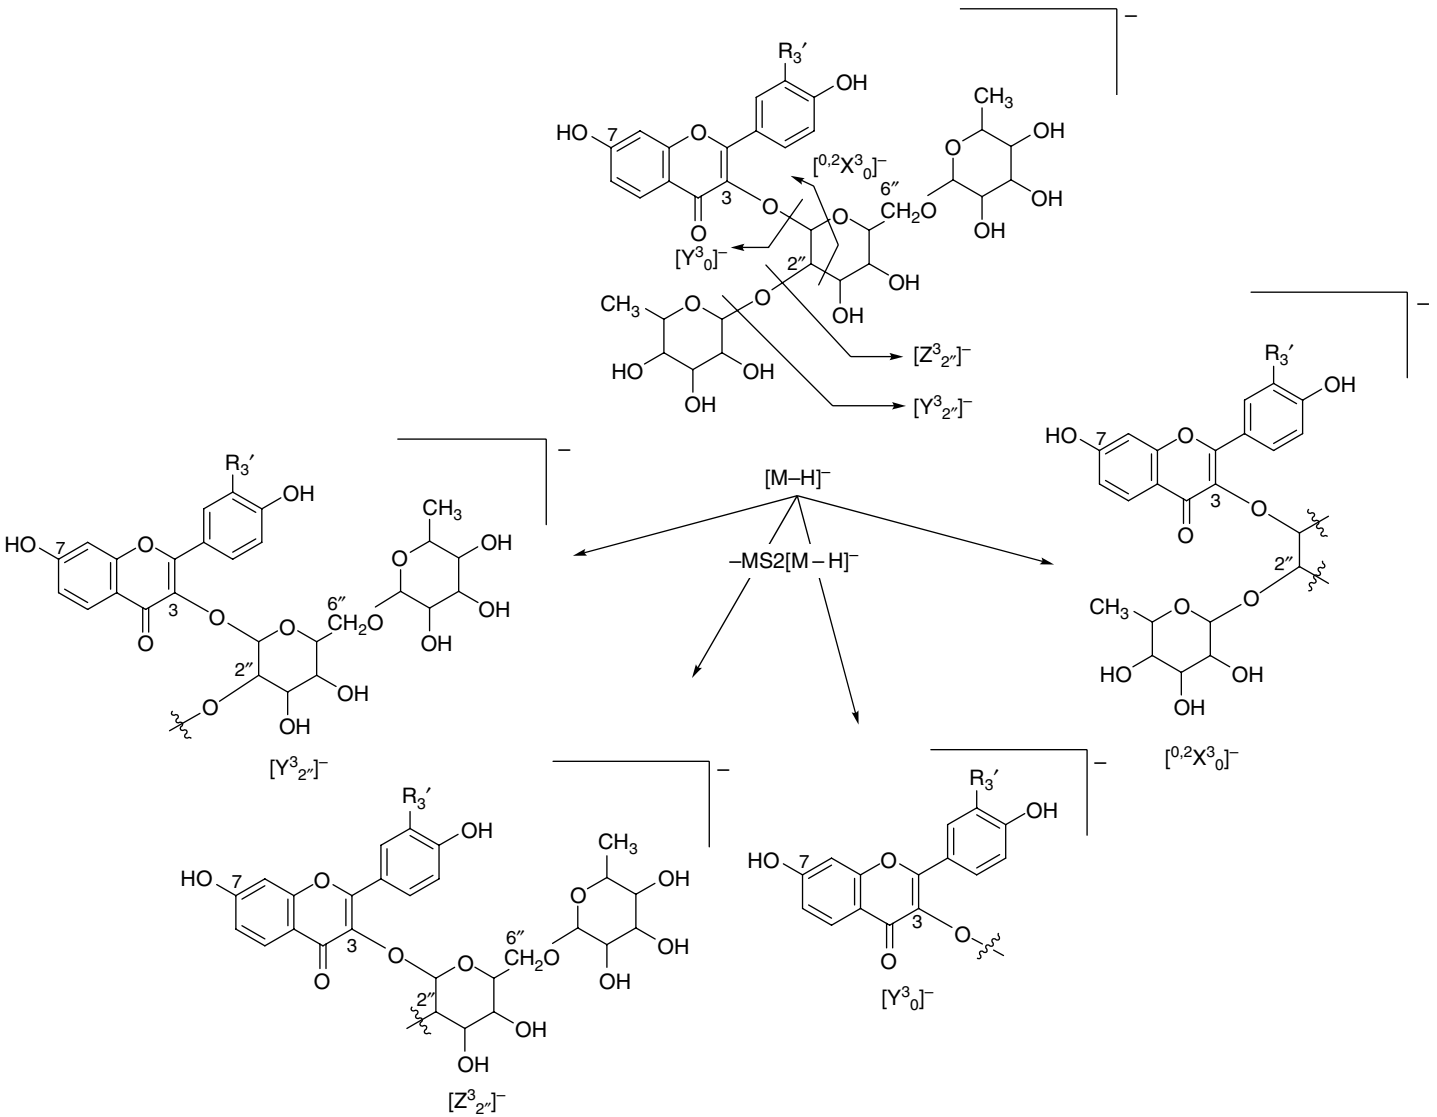

Fig. 3 —MS2[M–H]⁻ fragmentation of flavonol-3-*O*-(2,6-di-*O*-rhamnosyl-hexoside) from *Catharanthus roseus*. Adapted from New phenolic compounds and antioxidant potential of *Catharanthus roseus,* in J. Agric. Food Chem.[19]

LC–NMR

In recent years, LC–NMR has been attracting a lot of attention from the natural products area. Its main advantages include differentiation of isomers and information of substitution patterns on aromatic ring systems and sugar configurations. However, low sensitivity (consequence of small energy gap between the ground and excited nuclear spin rates), prohibitive prices (of both equipment and deuterated solvents), and long analysis time, sometimes reaching days, are the main disadvantages of this technique. The advantages and disadvantages of this analytical method have been carefully reviewed in many works.[24,25] Still, MS techniques have their place as they provide important information such as about functional groups and molecular mass. So, the ideal system would be LC–NMR–MS or LC–NMR–MS–MS.

When working with online flow NMR, the acquisition time is limited by the short presence of the sample in the detection coil as a consequence of the flow rates commonly used, thus resulting in poor signal-to-noise ratio. Also, when the flow rate is reduced by a factor of 3–10, better signal-to-noise ratio can be registered, followed by an increase in experimental acquisition time, which may lead to diffusion processes that can influence the separation of peaks eluting from the LC column. To surpass this problem, accumulation of peaks into storage loops for off-line NMR at a later stage has been proposed.[26]

As it has already been stated, one of the main disadvantages of LC–NMR is its low sensitivity (LC–NMR remains less sensitive than UV or MS detection). Some technical advances have successfully improved the analytical parameters such as cryogenic temperatures, making this technique even more attractive. The procedure consists of cooling the receiver coil to cryogenic temperatures, while the sample remains at ambient temperature. This limits the noise voltage associated with signal detection, and when compared with regular probes, signal-to-noise ratio is ameliorated by a factor of 3–4.

Alternatively, the application of SPE to concentrate the compounds of interest has been successfully developed as a way to counter the somewhat low sensitivity of LC–NMR. This method is a powerful technique for universal, quick, and selective sample preparation, which recently originated methods that combine LC–NMR with SPE.

CONCLUSIONS

Phenolic compounds are still the objects of numerous studies, mainly concerning their extraction, purification, and analytical methods. This is because these compounds, especially flavonoids, are responsible for an increasing number of beneficial biological activities in humans.

So, methods with higher sensitivity and lower detection limit are required as a tool to keep up with the recent developments in the knowledge of bioactivity of phenolics.

Phenolic Drugs: TLC Detection

Alina Pyka
Department of Analytical Chemistry, Medical University of Silesia, Sosnowiec, Poland

Abstract
This entry describes applications of indicators as new visualizing reagents (alkaline blue, aniline blue, neutral red, brilliant green, bromophenol blue, bromothymol blue, brilliant cresyl blue, thymol blue, phenol red, bromocresol green, helasol green, spands, titan yellow, eosin yellow, erythrosin B, eriochrome black T, dimethyl yellow, and thymolphthalein), and various visualizing systems, always including a saturated aqueous solution of variamine blue hydrochloride and other reagent [e.g., 0.1% aqueous HCl, 1% aqueous $Ni(NO_3)_2$, 2% aqueous $CuSO_4$, 0.1% aqueous Na_2CO_3, 1% dithizone in methanol, and 1% aqueous ethylenediaminetetraacetic acid (EDTA)] for the detection of selected phenolic drugs (bamethane, ethamivan, hexachlorophene, salicylanilide, pyrocatechin, thymol, pentazocine, phloroglucinol, eugenol, niclosamide, terbutaline, methyldopa, norepinephrine, eugenol, α-naphthol, polybasic phenols, adrenaline, dopamine, phenylephrine, metaraminol, fenoterol, and bithionol) in thin-layer chromatography (TLC). Six dyes as new visualizing reagents, namely, gentian violet, methylene violet, methylene blue, methyl green, malachite green, and Janus blue, have been used to detect ibuprofen on silica gel $60F_{254}$ and to detect estradiol on neutral aluminum oxide $60F_{254}$ and on neutral aluminum oxide $150F_{254}$. Broadening index, detection index, characteristic of densitometric band, modified contrast index, limit of detection, densitometric visualizing index (DVI), and linearity range of detected compounds were used for the evaluation of visualizing effects of applied visualizing reagents. It was shown that visualizing effect depends on the chemical structure of the visualizing reagent, the structure of the substance detected, and the chromatographic adsorbent applied. The usefulness of densitometry to direct the detection of some phenolic drugs was also shown.

INTRODUCTION

The separated substances on thin layer can be detected by the following methods:

- Physical (individual color of substance or fluorescence of substance in UV light)
- Chemical (colored reactions of separated substances with visualizing reagents)
- Physicochemical (e.g., the application of isotopes as visualizing reagent)
- Biological (the application of biodetectors)

The visualizing reagents are of special significance for detecting separated compounds on thin layers. In view of the detection mechanism of the compound, the visualizing reagents can be sorted as follows:

- Conservative reagents, which do not destroy separated substances
- Destructive reagents, which destroy or change the structure of separated substances[1–3]

Currently, the most important field of application of thin-layer chromatography (TLC) is pharmacy. The number of publications in the field of pharmacy has steadily increased.[1,3] It results from the fact that contemporary TLC is a fully instrumentalized and automated technique. Many phenol derivatives have definite pharmacological and biological properties.[4] For example, the drugs that command special attention are the drugs acting on the peripheral nervous system (adrenaline, dopamine, phenylephrine, metaraminol, fenoterol, bamethane, terbutaline, methyldopa, norepinephrine), drugs acting on the central nervous system (ethamivan), drugs applied in taeniasis (bithionol, niclosamide), analgesic drugs (pentazocine), and fungicidal and bacteriostatic drugs (hexachlorophene, salicylanilide, pyrocatechin, arbutin, thymol, phloroglucinol, eugenol, and *o*-, *m*-, and *p*-cresol). However, α-naphthol is often applied as a component of some dermatological ointments. Moreover, phenolic compounds are present in numerous phytomedicines. Phenolic compounds are very widespread, particularly among floral plants. Free phenols often occur as components of essential oils. Phenolic compounds are also widespread as phenolic glycosides, phenolic acids, and polyphenols. Phenolic compounds as phenolic acids are solid components of plants (caffeic acid, chlorogenic acid). Also, some alkaloids have phenolic character (morphine).[2,5]

There are good analytical and physicochemical reasons for describing new visualizing reagents; these reasons and the most important reagents and techniques for different

types of organic compounds, including phenols, have been described elsewhere.[1,3,6–20] For example, Barton's reagent was used to detect dopamine; chloramine T–sodium hydroxide, sucrose–hydrochloric acid, and Pauly's reagents to detect phloroglucinol; Emerson reagent to detect thymol and eugenol; fast black salt K–sodium hydroxide reagent to detect terbutalina; potassium hexaiodoplatinate reagent to detect pentazocine; potassium hexacyanoferrate(III)–ethylenediamine reagent to detect dopamine, noradrenaline, and adrenaline;[1,3,6] aniline–diphenylamine–phosphoric acid, lead(IV) acetate–dichlorofluorescein, Gibb's and Millons reagents, and Berlin blue reaction to detect arbutin; natural products–polyethylene glycol reagent to detect chlorogenic acid; vanillin–sulfuric acid reagent to detect eugenol, thymol, and carvacrol; and anisaldehyde–sulfuric acid reagent to detect thymol.[5] This entry describes applications of indicators as new visualizing reagents for the detection of selected phenolic drugs in TLC.

NEW VISUALIZING REAGENTS

The phenolic drugs bamethane, ethamivan, hexachlorophene, salicylanilide, pyrocatechin, thymol, pentazocine, phloroglucinol, eugenol, niclosamide, terbutaline, methyldopa, and norepinephrine on silica gel 60 (E. Merck, #1.05721, glass plates) were detected by Pyka, Gurak, and Bober.[7] Plates with methyldopa, norepinephrine, terbutaline, bamethane, and ethamivan were developed with a mixture of glacial acetic acid–*n*-butanol–water (1:4:1, v/v) as the mobile phase. Plates with phloroglucinol, pentazocine, hexachlorophene, pyrocatechin, niclosamide, salicylanilide, and thymol were developed with a mixture of chloroform–methanol (9:1, v/v). The plate with eugenol was developed with benzene as the mobile phase. Thirteen new visualizing reagents were used to detect the above-mentioned phenolic drugs. Alkaline blue, aniline blue, neutral red, and brilliant green were used as 50 mg/100 ml aqueous solutions. Bromophenol blue, bromothymol blue, brilliant cresyl blue, thymol blue, phenol red, bromocresol green, and helasol green were used as 50 mg/100 ml solutions in 2% aqueous sodium hydroxide solution. Bromophenol blue solution was prepared directly before use. Additionally, brilliant cresyl blue and bromocresol green were used as 50 mg/100 ml aqueous solutions. Plates were evaluated 5 min after spraying (variant 1). They were then heated at 100°C for 15 min and re-examined (variant 2).

By means of these visualizing reagents—alkaline blue, aniline blue, bromophenol blue, bromothymol blue, alkaline solution of brilliant cresyl blue, bromocresol green, thymol blue, and an aqueous solution of brilliant cresyl blue—it is possible to detect all of the drugs investigated at the level of 100 μg. Using the remaining visualizing systems (neutral red, brilliant green, phenol red, and aqueous solution of bromocresol green), it is also possible to detect 100 μg of the drugs investigated except methyldopa, terbutaline, norepinephrine, and ethamivan. These could not be detected by means of neutral red; ethamivan could not be detected by means of helasol green, thymol blue, and aqueous solution of bromocresol green; bamethane and salicylanilide could not be detected with phenol red. Detection limit (detectability), detectability index, and broadening index were used to describe visualizing effects for phenolic drugs, which were detected by particular visualizing reagents. The definitions and equations for calculation of the broadening index and detectability index were given earlier.[7,8,9]

A good visualizing reagent has a relatively large numerical value of broadening index (evaluation after heating at 120°C for 30 min) for a particular detected substance (small spot area, which refers to 100 μg of substance detected). The broadening indices for the drugs investigated, with the best visualizing reagents (evaluation after heating at 120°C for 30 min), are equal to 67 $\mu g/mm^2$ for methyldopa with brilliant cresyl blue (brown spot), 99 $\mu g/mm^2$ for norepinephrine with alkaline blue (orange-red spot), 270 $\mu g/mm^2$ for terbutaline with aniline blue (yellow-green spot), 455 $\mu g/mm^2$ for bamethane with brilliant green (white spot), 345 $\mu g/mm^2$ for ethamivan with aniline blue (white-blue spot), 152 $\mu g/mm^2$ for phloroglucinol with bromocresol green (orange spot), 84 $\mu g/mm^2$ for pentazocine with bromophenol blue (light blue), 71 $\mu g/mm^2$ for hexachlorophene with brilliant green (green spot), 62 $\mu g/mm^2$ for pyrocatechin with bromocresol green (brown spot), 278 $\mu g/mm^2$ for niclosamide with bromothymol blue (light brown spot), 217 $\mu g/mm^2$ for salicylanilide with alkaline solution of bromocresol green (light blue spot), 135 $\mu g/mm^2$ for thymol with bromocresol green (white-blue with white border spot), and 68 $\mu g/mm^2$ for eugenol with bromothymol blue (light yellow spot).[7]

The detection limits of the investigated phenolic drugs with the tested visualizing reagents, directly after spraying (variant 1), or after 30 min heating at 120°C (variant 2), as well as the detection indices were determined. For the detection limits, the investigated drugs revealed that only in some cases is the detection better after the plates are heated. Levels of detection of the phenolic drugs are in the following ranges (in microgram): for pyrocatechin 0.3–5.0; for pentazocine 0.5–100; for norepinephrine 0.6–100; for niclosamide 0.8–50; for salicylanilide 0.8–100; for methyldopa 1.2–4.8; for terbutaline 2.0–30; for thymol 2.0–100; for hexachlorophene 3.0–25; for phloroglucinol 3.0–30; for bamethane 10.0–100; for eugenol 5.0–10; and for ethamivan 40.0–100. The most sensitive detections are obtained for pyrocatechin with alkaline blue, brilliant green, helasol green (300 ng); pentazocine with aniline blue (500 ng); norepinephrine with bromothymol blue (600 ng); niclosamide and salicylanilide with brilliant green (800 ng); methyldopa with aqueous solution of bromocresol green (1.2 μg). The best visualizing reagents for

the drugs investigated (being phenol derivatives) are brilliant green as well as aniline blue. These two visualizing reagents were used for densitometric research (on Shimadzu densitometer). Hexachlorophene, niclosamide, and salicylanilide as well as methyldopa, terbutaline, and bamethane were detected with brilliant green, and then the densitometric analysis of chromatograms was determined. Norepinephrine and terbutaline were detected with aniline blue. For hexachlorophene (10 μg), niclosamide (5.0 μg), and salicylanilide (15.0 μg), an optimum wavelength of incident light $\lambda = 617.9$ nm was detected. Densitogram of hexachlorophene, niclosamide, and salicylanilide after spraying with brilliant green is as shown in Fig. 1A. Methyldopa (50 μg), terbutaline (100 μg), and bamethane (100 μg) were detected by means of brilliant green as optimum wavelength $\lambda = 380.5$ nm was selected. Densitogram for these three drugs is presented in Fig. 1B. The peak, derived from methyldopa, has an irregular shape, suggesting that methyldopa contained impurities that (using the given mobile phase) could not be completely separated. For norepinephrine (5.0 μg) and terbutaline (15.0 μg), detected by means of aniline blue, an optimum wavelength for densitometric analysis, $\lambda = 371$ nm, was chosen. Densitogram obtained for norepinephrine and terbutaline is presented in Fig. 1C. The densitograms show that both aniline blue and brilliant green have good properties as visualizing reagents with respect to the substances detected. However, brilliant green, because of its properties, causes heterogeneity of adsorbent surface, observed as noise. This effect is not observed for aniline blue. Some of the visualizing reagents reported here can be used as new visualizing reagents for the qualitative determination of phenolic drugs. The colors of chromatographic spots, detection limits, and detectability indices of phenolic drugs investigated, obtained with selected reagents (including the best reagents aniline blue and brilliant green), were presented earlier.[7–10] These reagents can be used to identify compounds analyzed by TLC, based on R_F values and on the different colors of the chromatographic spots. Further investigations showed that guaiacol cannot be detected using the above-mentioned visualizing reagents.[11] The quantitative determinations of pyrocatechin and norepinephrine were carried on silica gel 60 (E. Merck, #1.05721). The conditions used for chromatography were identical to those described earlier.[7] The plates were sprayed with alkaline blue, bromothymol blue, and phenol red, and heated at 120°C for 30 min. Six replicate analyses were performed; the areas (square millimeter) of the spots obtained were measured planimetrically and the average areas were calculated. It was stated that the pyrocatechin detected with alkaline blue can be quantitatively determined in the range from 2.0 to 90 μg. However, norepinephrine detected with bromothymol blue or phenol red can be quantitatively determined in the range from 5.0 to 100 μg.[11]

Arbutin, without visualizing reagents, was densitometrically analyzed. Standard solutions of arbutin were spotted on aluminum foil-backed plates precoated with a 0.2 mm layer of silica gel $60F_{254}$ (#1.05554, E. Merck). Ethyl acetate–methanol–water in volume composition 100:13.5:10 was used as the mobile phase. The plate was developed at a distance of 14 cm. After drying the plate, arbutin was densitometrically investigated on Camag TLC Scanner 3. The absorption photometric scan in reflectance (remission) was carried out at $\lambda = 285$ nm. Spectrodensitogram and densitogram of arbutin (10 μg) are presented in Fig. 2.[11] Densitometry without visualizing reagent was also used for the quantitative determination of arbutin (*Vaccinium vitis idaeae*) in the leaves of cowberry collected from Suwalszczyzna, Poland.[12] Arbutin was extracted using methanol. Chromatography was performed on glass TLC plates with layers of silica gel (E. Merck, #1.05715) and using the above-mentioned mobile phase. The quantitative densitometric analysis on Camag TLC Scanner 3 was performed using internal standard solution method. On the basis of densitometric analysis, it was shown that band characterized by absorption maximum of arbutin is placed at $\lambda_{max} = 285$ nm. The second absorption band is at $\lambda = 225$ nm. 35 mg and 47 mg arbutin were determined in 1 g of herbs in cowberry leaves coming from collections in 2005 and 2006, respectively. The method presented is accurate, selective, and precise, and can be used for routine quality control analysis and quantitative determination of arbutin in cowberry leaves.[12]

Pyka et al.[13] also applied various visualizing systems, always including a saturated aqueous solution of variamine blue hydrochloride and other reagent, for example, 0.1% aqueous HCl, 1% aqueous $Ni(NO_3)_2$, 2% aqueous $CuSO_4$, 0.1% aqueous Na_2CO_3, 1% dithizone in methanol, and 1% aqueous ethylenediaminetetraacetic acid (EDTA) to detect selected essential oil components after their separation on silica gel 60 (E. Merck, #1.05744). These visualizing reagents can be used for the qualitative identification of eugenol and thymol. Yet, guaiacol cannot be detected by using these visualizing reagents.[13]

Wardas and Pyka[14] and Wardas, Lipska, and Lebek[15] investigated spands, titan yellow, eosin yellow, helasol green, phenol red, thymol blue, bromothymol blue, bromophenol blue, bromocresol green, erythrosin B, eriochrome black T, and brilliant cresyl blue in aqueous sodium hydroxide (50 mg/100 ml of 5% NaOH), and dimethyl yellow and thymolphthalein in methanolic solution (50 mg/100 ml) as well as aniline blue and alkaline blue in aqueous solutions (50 mg/100 ml) as visualizing reagents to detect cresol and naphthol isomers, which were separated on three adsorbents (aluminum foil-backed plates precoated with 0.2 mm layers of either silica gel 60 or a mixture of silica gel 60 with Kieselguhr F_{254}, as well as on glass plates precoated with 0.15 mm layer of Polyamide $11F_{254}$). The best visualizing reagents for the detection of α-naphthol on silica gel 60 are titan yellow, eosin, helasol green, and

bromothymol blue (brown spots in each cases).[14,15] Detection limit of α-naphthol using these visualizing reagents is between 0.10 and 0.14 μg. Bromocresol green, titan yellow, and eosin yellow are the best visualizing reagents for the detection of α-naphthol chromatographed on a mixture of silica gel 60 and Kieselguhr F_{254} (detection limit: between 0.10 and 0.15 μg; brown, brown-gray, and green-gray spots, respectively).[14,15] However, for the detection of α-naphthol on Polyamide $11F_{254}$, bromocresol green (detection limit: 2.5 μg; brown spot) is best.[15] Titan yellow is the best visualizing reagent for the detection of *m*-cresol on silica gel 60 (detection limit: 1.08 μg; faint brown spot).[16]

Wardas, Lipska, and Lebek[17] also investigated the 16 new visualizing reagents (alkacymetric, complexometric, and redoxymetric indicators) to detect polybasic phenols. The best visualizing reagents for the detection of hydroquinone, pyrogallol, and phloroglucinol on silica gel 60 are brilliant cresyl blue to detect hydroquinone (detection limit: 500 ng; light brown spot); and alkaline blue to detect pyrogallol and phloroglucinol (detection limits: 500 ng and 100 ng, respectively; brown and orange spots, respectively). The best visualizing reagents for the detection of hydroquinone, pyrogallol, and phloroglucinol on a mixture of silica gel 60 and Kieselguhr F_{254} are erythrosin B to detect hydroquinone (detection limit: 500 ng; brown spot); thymolphthalein to detect pyrogallol (detection limit: 500 ng; light brown spot); and alkaline blue to detect phloroglucinol (detection limit: 500 ng; orange spot). The best visualizing reagents for the detection of hydroquinone, pyrogallol, and phloroglucinol on Polyamide $11F_{254}$ are bromocresol green to detect hydroquinone (detection limit: 500 ng; brown spot); brilliant cresyl blue to detect pyrogallol (detection limit: 100 ng; yellow spot); and brilliant green to detect phloroglucinol (detection limit: 100 ng; orange spot).[17]

Wardas, Lipska, and Bober[18] examined indicators for the detection of adrenaline, dopamine, phenylephrine, metaraminol, fenoterol, and bithionol after TLC

fractionation on silica gel $60F_{254}$, Polyamide $11F_{254}$, and mixture of silica gel 60 and Kieselguhr F_{254} using glacial acetic acid–*n*-butanol–water (1:4:1, v/v) as the mobile phase. They investigated the following indicators as visualizing reagents: phenol red, thymol blue, bromothymol blue, bromophenol blue, cresol green, erythrosin B, eriochrome black T, brilliant cresyl blue, eosin yellow, titan yellow, helasol green dissolved in 5% NaOH, as well as bromocresol green, aniline blue, alkaline blue, brilliant cresyl blue, and brilliant green dissolved in water. Additionally, dimethyl yellow and thymolphthalein dissolved in methanol were applied, but before being used, the chromatographic plate was sprayed with 5% NaOH. In each case, the concentration of the solutions was 0.5 mg/ml. Most reagents give positive visualizing effects on silica gel $60F_{254}$, a bit less on a mixture of silica gel 60 and Kieselguhr F_{254}, and the least on Polyamide $11F_{254}$. Detection levels of these phenolic drugs on silica gel $60F_{254}$ are in the following ranges (in microgram): for adrenaline 0.1–10.0; dopamine 0.1–10; for phenylephrine 0.25–20; for metaraminol 0.5–20; for fenoterol 0.1–15; and for bithionol 0.5–50. Detection levels of these phenolic drugs on a mixture of silica gel 60 and Kieselguhr F_{254} are in the following ranges (in microgram): for adrenaline 0.25–15.0; for dopamine 0.25–7.5; for phenylephrine 0.5–15; for metaraminol 0.5–15; for fenoterol 0.5–12.5; and for bithionol 2.5–10. Detection levels of these phenolic drugs on Polyamide $11F_{254}$ are in the following ranges (in microgram): for adrenaline 2.5–100; for dopamine 0.75–100; for metaraminol 50–100; and for fenoterol 5–100. The best detectability, equal to 100 ng, was obtained on silica gel $60F_{254}$, in the case of adrenaline with brilliant cresyl blue dissolved in water, as well as dopamine and fenoterol with bromocresol green and brilliant cresyl blue dissolved in 5% NaOH. The best detectability on mixture of silica gel 60 and Kieselguhr F_{254} is 250 ng for adrenaline and dopamine with bromocresol green in 5% NaOH, on the polyamide 750 ng for dopamine with eosin yellow. However, phenylephrine and bithionol are not detected on Polyamide $11F_{254}$ with the studied visualizing reagents. Characteristics of the visualizing effect for adrenaline, dopamine, phenylephrine, metaraminol, fenoterol, and bithionol with the best visualizing reagents investigated on Kieselgel $60F_{254}$, Kieselgel 60/Kieselguhr F_{254}, and Polyamide $11F_{254}$ were presented earlier.[8,9,10,18]

Recently, the modified broadening index, detection index, densitometric visualizing index (DVI), and modified contrast index were used for the evaluation of detectability effects of salicylanilide, estradiol, and ibuprofen.[19–21] Estradiol is a steroid compound, but it contains an aromatic ring with hydroxyl group about phenolic character. Salicylanilide was detected on glass plates precoated with a 0.50 mm layer of silica gel $60F_{254}$ (E. Merck, #1.05744) and with a 0.25 mm layer of silica gel $60F_{254}$ (E. Merck, #1.05715), as well as on aluminum plates precoated with a 0.20 mm layer of silica gel $60F_{254}$ (E. Merck, #1.05554), silica gel 60 (E. Merck, #1.05553), and a mixture of silica gel 60 and Kieselguhr F_{254} (E. Merck, #1.05567), with and without the use of brilliant green as a visualizing reagent. It was stated that salicylanilide bands without the use of a visualizing reagent are invisible on the chromatogram in a visible light. Dark green spots of salicylanilide on green background are visible on the chromatograms after an application of brilliant green as a visualizing reagent. The obtained chromatographic spots of the investigated salicylanilide on the applied chromatographic sorbents after the use of brilliant green were durable and visible for over 6 weeks. The R_F values of salicylanilide are in the range from 0.75 to 0.88 depending on the applied chromatographic plates. Spectrodensitometric evaluation of salicylanilide with and without the use of a visualizing reagent was performed. For example, spectrodensitograms of salicylanilide with and without the use of brilliant green as a visualizing reagent on the #1.05744, #1.05715, and #1.05567 plates are presented in Figs. 3–5, respectively. It was stated that salicylanilide without the use of a visualizing reagent has fundamental absorption band at the similar values of the wavelength equal to 307 or 308 nm on #1.05744, #1.05715, #1.05554, and #1.05553 plates. However, the absorption maximum of salicylanilide on a mixture of silica gel 60 and Kieselguhr F_{254} without the use of a visualizing reagent is somewhat shifted and it is equal to 312 nm, whereas the obtained spectrodensitograms of salicylanilide without the use of a visualizing reagent differ in the intensity of the additional absorption bands depending on the chromatographic sorbents. The resultant spectrodensitograms of salicylanilide after detection with brilliant green differ in the wavelength of absorption maximum. The absorption maximum of salicylanilide occurs at 268 nm on #1.05715, #1.05554, and #1.05553 plates; at 305 nm on #1.05567 plate, and at 597 nm on #1.05744 plate. Simultaneously, the resultant spectrodensitograms of salicylanilide after the use of brilliant green also differ in the number and intensity of the additional absorption bands on the particular chromatographic plates. The obtained spectrodensitograms of the studied salicylanilide with and without the use of brilliant green as a visualizing reagent indicate that applied sorbents have an influence on the wavelength of the obtained fundamental absorption band (λ_{max}) and the additional absorption bands, as well as on their intensity values (in astronomical units). This fact indicates the necessary standardization of the spectrodensitometric investigations regarding the applied chromatographic conditions. Therefore, the spectrodensitograms of salicylanilide can be correctly compared only on the same chromatographic plate. This fact has fundamental significance in identification analysis.

The absorption maximum, broadening index, detection index, characteristic of densitometric band, modified contrast index, limit of detection, DVI, and linearity range of salicylanilide on the particular chromatographic plates with and without the use of brilliant green are presented in Tables 1 and 2, respectively.

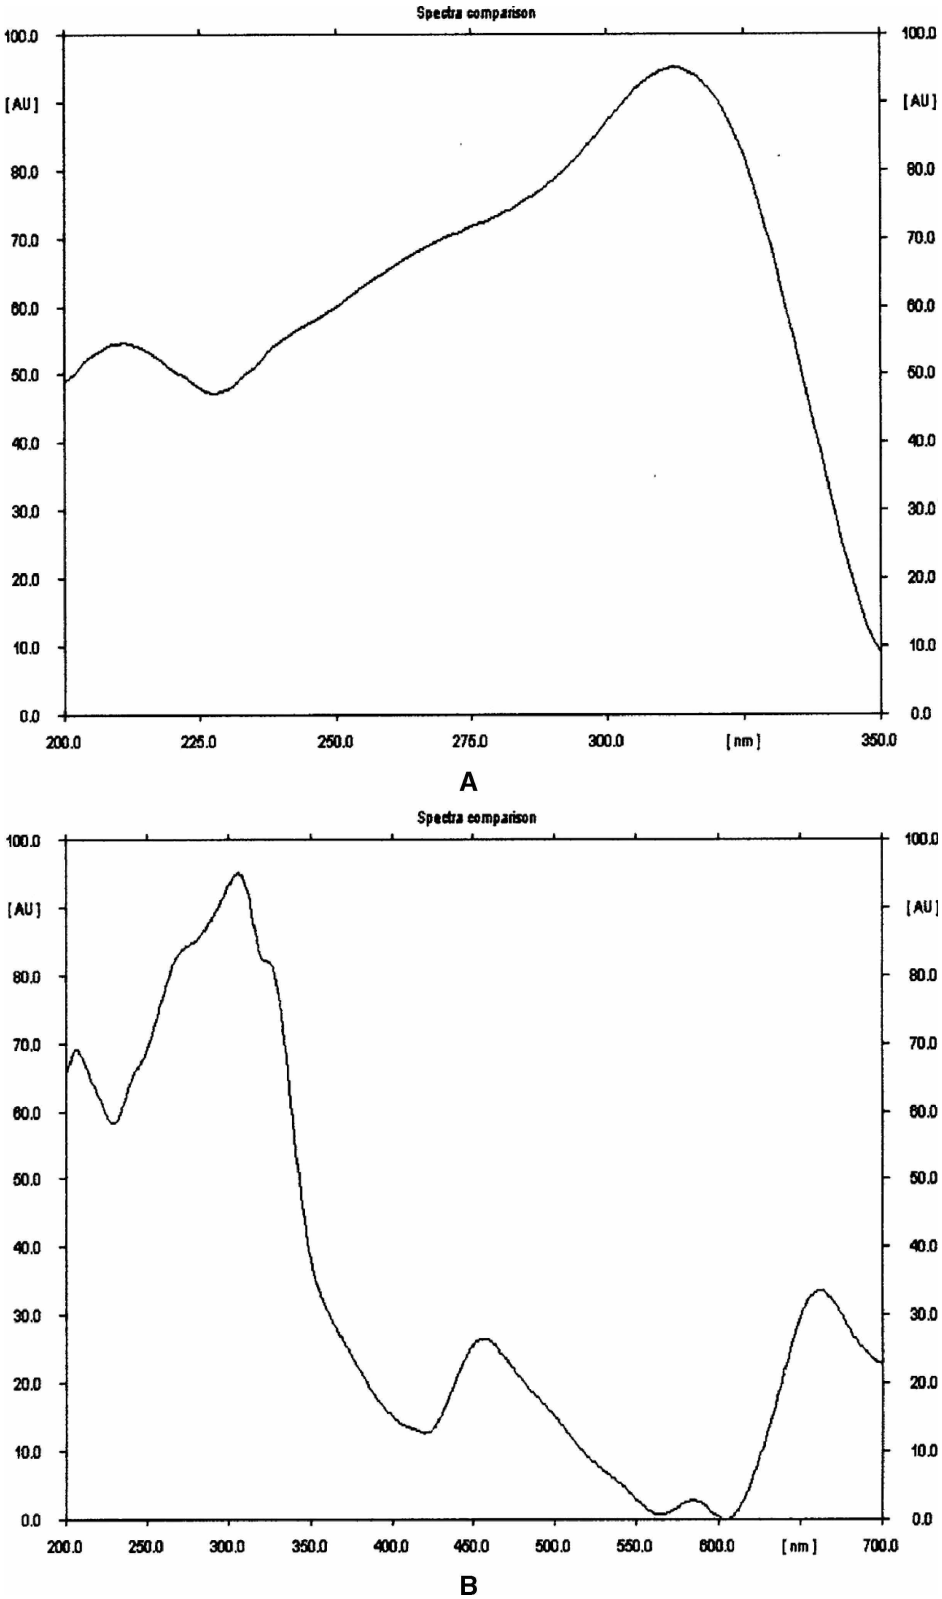

Fig. 5 Spectrodensitograms of salicylanilide on aluminum plates precoated with 0.20 mm layer of a mixture of silica gel 60 and Kieselguhr F_{254} (E. Merck, #1.05567): A, without the use of a visualizing reagent; B, with the use of brilliant green as a visualizing reagent.
Source: From The application of densitometry to evaluate the visualizing effects of salicylanilide using brilliant green, in J. Liq. Chromatogr. Relat. Technol.[19]

On the basis of values of DVI, it was stated that the best detection effects of salicylanilide were obtained without the use of a visualizing reagent. The worst detection effect of salicylanilide without the use of a visualizing reagent was obtained on a mixture of silica gel 60 and Kieselguhr F_{254}. However, on the remaining sorbents similar visualizing

effects of salicylanilide were obtained, whereas the best visualizing effect of salicylanilide with the use of brilliant green as a visualizing reagent was obtained on glass plates precoated with 0.50 mm layer of silica gel $60F_{254}$ (E. Merck, #1.05744). It was stated that the DVI is the objective parameter describing the visualizing effect of detected salicylanilide.[19]

Five dyes, namely, gentian violet, methylene violet, methylene blue, malachite green, and Janus blue, have been used as new visualizing reagents to detect estradiol on neutral aluminum oxide $60F_{254}$ and on neutral aluminum oxide $150F_{254}$. Barton's reagent, rhodamine B, and sulfuric acid were used as the comparative visualizing reagents. Limit of detection (detectability), detection index, modified broadening index, modified contrast index, and linearity range were determined for estradiol following the use of these visualizing reagents. It was stated that the proposed modified contrast index is the objective parameter describing the applied visualizing reagents. The influence of a solid support on obtained visualizing effects was found. The angles (α) between the tangents at the inflection points and the curves of the densitometric peaks are more compact on neutral aluminum oxide $60F_{254}$ than on neutral aluminum oxide $150F_{254}$. This observation indicates that the utility of any particular visualizing reagent depends on the type of chromatographic support used. For the quantitative research of investigated estradiol, sulfuric acid (VI), Barton's reagent, gentian violet, and methylene violet were found to be relatively good.[20]

Six dyes, namely, gentian violet, methylene violet, methylene blue, methyl green, malachite green, and Janus blue, have been used as new visualizing reagents to detect ibuprofen on silica gel $60F_{254}$. Rhodamine B was used as the comparative visualizing reagents. The limit of detection (detectability), detection index, broadening index, modified contrast index, DVI, and linearity range were determined for ibuprofen following the use of these visualizing reagents. It was stated that the earlier proposed DVI is an objective parameter describing the applied visualizing reagents. The best way for detecting ibuprofen is the densitometric method without using a visualizing reagent. Among all the new visualizing reagents studied, methylene violet is the best to detect ibuprofen.[21]

The obtained visualizing effects and the non-destructive properties of applied visualizing reagents, in relation to investigated salicylanilide, estradiol, and ibuprofen, indicate that there has been progress in the range of analysis for these compounds on a thin layer. This fact has definite analytical, pharmaceutical, and physicochemical significance.[19–21]

CONCLUSIONS

- Indicators and dyes described as visualizing reagents in this entry should serve as a supplement to those used previously for the detection of phenolic drugs.
- Broadening index, detection index, characteristic of densitometric band, modified contrast index, limit of detection, DVI, and linearity range of detected compounds are important parameters for the evaluation of visualizing effects of used visualizing reagents.
- The visualizing effect depends on the chemical structure of the visualizing reagent, the structure of the substance detected, as well as the chromatographic sorbent applied.
- Particular application will have these visualizing reagents, which, with substances present in analyzed mixtures, will give diversified colors of chromatographic spots.
- The best and most universal visualizing reagents for the detection of bamethane, ethamivan, hexachlorophene, salicylanilide, pyrocatechin, thymol, pentazocine, phloroglucinol, eugenol, niclosamide, terbutaline, methyldopa, and norepinephrine investigated on silica gel 60 are aniline blue and brilliant green dissolved in water. These visualizing reagents have relatively good properties for quantitative research of investigated phenolic drugs.[7]
- Eugenol and thymol can also be qualitatively detected on silica gel by using visualizing reagents based on a saturated aqueous solution of variamine blue hydrochloride.[13]
- The best visualizing reagents for the detection of α-naphthol are the following: titan yellow, eosin, helasol green, and bromothymol blue in aqueous sodium hydroxide (50 mg/100 ml of 5% NaOH) on silica gel 60; bromocresol green, titan yellow, and eosin yellow on mixture of silica gel 60 and Kieselguhr F_{254}; and bromocresol, titan yellow, and thymolphthalein on Polyamide $11F_{254}$.[14,15]
- Titan yellow is the best visualizing reagent for the detection of *m*-cresol on silica gel 60 (detection limit: 1.08 μg).[16]
- The best visualizing reagents are brilliant cresyl blue, erythrosin B, and bromocresol blue for the detection of hydroquinone; alkaline blue, thymolphthalein, and brilliant cresyl blue for pyrogallol; and alkaline blue and brilliant green for phloroglucinol.[17]
- The most universal visualizing reagents for adrenaline, dopamine, phenylephrine, metaraminol, fenoterol, and bithionol are the following: bromocresol green and brilliant cresyl blue dissolved in 5% NaOH on silica gel $60F_{254}$; bromocresol green, brilliant cresyl blue, and eriochrome black T dissolved in 5% NaOH on a mixture of silica gel and Kieselguhr F_{254}; eosin yellow dissolved in 5% NaOH on Polyamide $11F_{254}$.[18]
- The usefulness of densitometry for detection of some phenolic drugs was shown.[7,11]
- Visualizing effects and non-destructive properties of applied visualizing reagents (brilliant green, gentian violet, methylene violet, methylene blue, methyl green, malachite green, and Janus blue), in relation to investigated salicylanilide, estradiol, and ibuprofen,

indicate that progress in the range of analysis of these compounds on thin layer has taken place. This fact has definite analytical, pharmaceutical, and physicochemical significance.[19–21]

Phenols and Acids: TLC Analysis

Luciano Lepri
Alessandra Cincinelli
Department of Chemistry, University of Florence (UNIFI), Florence, Italy

Abstract
A wide variety of stationary phases have been used to separate substituted monocyclic phenols and phenolic acid compounds and their derivates by thin-layer chromatography (TLC). In particular, the composition of phenolic acids and flavonoids in leaves, roots, and fruits of several plants and in natural products has been extensively studied by the two-dimensional TLC by using cellulose or silica gel plates in one direction and silanized silica gel in the second direction. Quantitative determinations of flavonoids components of plant extracts were widely performed.

INTRODUCTION

Phenol is a weak acid (pK_a 9.98), and the effect of a ring substituent on the acid strength depends on whether the group is electron withdrawing or releasing, its position, and its ability to give resonating structures. Phenolic groups occur in a large number of natural and industrial products, ranging from phenolic resins, herbicides, fungicides, surfactants, alkaloids, steroids, aglycones, and glycosides to numerous other groups.

A comprehensive review of phenolic compounds in biochemical, environmental, industrial, and consumer products, as well as sample preparation prior to thin-layer chromatography (TLC), has been made by Tyman.[1]

CHROMATOGRAPHIC BEHAVIOR OF MONOCYCLIC PHENOLS

Substituted monocyclic phenols have been widely studied in several stationary phases (alumina, silica gel, cellulose, polyamide, chitin) and also on chemically modified adsorbents (silanized silica gel, cyano- and amino-silica plates), ion-exchange layers, and impregnated plates.

Phenols can be detected with Fast Blue Salt B, diazotized orthanilic acid or dianisidine, alkaline chloramine T reagent, by spraying an ammoniacal silver nitrate solution, followed by exposure to UV light, or with a modified potassium ferricyanide–ferric chloride reagent, and also by exposing the wet layer successively to nitrogen dioxide ($Cu + HNO_3$) and ammonia vapors.

Silica Gel, Alumina, Cellulose, and Polyamide

Layers of silica gel 60 and alumina have been employed for the separation and identification of 126 monocyclic phenols eluted with solvents of increasing polarity (benzene, di-isopropyl ether, and ethanol).[2] Alumina is more basic than silica gel and strongly retains phenolic compounds, particularly those with more acidic properties such as chloro- and nitrophenols, even when eluted with a medium-polarity solvent.

Table 1 reports the retention data relative to several substituted monocyclic phenols examined on silica gel 60 in benzene and di-isopropyl ether.

The presence of a 2-substituent or 2,6-substituent results in an increase in the R_f value with benzene as eluent. However, 2,6-dinitrophenol is retained more in benzene than are 2,4- and 2,5-isomers. The sequence of their R_f values ($R_{f2,6} = 0.04 < R_{f2,4} = 0.07 < R_{f2,5} = 0.38$) is in agreement with that of the corresponding pK_a values ($pK_{a2,6} = 3.71 < pK_{a2,4} = 4.09 < pK_{a2,5} = 5.22$); hence, these two facts can be closely bound up with one another.

Di-isopropyl ether allows the separation of nitrophenol isomers and of several nitroalkyl and nitrochlorophenols as well as of dihydroxy- and trihydroxybenzenes. Dimethyl and trimethylphenols are better resolved on alumina plates than on silica gel when eluting with the above-mentioned solvent:

Dimethylphenols

$$R_{f3,4} = 0.22 < R_{f3,5} = 0.26 < R_{f2,4} = 0.28 < R_{f2,3} = 0.39 < R_{f2,5} = 0.44 < R_{f2,6} = 0.52$$

Trimethylphenols

$$R_{f3,4,5} = 0.16 < R_{f2,4,5} = 0.23 < R_{f2,3,5} = 0.46 < R_{f2,4,6} = 0.51$$

Hydrogen bonding, steric effects, and acid–base properties of phenols are involved in their retention on silica gel and alumina with benzene and isopropyl ether as eluents.

[e]pK_a values at 29°C.

[f]Elongated spot.

Only a limited number of researches have focused on cellulose plates, microcrystalline cellulose being the most used stationary phase with solvents such as ethyl acetate–*n*-propanol–25% ammonia (3:5:2), water–formic acid (98:2), *n*-amyl alcohol–acetic acid–water (10:6:5), and benzene–propionic acid–water (4:9:3).

Polyamide is an especially useful adsorbent for the separation of phenols owing to the formation of hydrogen bonds between the phenolic compounds and the amide group of the polymer. Organic solvents of increasing polarity and aqueous–organic solutions have been used as eluents: benzene, chloroform, ethyl acetate, water–methanol, water–acetone, water–acetic acid, and cyclohexane–acetic acid (93:7) mixtures. Water–propanol–27% ammonia (1:8:1), *n*-butanol–5 *M* ammonia (100:33), and *n*-butanol–ethanol–ammonia (5:1:1) have been employed for nitrophenols.

Chemically Modified Sorbents, Ion-Exchange Resins, and Impregnated Plates

A wide study of the chromatographic behavior of alkyl, halogenated phenols, and phenols containing alkyl and halogen groups by reversed-phase TLC has been performed by Bark and Graham[3] on cellulose impregnated with ethyl oleate eluted with aqueous ethanol (Table 1).

The phenols can be removed by the stationary phase as a result of solvation of the phenolic group by the proton acceptor eluent (water or ethanol), which may be influenced by steric factors and by altering the polarity of the phenolic grouping. Under these chromatographic conditions, relationships between R_m values and structural descriptors of selected alkoxyphenols and also new methods of calculation of their partition coefficients were proposed by Pyka.[4]

Long-chain alkylphenols present in natural cashew nut shell liquid have been chromatographed on argentated silica gel G (10% w/w silver nitrate) with diethyl ether–light petroleum–formic acid (30:70:1) as eluent for the separation of unsaturated constituents.

Alkylphenols, nitrophenols, halogenophenols, and polyhydroxybenzenes have been extensively studied on thin layer of anion and cation exchangers with cellulose, paraffin, and polystyrene matrices and on silanized silica gel impregnated with anionic and cationic surfactants. The best results have been obtained by using cation exchangers and anionic surfactants as impregnating agents.[5,6]

The parameters that determine the retention of phenols on layers of silanized silica gel untreated and impregnated with anionic surfactants are the same that affect retention on cation exchangers (i.e., organic modifier percentage, ionic strength, and, particularly, pH of the eluent).

With regard to the influence of pH, the protonated form of the phenols exhibits a higher affinity toward the stationary phase than the deprotonated form.

In the relationship

$$K_d = \frac{[HA]_R + [A^-]_R}{[HA]_S + [A^-]_S} \frac{V}{W} \quad (1)$$

K_d represents the distribution coefficient, $[HA]_R$, $[A^-]_R$, $[HA]_S$, and $[A^-]_S$ are the concentrations of the protonated and deprotonated forms of the phenol in the resin and in the solution, V is the volume of the solution, and W is the weight of the resin. Introducing the K_a value in Eq. 1 and combining with the Martin–Synge equation for partition TLC, Lepri et al.[5] obtained the following relationship:

$$\left(\frac{1}{R_f} - 1\right) = \left(\frac{1}{R_{fac}} - 1\right) \frac{[H^+]}{K_a + [H^+]} + \left(\frac{1}{R_{falk}} - 1\right) \frac{K_a}{K_a + [H^+]} \quad (2)$$

where R_{fac} and R_{falk} are the R_f values of the protonated and deprotonated form of the phenol achieved by eluting with strong acidic and alkaline solutions, respectively.

Although the major change in $\left(\frac{1}{R_f} - 1\right)$ with pH occurs at pH = pK_a, by differentiating R_f twice with respect to log $[H^+]$ and equating to zero, the following relation is obtained:

$$[H^+] = K_a \frac{R_{fac}}{R_{falk}} \quad (3)$$

On the basis of Eq. 3, we can predict that the lower is the R_{fac}/R_{falk} ratio, the more will be the shift in the mean R_f value of R_{fac} and R_{falk} with respect to the pH = pK_a value.

Many nitrophenols, chlorophenols, and bromophenols can be easily separated by this technique by eluting with aqueous–organic solutions at different pH values (Table 1).

The mechanism of chromatographic separation of selected phenols on cyano-modified silica layers, eluted with nine non-aqueous and five aqueous solvents was studied, and it was concluded that both cyano and silanol groups participate in the interactions with solutes.

CHROMATOGRAPHIC BEHAVIOR OF PHENOLIC ACIDS AND THEIR DERIVATIVES

In general, silica gel has been more widely used than cellulose, polyamide, silanized silica gel, and aminopropylsilica for the separation of phenolic acids and their derivatives arising from clinical studies or extracted from plant material.

The selected eluents for silica gel are chloroform–ethyl acetate–formic acid (5:4:1), *n*-hexane–ethyl acetate–formic acid (15:9:2), chloroform–acetic acid–water (2:1:1), toluene–dichloromethane–formic acid (40:50:10), and dichloromethane–acetic acid–water (100:50:50, lower phase).

Table 2 hR_F of phenolic acids from the foliage of *P. tauricum* Bieb after acid hydrolysis on 10 × 10 cm cellulose plates (Merck) by 2-D TLC.

Phenolic acid	$hR_{F(1D)}$	$hR_{F(2D)}$	Color after derivatization with diazotized sulfanilic acid

Ferulic acid (*trans*)	76	12	Violet
Ferulic acid (*cis*)	76	58	Violet

First direction: toluene–methanol–acetic acid–acetonitrile (75.5:10:5:7.5 v/v); second direction: sodium formate–formic acid–water (10:1:200 w/v/v).

Recently, two-dimensional TLC (2-D TLC) on cellulose plates had been used for the separation of phenolic acids extracted from plants (i.e., leaves, roots, and fruits of *Peucedanum verticillare* L. Koch ex DC; leaves, inflorescences, and rhizomes of *Silphium perfoliatum*[7]) by eluting with benzene–methanol–acetonitrile–acetic acid (80:10:5:5) in the first direction and sodium formate–formic acid–water (10:1:200 w/v/v) in the second direction. Table 2 shows the hR_f values obtained for phenolic acids from *Peucedanum tauricum* Bieb foliage by 2-D TLC on cellulose plates.

Detection was performed by UV light (366 nm), by spraying with 3% methanolic $FeCl_3$ or by derivatization of phenolic acids with diazotized sulfanilic acid.

Selected phenolic compounds (i.e., phenolic acids and flavnoids) were separated by normal-phase and reversed-phase 2-D chromatography on connected plates (diol or silica plates connected to RP-18W plates). Optimization of mobile phases was performed by plotting retention against eluent composition. Phenolic compounds present in extracts from *Verbacum* sp. and *Polygonum* sp. were separated by 2-D TLC.[8]

Three ellagitannins (corilagin, gernaiin, dehydrogeraniin) and two gallotannins (methyl gallate-3-*O*-glucoside, 3-*O*-galloylshikimic acid) were isolated from the aerial parts of *Erodium cicutarium* (Geraniaceae) and identified by TLC on cellulose, silica gel 60, and silanized silica gel (RP-18W plates) by eluting with water–acetic acid (94:6), di-isopropyl ether–acetone–98% formic acid (5:4:1), and water–methanol–98% formic acid (69:30:1), respectively.

Phenolic aldehydes and ketones have been chromatographed on silica gel G and cellulose plates as their phenylhydrazones formed in situ. Toluene–chloroform–acetone (5:3:2), chloroform–acetone (8:2), anisole–methanol (8:2), and anisole–chloroform–acetone (5:3:2) are the eluents used for silica gel while the layers of cellulose have been eluted with 2% formic acid, 20% potassium chloride, 10% acetic acid, or 2-propanol–ammonia–water (8:1:1).

Long-chain alkylphenolic acids and their derivatives have been separated on silica gel G by eluting with light petroleum (60–80°C)–ethyl ether–dimethylformamide–acetic acid (75:85:5:1).

Reversed-phase TLC on silanized silica gel layers (OPTI-UPC$_{12}$, SilC$_{18}$-50, and RP-18 plates), untreated and impregnated with anionic and cationic surfactants has been used for the separation of catecholamines, phenolic acids, and glycols excreted in the urine. Many interesting separations have been achieved on OPTI-UPC$_{12}$ plates by eluting with 1 *M* HCl + 3% KCl in water (biogenic amines) and with 1 *M* sodium acetate in water (urinary phenolic acids and glycols). Recently, biogenic amines and their derivatives were separated on RP-18 plates and NH_2-bonded silica gel with chloroform–methanol (9:1) or ethanol–5% aqueous diethylamine (95:5) as eluents, respectively. Finally, very good separations of norepinephrine, dopamine, epinephrine, normetanephrine, and metanephrine were obtained on plates of silanized silica gel eluted with phosphate buffer (pH 6.98)–methanol (1:1 v/v).

A paper investigated 18 phenolic acids on aminopropylsilica plates; the best separations were achieved by eluting with heptane-di-isopropyl ether–acetic acid (4:5:1 v/v) or petroleum ether-di-isopropyl ether–acetic acid (6:3:1 v/v).[9]

Determination of the hydrophobicity of phenolic acids and flavonoids from chromatographic data is an important non-analytical application of reversed-phase TLC since experimentally obtained R_{Mw} values (R_M extrapolated at 0% organic modifier, usually methanol in water) are related to selected ADME (*a*bsorption, *d*istribution, *m*etabolism, *e*limination) data.[10] In addition, TLC chromatogram

fingerprints are generally employed for evaluation and comparison of the composition of herbal drugs. For example, flavonoid content was used for effective and reliable quality control of the drugs from dog rose on silica gel 60 F_{254} plates by 1-D and 2-D chromatography.[11]

QUANTITATIVE DETERMINATIONS

Phenols occurring in water have been quantified by in situ densitometry after coupling with diazotized *p*-nitroaniline or by using vanadium pentoxide and dichlorofluorescein.

An interesting paper analyzed phenols included in the list of priority pollutants of Environmental Protection Agency (EPA) on silica gel G F_{254} high-performance TLC (HPTLC) plates and polyamide plates after solid-phase extraction from water.[12]

In situ quantitation has been performed by adsorption UV or Vis light measurements of the color developed with Würster's salts.

Planar chromatography has also been used to separate and quantify several common phenols in contaminated land leachates after derivatization with 3-methyl-2-benzothiazolinone hydrazone and extraction of the resulting azo dyes.

Recently, phenolic acids and flavonoid content of Croatian propolis samples were identified and determined by scanning densitometry at UV absorption maximum of each compound.

Chromatographic analysis was performed on 10×20 cm silica gel F_{254} high-performance TLC plates by eluting with chloroform–methanol–formic acid (44:3.5:2.5).[13]

Phospholipids and Glycolipids: Normal-Phase HPLC Analysis

Yiwen Yang
Department of Chemical and Biochemical Engineering, Zhejiang University, Hangzhou, China

INTRODUCTION

Analytical methods for phospholipid and glycolipid classes by normal-phase high-performance liquid chromatography (HPLC) have been incompletely reviewed. Silica columns with evaporative light scattering detection (ELSD) were mostly used. The poly(vinyl alcohol)-grafted silica column with ELSD could be used to separate them, simultaneously.

PHOSPHOLIPIDS AND GLYCOLIPIDS

Phospholipids are divided into two main groups:[1] glycerolphospholipids and sphingolipids. Glycerolphospholipids are derived from glycerol with a polar headgroup and fatty acid esterified at the *sn-1* and/or *sn-2* positions of the glycerol backbone. Sphingolipids are derived from sphingosine. Principal phospholipids classes are phosphatidylcholine (PC), phosphatidylethanolamine (PE), phosphatidylinositol (PI), phosphatidylglycerol (PG), phosphatidic acid (PA), phosphatidylserine (PS), lysophosphatidylcholine (LPC), and sphingomyelin (Sph or SM).[2,3]

Glycolipids are glycosylated derivatives of lipids, such as acylglycerols, ceramides, and prenols.[4] They are divided into three main groups: glycoglycerolipids, glycosphingolipids, and glycophosphatidylinositols. Glycoglycerolipids designate glycolipids containing one or more glycerol residues. Glycosphingolipid designates lipids containing at least one monosaccharide residue and either a sphingoid or a ceramide. The glycosphingolipids can be subdivided into two groups: neutral glycosphingolipids, e.g., mono-, oligo-, polyglycosylsphingoids and mono-, oligo-, polyglycosylceramides, and acidic glycosphingolipids, e.g., sialoglycosphingolipids, uronoglycosphingolipids, sulfoglycosphingolipids, phosphoglycosphingolipids, phosphonoglycosphingolipids, etc. Glycophosphatidylinositols designate glycolipids, which contain saccharides glycosidically linked to the inositol moiety of PIs.

Every class of phospholipids and glycolipids contains many molecular species, owing to the structural and/or positional difference in the fatty acid moiety. Therefore, they are complex mixture.

The main purpose of normal-phase HPLC analysis of phospholipids and glycolipids is to separate and quantify according to class, although a few molecular species can be elucidated when HPLC–tandem mass spectrometry (MS/MS) is used.[5]

SEPARATION OF PHOSPHOLIPIDS AND GLYCOLIPIDS

Phospholipids and glycolipids have been usually fractionated from total lipids by thin-layer chromatography (TLC) or column chromatography.[6] Then, they were later analyzed by HPLC separately.

For phospholipids separation, various HPLC columns, e.g., silica,[1,2,7–9] NH_2,[10] diol,[5,11,12] and polyvinyl alcohol[13] have been used. Silica columns were most often used. Both isocratic[7] and gradient[1,2,5,6,8,9,11–13] mobile phases have been used. The most often used mobile phases are chloroform-methanol-water and hexane-isopropanol-water systems. The phospholipid classes can be separated very well by carefully adjusting the composition and time schedule of mobile phases.

For glycolipids separation, a few HPLC columns, e.g., NH_2,[14] and silica,[15–17] have been used. Isocratic[16] or gradient[14,15,17] mobile phases are used.

A few articles are concerned with the simultaneous separation of phospholipids and glycolipids.[18,19] The poly(vinyl alcohol) column gave excellent results.[20] However, complex mobile phases were needed.

DETECTION AND QUANTIFICATION

As detection methods, ultraviolet (UV) detection,[6,7,14–16] refractive index (RI),[9] ELSD,[1,8,9,12,13,17–20] MS,[2,11] and tandem MS[5,11] have been used. To quantify the phospholipid and glycolipid classes, ELSD has been very successful. But, ELSD does not always result in a linear response.[1,9] It should be noted that, because of the absence of a specific absorption peak for lipids, and every peak in normal HPLC is, in fact, a mixed response, UV detection does not allow their quantitative estimation.[21,22]

CONCLUSIONS

Normal-phase HPLC is useful for the separation and quantification of phospholipid and glycolipid classes. Silica columns with ELSD are mostly used. A poly(vinyl

alcohol)-grafted silica column, with ELSD, can be used to separate them, simultaneously.

Vince Serignese
Pharmaceutical Analysis Laboratory, King Faisal Specialist Hospital and Research Center, Riyadh, Saudi Arabia

INTRODUCTION

Analysis is an integral part of research, clinical, and industrial laboratory methodology. The determination of the components of a substance or the sample in question can be qualitative, quantitative, or both. Techniques that are available to the analyst for such determinations are abundant. In absorption spectroscopy, the molecular absorption properties of the analyte are measured with laboratory instruments that function as detectors. Those that provide absorbance readings over the ultraviolet–visible (UV–Vis) light spectrum are commonly used in high-performance liquid chromatography (HPLC). The above method is sufficiently sensitive for quantitative analysis and it has a broader application than other modes of detection.

DISCUSSION

The most advanced UV–Vis detector that is used in HPLC is the diode array. Compared to its predecessors, the diode array generates a large amount of spectral information without compromising sensitivity or wavelength resolution. In order to discuss the properties of the diode-array detector, a brief historical description of its technological development is presented.

HISTORICAL BACKGROUND AND SCHEMATICS

Early on, UV–Vis detectors produced data at one wavelength only fixed-wavelength detector (FWD). Because compounds of interest do not absorb light at a fixed wavelength with equal efficiencies, the next step was to develop a detector with an adjustable wavelength range. Modifications were required in the light source. The high-energy-emitting mercury lamp in the FWD was replaced with a deuterium and/or tungsten lamp. The latter light source gave detectable energies over a wider wavelength range. The addition of a wavelength selector (monochromator) provided accurate wavelength adjustments from 190 to 800 (UV–Vis) nm. Hence, the variable-wavelength detector (VWD) was established.

At this point, single-wavelength data acquisition remained a bottleneck, restricting the analyst to one basic characteristic tool to identify the analyte: the amount of time the analyte is retained on the chromatographic column (i.e., the retention time). If there are four compounds in the sample to be analyzed, this would require a minimum of four injections to identify them. Additional work would be needed for cross-identification and so on. The concept of multiple-wavelength detection was introduced.

The diode-array detector collects data with a maximum wavelength bandwidth of 190–800 nm. All wavelengths in that range are accounted for simultaneously. As shown in Fig. 1, the upper portion represents a single detector element with three components: the photodiode, a capacitor, and (FET) field effect transistor switch. Shining light onto a single detector element produces a signal which is processed and then expressed as a digital absorbance reading. This response is for one wavelength only. The FWDs and VWDs are equipped with a single detector element. The bottom portion of Fig. 1 displays the schematics of a linear diode-array detector. Many detector elements, all of the same composition as described above, are in a linear arrangement. Each detector element is dedicated to a particular wavelength bandwidth such that there are enough of them to cover the UV–Vis light spectrum. This unit produces signals that cover the entire UV–Vis light spectrum. Simultaneous wavelength detection was now possible with the diode array.

Fig. 2 displays the optical components of the diode-array detector. A deuterium lamp will emit light onto the flow cell, which has liquid continuously flowing through it. A shutter is provided between the light source and the flow cell, which can either be fully open or closed. The beam of light will then travel to the diffraction grating, where it will be separated into wavelengths ranging from 190 to 800 nm. The separated light will finally reach the diode array and a signal will be produced that is proportional to the amount of light received. For a detailed account of this topic, the reader is referred to the selected references cited.

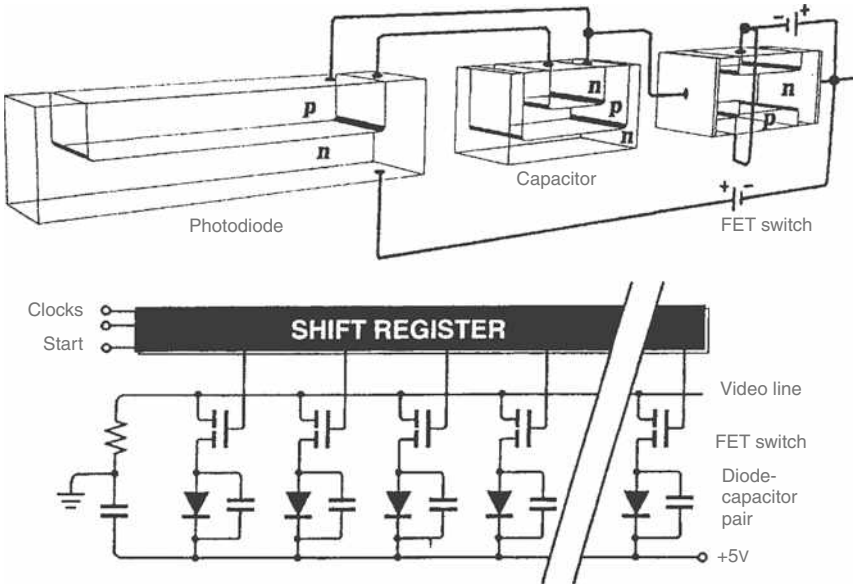

Fig. 1 Diagram of a single photodiode-capacitor switch (top) and an electronic schematic of the linear array (bottom).

APPLICATIONS

Thus far, we have given a brief account on the technological development of the diode-array detector. Its applications offer several advantages to the user, which have been made possible primarily by the current computer hardware and software that are available on the market. Data acquisition and analysis are computer driven. The information acquired from the diode array can be analyzed to tailor the user's preferences. This area represents an emerging field and further advancements in analytical software tools will ultimately determine the true potential of diode-array detection.

As stated previously, a major improvement achieved with the diode array is that fewer attempts are required to identify the components of a sample mixture. A single injection can be sufficient for sample identification when spectral information in addition to peak retention time is part of the collected data. Through software capabilities, spectra can be extracted from the chromatogram of each individual peak. The spectral information combined with the retention times can be used to identify the chromatographic peaks. Furthermore, the spectra can be compared to spectral libraries compiled from the literature for purposes of spectral matching. Many proprietary software programs have been developed for the diode-array instrument. It is up to the user's discretion to determine how he can best utilize these resources.

At first, one may show skepticism at the usefulness of diode-array detection because other analytical systems are more sensitive and offer similar features such as peak identification and purity checks. For these alternatives, one would have to refer to gas chromatography/mass spectroscopy (GC/MS), liquid chromatography/mass spectroscopy (LC/MS), and tandem mass spectrometry (MS-MS). However, one must keep in mind the significantly higher costs as a tradeoff for enhanced sensitivity.

When assessing the merits of the diode array, the user should consider the various steps that are involved in

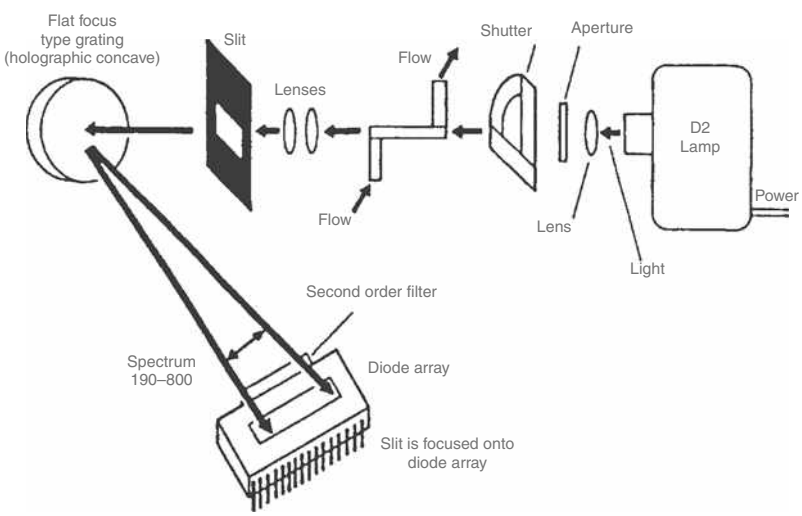

Fig. 2 Optics unit components.
Source: Reprinted from *Waters 990 + Photodiode Array Detector Operator's Manual 1989*; courtesy of Waters Corporation, Milford, MA.

methods development. It will become clear that for every hurdle one encounters, diode-array detection renders the task less laborious. It is most often than not that in developing new procedures you are confronted with drawbacks such as contaminants, peak overlap, artifacts, sample cleanup, and baseline noise. For instance, the presence of a shoulder on a major chromatographic peak raises questions as to its origin. With the aid of the diode array, a spectral profile of the shoulder peak will quickly determine its existence. A flat line of low absorbance throughout its spectra indicates that it is an artifact. The user can then go back to his procedure and ascertain if the root of the problem is systematic. The direction problem-solving takes is crucial and if gone astray, vast amounts of time are wasted. The same shoulder obtained with a FWD could have led the user to perform a time-dependent study. In this case, it was incorrectly assumed that the shoulder peak was a degradation product and additional injections at increased time intervals would show the shoulder peak increasing in size, indicating the compound of interest was degrading. Even though the analyst would eventually achieve the same result in the latter situation, the former approach is less time-consuming.

Diode-array detection has found its way into the pharmaceutical industry and the clinical laboratory. The widespread use of HPLC analysis in the product development cycle of pharmaceuticals provided an open door for the diode array. Throughout the different phases of drug development, the identification of a peak and its homogeneity must be established. The diode array confirms peak identity and compound purity by spectral analysis. Peak spectra are overlaid with spectra from standards (that are stored on the computer hard drive) for identification and spectra from the upslope, apex, and downslope of a chromatographic peak are overlaid to test for purity. Because the diode array performs continuous-flow spectral acquisition in the HPLC mode, the method can be automated to screen for thousands of compounds where only one will have the desired pharmacological action. Drug screening is common in drug development procedures, which goes hand-in-hand with drug metabolism and quantitative analysis. Diode-array detection is effective in all of these areas.

Peak purity is of utmost importance in the quality control of pharmaceutical products. The contents of the product must be known with great certainty before it is sold to the consumer. Adjunct laboratories test the stability of the product in order to determine its expiry date. All by-products are accounted for and the amount of active ingredient is referenced. The diode array in HPLC analysis is used to determine all of the above information.

In the clinical laboratory setting, methods of analysis are used to diagnose disease and for therapeutic drug monitoring. Diode array-HPLC techniques will determine the drug concentrations and its metabolite levels in biological matrices. From these results, dosing regimens can be outlined that are specifically tailored to patients with respect to therapeutic drug concentration and drug dose, thereby avoiding drug toxicity. These procedures will ensure the safety and efficacy of clinically administered drugs.

CONCLUSIONS

The photodiode-array detector is a powerful analytical instrument that has provided enhanced detection capabilities with the addition of detailed spectral information via its multisignal detection technology. Its applications are HPLC based and can be found in basic research, automated analysis, pharmaceutical product development, and the clinical laboratory environment. Through spectral acquisition and analysis, a wealth of information can be obtained about the identity and purity of a compound. Combined with high selectivity and sensitivity, this mode of detection is essential for qualitative and quantitative HPLC analysis.

Photophoretic Effects in FFF of Particles

Vadim L. Kononenko
Institute of Biochemical Physics, Russian Academy of Sciences, Moscow, Russia

INTRODUCTION

The basic principle underlying the field-flow fractionation (FFF) method of particle separation is the combination of the transversely non-uniform velocity profile of a carrier fluid in a channel with the transverse force field acting on the particles to be separated. Due to the different magnitudes of transverse force applied to the various fractions in a particle mixture, these fractions tend to occupy different laminas of a non-uniform channel flow. As a result, they move along the channel with effectively different velocities and become separated eventually. This universal principle underlies the high versatility and remarkable instrumental power of the FFF subtechnique family, due to the wide variety of driving forces used. Accordingly, further development of FFF is primarily associated with the use of new types and combinations of physical and physicochemical agents influencing particle and molecule redistribution across the flow.

Among the possible new force agents, the interaction of light with particles leading to their motion (photophoresis) attracts special attention. It is due to the universal nature of this interaction, present for all kinds of particles and molecules, as well as to the numerous interaction mechanisms that exist. Thus, photophoretic FFF techniques, if developed, have the potential to separate particles according to their size, optical constants, and physicochemical properties relevant to photophoretic mechanisms. The present entry considers the basic theoretical principles underlying the photophoretic effects, and their possible use in FFF. Both direct and indirect mechanisms of particle photophoresis are discussed, followed by a brief overview of experimental data on the photophoresis of particles and liquid droplets in fluids. Feasibility studies aimed at photophoretic FFF are outlined, and some possible instrumental realizations are discussed.

MECHANISMS OF PHOTOPHORESIS

The idea of photophoretic FFF emerged many years ago,[1] but it still remains one of the less developed branches of the rich family of FFF techniques.[2] However, its potential advantages seem to ensure eventual practical realization. The known photophoretic mechanisms can be classified into two families. The direct-type mechanisms are associated with momentum transfer from an electromagnetic field to a particle or a molecule irradiated during the scattering, refraction, or absorption of light. The known indirect photophoretic mechanisms involve, as a primary light action, non-uniform heating of particles and/or the establishment of a temperature gradient across a channel due to light absorption in the carrier fluid. Such heating leads to conventional thermophoresis of particles due to tangential gradients of interfacial energy arising near the particle surface. The whole phenomenon can be referred to as photothermophoresis.

Direct Photophoretic Mechanisms

The direct photophoretic mechanisms include light pressure and the action of the so-called gradient force.[3–8] The gradient force[6–8] arises from the spatial non-homogeneity of the electromagnetic field, if any. It has the same nature as the force acting on electric dipoles in a static divergent field. It is characteristic of focused light beams, evanescent waves near refractive index boundaries, etc. In general, calculation of the direct photophoretic force requires the solution of the optical problem of light scattering by a particle. In this problem, a particle is characterized either by the complex dielectric permittivity $\varepsilon(\lambda_0) = \varepsilon'(\lambda_0) - i\varepsilon''(\lambda_0)$ relative to the permittivity ε_m of the surrounding medium, or by the complex refractive index relative to that of the surrounding medium, n_0, at the wavelength λ_0 of light, $m(\lambda_0) = n_r(\lambda_0) - i\kappa(\lambda_0)$. Here, λ_0 is the wavelength of light in vacuum, n_r is the relative refraction index, κ is the index of absorption, and $\varepsilon' = n_r^2 - \kappa^2$, $\varepsilon = 2n_r\kappa$. The solution of the scattering problem is obtained using either wave optics theory,[3–5] or the geometrical (ray) optics description,[7,8] depending on the particle size parameter $\rho = 2\pi a n_0/\lambda_0$, where $2a$ is the characteristic particle dimension (the diameter for spherical particles). The wave optics approach is based on Lorenz–Mie theory in the case of plane incident waves,[3,4] and on various generalizations of this theory in the case of focused laser beams (see Ref.[5] and the references therein). In practice, the ray optics description is valid (and more suitable) starting from $a \sim 10$ μm for visible light. In both approaches, the calculations result in the following general-type expression for photophoretic force acting on the particle:

$$\vec{F}_{ph} = \varepsilon_m \frac{\pi a^2}{c} \widehat{Q}_{pr}(\varepsilon, \rho, \vec{r})\vec{J}_0 \qquad (1)$$

Here, $|\vec{J}_0|$ is the incident light irradiance (or light intensity) at the beam axis measured in units of energy per unit time per unit area, $\vec{J}_0/J_0$ gives the light propagation direction, c is the velocity of light in vacuum, and $\widehat{Q}_{\rm pr}(\varepsilon,\rho)$ is the dimensionless efficiency factor of the radiation pressure.[3] In a general case of a spatially non-homogeneous light beam, the photophoretic force has both longitudinal and transverse components relative to $\vec{J}_0$. Hence, $\widehat{Q}_{\rm pr}(\varepsilon,\rho,\vec{r})$ is a tensor; its components depend on the particle's coordinate vector $\vec{r}$.

According to Eq. 1, a particular relation of the direct photophoretic force to the optical characteristics of a particle, as well as to the beam parameters, is described by the radiation pressure factor $\widehat{Q}_{\rm pr}(\varepsilon,\rho,\vec{r})$. In general, it can be obtained only numerically. However, the analytical results exist in some limiting cases, namely, for Rayleigh scattering, Rayleigh–Gans scattering, and the case of very large particles.[3,4] In the context of FFF applications, it is instructive to consider a spherical particle of radius a placed in a wide, slightly divergent gaussian light beam under Rayleigh–Gans scattering conditions, i.e., $|\varepsilon-1| \ll 1$, $2\rho|\varepsilon-1| \ll 1$.

A Rayleigh–Gans particle in a gaussian beam

The light intensity distribution in a gaussian beam is as follows:

$$J(r,z) = J_0 \frac{{w_0}^2}{w(z)^2}\exp\left[-\frac{r^2}{w(z)^2}\right]$$
$$w(z)^2 = {w_0}^2\left(1+\frac{z^2}{{R_0}^2}\right) \tag{2}$$

Here, r is the distance from the beam axis, z is the distance along this axis, w_0 is the effective beam radius, $R_0 = 2\pi n_0 {w_0}^2/\lambda_0$ is the diffraction length of the beam, and $\Delta\theta = \lambda/(2\pi n_0 w_0)$ is its angular divergence. Assume that the beam width is comparatively large, $w_0 \gg a$, and divergence is small, $\Delta\theta \ll 1$. In this case, according to Refs.[9,10] the direct photophoretic force $F_{\rm ph}$ for a Rayleigh–Gans particle can be written as the sum of the radiation pressure force $F_{\rm pr}$ and the gradient force F_∇:

$$\vec{F}_{\rm ph} = \vec{F}_{\rm pr} + \vec{F}_\nabla$$
$$\vec{F}_{\rm pr}(r,z) = \varepsilon_{\rm m}\frac{\pi a^2}{c}Q_{\rm pr}(\varepsilon,\rho)\vec{J}(r,z)$$
$$\vec{F}_\nabla(r,z) = \varepsilon_{\rm m}\frac{2\pi a^3}{c}\left(\frac{\varepsilon'-1}{\varepsilon'+2}\right)\vec{\nabla}J(r,z) \tag{3}$$

The analytical expression for $Q_{\rm pr}(\varepsilon,\ \rho)$ is presented in Ref.[10] Calculating $\vec{\nabla}J(r,z)$ using Eq. 2 and regarding $(\varepsilon'+2) \approx 3$ because $|\varepsilon-1| \ll 1$, we obtain the following from Eq. 3.

$$F_{\rm ph||}(r,z) \equiv F_{\rm pr} + F_{\nabla||} \approx \varepsilon_{\rm m}\frac{\lambda^2\rho^2}{4\pi c}\left\{\frac{1}{4}(\varepsilon'-1)^2 I_1(\rho) + \frac{4}{3}\varepsilon''\rho - \frac{2\lambda\rho {w_0}^2 z}{3\pi {R_0}^2 w(z)^2} \times\left[1-\frac{r^2}{w(z)^2}\right](\varepsilon'-1)\right\}J(r,z)$$
$$F_{\rm ph\perp}(r,z) \equiv F_{\nabla\perp} \approx -\varepsilon_{\rm m}\frac{\lambda^3\rho^3 r}{6\pi^2 c w(z)^2}(\varepsilon'-1)J(r,z) \tag{4}$$

The analytical expression for $I_1(\rho)$ obtained in Ref.[9] and its plot are presented in Ref.[10,11] $I_1(\rho)$ is an increasing function, with the small-amplitude oscillations superimposed. For small particles ($\rho \ll 1$), $I_1(\rho) \approx (32/27)\rho^4$, whereas for large ones ($\rho \gg 1$), $I_1(\rho) \approx 2[\ln(4\rho) + 0.5772] - 3$. In the whole range $2 \le \rho \le 20$, the global variation of $I_1(\rho)$ rather closely approximates $2.37\ \ln(\rho)$.

Eq. 4 demonstrates clearly the basic dependences of the photophoretic force, namely, its variation with the size and optical parameters of the particle, with the beam's parameters, and with the particle position relative to the symmetry point $r = 0$, $z = 0$ of the gaussian beam. The longitudinal component $F_{\rm ph||}$ includes the common light pressure (the first two terms in the braces) and the gradient force (the third term in the braces), both dependent on the particle position. The light pressure is always directed away from the light source. Its magnitude varies with $J(r, z)$ according to Eq. 2, mainly due to the variation of the beam radius $w(z)$. The longitudinal component of the gradient force, $F_{\nabla||}$ depends on the particle distance z from the beam's symmetry plane $z = 0$ (linearly for small z). However, the magnitude of $F_{\nabla||}$ is very small for slightly divergent beams due to $w_0 \gg \lambda$. The transverse component, $F_{\rm ph\perp}$, has the gradient term $F_{\nabla\perp}$ only, varying as $rJ(r)$. The magnitude of $F_{\rm ph\perp}$ is substantially greater, $F_{\rm ph\perp}/F_{\nabla||} \sim (R_0/w_0)^2$. The direction of gradient components $F_{\nabla||}$ and $F_{\rm ph\perp}$ depends on the sign of $(\varepsilon'-1)$. If $\varepsilon' > 1$, the gradient force is directed to the symmetry point $r = 0$, $z = 0$, where the light intensity is maximal. If $\varepsilon' < 1$, this force pulls the particle out of the beam.

Consider now variation of light pressure with the size and optical parameters of a particle.[9–11] Fig. 1 illustrates the size dependence of $F_{\rm pr}$ according to Eq. 4. Depending on the value of ratio $|(\varepsilon'-1)|/\varepsilon''$,non-absorbing, "low absorbing," and "highly absorbing" particles can be distinguished conventionally. For non-absorbing particles with $\varepsilon'' = 0$, Eq. 4 gives $F_{\rm pr} \propto (\varepsilon'-1)^2\rho^6 J(r, z)$ practically up to $\rho \sim 1$ (Fig. 1, curves 1, 2). For "low absorbing" particles with $\varepsilon'' \ll (\varepsilon'-1)^2$, it follows from Eq. 4 that $F_{\rm pr} \propto \varepsilon''\rho^3 J(r, z)$ at $\rho \ll 1$, changing to $F_{\rm pr} \propto (\varepsilon'-1)^2\rho^6 J(r, z)$ at higher ρ, and returning to the initial ρ^3 dependence at very large ρ, if the inequality $2\rho|\varepsilon-1| < 1$ still holds at such ρ (Fig. 1, curves 4, 5).

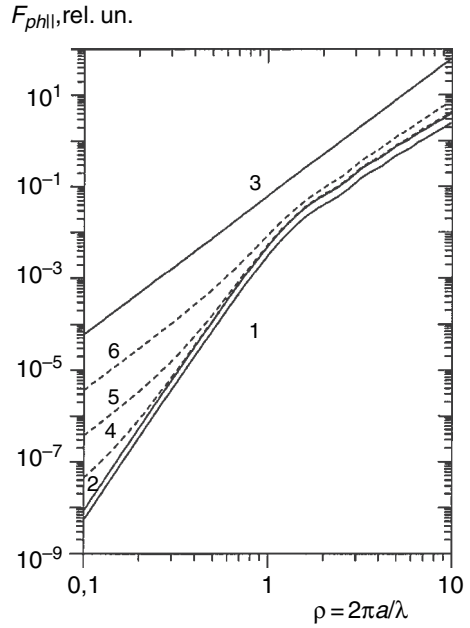

Fig. 1 Size dependence of photophoretic force, calculated for particles of various materials in water ($\varepsilon_m = 1.782$) according to Eq. 4. 1, Glass ($\varepsilon'\varepsilon_m = 2.28$, $\varepsilon'' \approx 0$ at $\lambda_0 = 589$ nm); 2, latex ($\varepsilon'\varepsilon_m = 2.53$, $\varepsilon'' \approx 0$ at $\lambda_0 = 589$ nm); 3, carbon black ($\varepsilon'\varepsilon_m = 2.4$, $\varepsilon'' = 2.38$ at $\lambda_0 = 489$ nm); 4–6, model substances with $\varepsilon'\varepsilon_m = 2.53$ and (4), $\varepsilon'' = 0.001$ (5), 0.01 (6), 0.1.

The transverse gradient force $F_{\nabla\perp}$ may exceed the radiation pressure F_{pr} for all $\rho < 1$ if the beam radius is as small as $w_0 < \lambda/|\varepsilon' - 1|$, while for the longitudinal gradient force $F_{\nabla\|}$, that requires $w_0 < \lambda\Delta\theta/|\varepsilon' - 1|$, i.e., high enough beam focusing. For the "highly absorbing" particles (Fig. 1, curves 3, 6), classified by condition $(\varepsilon' - 1)^2 \ll \varepsilon'' \ll |\varepsilon' - 1|$, the radiation pressure is due to the light absorption, mainly, and $F_{pr} \propto \varepsilon''\rho^3 J(r, z)$. Here, $F_{\nabla\perp} > F_{pr}$ if the beam radius $w_0 < \lambda|\varepsilon' - 1|/4\pi\varepsilon''$, and $F_{\nabla\|} > F_{pr}$ if $w_0 < \lambda\Delta\theta\,|\varepsilon' - 1|/4\pi\varepsilon''$.

In general, the analysis shows the pronounced and diverse character of the dependences of direct photophoretic forces on both the size and optical parameters of a particle. These features form the fundamental basis for FFF applications.

The analysis of the direct photophoretic mechanism presented above for Rayleigh–Gans scattering conditions gives a clear general insight into the problem. The range of quantitative validity of Eq. 4 is, in practice, $\rho < 2$–3. The results for higher ρ are summarized in Ref.[10] In the case of very large particles ($\rho \gg 1$ or $a > \sim 10$ μm for the visible range of light), the direct photophoretic force is better calculated using the geometrical optics approach. It considers the incident light as a multitude of elementary rays reflected and refracted at the particle boundary, including multiple reflections/refractions inside the particle. Each reflection/refraction is accompanied by a change of ray momentum, which results in light pressure on the particle surface at the ray incidence point. The total acting force is obtained by integrating this pressure over the particle surface.[7,8] In the framework of the ray approach, there is no computational difference between the radiation pressure and the gradient force.

Indirect Photophoretic Mechanisms

The indirect mechanisms of photophoresis considered so far are associated with heating due to light absorption. Consequently, the solution of the photothermophoretic problem consists of three consecutive steps: first, determination of the light intensity distribution inside and outside the irradiated particle; second, the calculation of the temperature field within the particle and in the surrounding medium generated by the light absorption; third, the calculation of thermophoretic mobility of a particle in this field using appropriate physicochemical models for the particle, the surrounding medium, and their interface. These three constituent problems are rather independent mutually. Thus, in principle, the results of various independent treatments can be combined to obtain the final solution. It is natural also to consider two complementary extremes: a light-absorbing particle surrounded by transparent liquid, and a transparent particle placed in a channel flow of light-absorbing fluid.

An absorbing particle in a transparent fluid

Here, the aim of the optical problem is the calculation of the light intensity distribution (heat source function) inside the particle, $B(x, z) = E_i^2(x, z)/E_0^2$, $E_i(x, z)$ being the internal electric field strength, E_0 the incident wave amplitude, x the radial distance from the main particle diameter parallel to the light propagation direction, and z the distance from the particle center along this diameter. There are three domains of the particle size parameter ρ where both the internal field patterns and their calculation procedures are essentially different. If $\rho \ll 1$ (Rayleigh scattering), the internal field can be considered as a plane wave, decaying along the main diameter due to absorption. For intermediate $\rho \sim$ 1–10, the particle behaves like a spherical cavity, and the internal field distribution is a complicated system of minima and maxima.[12–14] Here, the $B(x, z)$ distribution depends strongly on a particular combination of particle size parameter and optical constants, and can be found only using the rigorous Mie theory. Qualitatively, the general tendency of $B(x, z)$ transformation with the increase of ρ is the formation of two global maxima ("hot spots" in a case of moderate absorption) at the main particle diameter. This is an early stage of geometrical optics focusing of light rays entered the particle and undergoing the first and the second internal reflections. Another important feature is morphology-dependent resonances occurring in large ($\rho \sim$ 40–50) transparent particles.[13,14] The physical nature of such resonances is the formation of standing light

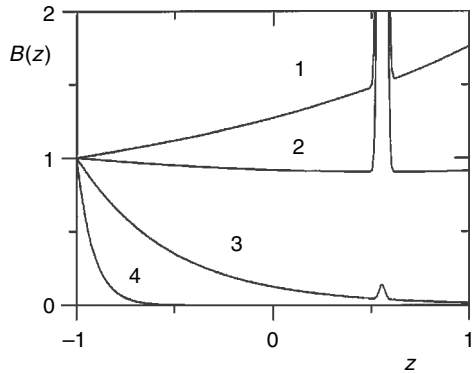

Fig. 2 Light intensity distribution along the main diameter inside a large particle, calculated using the geometrical optics approach and considering the first internal reflection of rays. (1), $\kappa\rho = 0.06$ (2), 0.23 (3), 1.22 (4), 6.1; $n_r = 1.2$, however, the picture is qualitatively valid for $1 < n_r < \sqrt{2}$.

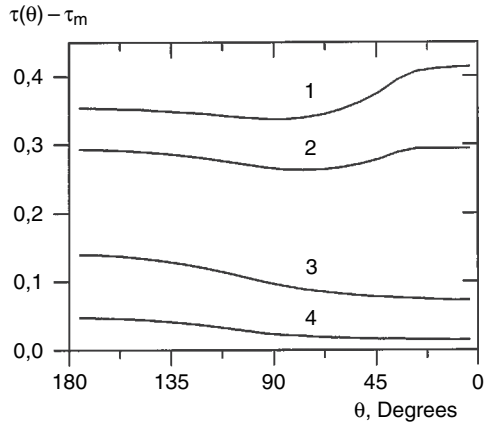

Fig. 3 Distributions of dimensionless surface temperature calculated for a large light-absorbing particle. $k_i = k_e$, $n_r = 1.2$, $\kappa\rho = 0.06$ (1), 0.23 (2), 1.22 (3), 6.1 (4). $\theta = 180°$ corresponds to illuminated pole.

waves near the particle surface from the traveling waves confined by almost total internal reflection. They accumulate the energy of the incident wave near the surface periodically in ρ. In the third domain, $\rho \gg 10$, the particle behaves like a tiny spherical lens, which focuses (if $n_r > 1$) or expands (if $n_r < 1$) the incident radiation. The focusing (expansion) process begins inside the particle due to refraction of the incident rays at the illuminated hemispherical boundary. Here, the $B(x, z)$ distribution is calculated using the geometrical optics approach,[10,15,16] and the general relations are obtained between the field distribution and particle parameters.[10]

Fig. 2 shows the distribution of $B(x, z)$, and hence the heat sources, along the main optical axis of a large particle calculated for various magnitudes of absorption.[10] When the absorption is small, the shadow hemisphere is heated preferentially due to internal focusing of light. With the increase of absorption, the light is attenuated considerably before it reaches the central plane $z = 0$, and so the illuminated hemisphere shows greater heat production. These features are illustrated by the distributions of the surface temperature of a particle, as shown at Fig. 3. They are obtained by solution of the thermal conductivity problem for a spherical particle in a medium, with the density of internal heat sources given by $B(x, z)$. The procedure is described in Refs.[10,16] The dimensionless temperature $\tau(r, \theta)$ is expressed in the units of characteristic temperature $T_0 = 2\kappa\rho n_r a J_0/n_0 k_i$ of particle heating due to light absorption. Here, k_i is the thermal conductivity of the particle material, $T_0\tau_m$ is the ambient temperature far from the particle, r is the distance from the particle center, and θ is the polar angle measured from the shadow pole of the particle. Hence, with the increase of absorption coefficient, not only does the particle temperature increase, but the mean temperature gradient across the particle surface $[T(180°) - T(0°)]/2a$ changes its sign. Fig. 4 illustrates such dependence calculated for a particle irradiated with a 1 W Ar^+-ion laser beam focused onto a spot of $\sim 2 \times 10^{-4}$ m diameter. As Fig. 4 shows, for $\kappa > (3–5) \times 10^{-3}$, the temperature gradient may exceed 5×10^5 K m^{-1}, which is a typical value of thermal FFF.[17]

In general, the analysis presented evidences a real possibility of strong non-homogeneous heating of particles by focused light. It is very important that internal heating by light generate a strong temperature gradient just along the particle surface (Fig. 4), which is rather difficult to achieve with an external temperature gradient because of the high thermal conductivity of the particles. Hence, this feature of heating with light should naturally lead to pronounced thermophoretic effects.

The final step in considering photothermophoresis is the calculation of thermophoretic mobility of a light-absorbing

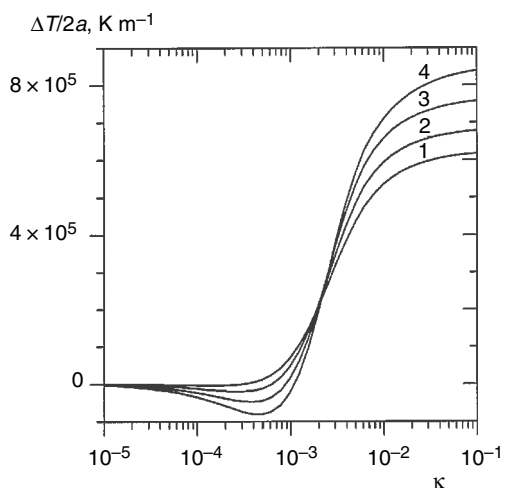

Fig. 4 Dependence of characteristic temperature gradient across the particle surface on the light absorption coefficient. $a = 25 \times 10^{-5}$ m, $\rho = 406$, $J_0 = 10^7$ W m^{-2}, $k_i = k_e = 1$ W m^{-1} K^{-1}, (1), $n_r = 1.1$ (2), 1.2 (3) 1.3 (4), 1.4.

particle in a temperature field generated due to absorption. To keep the connection with normal thermophoresis, it is natural to define the magnitude of photothermophoretic mobility of a particle b_{phth} by the relation[10]

$$u_{\text{phth}} = b_{\text{phth}} \frac{T_0}{a}, \qquad \frac{T_0}{a} = \frac{2\kappa\rho n_{\text{r}}}{n_0 k_{\text{i}}} J_0 \tag{5}$$

Here, T_0/a is the characteristic gradient of the temperature field, u_{ph} is particle velocity, and k_{i} is the thermal conductivity of the particle. The sign of b_{phth} is taken, usually, as positive when the directions of $\vec{u}_{\text{ph}}$ and $\vec{J}_0$ coincide. The calculations of u_{ph}, and hence b_{phth}, can be done on the basis of well-established approaches[18,19] developed for a constant external temperature gradient, with appropriate modifications accounting for a local non-homogeneity.[10] The results are essentially different for liquid droplets in immiscible fluid, and for solid particles in a liquid. In the former case, the motion of a droplet is induced by the gradient of the temperature-dependent surface tension. The whole phenomenon is usually referred to as "thermocapillary motion." It is directed parallel to the temperature gradient, i.e., to the heat source in the case of external heating, because the surface tension diminishes with the increase of temperature. The thermophoretic mobility of a droplet in external constant-gradient temperature field b_{th} is shown to be[20,21]

$$b_{\text{th}} = \frac{2k_{\text{e}}a}{(2\eta_{\text{e}} + 3\eta_{\text{i}})(2k_{\text{e}} + 3k_{\text{i}})} \left|\frac{\text{d}\sigma}{\text{d}T}\right| \tag{6}$$

Here, η_{i} and η_{e} are viscosity coefficients, k_{i} and k_{e} are thermal conductivities of a droplet and a fluid, σ is the surface tension, and T is the absolute temperature. A specific variation of the surface temperature $T_0\tau(r, \theta)$ of an irradiated particle (Fig. 3) formally results in certain weighted averaging of b_{th} over the polar angle θ. The exact solution has not been obtained yet, but arguments similar to those used in the case of a solid particle[10] suggest the following form for the final b_{phth} expression for a fluid droplet:

$$\begin{aligned} b_{\text{phth}} &= b_{\text{th}} g_{\text{an}}(n_{\text{r}}, \kappa\rho) \\ g_{\text{an}}(n_{\text{r}}, \kappa\rho) &= -A \int_0^{\pi} \frac{\text{d}\tau(a,\theta)}{\text{d}\theta} \sin^2\theta \, \text{d}\theta \end{aligned} \tag{7}$$

Here, A is a positive constant of the order of unity, and $\tau(a, \theta)$ is the dimensionless temperature of the particle surface in units of T_0.

The thermophoretic mobility of a solid particle in a liquid is considered in Ref.[10] The result has the form

$$\begin{aligned} b_{\text{phth}} &= b_{\text{th}} g_{\text{an}}(n_{\text{r}}, \kappa\rho) \\ g_{\text{an}}(n_{\text{r}}, \kappa\rho) &= -\frac{1}{4}\left(2 + \frac{k_{\text{i}}}{k_{\text{e}}}\right) \int_0^{\pi} \frac{\text{d}\tau(a,\theta)}{\text{d}\theta} \sin^2\theta \, \text{d}\theta \end{aligned} \tag{8}$$

Here, b_{th} is the conventional thermophoretic mobility of a particle, which corresponds to a constant temperature gradient in the fluid.[10]

The function $g_{\text{an}}(n_{\text{r}}, \kappa\rho)$ in Eqs. 7 and 8 accounts for the anisotropy of particle heating by light. Its behavior due to variation of particle size and optical parameters is considered in Refs.[10,16] For small $\kappa\rho \ll 1$, when the shadow hemisphere is heated preferentially due to internal focusing of light (Fig. 3), the temperature gradient $\text{d}\tau(a, \theta)/\text{d}\theta$ is negative, and so $g_{\text{an}}(n_{\text{r}}, \kappa\rho)$ is positive. With the increase of $\kappa\rho$, the surface temperature gradient changes its sign (Fig. 4), and $g_{\text{an}}(n_{\text{r}}, \kappa\rho)$ goes through zero in the range $\kappa\rho \sim 0.1$–0.3 and then stays positive. According to Eqs. 7 and 8, the product $b_{\text{th}} g_{\text{an}}(n_{\text{r}}, \kappa\rho)$ defines the magnitude and the sign of photothermophoretic velocity of a particle, while the product $g_{\text{an}}(n_{\text{r}}, \kappa\rho)\kappa\rho$ describes the variation of indirect photophoretic force with particle parameters, according to Eq. 5. For liquid droplets $b_{\text{th}} > 0$, according to Eq. 7. Therefore, for small values of $\kappa\rho$, the indirect photophoretic force acting on a droplet is positive, i.e., parallel to the light propagation vector. With the increase of $\kappa\rho$, it goes through zero and becomes negative (antiparallel to the light direction). The situation is just the opposite with solid particles in an electrolyte solution. Here, b_{th} is negative;[10] consequently, the indirect photophoretic force is negative for $\kappa\rho \ll 1$, goes through zero in the range $\kappa\rho \sim 0.1$–0.3, and then stays positive and increases monotonically for $\kappa\rho > 0.5$, saturating at very high $\kappa\rho$ values ~ 40.[10]

Thus, the analysis shows a pronounced dependence of indirect photophoretic force on the size, optical, and thermophysical properties of particles. It is essential that this force is always accompanied by direct light pressure and, for non-homogeneous light beams, by the gradient force. So, the question of their proportion arises. The estimates for large absorbing solid particles ($2a \sim 5 \times 10^{-5}$ m, $\kappa \sim 0.1$) show that the photothermophoretic force could be comparable to the light pressure.[10] What is more, experiments with various emulsions of oil/water or water/oil type containing resonantly absorbing additives to the dispersed phase demonstrated negative phoresis, i.e., the motion of liquid droplets toward the laser source.[21] The velocities measured were as high as 10 cm/s. This means that in the measuring conditions,[21] the indirect photophoretic force exceeded the light pressure substantially. These features of interrelation between direct and indirect photophoretic mechanisms further increase the potentialities of FFF applications, due to the variety of possible combinations.

A transparent particle in a strongly absorbing fluid

This limiting case is physically identical to common thermophoresis, however, with unusual temperature profile in the channel flow due to the specific way of heat production. According to FFF geometry, the light propagation

direction should be perpendicular to the transparent wall of a flat channel of width w_c. If the absorption coefficient of the carrier fluid, κ_f is high enough, $w_c\kappa_f > 1$, the heat source function $B(z)$, and hence the heat production, is localized mainly near the illuminated wall. The exact solution for the transverse temperature profile in the channel can be obtained numerically, using the equation of convective heat transfer with the source function $B(z)$ and the Navier–Stokes equation. In these equations, the temperature dependence of fluid viscosity should be taken into account. Qualitatively, for $w_c\kappa_f > 1$, the temperature profile has a small rise and the maximum near the illuminated wall, followed by a steep decay toward the rear wall. Thus, near the less heated ("cold") wall of a channel, where the particles are accumulated usually in conventional Thermal FFF, this profile is quite similar to the conventional one. However, in the photophoretic arrangement discussed, particles will be pressed additionally against the "cold" wall by the light pressure.

OBSERVATIONS AND USE OF PHOTOPHORETIC EFFECTS

Systematic experimental studies of direct and indirect photophoretic mechanisms of particle and droplet motion in fluids have not been conducted yet. However, some data are available on characteristic velocities and their dependence on the size, refractive index, and absorption coefficient of irradiated objects.[10,11,21–23] For fluid droplets, both negative (in the case of high absorption[21]) and positive (for transparent droplets[22]) photophoresis has been observed. This is in agreement with the theory of indirect photophoresis reviewed above. For nine oil-in-water emulsion systems with droplet size 1–5 μm studied in,[22] the positive photophoretic velocity of a droplet was found to be linearly proportional to the droplet radius, and almost linearly dependent on the refractive index of the droplet substance in the range $n_r n_0 = 1.42$–1.59. Typical velocities were 5–20 μm/s at a CW Nd:YAG ($\lambda_0 = 1064$ nm) laser power of 100–300 mW focused into the beam with $w_0 \sim 20$ μm.

For solid particles, both transparent and absorbing ones, in water, only positive photophoresis has been observed.[10,11,23] The relation between particle velocity u_{phth} (in μm/s) and laser beam intensity J_0 (in 10^7 W m^{-2}) was measured in Ref.[10] using an Ar^+-ion laser ($\lambda_0 = 514.5$ nm) power of 0.1–0.8 W focused into a beam with $w_0 \sim 40$ μm. The result was $u_{phth} \approx 1.1J_0$ for latex particles of 9.87 μm diameter with $m(589\text{ nm}) = 1.191$, and $u_{phth} \approx 4.8J_0$ for carbon black particles of ~ 12 μm diameter with $m(489\text{ nm}) = 1.27 - i \times 0.52$. The observed variation of velocity with particle size and optical constants[10] corresponded qualitatively to Eq. 4. The authors of Ref.[23] measured the size dependence of photophoretic velocity for polystyrene microparticles ($n_r n_0 = 1.59$) in water in the range $2a = 0.78$–2.84 μm, using a CW Nd:YAG ($\lambda_0 = 1064$ nm) laser power of 120 mW focused into a beam with $w_0 \sim 20$ μm. The size variation of $u_{phth} \sim 7$–37 μm/s was practically linear. It was also described rather well by Eq. 1, where the optical pressure efficiency $Q_{pr}(\varepsilon, \rho)$ was calculated using Mie theory.[23]

Therefore, both experimental observations and theoretical estimates of photophoretic effects show that particle velocities in the range 10–100 μm/s (depending on the particle material and the light intensity) can be easily achieved with focused laser radiation. These values are comparable with the flow velocities used in some FFF subtechniques,[2,17] and hence can be exploited for particle separation. Some initial studies have been done already, but, not in the classical FFF arrangement yet. In the experiments described in Ref.[10] the laser beam was focused onto the entrance glass window of a round metallic capillary in the direction of suspension flow inside the capillary. The elution curves for polydisperse carbon black particles were registered in the gravity-sedimentation FFF mode with the laser power switched on and off. Typical curves had a strong initial maximum corresponding to elution of small particle' fractions, and a considerably lower secondary maximum corresponding to large particles. The light action resulted in shape changes of elution curve, which evidenced the acceleration of the large particles along the flow.[10]

In another series of works (see Ref.[24] and the references therein), the laser beam was combined with a coaxial capillary flow in the opposite, i.e., counterflow, manner. That gave the possibility to balance the light pressure acting on the particle with the hydrodynamic drag force, and to nearly (or completely) arrest the particle movement along the axis. Another feature was that the gaussian beam waist ($z = 0$ in Eq. 2) was positioned at the capillary axis far from the entrance window. Due to the axial divergence of the gaussian beam Eq. 2, the light pressure F_{phll} acting on the particle depended on its axial position z (Eq. 4). As a result, the arresting points were different for particles of various sizes and/or optical properties, thus enabling particle separation. The separation process was monitored microscopically using a video system coupled with a CCD camera. A gradual reduction of laser power after achieving the separation permitted the elution of small to large particles. Particle size was calculated from the laser power corresponding to the fraction eluted. The authors called their technique "optical chromatography."[24]

POSSIBLE ARRANGEMENTS OF PHOTOPHORETIC FFF

The results[10,24] evidence that photophoretic effects can be used successfully for particle separation in the longitudinal field-flow geometry. The practical implementation of photophoretic FFF in the canonical transverse field-flow geometry requires high irradiance of a whole strip along a

transparent channel wall, instead of focusing light onto a spot. Estimates show that high enough levels of irradiance can be achieved for this purpose using some known arrangements for the optical pumping of lasers. Another way is to exploit the gradient photophoretic force generated in the carrier fluid by evanescent light waves at the boundary with the transparent channel wall, the latter acting as a waveguide for a pumping laser beam. Regardless of particular arrangement, photophoretic FFF techniques encounter another major problem: The transparency of the channel wall should not degrade substantially with time despite the permanent contact with the suspension flow and high irradiation levels. One of the most promising ways of practical implementation is the use of photophoretic force in combination with some counterbalancing force, primarily the gravitational force. That enables implementation of photophoretic FFF in the particle-focusing mode of operation. This mode is very efficient for particle separation.[1,2,17]

CONCLUSIONS

The use of photophoretic effects in FFF of particles is a very promising direction for the further development of this separation method, offering a broad field of practical applications. As the theoretical overview has demonstrated, these effects are influenced by the remarkable diversity of particles' material properties, including geometrical, optical, and thermophysical characteristics. The use of these effects offers a unique possibility of including the optical properties of particles and molecules in the nomenclature of separation parameters. It promises to exploit the high spectral selectivity, in particular the resonant character, of light pressure exerted upon some solid state and molecular structures, to separate species identical in their density and geometry parameters. Such selectivity can be achieved in several ways: first, by exploiting the intrinsic optical properties of the species, and second, using special preparative procedures, such as selective staining of species, or their chemical and immunological binding to special carrier particles (molecules), having appropriately designed optical characteristics and serving as a kind of photonic tug.

The overview of experimental investigations of photophoresis of particles and droplets in fluids shows that particle velocities large enough for separation purposes can be readily achieved with the modern techniques of light generation. Based on these theoretical and experimental fundamentals, the analysis of some possible arrangements of photophoretic FFF leads to the conclusion that the practical implementation of this novel FFF subtechnique is quite realistic. The implementation of photophoretic FFF may possibly have a general impact on the further development of this separation method. With the present instrumental realizations, FFF is accomplished mainly using macroscopically designed external fields, such as the acceleration field or external temperature gradient and, in this sense, separation channels with "macroscopic" dimensions. The new concepts of optical trapping and micromanipulation of particles,[25] together with modern optical technologies and technologies of channels microfabrication, offer quite novel approaches in FFF, based on microscopically designed optical fields. Such approaches, apart from new separation possibilities, may lead to substantial miniaturization of FFF instruments, and to operation with microscopic samples—in other words, to FFF implementation at the microscopic level.

INTRODUCTION

These two countercurrent chromatography (CCC) techniques are mutually related: pH-peak-focusing CCC is for analytical-scale separations and pH-zone-refining CCC is for preparative-scale separations.

DISCUSSION

The pH-peak-focusing CCC technique was developed from an accidental finding that a thyroxine analog produced an unusually sharp elution peak.[1,2] The cause was found that an acid present in the sample solution affected the retention time of the analyte (Fig. 1A). The mechanism of this peak-sharpening effect is shown in Fig. 1B, where a portion of the separation column contains the organic stationary phase in the upper half and the aqueous mobile phase in the lower half. Because of its non-linear isotherm, the acid in the sample solution forms a sharp trailing border which traps the analyte in the following manner: When the analyte molecule is present in the mobile phase (position 1), it is protonated by low pH and transferred into the organic stationary phase (position 2). As the sharp acid border moves forward, the analyte molecule is exposed to high pH (position 3), deprotonated, and transferred back to the aqueous mobile phase (position 4), where it quickly migrates through the acid border to repeat the above cycle. Consequently, the analyte molecules are trapped with the sharp acid border and eluted as a sharp peak, together with the acid border. A similar effect can be produced by introducing an organic acid in the stationary phase.

Fig. 2A shows the separation of DNP-amino acids using three spacer acids (i.e., acetic acid, propionic acid, and *n*-butyric acid) in the stationary phase.[2] Hydrophilic DNP-glutamic acid is eluted between acetic and propionic acids; DNP-alanine between propionic and *n*-butyric acids, and hydrophobic DNP-leucine after *n*-butyric acid. The method can be effectively applied for the separation and concentration of a small amount of organic ions present in a large volume of the sample solution. However, the most useful application has been found in the preparative-scale separation. When the sample size of the above DNP-amino acids is increased each from 6 mg to 600 mg, a strange chromatogram was produced as shown in Fig. 2B, where all peaks became rectangular in shape, each associated with its own specific pH. The elimination of the spacer acids resulted in the fusion of

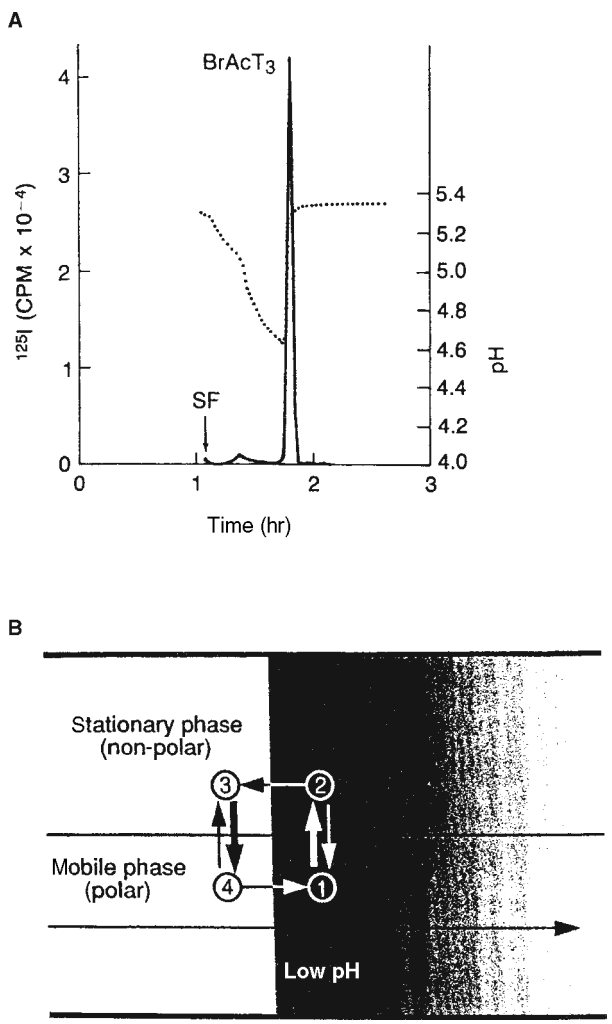

Fig. 1 A, Sharp analyte peak produced by an acid in the sample solution; and B, mechanism of sharp peak formation.

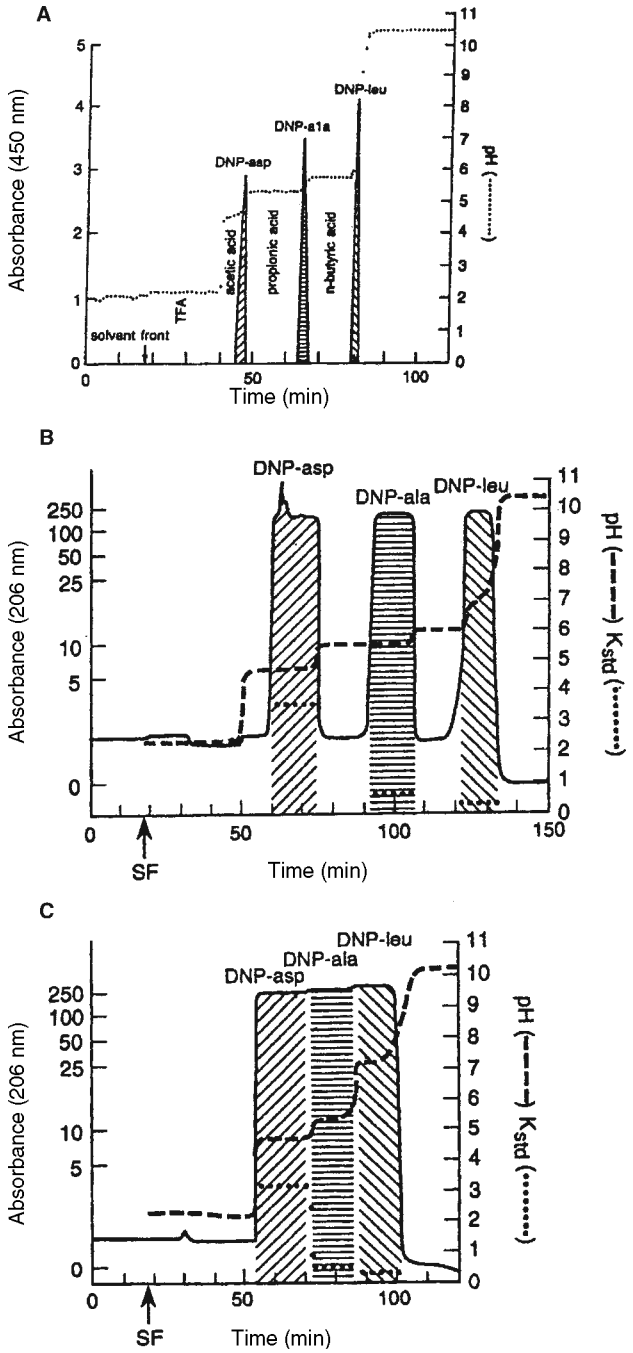

Fig. 2 Separation of three DNP-amino acids showing a transition from pH-peak-focusing CCC to pH-zone-refining CCC. A, Analytical separation by pH-peak-focusing CCC (6 mg each component); B, formation of rectangular peaks by increasing sample size (600 mg each component); and C, elimination of three spacer acids to form fused rectangular peaks.

these peaks while maintaining their own pH, suggesting that the rectangular shape of each peak is well preserved (Fig. 2C).[2–4]

The mechanism of this pH-zone-refining CCC (for the separation of acidic compounds) is illustrated by the following model experiment.[2,4,5] Fig. 3A shows the preparation of the solvent phases. Ether and water are equilibrated in a separatory funnel and separated. A suitable amount (usually 10–40 m*M*) of TFA (trifluoroacetic acid) ("retainer") is added to the lighter organic phase, which is then used as the stationary phase. Ammonia (10–40 m*M*) ("eluter") is added to the heavier aqueous phase, which is used as the mobile phase. The experiment

is initiated by filling the entire column with the stationary phase, followed by injection of a sample solution containing three major acidic analytes and then, the column is eluted with the mobile phase while the apparatus is rotated at a desired g-force. Fig. 3B shows steady-state chemohydrodynamic equilibrium established in the separation column. The retainer acid TFA forms a sharp trailing border which travels through the column at a constant rate substantially lower than that of the mobile phase.

Three analytes S_1, S_2, and S_3 each form a discrete pH zone behind the sharp retainer border in the order of their pK_a's and hydrophobicities. The proton transfer takes place at each zone boundary according to the difference in pH between the neighboring zones, causing solute exchange between the two phases, as indicated by curved arrows. Once the equilibrium is established, all solute zones move at a same rate determined by that of the sharp retainer border. Charged impurities present in each zone are eliminated either forward or backward according to their pK_a's and hydrophobicities, and accumulated at the zone boundaries. Consequently, the analytes are eluted as fused rectangular peaks with minimum pK_a overlap associated with sharp impurity peaks at their boundaries (Fig. 3C).

The relationship between the zone pH (pH_{zone}) and pK_a in the present method is given by the following equation:[2,4,5]

$$\mathrm{pH}_{\mathrm{zone}} = \mathrm{p}K_{\mathrm{a}} + \log\left(\frac{K_D}{K} - 1\right) \quad (1)$$

where K_D and K indicate the distribution coefficient (an indicator for hydrophobicity) and distribution ratio of the analytes, respectively. When the pK_a and K_D of the analyte are known, the zone pH can be computed from the K value.

Table 1 Samples and solvent systems applied to standard pH-zone-refining CCC.

Sample[a]	Solvent system[b] (vol. ratio)	Pair of acid–base reagents[c]	
		Retainer	Eluter
DNP-Amino acids	MBE/AcN/H_2O (4 : 1 : 5)	TFA (200 μl/SS)	NH_3 (0.1%/MP)
Proline (OBzl) (1 g)	MBE/H_2O	TEA (10 m*M*/SP)	HCl (10 m*M*/MP)
Amino acid (OBzl) (0.7 g)	MBE/H_2O	TEA (10 m*M*/SP)	HCl (10 m*M*/MP)
Amino acid (OBzl)) (10 g)	MBE/H_2O	TEA (5 m*M*/SP)	HCl (20 m*M*/MP)
CBZ dipeptides (0.8 g)	MBE/AcN/H_2O (2 : 2 : 3)	TFA (16 m*M*/SP)	NH_3 (5.5 m*M*/MP)
CBZ dipeptides (3 g)	MBE/AcN/H_2O (2 : 2 : 3)	TFA (16 m*M*/SP)	NH_3 (5.5 m*M*/MP)
CBZ tripeptides (0.8 g)	BuOH/MBE/AcN/H_2O (2 : 2 : 1 : 5)	TFA (16 m*M*/SP)	NH_3 (2.7 m*M*/MP)
Dipeptide-(0.3 g)	MBE/AcN/H_2O (2 : 2 : 3)	TEA (5 m*M*/SP)	HCl (5 m*M*/MP)
Indole auxins (1.6 g)	MBE/H_2O	TFA (0.04%/SP)	NH_3 (0.1%/MP)
TCF (0.01–1 g)	DEE/AcN/10 m*M* $AcONH_4$ (4 : 1 : 5)	TFA (200 μl/SS)	MP
Red #3 (0.5 g)	DEE/AcN/10 m*M* $AcONH_4$ (4 : 1 : 5)	TFA (200 μl/SS)	MP
Orange #5 (0.01–5 g)	DEE/AcN/10 m*M* $AcONH_4$ (4 : 1 : 5)	TFA (200 μl/SS)	MP
Orange #10 (0.35 g)	DEE/AcN/10 m*M* $AcONH_4$ (4 : 1 : 5)	TFA (200 μl/SS)	MP
Red #28 (0.1–6 g)	DEE/AcN/10 m*M* $AcONH_4$ (4 : 1 : 5)	TFA (200 μl/SS)	MP
Eosin YS (0.3 g)	DEE/AcN/10 m*M* $AcONH_4$ (4 : 1 : 5)	TFA (200 μl/SS)	MP
Amaryllis alkaloids (3 g)	MBE/H_2O MBEH_2O (DPCCC)	TEA (5 m*M*/SP) HCl (10 m*M*/SP)	HCl (5 m*M*/MP) TEA (10 m*M*/MP)
Vinca alkaloids (0.3 g)	MBE/H_2O (DPCCC)	HCl (5 m*M*/SP)	TEA (5 m*M*/MP)
Structural isomers (15 g)	MBE/AcN/H_2O (4 : 1 : 5)	TFA (0.32%/SP)	NH_3 (0.8%/MP)
Stereoisomers (0.4 g)	Hex/EtOAc/MeOH/H_2O (1 : 1 : 1 : 1)	TFA, octanoic acid	NH_3 (0.025%/MP)
Fish oil (0.5 g)	Hex/EtOAc/H_2O (4 : 1 : 5)	TFA (10 m*M*/SP)	NH_3 (0.1%/MP)
NDGA derivatives (10 g)	MBE/H_2O	TFA (25 m*M*/SP)	NaOH (100 m*M*/MP)

[a]DNP: dinitrophenyl; CBZ: carbobenzoxy; OBzl: benzylesters; bNA: naphthyl amide; TCF: tetrachlorofluorescein; amaryllis alkaloids: crinine, powelline, and crinamidine; vinca alkaloids: vincamine and vincine; structural isomers: 2- and 6-nitro-3-acetamido-4-chlorobenzoic acid; stereoisomers: 4-methoxymethyl-1-methyl-cyclohexane carboxylic acid; fish oil: mixture of docosahexaenoic acid and eicosapentaenoic acid; NDGA: nordihydroguaiaretic acid.

[b]The upper organic phase was used as the stationary phase (SP) and the lower aqueous phase as the mobile phase (MP), except in DPCCC, where the relationship is reversed MBE: methyl-*t*-butyl ether; AcN: acetonitrile; BuOH: *n*-butanol; Hex: hexane; EtOAc: ethyl acetate; MeOH: methanol; $AcONH_4$ ammonium acetate; DEE: diethyl ether; DPCCC: displacement mode.

[c]TFA: trifluoroacetic acid; AcOH: acetic acid; SP: in stationary phase; MP: in mobile phase; SS: in sample solution; TEA: triethylamine.

Table 2 Samples and solvent systems applied to affinity pH-zone-refining CCC.

Sample[a]	Solvent systems[b] (vol. ratio)	Set of key reagents[c]		
		Retainer	Eluter	Ligand
(±)-DNB-leucine (2 g)	MBE/H_2O	TFA (40 m*M*/SP)	NH_3 (20 m*M*/MP)	DPA (40 m*M*/SP)
(±)-DNB-valine (2 g)	MBE/H_2O	TFA (40 m*M*/SP)	NH_3 (20 m*M*/MP)	DPA (40 m*M*/SP)
Catecholamines (3 g)	MBE/H_2O	NH_4OAc (200 m*M*/SP)	HCl (50 m*M*/MP)	DEHPA (20%/SP)
Dipeptides (1 g) (hydrophobic)	MBE/AcN/50 m*M* HCl 4 : 1 : 5 (SP) MBE/AcN/H_2O (4 : 1 : 5) (MP)	TEA (20 m*M*/SP)	HCl (20 m*M*/MP)	DEHPA (10%/SP)
Dipeptides (1 g) (hydrophilic)	MBE/BuOH/AcN/50 m*M* HCl (2 : 2 : 1 : 5) (SP) MBE/BuOH/AcN/H_2O (2 : 2 : 1 : 5) (MP)	TEA (20 m*M*/SP)	HCl (20 m*M*/MP)	DEHPA (30%/SP)
Bacitracins (5 g)	MBE/50 m*M* HCl (1 : 1)(SP) MBE/H_2O (MP)	TEA (40 m*M*/SP)	HCl (20 m*M*/MP)	DEHPA (10%/SP)
FD&C Yellow #6 (2 g)	MBE/AcN/H_2O (2 : 2 : 3)	H_2SO_4 (0.2%/SP)	NH_3 (0.4%/MP)	TDA (5%/SP)

[a]DNB: dinitrobenzoyl.
[b]MBE: methyl *t*-butyl ether; AcN: acetonitrile; BuOH: *n*-butanol.
[c]TFA: trifluoroacetic acid; ammonium acetate; TEA: triethylamine; DPA: *N*-dodecanoyl-L-proline-3,5-dimethylanilide; DEHPA: di-(2-ethylhexyl) phosphoric acid; TDA: tridodecylamine; SP: organic stationary phase; MP: aqueous mobile phase.

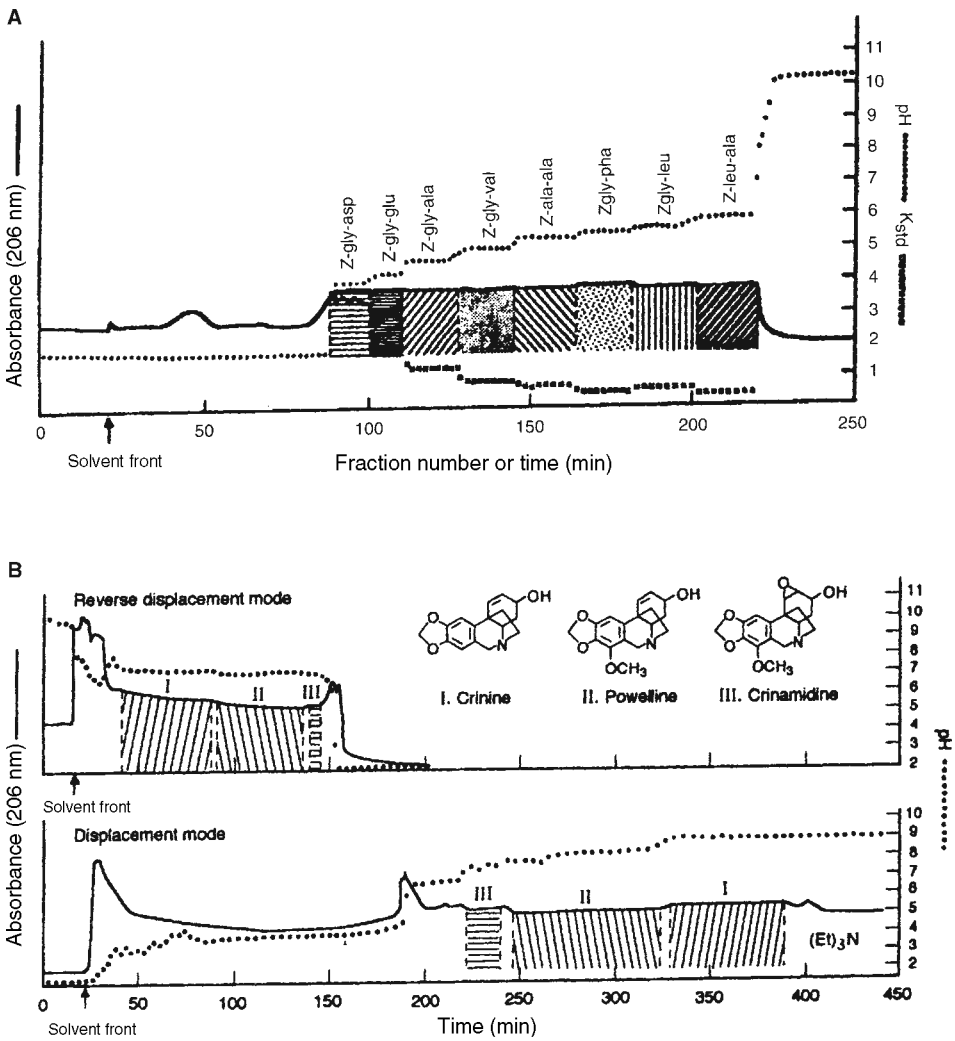

Fig. 4 Some applications of pH-zone-refining CCC. A, Separation of eight CBZ dipeptides (see Table 1);[4,8] B, separation of amaryllis alkaloids using both the lower phase (upper chromatogram) and upper phase (lower chromatogram) as the mobile phase (see Table 1);[4,9] C, separation of catecholamines using a ligand (see Table 2);[4,12] and D, separation of two groups of dipeptide each using an affinity ligand,[4,13] (see Table 2).

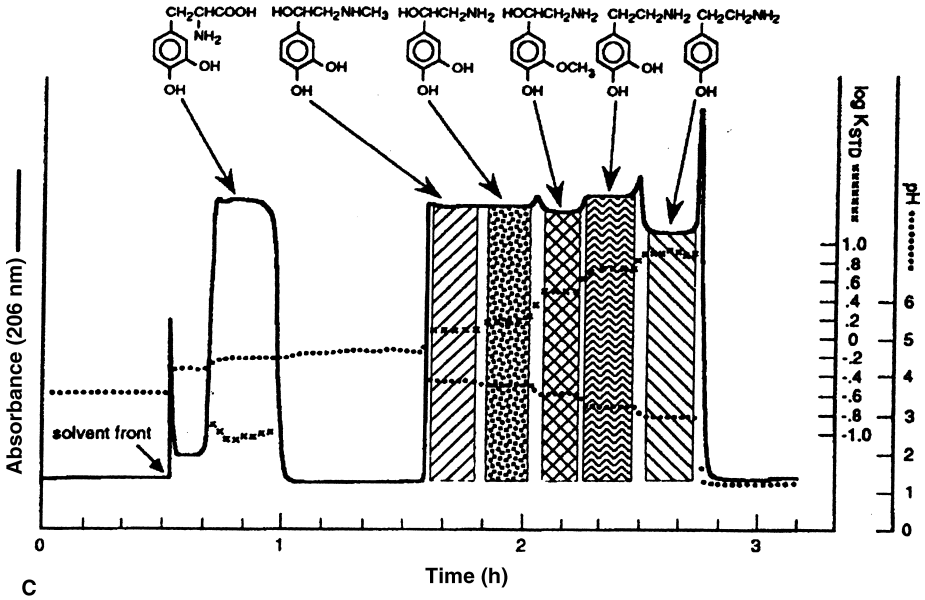

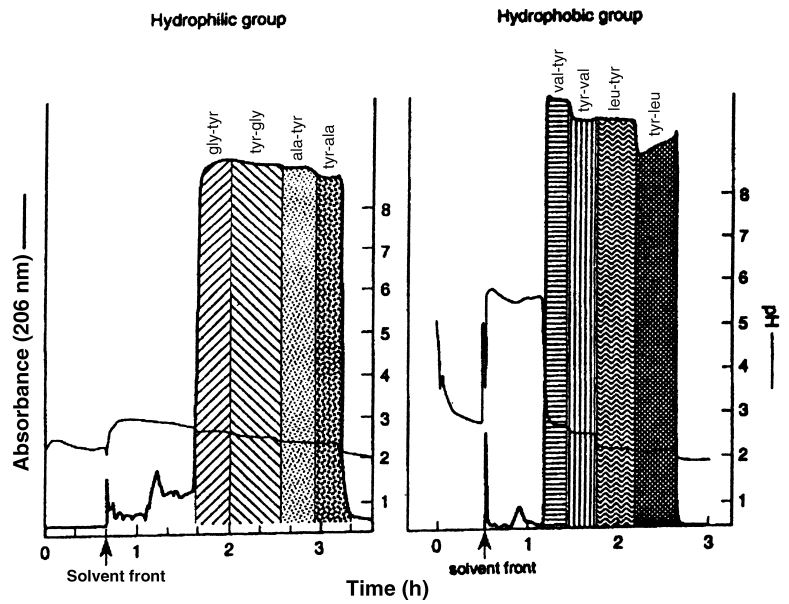

Fig. 4 (*Continued*)

The pH-zone-refining CCC technique shares many unique features with displacement chromatography[6] and has several important advantages over the standard CCC technique such as (a) large sample-loading capacity, (b) highly concentrated fractions, (c) concentration and detection of minor impurities, and (d) monitoring the effluent by pH. The method has been successfully applied to the separation of various organic acids and bases, including the derivatives of amino acids[4,7] and peptides,[8] alkaloids,[4,9] hydroxyxanthene dyes,[3,4,10] anti-human immunodeficiency virus lignans,[11] indole auxins,[4] structural and stereoisomers,[4] and so forth. (Table 1). By being analogous to affinity chromatography, the method allows the use of an affinity ligand dissolved in the liquid stationary phase for separations of special analytes, including highly polar compounds such as catecholamines,[4,12] and sulfonated dyes,[4] enantiomers,[4] and zwitterions such as free peptides,[4,13] (Table 2). Fig. 4A and B illustrates a few examples of these applications.

Planar Chromatography: Automation and Robotics

Wojciech Markowski
Department of Inorganic and Analytical Chemistry, Medical University of Lublin, Lublin, Poland

INTRODUCTION

Automation involves the use of systems (instruments) in which an element of non-human decision has been interpolated. It is defined as the use of combinations of mechanical and instrumental devices to replace, refine, extend, or supplement human actions and faculties in the performance of a given process, in which at least one major operation is controlled, without human intervention, by a feedback system. A feedback system is defined as an instrumental device combining sensing and commanding elements that can modify the performance of a given act.[1]

Three approaches to the automation process can be distinguished, taking into account the criterion of flexibility of the automation device.[2,3] The first, denoted as flexible, is characterized by the possibility of adaptation of the instruments to new and varying demands required from the laboratory; examples of these instruments are robots. The second approach, denoted as semiflexible, involves some restrictions for the tasks executed by the instrument; the tasks are controlled by software via a keyboard. As examples, autosamplers or robots of limited capacity can be cited. In the third approach, the instruments can execute one or two tasks, without the possibility of adapting to new requirements; examples include supercritical fluid extractors and diluters. Automation of an analytical laboratory gives several benefits: better reproducibility, increase in the number of samples that can be analyzed, and freedom of personnel to do more creative tasks (e.g., method development and interpretation of results). Harmful conditions in the laboratory or other workplace can be avoided, and the equipment of the laboratory can be more effectively utilized. Automation improves worker safety and product quality. It provides exact timing and uniform sample handling, which ensure precision and accuracy. It allows for the transfer of methods from one laboratory to another, since the methods are saved on any medium (diskette, CD), and they can be executed by instruments that are identical wherever they are implemented. Before illustration of the possibility of automation in thin-layer chromatography (TLC), let us consider the ideal, fully automated analytical laboratory. In such a laboratory, the sample is processed from its entry into the laboratory hopper, through the many operations until the final report is printed out and the sample is stored for future analysis. To illustrate the feasibility of automation in TLC,[4] the fundamental operations in an analytical laboratory, including the chromatographic process, are given in Fig. 1. The first and basic stage of the process, not limited to TLC, but also occurring in other chromatographic techniques, is the preparation of samples. This is the most tedious, time-consuming, and error-generating process in the whole analytical cycle and can be fully automated, or the automated stations may be complementary to operations or tasks executed individually. For instance, in a station, a volume of liquid is transferred from the first to a second container, an internal standard is added, and the solution is diluted and mixed. Further actions may be executed manually. Another, more advanced solution consists in automated execution of the tasks by the station, and the sample is transferred from one station to the other by a robot or another transport device. In a limited version, only the most critical stages are automated by the use of robots with limited, strictly defined movements; examples are automated processes of solid-phase extraction (SPE), heating, and mixing. The robots are controlled by software and the operator chooses the suitable values of the parameters from given ranges (e.g., autosampler).

At the end of the procedures, with chromatographic methods as the last step, the raw data collected during chromatographic analysis are critically reviewed by specific software designed for this purpose. If the results are not as expected, samples will be available for repeated analysis.

PREPARATION OF PLATES

In most laboratories using planar chromatography, precoated plates are used in everyday practice. Self-coating plates should be considered when special layers are required and when suitable precoated plates are not available on the market. Another reason for the application of the self-coating procedure is the cost of precoated plates following from the very high throughput—number of analyzed samples—and the limited budget of most laboratories. Special layers contain silver nitrate, buffer components, or a mixture of adsorbents. A special case is when the binder used in a commercial precoated plate might interfere with detection. A self-prepared layer of good quality can be obtained by automatic coating. Fig. 2 presents an example of an automatic coating device.[5] The glass plates to be coated are conveyed underneath a hopper filled with the adsorbent suspension. The automatic TLC plate coater is supplied with a fixed gate for preset layers of 300 and 500 μm, an adjustable gate for layer

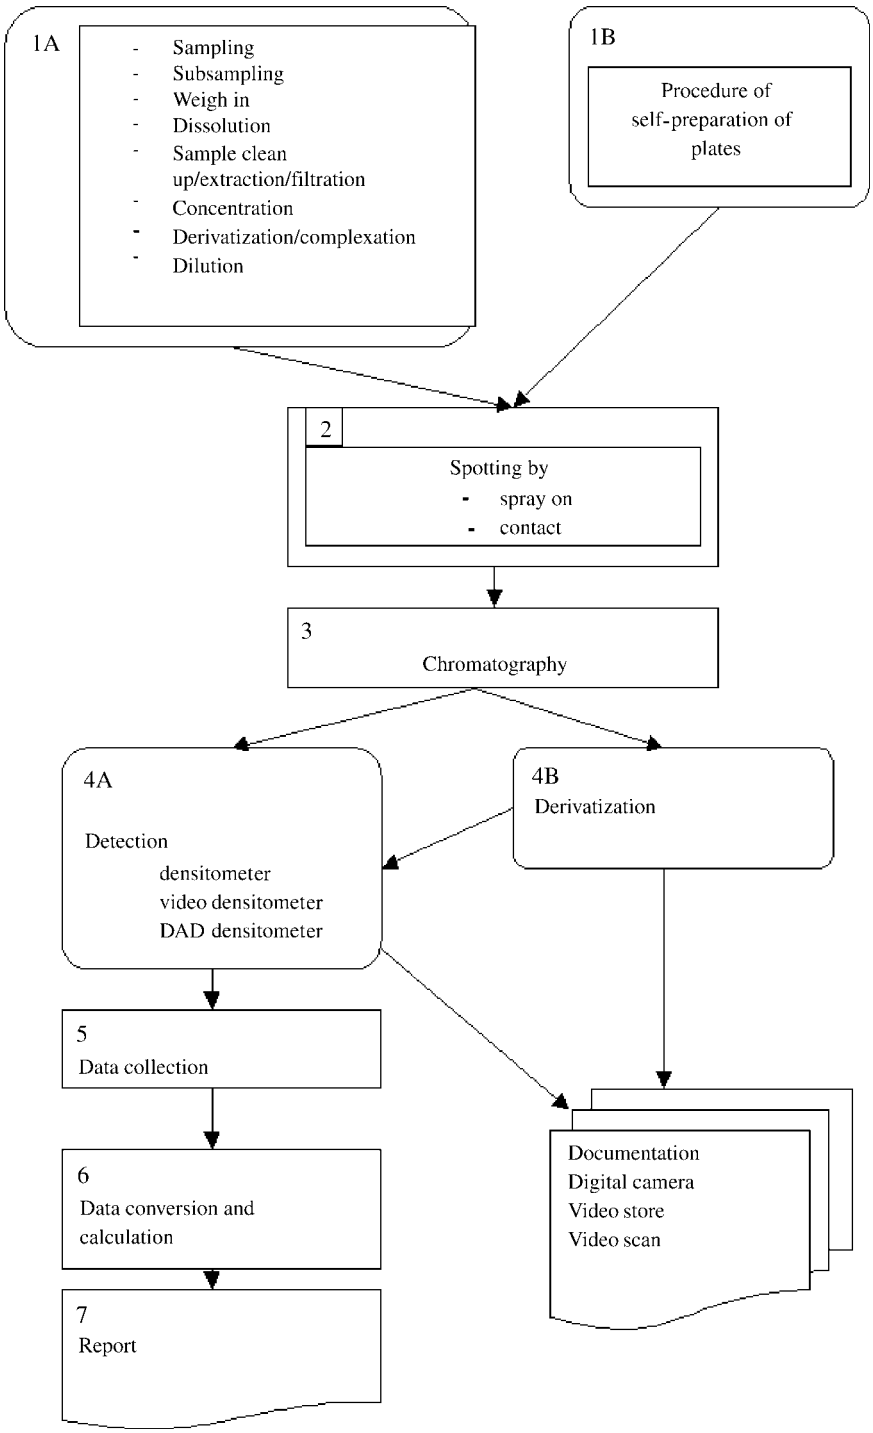

Fig. 1 Possible steps in an analytical laboratory for the process of automation.

thicknesses of 0–2 mm, and a plate holder for eight 20 × 20 cm plates. The plates are moved by a motorized conveying system at a uniform feed rate of 10 cm/sec to ensure a uniform layer.

SAMPLE APPLICATION

The selection of the sample application technique and the device to be used depends on sample volume, number of samples to be deposited, and precision and degree of automation required. During sample application, some minimum requirements must be fulfilled. The application of the sample onto the thin layer is a critical moment, owing to later localization by the scanner (densitometer) and the beginning of the chromatographic process at the moment of contact of the liquid sample with the chromatographic bed. There are two principal ways to deposit a sample onto the plate. They are contact spotting and spray-on application. Therefore, the applicator must

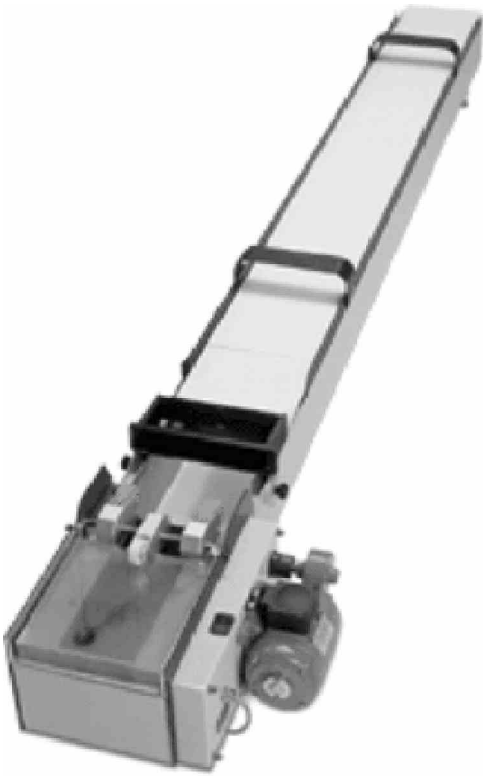

Fig. 2 Camag automatic TLC plate coater.
Source: Courtesy of Camag.[5]

guarantee the exact localization of the sample, particularly for quantitative analyses and uniform compact cross-section of the starting band. Typical values are from 1 to 4 mm for conventional layers (TLC), and for high-precision TLC (HPTLC) the upper limit is 1.5 mm. These demands limit the volume of sample applied to the layer. For TLC, the typical volume is from 0.5 to 5 μl but for HPTLC, typical volumes spotted can be from 0.1 to 1.0 μl. The above limitation is valid when samples are applied as spots. In the case when the spray-on technique (narrow bands) is used, there is possibility of the application of larger volumes. The simplest version of applicator is presented in Fig. 3 (Nanomat 4).[5] It serves for easy application of samples onto TLC and HPTLC plates or sheets, precisely positioned and without damage to the layer. The actual sample dosage is applied with disposable capillaries that are precisely guided by the universal capillary holder. Capillaries are loaded into the holder from dispenser magazines, then filled with sample solution and placed on the applicator head of the device. Capillary volumes of 0.5, 1, 2, and 5 μl are available. The volume precision is $R = \pm 0.25\%$, $CV = \pm 0.6\%$. The next stage with a more complicated degree of automation represents semiautomatic applicators. Semiautomatic applicators presently available have the volume range of 20 nl–10 μl (e.g., TLC—Spotter PS 01 Desaga). The sample is delivered from 0.5, 1.0, and 10 μl syringes. The piston stroke can be set in a continuous

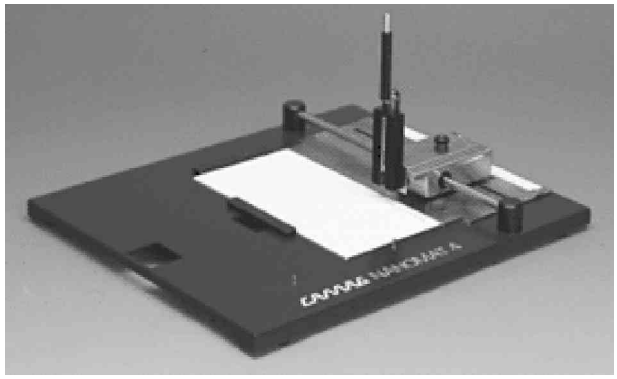

Fig. 3 Simplest automatic applicator (Nanomat 4).
Source: Courtesy of Camag.[5]

manner. To apply the sample, the piston is stopped and the solution is injected from the end of the capillary; the whole volume of the sample is displaced from the capillary. The position of the end of the capillary is adapted to the layer thickness; the spring-relieved syringe guide warrants that the capillary needle only lightly touches the adsorbent layer, avoiding damage to it. The change of position is automatic. The device permits application of spots or streaks at a distance of 5 mm from the edge of the plate; the syringe can be washed twice. The next step in automation is represented by Desaga TLC Applicator AS 30 or Camag Linomat 5. These automatic applicators can be operated in stand-alone mode or under the control of computer software. They are composed of an application module, interface, software, and an IBM PC-AT. The application module dispenses samples from a stainless-steel capillary that is connected to a dosage syringe operated by a stepping motor. Samples can be applied as spots or bands onto TLC plates or sheets up to 20×20 cm. Bandwise sample application uses the spray-on technique; for spotwise application, either contact transfer or spraying may be selected. The samples are contained in vials, which may be sealed with regular septa. The vials are arranged in racks with 16 positions; two racks may be inserted per application program. The application pattern can be selected for normal development, for development from both sides, and for circular and anticircular chromatography. Camag Automatic TLC Sampler 4 (ATS 4) meets all the requirements for fully automatic sample application (Fig. 4).[5] The device allows for both methods of application of samples and additionally for "overspotting," which can be used in prechromatographic derivatization, spiking, etc.

DEVELOPMENT OF THE CHROMATOGRAM

The next important stage is chromatogram development. Automatic developing chambers (Automatic Developing

Fig. 4 Full automatic applicator (ATS 4).
Source: Courtesy of Camag.[5]

Chamber, Camag), DC-MAT (Byron), and TLC-MAT (Desaga) are automatically operating development systems. They increase the reproducibility of the chromatographic results because the development is carried out under controlled conditions. The progress of the solvent front is monitored by a sensors. The development process is terminated as soon as the mobile phase has traveled the programmed distance. Preconditioning, tank or sandwich configuration, solvent migration distance, and the drying conditions are selectable. All relevant parameters are entered via a keypad. The AMD2 system (Automated Multiple Development, Camag)[5] is a fully automated version of multiple development and stepwise technique with a free choice of mobile-phase gradient (Fig. 5). Because the chromatogram is developed repeatedly in the same direction and each individual run is somewhat farther than the last, a focusing of the separated substance zones takes place in the direction of development. The chromatography is reproducible because the mobile phase is removed from the separation chamber after each step and the layer is completely freed from the mobile phase, in vacuum. Then, a fresh mobile phase is introduced for the next run. Provided all parameters, including solvent migration increments, are properly maintained, which is only possible with a fully automatic system, the densitogram of a chromatogram track can be superimposed with a matched-scale diagram of the gradient. Another device for automated development is the chamber constructed by Tyihak and Mincsovics,[6] in which the adsorbent layer is placed between two plates and the mobile phase flows under increased applied pressure. It can be operated in the linear or radial mode. Another automated device is the ultra-micro-rotation chromatograph (UMRC), where the eluent is delivered to the center of a rotating TLC plate.[7] A simple device was constructed by Delvordre, Reynault, and Postaire[8] in which the liquid is pumped out (by vacuum), which causes the flow of the mobile phase and decreases the vapor pressure.

DERIVATIZATION

Derivatization can be carried out both before and after development of the plate. In the latter case, it may be

Fig. 5 Device for automated multiple development (AMD2).
Source: Courtesy of Camag.[5]

Fig. 6 Chromatogram immersion device.
Source: Courtesy of Camag.[5]

applied before detection or after scanning densitometry. Derivatization may be carried out using the device constructed by Kreuzig (Anton Paar KG), where the sprayer moves along a vertical guide while the plate moves horizontally.[9] Another method of derivatization consists in immersion of the plate into a suitable reagent solution. For this purpose, devices available from Camag or Desaga can be used (Camag Chromatogram Immersion Device III, or Desaga TLC Dip-Fix), in which a low-velocity motor causes the immersion and removal of the plate from the reagent solution (Fig. 6).[5]

EVALUATION

Thin-film chromatographic detection, in contrast to other chromatographic techniques, requires stopping of development, drying of the layer, and scanning with an appropriate detector. There are basically two alternatives for the evaluation of thin-layer chromatograms: elution of the separated substance from the layer followed by photometric determination (indirect determination), and in situ evaluation (scanning) directly on the TLC plate. The in situ evaluation of the chromatogram is carried out using a high-resolution chromatogram spectrophotometer (densitometer) (Fig. 7) [5] to scan each chromatogram track, from start to solvent front in the direction of development, by means of a slit. The measurements are carried out either in the visible-light range for colored or fluorescent substances or in the ultraviolet (UV) range for UV-light-absorbing solutes. The wavelength of maximum absorption is generally selected as the measurement wavelength. The scanning process yields absorption or fluorescence scans (peaks), which are also used to assess the quality of chromatographic separation. TLC plates are generally scanned in the reflectance mode (diffuse reflectance), meaning that monochromatic light is directed by a mirror onto the layer surface at 90° and the diffuse reflectance is measured at 45° by means of a detector. The optical pathways used for absorption and fluorescence measurements are identical in commercially available scanners. The only difference is the light source : visible-light measurements are performed using tungsten lamps, whereas high-pressure mercury lamps are used for fluorescence measurements and deuterium lamps for absorption measurements in the UV range. In the case of fluorometric detection, it is also necessary to place a cutoff filter in front of the detector to prevent comeasurement of the short-wavelength excitation radiation. All functions of the scanner are controlled from a personal computer that is linked via an RS232 interface. The scanner transmits all measurement data, in digital form, to the computer for processing with the specific software. The final report is based on the following sequence: raw data acquisition, integration, calibration, and calculation. Integration is performed, post run, from the raw data gathered during scanning (i.e., after all tracks of a chromatogram plate have been measured). Integration results can be influenced by selecting appropriate integration parameters. As all measured raw data remain stored on a disk, reintegration with other parameters is possible at any time. The system automatically defines and corrects the baseline and sets fraction limits. The operator can accept these or override the automatic process by video integration. All steps can be followed on the screen. The option to get a "visual impression" of the chromatogram is one of the inherent advantages of planar chromatography over all other chromatographic techniques. White light is required for imaging colored chromatogram zones; long-wave UV light reveals fluorescing substances. Ultraviolet-absorbing substances can be visualized under short-wave UV light, provided the layer contains a UV indicator. The well-established lighting unit Camag Reprostar (Fig. 8) [5] provides all three types of light. Combined with a modern high-resolution digital camera, it forms an affordable documentation system for planar chromatograms and similar objects.

ROBOTS

Laboratory robots are adapted now for linking all of the steps between extraction and obtaining the analysis results. They are able to automate lengthy, routine, multistep analyses. They require electronic

Fig. 7 Densitometer linked with personal computer.

communication in real time to know the operating time and possible breakdowns exactly. A robotics system allows space saving and easier integration of equipment in the laboratory. Today, a conventional robot has a movable arm. The purpose of the arm is to extend the capabilities of the human arm. There are five basic parts to every robotic arm: controller, arm, drive, end effector, and sensor. There are also five basic functions: base, shoulder, elbow, pitch, and roll. Most modern robots belong to one of four categories: Cartesian, spherical, and cylindrical robots, and revolute arms.[10] In 1989, Prosek et al.[4] developed a planar chromatography robot (Fig. 9). Its arm, supported by a rotating base, executed movements with four degrees of freedom. Its work envelope comprised four tanks: the first for cleaning, the second for development, and the last two for

derivatization by dipping. Also required were a hot plate, a drying system, and a digital camera for evaluation of the derivatized plate. The system was controlled by an Apple IIe computer. The planar chromatography automaton was designed by Delvordre and Postaire with the objective of reducing the number of human movements required for the handling of precoated plates.[10] This device uses a conveyor-belt-like system to sustain all the chromatographic steps along with their own supply of reagents and tools. The procedure comprises six stages. Using this method, qualitative and quantitative data are obtained 50–150 min after starting the procedure.

CONCLUSIONS

Technological progress has enabled semi- and full automation of every stage of the planar chromatography technique. Coupling of automation of the sample preparation process and automation of TLC have strongly enhanced the advantages this separation method. Such improvements will now meet the requirements of the industrial sector (mainly pharmaceutical and plant industries) not only in terms of productivity, effectiveness, reduced cost, good laboratory practice (GLP), and environmental quality, but also on the technical side (validation, flexibility, evolution). Complete chromatographic automation will bring planar chromatography to the same level as other chromatographic methods.

Plant Extracts: TLC Analysis

Gabriela Cimpan
Sirius Analytical Instruments Ltd., East Sussex, U.K.

INTRODUCTION

Thin-layer chromatography (TLC) is a powerful method for separating mixtures of compounds of very different polarity. Plant extracts are usually hydroalcoholic solutions, containing complex mixtures of compounds, many of them being still unidentified. Although plant extracts are widely used in homeopathic medicine for the treatment of different medical conditions the control of these drugs is often performed by qualitative analysis. TLC can provide a chromatographic "fingerprint" of a plant extract used for identification purposes, and usually a photograph is attached to the analysis certificate.[1] The colors of the separated spots and their position relative to standard substances are important characteristics for the plant extract identification. Quantitative analysis is usually performed by spectrophotometry or by chromatographic methods and spectrophotometric detection. Some methods are included in pharmacopeias.

DISCUSSION

TLC Analysis of Plant Extracts in Pharmacopeias

The TLC separation of plant extracts is described in different pharmacopeias,[2–5] and is usually performed on silica layers, and sometimes on silica hydrocarbon (C8, C18) bonded layers. Alumina and other stationary phases are not excluded.

The plant extract samples can be applied directly onto the plate, or a specific class of compounds is extracted in a suitable solvent before TLC. The polarity of the solvent used for extraction should be similar with that of the compound mixture to be separated and analyzed. The samples can be applied onto the plates manually by using calibrated micropipettes or by automated applicators. The samples are applied as spots or bands, and the mobile phase migration distances vary between 8 and 15 cm, depending on the sample complexity and/or the plate size.

Normal presaturated chambers are the most common chambers used for sample development. The mobile phases used for the TLC development are characteristic to different classes of compounds. The classification of medicinal plants takes into account the presence of different classes of compounds, which are separated by using the so-called TLC fingerprint method. The analyzed compounds can be: alkaloids, anthracene derivatives, bitter drugs, cardiac glycoside drugs, coumarin drugs, drugs containing essential oils, flavonoids, saponin drugs, drugs containing triterpenes, etc. For example, mixtures containing chloroform and diethylamine are used for the TLC separation of plant extracts containing alkaloids, and toluene–ethyl acetate for drugs containing essential oils.[1]

After development, the plates are dried in a gentle air stream, at room temperature, and are examined in ultraviolet (UV) or visible light, with or without derivatization, depending on the chemical nature of the separated compounds. The examination in UV light is performed at 254 nm by quenching the thin-layer fluorescence, or at 366 nm when the natural fluorescence of compounds is observed. Several alkaloids (quinine, quinidine, cinchonine, cinchonidine, noscapine, berberine), anthraglycosides, coumarin derivatives (scopoletin, aesculetin), or flavonoids (chlorogenic acid, rutin) have natural fluorescence and can be visualized at 366 nm. The natural fluorescence of compounds can be enhanced by spraying with different reagents, leading to low detection limits. Flavonoids show a yellow-green fluorescence after consecutively spraying with alcoholic solutions of diphenylboryloxyethylamine and polyethylene glycol 4000. The compounds that cannot be derivatized for fluorescence at 366 nm, are sprayed with specific reagents and examined in visible light. The derivatization reactions can take place at room temperature or the TLC plate should be heated on a thermostated plate, at a specific temperature, for approximately 10 min. In both situations, the chromatographic plate should be examined immediately, and eventually photographed. Ninhydrin is a good detecting reagent for amino acids and other biocompounds containing the primary amino group, and the compounds can be observed as blue-violet spots after heating at 100°C. Terpenoids, bitter principles, or saponins can be visualized as red-violet spots by spraying the plate with an acidic solution of anisaldehyde and heating at 100°C.

The pharmacopeias describe the quality control of the plant extracts by the succession of the separated spots obtained after TLC, including the color, order and position on the plate compared to the reference substances. The description should match the TLC separation of the plant extract. The correspondence of the spots is important for the qualitative analysis of the medicinal plant. The reference substances chosen and mentioned in pharmacopeias can also be present in the analyzed plant extract, or can be

used for a comparison with the R_F values of the separated compounds in the plant extract.

Trends in the TLC Analysis of Plant Extracts

The exact chemical composition of a plant extract is not always completely known. Many published papers have tried to identify the compound's structure by coupling chromatography with spectrometric methods. Modern densitometers are able to record the "in-situ" UV/Vis spectra of a separated substance on a TLC plate.[6] TLC can also be coupled with other methods in order to enhance the compound identification, e.g., mass spectrometry (MS) or nuclear magnetic resonance (NMR). There is instrumentation available to record the "in-situ" spectra on the TLC plate, or of the separated substance, removed from the plate together with the layer, and then extracted in a small volume of an adequate solvent.[6,7]

It is well known that the concentration of active substances in medicinal plants can vary widely in different parts of the plant, and it depends on the harvesting time. The quantitative determination of active substances is then very useful for a plant extract analysis. Densitometry is used for the evaluation of the separated substances on a TLC plate. The quantitative determination uses a calibration curve of a reference substance, or a standard method using internal or external standards. Fig. 1 shows the densitograms of two medicinal plant extracts, *Uva ursi* and *Vaccinium vitis-idaea*, both containing arbutin as one of the bioactive substances. The TLC plates are scanned in UV or Vis light, usually in the reflectance mode.

Automated Multiple Development (AMD) has been successfully applied for the separation of compounds from plant extracts. This is a technique using the concentration gradient to separate substances differing widely in polarity. Usually, the gradient starts from a polar composition decreasing in steps to a medium polar mobile phase, and ending with non-polar mixtures of solvents or to a single non-polar solvent. In this way, complex mixtures of compounds from a plant extract can be separated, from very polar to non-polar, between the start and the front solvent line. Usually, the migration distance is 8 cm, and the number of steps can be a maximum of 25 in order to achieve a reasonable development time. The development distances increase as the solvent polarity is decreased. As the total number of compounds in a plant extract is very difficult to estimate, the AMD technique always yields a greater number of separated spots than a monodimensional or a two-dimensional isocratic TLC development.[8] Most of the reference substances used in plant extract analysis have natural origin. As a consequence, they are not always very pure or can lead to decomposition compounds. The separation power of an AMD method can show a greater number of compounds in a reference substance than an isocratic TLC method.

Glycerinic plant extracts have various applications in traditional medicine, but they cannot be analyzed directly by TLC due to the presence of glycerin that should be removed first from the sample.[9] Solid-phase extraction (SPE) is a fast and convenient method for the separation of glycerin. The organic compounds from the analyzed plant extract are retained in the SPE cartridge on a non-polar stationary phase (usually silica-C18); the glycerin and the non-selectively retained compounds are eluted with a polar mobile phase (which can be a diluted solution of methanol in water). The retained compounds are eluted from the cartridge with a stronger mobile phase, usually acidified with a mineral acid, and the obtained solution can be analyzed by TLC directly or after concentration. The SPE recovery is very good, around 100%, and the method is successfully applied for the plant extract cleanup before TLC.

Planar chromatography is widely used in medicinal plant research for the identification of new active

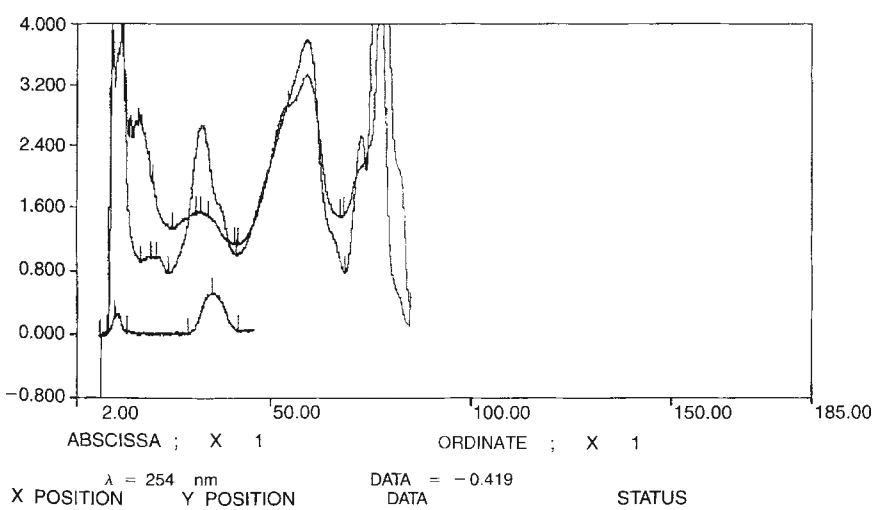

Fig. 1 The densitometry of *Uva ursi* and *Vaccinium vitis-idaea*, two alcoholic plant extracts containing arbutin. Arbutin (reference substance) is the last one, and *Vaccinium vitis-idaea* contains less arbutin than *Uva ursi*; silica gel plate, $\lambda = 254$ nm.

compounds, control of selective isolation procedures of active compounds (extraction, purification, fractionation, etc.), qualitative and quantitative analysis.[10]

Plant Toxins: TLC Analysis

Philippe J. Berny
Toxicology Unit, National Veterinary School of Lyon, Marcy L'Etoile, France

INTRODUCTION

Analysis of plants is a vast and complex field of analytical chemistry. There is a constant need for new compounds or active ingredients for pharmaceutical or other interesting properties. Plant chemistry is such that a wide variety of compounds may be produced within the different organs. Toxins usually represent only a small fraction of the total organic matter of the plant. It is important, however, to be able to analyze and detect those toxins, especially when poisoning cases are suspected. Although vegetal toxins are extremely diverse in nature, a common feature among them is that they are heatunstable. Consequently, standard GC or GC/MS procedures cannot be routinely used to detect them, and the use of LC appears of benefit.

Analysis of plant toxins is required in the following circumstances:

1. When plant poisoning is suspected in human beings or in animals: In this situation, the analyst must be able to separate the plant toxin from its plant matrix and/or from an animal tissue of fluid. The toxin is also diluted as compared with the plant product.
2. For research or development purposes: when a family of plants is under investigation and the presence of a toxin is suspected and not expected (therapeutic use).
3. When a family of toxins is well known, like the pyrrolizidine alkaloids,[1] it is highly interesting to screen suspected plants for their presence when poisoning is suspected in animals and there may be some residues in food, even in animals which did not present any disorder.

In this entry, we will review some examples of these three areas of plant chemistry and see how TLC or high-performance thin-layer chromatography (HPTLC) can fulfill the various requirements.

INVESTIGATION OF SUSPECTED POISONING CASES

Poisoning by plants can occur with various animal species, including human beings. It obviously occurs most frequently in herbivores like cattle or sheep and examples of analytical investigation are more common in these species. Unfortunately, it is generally necessary to screen rumen content for plant toxins and this matrix is extremely rich in organic constituents, including natural pigments. Careful and adapted cleaning steps are necessary. When alkaline or acidic substances are to be determined, pH-based liquid–liquid separation may be used.

Our first example is based on a very severe acute poisoning case with yew trees (*Taxus* sp.). These trees contain a highly toxic group of toxins known as taxins. Cattle or sheep usually do not eat the leaves or branches of yew trees because of their bitter taste. Unfortunately, bitterness tends to disappear when the leaves are dessicated, but toxicity remains and animals may eat enough to become deadly sick. One published example mentioned poisoning in 43 cattle, with 17 dead before any treatment or diagnosis could be attempted.[2] Diagnosis may rely on the epidemiological evidence of poisoning (cut branches) or on necropsy (branches in the rumen), but these elements may not necessary be conclusive and analytical techniques may represent the only way of confirming a tentative diagnosis. The published method for yew tree analysis in cattle relied on the analysis of rumen contents and identification of taxol. This alcohol is specific of the *Taxus* genus, although it may not be the toxic substance, but it is easily obtained from commercial dealers, whereas taxins have to be extracted and purified.

The development of scanners for HPTLC also offers better potential and we have further developed the method of Panter et al.[2] with ultraviolet (UV) scanning (at 238 nm) and quantification prior to derivatization (confirmatory analysis). Eventually, diagnosis relies on the determination of Taxins (primarily taxin B) in the rumen content. As an example, Fig. 1 provides a densitogram of a rumen content with identification of taxin peaks and the solid-phase UV spectrum of this compound in a case of confirmed yew tree poisoning. The same technique could be applied to determine the most toxic part of the plant, the effect of season on the toxin content, and so forth. For example, it was found that the leaves contained about 0.03% taxol, while the stem and twigs contained around 0.001% and 0.0006%, respectively.[2]

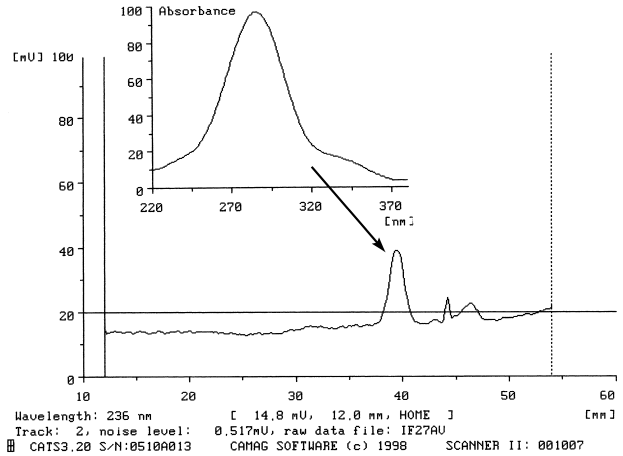

Fig. 1 Rumen content with taxin B (arrow) and its UV spectrum.

IDENTIFICATION OF TOXINS IN PLANT SCREENINGS FOR RESEARCH OR DEVELOPMENT PURPOSES

Some plants are famous for the presence of toxic substances. One major group of toxicants involved is the pyrrolizidine alkaloids. These substances induce severe poisoning manifested by emaciation, anemia, and skin lesions which may develop over months or years and may eventually result in the death of the poisoned animals. These compounds represent both a toxic and economic threat in some areas of the world, (e.g., in the Himalayans).[1] Screening of plants may be highly desirable to prevent these losses. Winter et al.[1] developed screening methods based either on HPLC or on TLC. They used silica gel plates with a mixture of ethylacetate, acetone, ethanol, and ammonia (5/3/1/1) and postchromatographic derivatization with *o*-chloranil and Erlich's reagent. This technique was only qualitative but gave results in accordance with reference HPLC techniques. With these two techniques, the authors analyzed over 350 samples (various plants, plant parts, and locations) to determine the presence and amount of alkaloids.

Another example of the use of TLC in research is given by Ma et al.,[3] who used TLC as a taxonomic tool to classify plants. Their example was based on the lycopodium alkaloids of plants from the Lycopodiacae family. The TLC technique used was qualitative and also relied on postchromatographic derivatization with Dragendorff's reagent.[3] It should be stated that plant toxins are usually recognized by means of qualitative TLC and visualization based on postchromatographic derivatization procedures. Common solutions rely on common reactions of alkaloids, and the use of Dragendorff's reagent is one of these solutions (combined mixture of tartaric acid, bismuth nitrate, and potassium iodide), and vanillin reagent enables the detection of amines and amino acids.

The Chinese pharmacopoea uses a wide range of plants and herbal medicines and Chinese scientists have been publishing methods and techniques for decades, identifying therapeutic substances or toxic ingredients of traditional remedies. The interested reader should refer preferentially to the *Journal of Chinese Herbal Medicine* to find analytical methods.

Identification of new compounds may start with TLC analysis of plant extracts. For instance, Jakupovic et al.[4] isolated and further identified several diterpenes from *Euphorbia segetalis*. Similarly, chamomile essential oil (*Chamomilla reticulata*) was analyzed with 11 different development systems and the authors discussed both the most efficient (separation power) and the ideal way they are to be used to identify an unknown component in such a complex mixture, using the minimum number of TLC systems.[5] This area of work still has to be investigated, considering the wide variety of the vegetal reign and of potential plant toxins.

DETECTION OF RESIDUES IN FOOD

This part is certainly the least developed, to our knowledge. It is important to remember, however, that an animal may ingest a toxic plant and may also survive. If this is the case, and provided this animal or its production are intended for human consumption, one should be able either to analyze tissues and fluids for toxin residues or to monitor fluids (plasma, milk, urine) to determine whether this animal or its productions can be considered safe for human consumption. There are very limited examples of such occurrences. In our laboratory, we analyzed muscular tissues after a confirmed yew tree poisoning case (*Taxus baccata*).

Three animals did not display any significant trouble except for a transient depression, which resolved itself after 12 h. These animals were butchered and muscle samples were analyzed for taxin residues, as they were known to be exposed to it. Our analytical technique (extraction in alkalinized methylene dichloride) followed by TLC development based on a modification of a published technique (9685), showed that the muscle samples contained between 0.012 and 0.015 μg/g taxin (wet weight). The presence of taxin in muscle tissues had never been previously reported in cattle after moderate poisoning. Based on this result, the meat was not considered edible. This example is, simply, to illustrate that residues of plant toxins in food-producing animals should be part of a research or development protocol whenever possible.

CONCLUSIONS

Plant toxins represent one of the most important areas of analytical development and the few techniques related herein

should only be considered as mere examples of the numerous possibilities of TLC in this field. With the development of densitometry and multiple development systems, the separation power of TLC and its quantitative potential are increasing as well. Considering the usual thermal instability of many plant toxins and their high polarity, HPTLC certainly offers one of the most powerful technologies for the detection, identification, and quantification of plant toxins.

Plate Number: Effective

Raymond P.W. Scott
Scientific Detectors Ltd. Banbury, Oxfordshire, U.K.

INTRODUCTION

The concept of the effective plate number was introduced in the late 1950s by Purnell and Bohemen[1] and Desty and Golup.[2] Its introduction arose directly as a result of the development of the capillary column. It was noted that the very high efficiencies were only realized from open-tubular columns for solutes eluted close to the column dead volume (i.e., for solutes eluted at very low k' values). In addition, the high efficiencies in no way reflected the increase in resolving power that would be expected from a packed column with much higher stationary-phase loading.

This poor performance, relative to the high efficiencies produced, results from the high phase ratio inherent with open-tubular columns. The high phase ratio is due to there being very little stationary phase in the capillary column (the film is very thin). The corrected retention volume of a solute is directly proportional to the amount of stationary phase in the column, and solutes, in general, are eluted from a capillary column at relatively low k' values relative to the magnitude of their distribution coefficient.

DISCUSSION

To compensate for what appeared to be very misleading efficiency values, the *effective plate number* was introduced. The effective plate number uses the *corrected retention distance*, as opposed to the *total retention distance* to calculate the efficiency. Thus, the effective plate number is significantly smaller than the true plate number for solutes eluted at low k' values. At high k' values, the two measures of efficiency converge. In this way, the effective plate number appears to more nearly correspond to the column resolving power. The efficiency of the column (n) in number of theoretical plates has been shown to be given by

$$n = 4\frac{y^2}{x^2}$$

where y is the retention distance, and x is the peak width.

Now, the number of "effective plates" (N), by definition, is given by

$$N = 4\frac{(y - y_0)^2}{x^2} \tag{1}$$

where y_0 is the retention distance of an unretained solute (the position of the dead point). Now, from the plate theory,

$$\frac{y}{x} = \frac{n(v_m + Kv_s)}{2\sqrt{n}(v_m + Kv_s)}$$

thus,

$$\frac{y - y_0}{x} = \frac{n(v_m + Kv_s) - nv_m}{2\sqrt{n}(v_m + Kv_s)}$$

By dividing through by v_m and noting that

$$\frac{Kv_s}{v_m} = k'$$

then,

$$\frac{y - y_0}{x} = \frac{\sqrt{n}k'}{2(1 + k')}$$

Consequently,

$$4\left(\frac{y - y_0}{x}\right)^2 = n\left(\frac{k'}{1 + k'}\right)^2 = N \tag{2}$$

Equation 2 describes the relationship between the efficiency of a column in theoretical plates and the efficiency given in "effective plates." It is also seen that the calculation of the number of "effective plates" in a column does not provide an arbitrary measure of the column performance, but is directly related to the number of theoretical plates in the column as defined by the plate theory. It should be noted that as k' becomes large, n and N converge to the same value.

The effective plate number has an interesting relationship to the function for the resolution of a column that was suggested by Giddings.[3] Giddings proposed that the function $k'\Delta k'$ could be a means of defining the resolving power R of a column. He employed this function in an analogous manner to the function used in spectroscopy to define resolution (i.e., $\lambda/\Delta\lambda$, where $\Delta\lambda$ is the minimum wavelength increment that can be differentiated at a wavelength λ). The value taken by Giddings for $\Delta k'$ was the bandwidth at the base of the eluted peak which is equivalent to twice the peak width or 4σ. Thus, from the plate theory,

$$R = \frac{k'}{\Delta k'} = \frac{nkv_s}{4\sqrt{n}(v_m + Kv_s)}$$

Again, dividing through by v_m and noting that

$$\frac{Kv_s}{v_m} = k'$$

then,

$$R = \frac{\sqrt{n}k'}{4(1 + k')} = \frac{\sqrt{N}}{4} \quad (3)$$

It is seen from Eq. 3 that the resolving power of the column, as defined by Giddings, will be directly proportional to the square root of the number of effective plates. As a consequence, R can be used by the chromatographer to directly compare the resolving power of columns of any size or type. However, the value of R will vary with the value of k' for the solute, and so comparison between columns must be made using solutes that have the same k' value.

Plate Theory

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

Originally derived by Martin and Synge[1] and extended by Said,[2] the plate theory provides an equation that describes the elution curve (the chromatogram) of a solute. By differentiating the elution curve equation and equating to zero, an expression for the retention volume of a solute can be obtained. By equating the second differential to zero, an equation for the variance and standard deviation (the peak width) can be obtained, and from these equations, methods for calculating the column efficiency can be derived, together with the numerous equations that describe resolution.

DISCUSSION

The plate theory assumes that the solute is in equilibrium with the mobile and stationary phases. Due to the continuous exchange of solute between the two phases as it progresses down the column, equilibrium between the phases can *never* actually be achieved. To accommodate this non-equilibrium condition, a technique originally introduced in distillation theory is adopted, where the column is considered to be divided into a number of cells or plates. Each cell is allotted a finite length and, thus, the solute spends a finite time in each cell. The size of the cell is such that the solute is considered to have sufficient residence time to achieve equilibrium with the two phases. Thus, the smaller the plate, the more efficient the solute exchange between the two phases and, consequently, the more plates there are in the column. As a result, the number of theoretical plates contained by a column has been termed the *column efficiency*. The *plate theory* shows that the peak width (the dispersion or peak spreading) is inversely proportional to the square root of the efficiency and, thus, the higher the efficiency, the narrower the peak. Consider the equilibrium that is assumed to exist in each plate; then

$$X_s = KX_m \tag{1}$$

where X_m is the concentration of solute in the mobile phase, X_s is the concentration of solute in the stationary phase, and K is the distribution coefficient of the solute between the two phases.

It should be noted that K is defined with reference to the stationary phase (i.e., $K = X_s/X_m$), thus the larger the distribution coefficient, the more the solute is distributed in the stationary phase. Differentiating Eq. 1,

$$dX_s = KdX_m \tag{2}$$

Consider three consecutive plates in a column, the $p-1$, the p, and the $p+1$ plates and let there be a total of n plates in the column. The three plates are depicted in Fig. 1.

Let the volumes of mobile phase and stationary phase in each plate be v_m and v_s, respectively, and the concentrations of solute in the mobile and stationary phase in each plate be $X_{m(p-1)}$, $X_{s(p-1)}$, $X_{m(p)}$, $X_{s(p)}$, $X_{m(p+1)}$, and $X_{s(p+1)}$, respectively. Let a volume of mobile phase, dV, pass from plate $p-1$ into plate p, at the same time, displacing the same volume of mobile phase from plate p to plate $p+1$. In doing so, there will be a change of mass (dm) of solute in plate p that will be equal to the difference in the mass entering plate p from plate $p-1$ and the mass of solute leaving plate p and entering plate $p+1$. A simple mass balance procedure can be applied to plate p. Thus, bearing in mind that mass is the product of concentration and volume, the change of mass of solute in plate p will be

$$dm = (X_{m(p-1)} - X_{m(p)})dV \tag{3}$$

Now, if equilibrium is to be maintained in the plate p, the mass (dm) will distribute itself between the two phases, which will result in a change of solute concentration in the mobile phase of $dX_{m(p)}$ and in the stationary phase of $dX_{s(p)}$. Then,

$$d_m = v_s dX_{s(p)} + v_m dX_{m(p)} \tag{4}$$

Substituting for $dX_{s(p)}$ from Eq. 2,

$$d_m = (v_m + Kv_s)dX_{m(p)} \tag{5}$$

Equating Eqs. 3 and 5 and rearranging,

$$\frac{dX_{m(p)}}{dV} = \frac{X_{m(p-1)} - X_{(p)}}{v_m + Kv_s} \tag{6}$$

The volume flow of the mobile phase will now be measured in units of $v_m + Kv_s$, instead of milliliters. Thus, the new variable (v) can be defined as

$$v = \frac{V}{v_m + Kv_s} \tag{7}$$

The function $v_m + Kv_s$ is termed the "plate volume" and, thus, the flow of mobile phase will be measured in "plate volumes" instead of milliliters. The "plate volume" can be defined as that volume of mobile phase that would

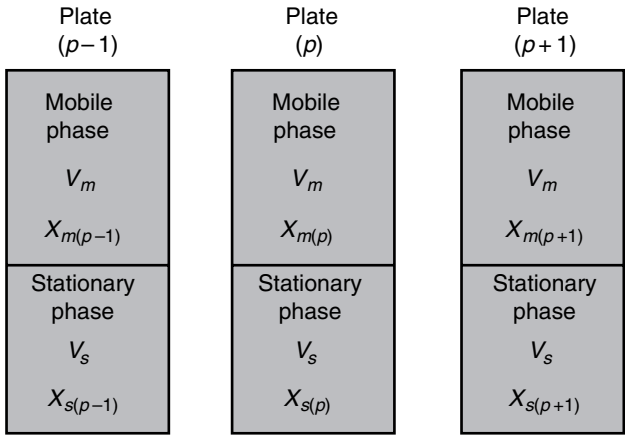

Fig. 1 The three consecutive plates in a column.

contain all the solute that is in the plate at the equilibrium concentration of the solute in the mobile phase.

Differentiating Eq. 7,

$$dv = \frac{dV}{v_m + Kv_s} \tag{8}$$

Substituting for dV from Eq. 8 in Eq. 6,

$$\frac{dX_{m(p)}}{dV} = X_{m(p-1)} - X_{(p)} \tag{9}$$

Eq. 9 is the basic differential equation that describes the rate of change of concentration of solute in the mobile phase in plate p with the volume flow of mobile phase through it. Thus, the integration of Eq. 9 will provide the equation for the elution curve of a solute eluted from any plate in the column. A simple algebraic solution to Eq. 9 is given in Ref.[3] and the resulting elution curve equation for plate n of a column of n plates is shown to be

$$X_{m(n)} = \frac{X_0 e^{-v} v^n}{n!} \tag{10}$$

Eq. 10 is the basic elution curve equation; it is a Poisson function, but when n is large, the function approximates to a normal error function or Gaussian function. In practical chromatography systems, n is always greater than 100 and, thus, all chromatographic peaks will be Gaussian or nearly Gaussian in shape.

THE RETENTION VOLUME OF A SOLUTE

The retention volume of a solute is that volume of mobile phase that passes through the column between the injection point and the peak maximum. It is, therefore, now possible to determine that volume by differentiating Eq. 10 and equating to zero and solving for v. Restating Eq. 10,

$$X_{m(n)} = X_0 \frac{e^{-v} v^n}{n!}$$

$$\frac{dX_{m(n)}}{dv} = X_0 \frac{-e^{-v} v^n + e^{-v} n v^{n-1}}{n!}$$

$$= X_0 \frac{-e^{-v} v^{n-1}}{n!} (n - v)$$

Equating to zero and solving for v,

$$n - v = 0 \quad \text{or} \quad v = n$$

Thus, n plate volumes of mobile phase have passed through the column (remembering that the volume flow is measured in "plate volumes" and not in milliliters). Thus, the volume passed through the column (in ml) will be

$$V_r = n(v_m + Kv_s)$$
$$= nv_m + nKV_s \tag{11}$$

Now, the total volume of mobile phase and stationary phase in the column (V_m and V_s, respectively) will be the volume of mobile phase and stationary phase per plate multiplied by the number of plates (i.e., nv_m and nv_s). Thus,

$$V_r = V_m + KV_s \tag{12}$$

Returning to Eq. 13, it is also possible to derive an equation for the adjusted retention volume, V_r'. Now,

$$V_r{}' = V_r - V_m \tag{13}$$

Thus, from Eqs. 11 and 13,

$$V_r{}' = V_m^+ KV_s - V_m = KV_s \tag{14}$$

For the use of the plate theory to determine peak widths and column efficiency, see *Columns: Resolving Power*, p. 491.

INTRODUCTION

The association of pollutants such as trace metals, nutrients, and toxic organic molecules to colloids is intimately connected to the health of natural waters. Colloids, with their large specific surface area, play a dominant role in the transportation and eventual deposition of these pollutants. Of particular interest is the size speciation data. It is important to know not only the total amount of pollutant present but also where it is distributed. It has been inherently difficult to study pollutant–colloid interactions because of the lack of methods for particle size determination and fractionation as well as the low concentrations of pollutants present in many systems.This entry outlines a new approach using field-flow fractionation (FFF).

DISCUSSION

Field-flow fractionation is a separation and elution technique similar to chromatography.[1] It is based on the application of a field perpendicular to the flow of the axis of a thin (100–500 μm) channel. An externally applied field drives unlike particles to different positions across the thin channel, where they are caught up in different flow velocities. For small particles, typically less than 1 μm, the elution time depends on the particle's interaction with the field and its diffusivity. Separations in this mode, termed the *normal* mode, have the smaller particles eluting ahead of the larger particles. Larger particles tend to stay near the channel wall and move through the channel with the lower flow velocities.An alternate mode, termed the *steric* or *hyperlayer* mode, is for particles greater than about 1 μm. A reversal of the elution order is observed because they necessarily protrude into the higher flow velocities (due to their physical size). Utilizing these two modes, it is possible to probe a mass range spanning 15 orders of magnitude, starting from molecules of 1000 Da molecular weight up to particles 50 μm in diameter.

Further, it is possible to utilize different fields to yield the various FFF subtechniques. The two most common fields are centrifugal and fluid cross-flow, which give rise to the sedimentation and flow FFF subtechniques. Other fields currently in use include thermal, electrical, and magnetic fields. In the normal mode, it is possible to extract physical parameters from retention data. For example, sedimentation FFF using a centrifugal force gives information about the buoyant mass, and flow FFF gives information about the sample's diffusivity or hydrodynamic diameter.

Environmental samples often have a broad size distribution and are often heterogenous in density and chemical composition, and to add to the complexity, natural particles often have an irregular shape.[2] Thus, it is easy to appreciate that FFF with its wide and flexible range of operating parameters is the ideal tool to divide these broad distributions into discrete, roughly monodisperse fractions for subsequent analysis. Sedimentation and flow FFF, in particular, have been used to measure the size distribution of environmental samples. Karaiskakis et al., first demonstrated that it is possible to correlate chemical content (major elements such as Al, Ca, Fe, Si, and S found in bulk minerals) with particle size using sedimentation FFF with energy dispersive X-ray analysis (EDXA).[3] However, due to the low sensitivity and long analysis time of FFF–EDXA,the technique was abandoned for the analysis of pollutants.

Much more sensitive and less time-consuming techniques such as mass spectrometry, atomic emission, and atomic absorption are needed for the analysis of pollutants. Detectors such as graphite furnace–atomic absorption spectrometer (GF–AAS), inductively coupled plasma–mass spectrometer (ICP–MS), or inductively coupled plasma–atomic emission spectrometer (ICP–AES) seem to be ideal candidates for the analysis of trace metals because of their very low detection limits. The high temperatures used avoid the need for tedious digestions in many samples. FFF–gas chromatography–mass spectrometry could perhaps be used in the analysis of particular organic molecules. Another extremely sensitive technique applied in the study of adsorption behavior of pollutants is to add radiolabeled adsorbates (such as $^{33}PO_4^{3-}$, ^{14}C-atrazine, and ^{14}C-glyphosate) to study the distribution of the pollutant as a function of size.

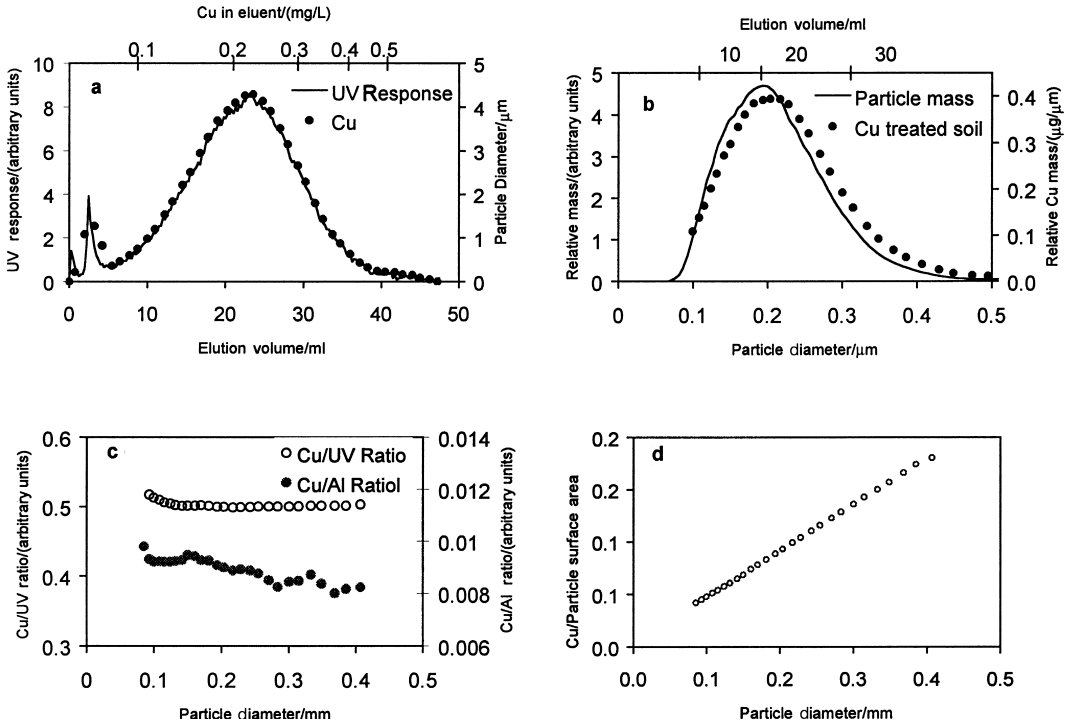

Fig. 1 Graphs showing (a) fractogram and copper concentration in eluent, (b) corresponding size distribution, (c) copper concentration distribution and element ratio distribution of copper in soil sample, and (d) copper per unit surface area distribution.

CONTAMINANT SPECIATION DATA

In recent years, the direct coupling of the FFF channel to GF–AAS, high-resolution ICP–MS, and ICP–AES has been implemented. It has enabled high resolution size-based speciation data for pollutants to be collected. In the first instance, the data acquired by these methods is a fractogram [an instrumental signal, usually but not necessarily from an ultraviolet (UV) detector, representing the mass of eluted sample as a function of the retention time]. The retention time is rigorously but not linearly related to the particle size (i.e., diameter) and may be easily calculated from FFF theory. Suitable algorithms can be used to generate a mass-based size distribution. Fig. 1a and b show an example of recent work conducted in our laboratory demonstrating the distribution of copper in contaminated soils represented as a fractogram and a size distribution.

Element concentrations in the eluent are also recorded if a suitable detector is used. This can be processed in a similar fashion to the UV signal to yield an eluent-based size distribution. If the element detector signal is divided by the mass detector signal, we obtain a quantity which is proportional to the concentration in the sample particles. When this quantity is plotted against particle diameter, we obtain the element concentration distribution for the sample (Fig. 1c). It is often useful to plot the element atomic ratio distributions for elements of interest.This graph is particularly useful for deducing size-based speciation data for trace elements.

The main feature of this experiment is that although the copper content in the soil roughly follows the fractogram (Fig. 1a) and the size distribution (Fig. 1b), the concentration of copper is higher for the smaller particles (Fig. 1c). However, a comparison of the copper/aluminium ratio shows that there is no change across the size distribution for this sample. Fig. 1d shows that the surface-coating density of copper is increasing with particle size, suggesting a denser or thicker coating of copper as the particle size increases.

Contado et al.,[4] coupled sedimentation FFF indirectly to GF–AAS as well as directly to ICP–MS to produce element composition data across the size distribution. The high levels of Cu, Pb, Cr, and Cd found were associated with colloidal particles taken from a river situated in a highly industrialized site. The two methods give comparable results, with online coupling of ICP–MS having a higher resolution, but ICP–AES yields data for some elements (such as potassium and calcium) where ICP–MS produces interferences.

ADSORPTION BEHAVIOR OF POLLUTANTS

The adsorption behavior of colloidal material onto river particles can play a vital role in the transport and fate of pollutants. FFF methods provide a means to evaluate the relative importance of different fractions in adsorption of contaminants in soils and sediments.

One particularly sensitive method employs the adsorption of radioactive material to natural particles.[5] Radiolabeled ^{32}P (as H_3PO_4) and ^{14}C (as glyphosate and atrazine) were adsorbed onto the river water colloid samples for several hours, then separated using sedimentation FFF and specific size fractions were collected. The

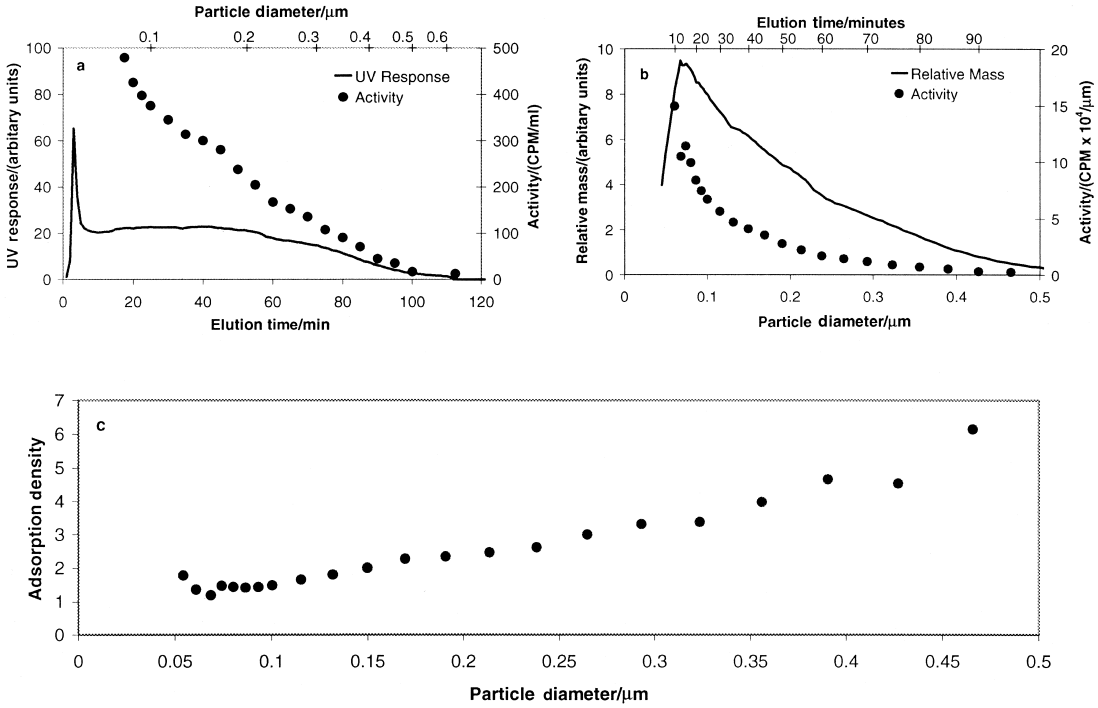

Fig. 2 Graphs showing ^{14}C-glyphosate on river suspended-particulate matter. (a) Particle mass and adsorbate fractograms; (b) particle size distribution and pollutant adsorption distribution; (c) surface-adsorption density distribution.

fractions were subsequently analyzed for their β-activity. These data yield adsorbate (activity)-based fractograms and size distribution (Fig. 2a and b).

Dividing the adsorbate size distribution by the mass size distribution gives an adsorbate concentration (i.e., the amount adsorbed per mass of particles) distribution as outlined previously. Fig. 2b shows that the smaller particles contain the highest pollution content. This is consistent with the concept that smaller particles have a higher specific surface area, but changes in geochemistry of the particle with size could also be involved.

If the adsorption were uniform, we would expect the adsorbate concentration to increase with decreasing size.This effect can be eliminated if the amount of adsorbate per unit area of particles is estimated. Assuming that the particles are spherical and have constant density, it is possible to calculate the relative amount adsorbed per unit surface area as a function of particle diameter. This plot is known as a surface adsorption density distribution (SADD). Fig. 2c shows the SADD plot for ^{14}C-glyphosate adsorbed onto a river suspended-colloid sample. This trend could be attributed to changes of particle size (as these calculations are based on a spherical particle), changes in mineralogy, and coating density across the size range.

The method outlined is also applicable to trace metal data collected by ICP–MS and ICP–AES. Recently, Hassellov et al., demonstrated that it is possible to measure major elements as well as a range of trace metals, including Cs, Cd, Cu, Pb, Zn, and La.[6] Further, they showed that it was possible to obtain speciation data across the size range.

Field-flow fractionation separations combined with other high-sensitivity analytical techniques are capable of yielding more detailed information than has been possible with existing methods. Although, at this stage, there are still many uncertainties to the interpretation of the trends observed, this method is certain to provide further insights into the nature of pollutant–colloid interactions in natural waters.

Abstract
Analysis of chiral pollutants by capillary electrophoresis (CE) is a new trend in separation science. This entry describes separation and identification of chiral xenobiotics by using CE. Attempts have been made to describe types of chiral selectors, applications, optimization of separations, detection strategies, mechanisms of chiral separations, CE *vs* chromatography and sample preparation methods.

INTRODUCTION

More than 60,000 organic compounds are in use by human beings globally and, presumably, some of these are toxic and contaminating our environment. Some pesticides, phenols, plasticizers, and polynuclear aromatic hydrocarbons are chiral toxic pollutants. About 25% of agrochemicals are chiral and are sold as their mixtures. It is well known that one of the two enantiomers of the chiral pollutants/xenobiotics may be more toxic than the other enantiomer.[1] This is an important information to the environmental chemist when performing environmental analysis, as the data of simple analyses do not distinguish which enantiomeric structure of a certain pollutant is present and which is harmful. Biological transformation of the chiral pollutants can be stereoselective; thus uptake, metabolism, and excretion of enantiomers may be very different.[1] Therefore, the enantiomeric composition of the chiral pollutants may be changed in these processes. Metabolites of the chiral pollutants are often chiral. Thus to obtain information on the toxicity and biotransformation of the chiral pollutants, it is essential to develop a suitable method for the analysis of the chiral pollutants. Therefore, diverse groups of people ranging from the regulators to the materials industries, clinicians and nutritional experts, agricultural scientists, and environmentalists are asking data on the ratio of the enantiomers of the chiral pollutants. Chromatographic modalities, e.g., gas chromatography (GC) and high-performance liquid chromatography (HPLC), have been used for the chiral analysis of the pollutants. The high polarity, low vapor pressure, and the need for derivatization of some environmental pollutants make GC method complicated. The inherent limited resolving power, complex procedures involved in the optimization of the chiral resolution of the pollutant, and the use of large amounts of solvents and sample volumes are the main drawbacks of HPLC. Conversely, capillary electrophoresis (CE) is a versatile technique of high speed and sensitivity, which is a major trend in analytical science; some publications on the chiral analysis of pollutants have appeared in recent years. The high efficiency of CE is due to the flat flow profile originated and to a homogeneous partition of the chiral selector in the electrolyte which, in turn, minimizes the mass transfer. Some reviews have appeared in the literature on the chiral analysis of the environmental pollutants by CE.[2–5] These authors have discussed analytical chemistry, environmental occurrence, environmental fate of chiral pollutants, and chiral analyses. Therefore, in this entry, attempts have been made to explain the advancement in the art of enantiomeric resolution of the chiral pollutants by CE.

CHIRAL SELECTORS

As in the case of chromatography, a chiral selector is also required in CE for enantiomeric resolution. Generally, suitable chiral compounds are used in the background electrolyte (BGE) as additives and hence are called chiral selectors or chiral BGE additives. There are only a few publications available that deal with the chiral resolution on a capillary coated with the chiral selector in CE.[6] The analysis of the chiral pollutants discussed in this entry is restricted only to the use of chiral selectors in the BGE. The most commonly used chiral BGE additives are cyclodextrins (CDs), macrocyclic glycopeptide antibiotics, proteins, crown ethers, ligand exchangers, and alkaloids.[7,8] A list of these chiral BGE additives is presented in Table 1.

Table 1 Some of the most commonly used chiral selectors.

Chiral selectors (chiral BGE additives)	Refs.
Cyclodextrins	[8,9]
Macrocyclic glycopeptide antibiotics	[9]
Proteins	[9,10]
Crown ethers	[9,11]
Alkaloids	[9]
Polysaccharides	[9,12]
Calixarines	[9,12]
Imprinted polymers	[13]
Ligand exchangers	[13]

APPLICATIONS

CE has been used for the analysis of chiral pollutants, e.g., pesticides, polynuclear aromatic hydrocarbons, amines, carbonyl compounds, surfactants, dyes, and other toxic compounds. Moreover, CE has also been utilized to separate the structural isomers of various toxic pollutants such as phenols, polyaromatic hydrocarbons, and so on. Sarac, Chankvetadze, and Blaschke[14] resolved the enantiomers of 2-hydrazino-2-methyl-3-(3,4-dihydroxyphenyl)propanoic acid using CD as the BGE additive. The CDs used were native, neutral, and ionic in nature with phosphate buffer as BGE. Welseloh, Wolf, and Konig[15] investigated the CE method for the separation of biphenyls, using a phosphate buffer as BGE with CD as the chiral additive. Miura et al.,[16] used CE for the chiral resolution of seven phenoxy acid herbicides using methylated CDs as the BGE additives. Furthermore, the same group[17] resolved 2-(4-chlorophenoxy) propionic acid (MCPP), 2-(2,4-dichlorophenoxy) propionic acid (DCPP), (2,4-dichlorophenoxy) acetic acid (2,4-D), 2-(4-chlorophenoxy) propionic acid (2,4-CPPA), [(2,4,5-trichlorophenoxy) acetic acid (2,4,5-T)], 2-(3-chlorophenoxy) propionic acid (2,3-CPPA), 2-(2-chlorophenoxy) propionic acid (2,2-CPPA), 2-phenoxypropionic acid (2-PPA), and silvex pesticides using CDs, with negatively charged sulfonyl groups, as the chiral BGE additives. Gomez-Gomar et al.,[18] investigated the simultaneous enantioselective separation of (±)-cizolirtine and its impurities, (±)-*N*-desmethylcizolirtine, (±)-cizolirtine-*N*-oxide, and (±)-5-(hydroxybenzyl)-1-methylpyrazole by CE. Otsuka et al.,[19] described the latest advancement by coupling CE with mass spectrometry (MS); this setup was used for the chiral analysis of phenoxy acid herbicides. The authors also described an electrospray ionization (ESI) method for the CE–MS interface. Generally, non-volatile additives in sample solutions sometimes decrease the MS sensitivity and/or signal intensity. However, heptakis(2,3,6-tri-*O*-methyl)-β-CD (TM-β-CD) was used as a chiral selector; it migrated directly into the ESI interface. By using the negative-ionization mode, along with a methanol–water–formic acid solution as a sheath liquid and nitrogen as a sheath gas, stereoselective resolution and detection of three phenoxy acid herbicide enantiomers were successfully achieved with a 20 m*M* TM-β-CD in a 50 m*M* ammonium acetate buffer (pH 4.6).[20] Zerbinati et al.,[21] resolved the four enantiomers of the herbicides mecoprop and dichlorprop using an ethylcarbonate derivative of β-CD with three substituents per molecules of hydroxypropyl-β-CD and native β-CD. The performances of these chiral selectors have been quantified by means of two-level full-factorial designs and the inclusion constants were calculated from CE migration time data. Klein et al.,[22] reported the analysis of stereoisomers of metolachlor and its two polar metabolites [ethane sulfonic acid (ESA) and oxanilic acid (OXA)] by CE by taking γ-CD. Jarman et al.,[23] separated the enantiomers of metalaxyl, imazaquin, fonofos (dyfonate), ruelene (cruformate), and dichlorprop in CE with CD chiral selectors. Metalaxyl underwent enantioselective transformation; in one soil, the half-life for the *R*-(+)-enantiomer was 17 days while that for the *S*-enantiomer was 69 days. On the contrary, imazaquin and fonofos exhibited non-selective enantiomer loss over the three months of their incubation time. Furthermore, ruelene and dichlorprop were transformed selectively in a variety of soils. As per the authors, CE is supposed to be a simple, efficient, and inexpensive technique to study the transformation of chiral pesticides. Fig. 1 indicates electropherograms of metalaxyl enantiomers in a series of slurry samples revealing the change in enantioselective degradation pattern with the incubation time. Recently, Garrison, Schmitt-Kopplin, and Avants[24] described CE with CD as chiral selectors for the enantiomeric separation. For neutral analytes, sodium dodecyl sulfate was added. The pesticides in soils and sediment samples are extracted with methanol and analyzed by CE. The analysis of the chiral pollutants by CE is summarized in Table 2. To show the nature of the electropherograms, the chiral separation of dichlorprop enantiomers is shown in Fig. 2 with different concentrations of α-CD.[21]

OPTIMIZATION OF SEPARATIONS

The analysis of the chiral pollutants by CE is very sensitive and, hence, is controlled by a number of experimental parameters. The optimization parameters may be categorized into two classes, i.e., the independent and dependent parameters. The independent parameters are under the direct control of the operator. These parameters include the choice of the buffer, pH of the buffer, ionic strength of the buffer, type of chiral selectors, voltage applied, temperature of the capillary, dimension of the capillary, BGE additives, and various other parameters. Conversely, the dependent parameters are those directly affected by the independent parameters and are not under the direct control of the operator. These types of parameters are field strength (V/m), electro-osmotic flow (EOF), Joule heating, BGE viscosity, sample diffusion, sample mobility, sample charge, sample size and shape, sample interaction

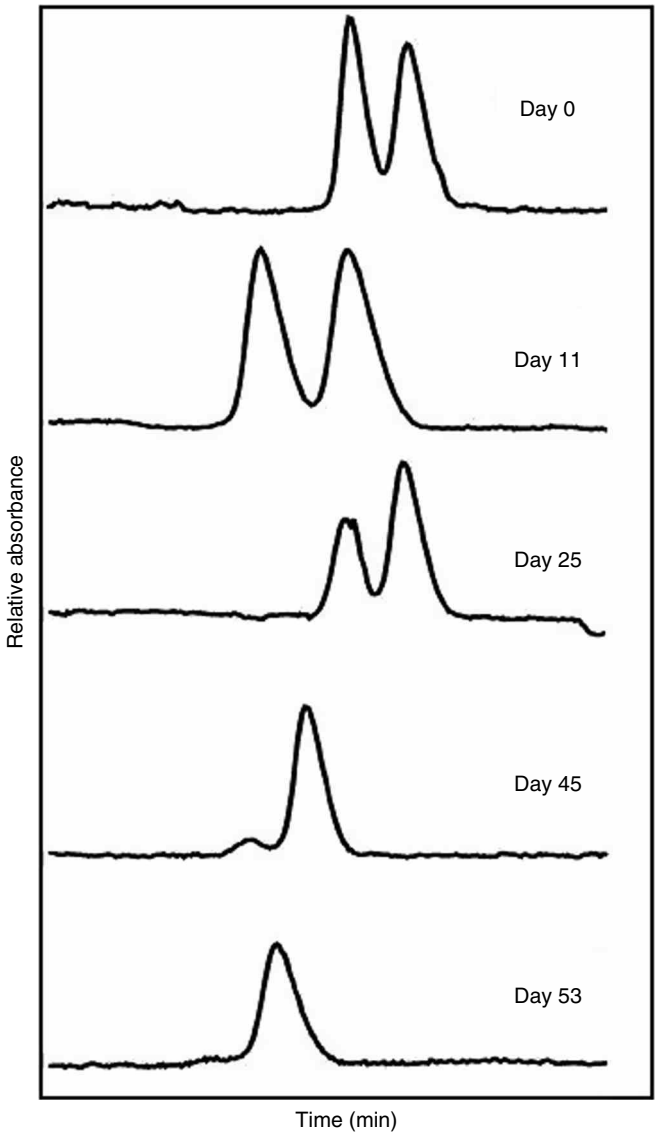

Fig. 1 Electropherograms of metalaxyl enantiomers in a series of slurry samples revealing the change in enantioselective degradation pattern with incubation time. The first peak is *R*-(+)-metalaxyl. Migration times vary with time due to changes in the CE column EOF. **Source:** From Application of capillary electrophoresis to study the enantioselective transformation of five chiral pesticides in aerobic soil slurries, in J. Agric. Food Chem.[23]

with capillary and BGE, molar absorptivity, and so on. Therefore, the optimization of chiral resolution can be controlled by varying all of the parameters mentioned above. For detailed information on the optimization of chiral analysis, one should consult our review.[2] Yi et al.,[27] reported a fast, simple, and sensitive CE method to study the separation and degradation of imazaquin enantiomers in field soils. The separations were optimized by pH, concentration of the buffer electrolyte, type and concentration of the chiral selectors, applied voltage, and temperature. The chiral selector used was hydroxypropyl-β-CD. However, a protocol for the optimization of the chiral analysis is given in Fig. 3.

DETECTION

Normally, the chiral pollutants in the environment occur at low concentrations and, therefore, a sensitive detection method is essential and is required in chiral CE. The most commonly used detectors in the chiral CE are UV, electrochemical, fluorescence, and MS. Mostly, the detection of the chiral resolution of drugs and pharmaceutical in CE has been achieved by a UV mode[16,34] and therefore the detection of the chiral pollutants may be achieved by the same method. The selection of the UV wavelength depends on the type of buffer, chiral selector, and the nature of the environmental pollutants. The concentration and sensitivity of UV detection are restricted insofar as the capillary diameter limits the optical path length. It has been observed that some pollutants, especially organochlorine pesticides, are transparent to UV radiation and, therefore, for such applications, electrochemical detection and MS are the best choices. Some chiral selectors, such as proteins and macrocyclic glycopeptide antibiotics, are UV-absorbing in nature and, hence, the detection of enantiomers becomes poor.

Table 2 Chiral analysis of some pollutants by capillary electrophoresis.

Chiral pollutants	Electrolytes	Detection	Refs.
Fenoprop, mecoprop, and dichloroprop	20 m*M* tributyl-β-CD in 50 m*M* ammonium acetate, pH 4.6	MS	[19]
Dichloroprop and 2-(2,4-dichlorophenoxy) propionic acid	100 m*M* acetic acid-sodium acetate buffer (pH 5.0) containing α-, β-, and γ-CDs	UV 206 nm	[21]
Metalaxyl, imazaquin, fonofos (dyfonate), ruelene (cruformate), and dichlorprop	30 m*M* Na-TB, pH 8.5, buffer with 100 m*M* SDS as the micelle, 15% AcN, and 40 m*M* γ-CD as the chiral selector	—	[23]
2-Phenoxypropionic and, dichloroprop, Fenoxaprop, fluaziprop, haloxyfop, and Diclofop enantiomers	75 m*M* Britton-Robinson buffer with 6 m*M* Vancomycine	—	[26]
Imazqaquin isomer	50 m*M* sodium acetate, 10 m*M* dimethyl-B-CD, pH 4.6	—	[27]
Imazaquin enantiomers	Sodium hydrogen phosphate (50 m*M*) at pH 10.1 containing 30 m*M* hydroxypropyl-β-CD (HP-β–CD)	—	[25]
Phenoxy acid herbicides	200 m*M* sodium phosphate, pH 6.5 with various Concentration of OG	—	[27]
Diclofop	50 m*M* sodium acetate, 10 m*M* trimethyl-β-CD, pH 3.6	—	[27]
Imazamethabenz isomers	50 m*M* sodium acetate, 10 m*M* trimethyl-β-CD, pH 4.6	—	[27]
2-(2-Methyl-4-chlorophenoxy) propionic acid	0.05 *M* lithium acetate containing α-CD	UV 200 nm	[28]
2-(2-Methyl-4-6-dichlorophenoxy) propionic acid	0.05 *M* lithium acetate containing β-CD	UV 200 nm	[28]
2-(2-4-Dichlorophenoxy) propionic acid	0.05 *M* lithium acetate containing Heptakis-(2,6-di-*O*-methyl)-β-CD	UV 200 nm	[28]
2-(2-Methyl chlorophenoxy) propionic acid and 2-(2-4-Dichlorophenoxy) propionic acid	0.05 *M* lithium acetate containing Heptakis-(2,6-di-*O*-methyl)-β-CD	UV 200 nm	[29]
2-(2-Methyl chlorophenoxy) propionic acid	0.05 *M* NaOAc, pH 4.5 with a-CD	UV230 nm	[30]
Phenoxy acid	0.1 *M* phosphate buffer, pH 6 with		
	Vancomycine	—	[31]
	Ristocetin	—	[31,32]
	Teicoplanin	—	[31,33]
	0.1 *M* phosphate and acetate buffer	—	[34]
	containing OM-OG	—	[35]
Phenoxy acid derivatives	β-CD and TM β-CD	—	[31,36]
Silvex	0.4 *M* borate, pH 10 containing *N,N-bis*-(D-gluconamidopropyl)-cholamide (Big CHAP) and deoxycholamide (Deoxy big CHAP)	—	[37]

Only few reports are available in the literature dealing with the limits of the detection for the chiral resolution of environmental pollutants by CE, indicating milligram per liter to microgram per liter as the limits of the detection. Tsunoi et al.,[17] carried out an extensive study on the determination of the limits of the detection for the chiral resolution of herbicides. The authors used a 230 nm wavelength for the detection and the minimum limit of the detection achieved was 4.7×10^{-3} *M* for 2,4-dichlorophenoxy acetic acid. On the contrary, Mechref and El Rassi[36] reported better detection limits for herbicides in the derivatized mode, in comparison to the underivatized mode. For example, the limit of the detection was enhanced by almost 1 order of magnitude from 1×10^{-4} *M* (10 pmol) to 3×10^{-5} *M* (0.36 pmol). In the same study, the authors reported 2.5×10^{-6} *M* and 1×10^{-9} *M* as the limits of the detection for the herbicides by fluorescence and laser-induced fluorescence detectors, respectively. Asami and Imura[38] described the trace enantiomeric compositions of glufosinate (D,L-GLUF); a phosphorus-containing amino acid-type herbicide; in a river. The chiral separation and detection (10^{-9} *M*) were achieved by solid-phase extraction and γ-CD-based CE.

SAMPLE PREPARATION

Many impurities are present in the samples of environmental or biological origin. Therefore, sample pretreatment is a

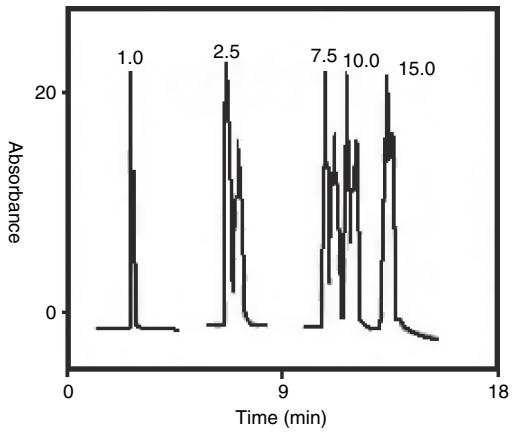

Fig. 2 Electropherograms of dichlorprop herbicide enantiomers with increasing concentrations of α-cyclodextrin (CD).
Source: From New derivatives of cyclodextrins as chiral selectors for the capillary electrophoretic separation of dichlorprop enantiomers, in J. Chromatogr. A.[21]

very important and necessary step for reproducible chiral resolution. Real samples often require the application of simple procedures, such as filtration, extraction, dilution, and so on. A search of the literature conducted and discussed herein (Table 2) indicates that all of the chiral resolution of the environmental pollutants was carried out by CE in laboratory synthesized samples only. Therefore, no report is published on the sample pretreatment before the chiral resolution of the environmental pollutants by CE. Some reviews have been published, however, on the pretreatment and sample preparation methodologies for the achiral analysis of pollutants.[39,40] Therefore, these approaches may be utilized for the preconcentration and sample preparation in the chiral CE of the environmental pollutants. Dabek-Zlotorzynska, Aranda-Rodriguez, and Keppel-Jones[40] reviewed the sample pretreatment methodologies for environmental analysis before CE. Moreover, some reviews have also been published in the

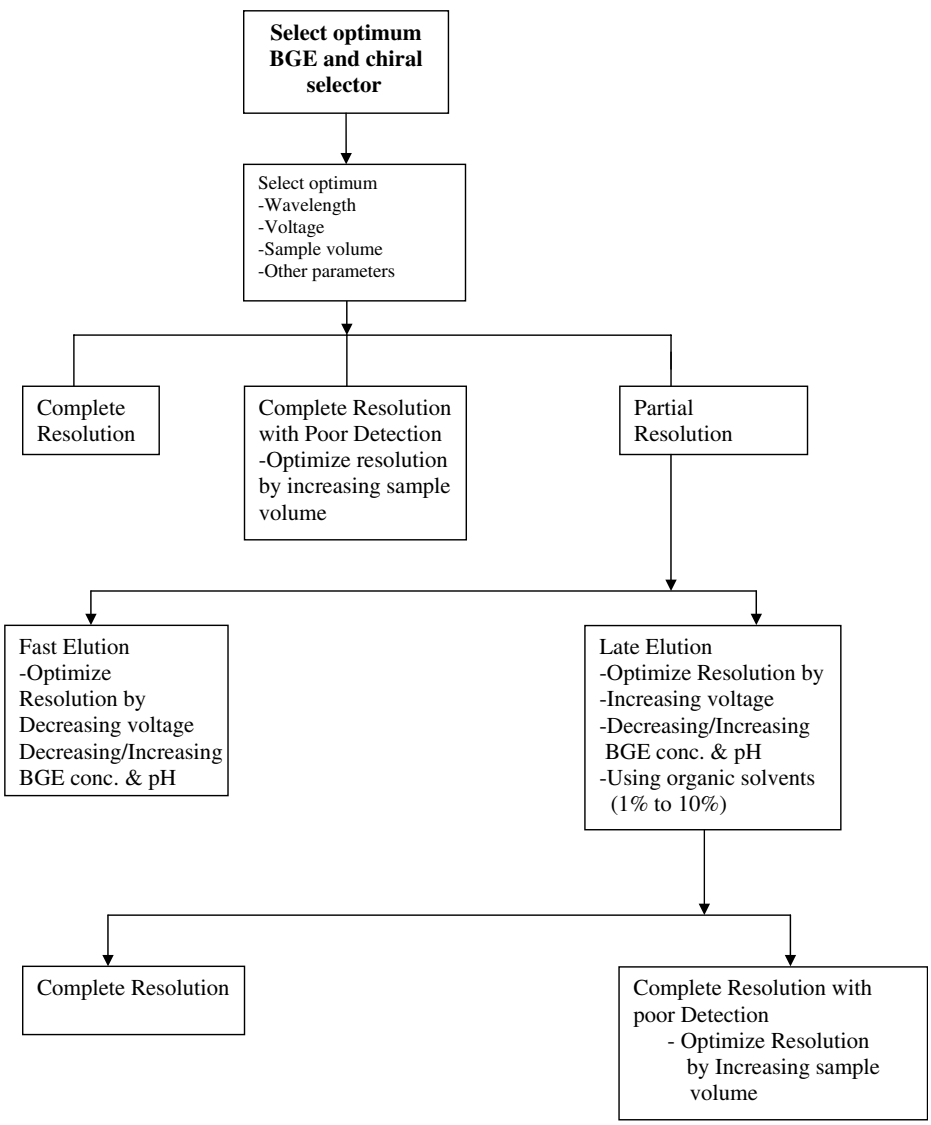

Fig. 3 The protocol for the development and optimization of CE conditions for the chiral separation.

last few years on this issue.[41–43] Whang and Pawliszyn[44] designed an interface that enables the solid-phase microextraction (SPME) fiber hyphenation to CE. They prepared a semi-custom-made polyacrylate fiber to reach the SPME–CE interface. The authors tested the developed interface to analyze phenols in water and, therefore, the same may be used for the chiral resolution of the pollutants.

MECHANISMS OF CHIRAL SEPARATIONS

It is well known that a chiral environment is essential for the enantiomeric resolution of the racemates. In CE, this situation is provided by the chiral compounds used in the BGE and is known as the chiral selector or chiral BGE additive. Basically, the chiral recognition mechanisms in CE are similar to those in chromatography using a chiral mobile-phase additive mode, except that the resolution occurred through different migration velocities of the diastereoisomeric complexes in CE. The chiral resolution occurred through diastereomeric complex formation between the enantiomers of the pollutants and the chiral selector. The formation of the diastereomeric complexes depends on the type and the nature of the chiral selectors used and the nature of the pollutants.

In the case of CDs, the inclusion complexes are formed and the formation of diastereomeric complexes is controlled by a number of interactions, such as π–π complexation, hydrogen bonding, dipole–dipole interaction, ionic bonding, and steric effects. Zerbinati, Trotta, and Giovannoli[20] used ethylcarbonate-β-CD and native α-CD for the chiral resolution of mecoprop and dichlorprop. The authors calculated the performance of these chiral selectors by means of a two-level full factorial design and calculated inclusion constants from the CE migration time data. Furthermore, they have proposed the possible structure of inclusion complexes on the basis of molecular mechanics simulations. Chankvetadze et al.,[45] explained the chiral recognition mechanisms in CD-based CE using UV, nuclear magnetic resonance (NMR), and ESI–MS methods. Furthermore, the authors determined the structures of the diastereomeric complexes by an X-ray crystallographic method.

The macrocylic antibiotics have some similarities and differences with the CDs. Most of the macrocyclic antibiotics contain ionizable groups and, consequently, their charge and possibly their three-dimensional conformation can vary with the pH of BGE. The complex structures of the antibiotics containing different chiral centers, inclusion cavities, aromatic rings, sugar moieties, and several hydrogen donor and acceptor sites are responsible for their surprising chiral selectivities. This allows for an excellent potential to resolve a greater variety of racemates. The possible interactions involved in the formation of diastereomeric complexes are π–π complexation, hydrogen bonding, inclusion complexation, dipole–dipole interactions, steric interactions, and anionic and cationic binding. Similarly, the diastereomeric complexes are formed with other chiral selectors involving specific interactions. In this way, the diastereomeric complexes possessing different physical and chemical properties are separated on the chiral path (achiral phase). The different migration times of these formed diastereomeric complexes depend on their sizes, charges, and their interactions with the capillary wall and, as a result, these complexes are eluted at different time intervals.

CAPILLARY ELECTROPHORESIS VS. CHROMATOGRAPHY

Today, chromatographic modalities are used frequently for the analysis of chiral pollutants. The wide application of HPLC is due to the development of various chiral stationary phases and excellent reproducibility. However, HPLC suffers from certain drawbacks, as the chiral selectors are fixed on the stationary phase and, hence, no variation in the concentrations of the chiral selectors can be carried out. Moreover, a large amount of the costly solvent is consumed to establish the chiral resolution procedure. Additionally, the poor efficiency in HPLC is due to the profile of the laminar flow, mass transfer term, and possible additional interactions of enantiomers with the residual silanol groups of the stationary phase. GC also suffers from certain drawbacks as discussed in the "Introduction."

On the contrary, the chiral resolution in CE is achieved using the chiral selectors in the BGE. The chiral separation in CE is very fast and sensitive, involving the use of inexpensive buffers. In addition, the high efficiency of CE is due to the flat profile created and to a homogeneous partition of the chiral selector in the electrolyte which, in turn, minimizes the mass transfer. Generally, the theoretical plate number in CE is much higher in comparison to chromatography and, thus, a good resolution is achieved in CE. In addition, more than one chiral selector can be used simultaneously for optimizing the chiral analysis. However, reproducibility is the major problem in CE and, therefore, the technique is not popular for the routine chiral analysis. The other drawbacks of CE include the waste of the chiral selector as it is used in the BGE. In addition, chiroptical detectors, such as polarimetric and circular dichroism, cannot be used as detection devices because of the presence of the chiral selector in the BGE. Moreover, some of the well-known chiral selectors may not be soluble in the BGE and, thus, a stationary bed of a chiral selector may allow the transfer of the advantages of a stationary bed inherent in HPLC to electrically driven technique, i.e., CE. This will allow CE to be coupled with the MS, polarimeter, circular dichroism, and UV detectors without any problem. Briefly, at present CE is not a very popular technique as is chromatography for the chiral analysis of pollutants, but it will gain momentum in the near future.

CONCLUSION

Monitoring of the chiral pollutants at trace levels is a very important and demanding field in the present scenario. CE has been gaining importance in the area of chiral analysis of various racemates. This entry indicates only few reports on the chiral resolution of environmental pollutants by CE. Moreover, it has not achieved a respectable place in the routine chiral analysis of these pollutants due to its poor reproducibility and to the limitations of detection. Therefore, many scientists have suggested various modifications to make CE a method of choice. To achieve good reproducibility, the selection of the capillary wall chemistry, pH and ionic strength of the BGE, chiral selectors, detectors, and optimization of BGE have been described and suggested for the analysis of organic and inorganic pollutants.[46–51] In addition, some other aspects should also be addressed so that CE can be used as a routine method in this field. The most important points related to this include the development of new and better chiral selectors, detector devices, and addition of a cooling device in the CE apparatus. In addition, chiral capillaries should be developed and the CE device should be coupled with sample preparation units, MS, polarimetric, and circular dichroism detectors, which may result in good reproducibility and improved limits of detection. The advancement of CE as a chiral analysis technique has not yet been fully explored and research in this direction is currently underway. In summary, the growth of CE is underway and will be developed fully in the near future. Let's hope for the best future and perspectives of CE in chiral pollutants analyses.

Pollutants: HPLC Analysis in Water

Silvia Lacorte
Department of Environmental Chemistry, Chemical and Environmental Research Institute of Barcelona (IIQAB), Barcelona, Spain

INTRODUCTION

Over the last decade, industry, agriculture, and human activities have led to the discharge of organic compounds to surface and coastal waters through accidental spills and waste discharges, resulting in waters of poor chemical quality. Among others, pesticides, detergents, halogenated aromatics, and pharmaceutical compounds are commonly found in continental waters at levels of ng/L or μg/L. To control the sources of pollution and spills, the Environmental Protection Agency of the United States (USEPA), Environment Canada, and the European Union have set quality indices and directives to protect the water quality, human salubrity, and guarantee the utilization of natural resources. Compounds of environmental interest are toxic and persistent organic pollutants, listed in the American and European Priority Lists, and emerging contaminants for which more analytical and toxicological information is needed to evaluate their potential impact upon the environment. Examples of emerging contaminants are surfactants, hormones, plasticizers, and pharmaceuticals. Some of those have endocrine disrupting properties and are capable of mimicking or antagonizing the actions of steroid hormones, affecting the health of humans and wildlife species by disrupting their normal endocrine function. Because pollutants of different physicochemical properties are present at extremely low concentrations in complex environmental water samples, the analytical procedure should provide both a sensitive and selective detection and should generate accurate and precise data.

DISCUSSION

Traditionally, gas chromatography (GC) was the preferred approach for the analysis of pollutants in water, due to the high sensitivity and selectivity of a variety of detectors such as the nitrogen–phosphorus detector (NPD), flame ionization detector (FID), or flame photometric detector (FPD), and the ease of coupling to mass spectrometry (MS). However, high-performance liquid chromatography (HPLC) or LC is the most powerful approach for the determination of polar, non-volatile, and thermolabile compounds (i.e., those which are not GC amenable). The purpose of this entry is to provide an overview of the main liquid chromatography (LC) techniques to determine priority and emerging organic pollutants in water.[1] The recent developments in detection techniques [including diode-array detection (DAD), fluorescence detection (FD), electrochemical detection (ECD)] and especially the ability to connect an LC to MS through atmospheric pressure ionization sources (API) have increased substantially the use of LC for water monitoring. The methods described here are group-specific and cover the analysis of 1) pesticides and herbicides, including metabolites, 2) polycyclic aromatic hydrocarbons (PAHs), 3) phenols, 4) surfactants, 5) phthalates, 6) steroid hormones, and 7) pharmaceutical and personal care products. The objective is to recommend suitable LC techniques for several chemical families and to provide information on quality parameters and applicability in water analysis. Table 1 classifies pollutants commonly found in water and summarizes the main LC techniques used for their determination. All methods proposed achieve limits of detection (LODs) at the low ppb–ppt level and reproducibilities below 10%, provided LC is combined with a preconcentration and adequate cleanup step.

PESTICIDES

Much concern is being given to the determination of pesticides in water due to their toxicological and neurotoxicological properties and to the severe rules imposed by the legislation that aims to protect natural resources. Many pesticides, including their degradation products, are water soluble, non-volatile, and polar, which leads to LC as the preferred approach. LC with ultraviolet (UV) or DAD are especially used for the analysis of organophosphorus and phenoxyacid pesticides, triazines and phenylurea herbicides, and quat herbicides and, in general, for compounds presenting a suitable chromophore (e.g., an aromatic moiety). The main advantages of LC/DAD are related to its robustness and ease of use and to the fact that it offers absorbance spectra that can be used to identify pesticides through spectral comparison. UV/DAD can be combined with acetonitrile–water mixtures because of their absorbance cutoff. Interferences caused by UV-absorbing compounds (e.g., humic and fulvic acids) can affect the quantification of target analytes.

LC/FD is more selective than LC/DAD and provides better sensitivity for naturally fluorescent compounds, as well as for many other compounds, such as glyphosate or

Table 1 Families of priority and emerging pollutants, principal method of analysis proposed, and main sources.

Compound class	Extraction	LC method	Main sources
Pesticides (organophosphorus phenoxyacid, phenylurea, triazines, carbamates, quats)	LLE, SPE, SPME, online SPE	UV, DAD, FD, MS	Agriculture, household, non-agricultural
Polycyclic aromatic hydrocarbons	SPE, LLE	FD, DAD, MS	Natural, anthropogenic
Chlorophenols	SPE, LLE	DAD, ED, CD, MS	Paper, pulp, plastic industry
Surfactants (alcohol ethoxylates, linear alkylbenzene sulfonates, nonylphenol ethoxylates)	LLE, SPE, online SPE, SPME	DAD, MS, MS/MS	Leather, textile, metal, food industry, household
Phthalates	LLE, SPE, SPME	DAD, MS	Plasticizers, additives
Steroid sex hormones (estrogens, progestrogens)	SPE, Online SPE	UV, DAD, MS/MS	Natural and synthetic sex hormones
Pharmaceuticals and personal care products	LLE, SPE	DAD, FD, MS, MS/MS, IT/MS, TOF/MS	Household, veterinary, pharmaceutical industry, not prescription drugs, diagnostic agents, fragrances
Antibiotics (tetracyclines, macrolide, penicillins, quinolones)			
Analgetics/antiinflammatory drugs (ibuprofen, diclofenac)			
Lipid regulators (fenofibric acid, gemfibrozil, clofibric acid)			
Antiseptic (triclosan) Musk compounds (galaxolide, tonalide, muskketone; muskxylene)			

SPE, solid-phase extraction; LLE, liquid–liquid extraction; SPME, solid-phase microextraction; DAD, diode-array detector; CD, coulometric detector; ED, electrochemical detector; FD, fluorescence detector; MS, mass spectrometry; IT, ion trap; TOF, time-of-flight.

carbamates, which are precolumn or postcolumn derivatized to yield fluorescent reaction products. An alternative to LC/FD for the analysis of aryl *N*-methylcarbamates and *N*-phenylcarbamates is LC with ED because these compounds can be easily oxidized at 1.1 V. However, complex water samples, such as wastewater or industrial effluents, might 1) increase the detection limits, 2) inhibit analyte detectability, or 3) interfere or coelute with the analytes.

Matrix effects can be avoided by using MS. Mass spectrometry is characterized by being highly selective and sensitive and, in addition, it offers spectral information that permits the unequivocal identification of target compounds. LC/MS with atmospheric pressure chemical ionization (APCI) and electrospray ionization (ESI) interfaces have been applied to monitor pesticides and produce chemical ionization mass spectra with molecular information, depending on set-up conditions. Limits of detection at ng/L and the linear response range over two orders of magnitude have been reported.[2]

POLYCYCLIC AROMATIC HYDROCARBONS

Polycyclic aromatic hydrocarbons are considered as priority pollutants due to their mutagenic and carcinogenic properties. They are introduced in the environment from natural sources [e.g., incomplete combustion of organic matter from natural processes (volcanic eruptions, fires)] or anthropogenic, such as burning of fossil fuels, waste incineration, and traffic. The concentration of PAHs in water is generally low due to the hydrophobicity of some compounds, and hence, very sensitive methods are needed to detect ng/L levels. GC with FID or MS are commonly used for their determination. However, because PAHs have natural fluorescent properties, LC/FD is advantageous over GC/MS because of its ability to measure the different PAH isomers, and comparable detection limits are obtained. LC/DAD and LC/APCI/MS can also be applied and have the advantage that hydroxylated PAH transformation products can be identified.[3]

PHENOLIC COMPOUNDS

Phenol and its derivatives are generated in a wide variety of industrial processes (e.g., manufacture of plastics, dyes, drugs, glues) and in the pulp and paper industry, and can also be formed as degradation products of some pesticides. Chlorophenols are toxic to aquatic organisms and to man, and even at low concentrations in water, they can be the cause of unpleasant taste and odor.

Current official analytical methods include GC with FID or MS and involve a derivatization step. However, there is a general trend to switch to LC procedures to avoid sample manipulation and because derivatization of phenols is not straightforward. Common detection techniques are

UV detection at 280 and 310 nm for nitrophenols and pentachlorophenol. LC/DAD is recommended because spectral libraries can be used for confirmation purposes. In terms of sensitivity, LC with ED or coulometric detectors (CD) produces better response than UV or DAD. However, electrochemical detection for LC has never become so popular as its inherent sensitivity and selectivity is affected by electrode fouling and poor reproducibility. Moreover, electroactive matrix components can increase the background current and make ED less robust for water monitoring. Therefore, this technique can only be recommended for monitoring clean water samples such as groundwater. LC with direct or indirect FD for phenols provided acceptable detection limits, but problems related to the derivatization step made the technique less attractive. Similar to other organic pollutants, phenolic compounds can be detected by LC/APCI/MS and LC/ESI/MS in negative ion mode and produce, in general, the deprotonated molecule as base peak. The advantage of APCI and ESI is that an increase of the extraction voltage enhances fragmentation via collision-induced dissociation (CID) and provide structural information, useful for confirmation and identification purposes.[4] Moreover, phenols are good candidates for capillary electrophoresis (CE) and capillary zone electrophoresis (CZE) because they permit a fast separation of polar and ionic compounds, have a high resolution, and are compatible with most LC detectors, including MS. In addition, trace enrichment can be performed in the capillary using isotachophoresis, making the technique suitable for water analysis.

SURFACTANTS

Linear alkylbenzenesulfonates (LAS), alcohol ethoxylates (AEO), and nonylphenol ethoxylates (NPEO) are synthetic surfactants used in the formulation of detergents and other cleaning products and are widely applied in the dye and leather industry and other industrial processes. These compounds have aroused considerable interest due to the large quantities produced globally and to the potential estrogenic effect of some of their degradation products. Their low volatility and anionic form of some make LC-based methods the preferred approach.[5] Due to the presence of different positional isomers and the biodegradation intermediates, LC/MS, and in particular with ESI, is the only technique that enables their identification and quantification in environmental waters. In addition, nonylphenol and octylphenol, are the main persistent metabolites of alkylphenol ethoxylates (APEs), which are both GC and LC amenable.

PHTHALATES

Phthalate esters (PAEs) are plasticizers used in the manufacturing of polyvinyl chloride (PVC) epoxy resins, adhesives, and lacquers for coating the inside of food containers. Minor applications are in cosmetics, insect repellents, insecticide carriers, and propellants. They are considered ubiquitous pollutants but show slight endocrine disrupting properties. The main problem of analyzing phthalate ethers still remains as regards the external contamination coming either from the extraction procedure or from the injection port. Provided an efficient extraction method is used (employing LLE, SPE with glass cartridges or SPME), phthalates can be detected at ppb levels using LC/DAD or at somewhat lower levels using LC/MS with either ESI or APCI interfaces.[6] One of the main problems is the difficulty to provide 100% recoveries using those techniques due to blank interferences. It is thus important to work with appropriate surrogate standards, e.g., deuterated compounds.

STEROID SEX HORMONES

Natural and anthropogenic steroid sex hormones are released to the environment in the proximity of large urban areas. Synthetic hormones can mimic the 17-β-estradiol and can produce estrogenic or feminizing effects at concentrations as low as 1 ng/L. Since many hormones are thermally unstable, ionic, or polar, LC combined with a highly efficient preconcentrating technique is the method of choice for their analysis. Detection can be performed by UV and DAD, although in many instances a more selective and sensitive detector is needed. As a result, MS is commonly used since it permits the identification, quantification, and confirmation in one single analysis. Among the LC/MS interfaces, both ESI and APCI can be used. ESI is well suited for the analysis of polar compounds, whereas APCI is more effective for medium polarity substances.[1] In most applications, ESI is operated in negative ion mode ionization, which offers better sensitivity than positive ion mode. In general, the $[M - H]^-$ and $[M + H]^+$ modes are formed under negative and positive modes. Since high sensitivity and selectivity is needed and not always met by single quadrupole mass analyzers, ion trap, time-of-flight analyzers or tandem MS are generally used to determine these compounds. Mode of operation includes selected ion monitoring (SIM) or selected reaction monitoring (SRM). Identification is performed by retention time match against a standard and by identification of target compounds at three ions or by monitoring the MS/MS transitions. In such cases, selectivity is enhanced and the problem of false positives is minimized.

PHARMACEUTICALS AND PERSONAL CARE PRODUCTS

The extensive use of pharmaceutical compounds and active ingredients in personal care products (PPCPs) has generated concern due to their ubiquity, persistence, and

bioaccumulation. Pharmaceuticals are continuously released to the environment via wastewaters from manufacturing industries, hospital effluents, and disposal of expired products. Most relevant pharmaceuticals in water are antibiotics, anti-inflammatory drugs, lipid regulators, and musk compounds. Their risk is often associated to imperceptible effects that can accumulate over time to yield serious changes. One clear example is the development of resistant bacteria due to the release of antibiotics in the environment. Concentrations found in wastewaters are generally of 1–100 μg/L, whereas in surface waters they are found at ng/L concentration. One of the main issues in the analysis of pharmaceuticals is to provide unequivocal identification. For such purposes, LC/MS based methods are used. Due to the lack of fragmentation of some compounds using a single quadrupole, ion trap or tandem MS are the preferred options. Among the interfaces used, both APCI and ESI provide good sensitivity although ESI gives lower LODs. A review of the methods used for several families of pharmaceuticals is given by Sacher et al.,[7] who indicate LC/ESI/MS/MS method performance and quality parameters (limits of detection, limits of determination, and limits of identification) for several families of pharmaceuticals.

CONCLUSIONS

Many organic pollutants in water can be analyzed with LC techniques at trace levels. From the different LC methods discussed in this entry, several remarks can be made: 1) For routine water monitoring, LC/DAD is the most common detection device used to analyze polar, thermolabile, and non-volatile compounds due to its robustness, high sample throughput, and the possibility of obtaining a UV spectrum that can be used for analyte confirmation; 2) LC/FD and ECD are more selective and sensitive than DAD and are especially useful for the monitoring of PAHs, carbamates, and phenols; 3) LC/MS with API sources and different combinations of mass analyzers have become highly robust techniques and the preferred option for the identification, confirmation, and quantification of organic pollutants in water. In addition, all LC techniques described can be coupled, on line, with solid-phase extraction, so that LODs can be decreased and their total automation permits to achieve high-sample throughput.

Polyamides: GPC/SEC Analysis

Tuan Q. Nguyen
Department of Materials Science, Polymer Laboratory, Swiss Federal Institute of Technology, Lanne, Switzerland

INTRODUCTION

Synthetic polyamides (PA) are among the mostly widely used engineering thermoplastics, owing to their high strength and toughness, stiffness, abrasion resistance, and retention of physical and mechanical properties over wide temperature ranges. The material's outstanding properties are, to a large extent, due to their semicrystalline morphology and the cooperative intermolecular hydrogen-bonding of the amide groups. The strength of these dipolar interactions are reflected in the melting points, which are much higher in polyamides than in polyesters having comparable structures.

Proteins, including wool and silk fibers, are made up by the linkage of α-amino acids and constitute the most widespread source of natural polyamides.

Synthetic PAs are produced by polycondensation of bifunctional monomers or by cationic and anionic ringopening polymerization of lactams. Polymers obtained with the first technique are linear, whereas chain branching may occur with anionic polymerization. Based on their chemical structure, synthetic polyamides may be classified into two categories:[1]

1. Aliphatic polyamides, also known under the generic name nylon. Industrial nylons with the general structure $[\text{-RNHCO-}]_n$, such as PA-6, PA-11, and PA-12, are called monadic; those with the general structure $[\text{-NHR}_1\text{NHCOR}_2\text{CO-}]_n$ are called dyadic (PA-4,6, PA-6,6, PA-6,9, PA-6,10, and PA-6,12).
2. Aromatic polyamides or aramids. The best known in the specialty fiber market are Nomex™ (poly-*m*-phenyleneisophthalamide) and Kevlar™ (poly-*p*-phenyleneterephthalamide).

A number of polymers with structures related to those of polyamides have been developed, some of which have achieved commercial importance, such as

CONHNH (polyhydrazide), OOCNR (polyurethane), and CONRCO (polyimide).

SEC ELUANTS FOR POLYAMIDES

High cohesive strength confers an exceptional solvent resistance to PAs, which can be dissolved only under rather drastic conditions (i.e., in highly corrosive solvents at temperatures close to the polymer melting point). This limited solubility leads to serious difficulties in the solution characterization of these polymers, such as in the determination of molecular-weight distribution (MWD). Selection of a solvent medium which is good for the polymer, chemically inert, and compatible with the stationary phase is crucial to a successful size-exclusion chromatographic (SEC) analysis.[2] These criteria are particularly demanding for many aramids, which are also rigid-rod polymers. Poly-*p*-phenyleneterephthalamide, for instance, has been analyzed in 97% sulfuric acid on silica columns.

Recently, a less corrosive room-temperature eluant consisting of methane sulfonic acid + 5% methane sulfonic anhydride + 0.1 *M* sodium methane sulfonate has been reported for Kevlar and Technora fibers. Separation was performed on Hastelloy C columns packed with 4000 Å SAX 10 μm particles (Polymer Laboratories), using ultraviolet (UV) detection and poly(benzoxazole) for calibration.[3] Work on the SEC characterization of aramids is extremely limited and generally lacks details of molecular-weight (MW) accuracy. In the following section, we will focus exclusively on aliphatic polyamides.

HIGH-TEMPERATURE SOLVENTS

The first mention of SEC analysis of PA-6 and PA-6,6 is by Goebel (1967), using *m*-cresol at 135°C with Styragel® columns. It was soon realized, however, that PA degrades extensively within a few hours under the above experimental conditions; alternative solvents have been proposed, most of which can be used only at elevated temperatures, due to solubility or viscosity problems:[4]

- *O*-Chlorophenol at 100°C
- Hexamethylphosphoramide (85°C)
- Dimethylacetamide + 2.5% LiCl (100–130°C)
- Benzyl alcohol (130°C).

In addition to the necessity for high-temperature SEC, each of the above solvents has its own drawbacks, such as adsorptive effects with phenol derivatives, column blocking, and carcinogenicity with hexamethylphosphoramide and corrosion of stainless steel by the dimethylacetamide–LiCl mixture.

Benzyl alcohol has been tested at 100°C on silica columns. To prevent potential solute interactions with silica stationary phase, it is recommended to prefer cross-linked PS columns with benzyl alcohol at 130°C and polytetrahydrofurans as calibration standards (polystyrene and polyethylene oxide standards interact with the stationary phase under the analytical conditions).[5]

LOW-TEMPERATURE ELUANTS

Fluorinated Alcohols

Most solvents which dissolve nylon at room temperature are either too toxic (nitrobenzene) or too corrosive [strong acids: sulfuric, formic, dichloroacetic; concentrated alcoholic salt solutions (e.g., methanol + $CaCl_2$)] to be safely used as an SEC eluant. Fluorinated alcohols constitute an exception: It has been known for a long time that trifluoroethanol (TFE), tetrafluoropropanol (TFP), or hexafluoroisopropanol (HFIP), owing to the presence of strong electron-withdrawal groups ($-CF_2-$ and $-CF_3$), have the propensity to dissolve a large number of polymeric materials which possess receptive sites for H-bonding formation (proteins, stereoregular polyesters, and, more recently, polyaniline).

The application of fluoroalcohols for dissolving polyethylene terephthalate (PET) and polyamides dates back from the early 1960s. Dissolution tests show that the solubility of polyamides improves with the acidity of the fluoroalcohol and decreases with increasing steric hindrance of substituents adjacent to the hydroxyl group. The use of HFIP for the SEC of PA-6,6 and PET on porous glass and μ-Styragel columns was described by Drott in 1971. TFE was tested in the following year for the SEC separation of Nylon 6, using fractionated PMMA for calibration. Fluoroalcohols are hygroscopic and should be dried before use to avoid formation of corrosive products. Polymer adsorption was observed when the water content in the eluent is $>0.03\%$. Moisture in TFE and HFIP can induce the formation of carboxylate end groups in nylon. Electrostatic repulsion between these groups and residual carboxyl ions present in cross-linked PS packings will lead to ion exclusion, which can be suppressed with the addition of a salt (sodium acetate, sodium trifluoroacetate, or tetraethyl ammonium chloride) in the 10^{-2} M concentration range. At present, HFIP is the preferred room-temperature eluant for the SEC characterization of nylons and polyesters. TFE, although four times less expensive than HFIP, is more toxic and has limited dissolution capability for polyesters and for nylons with long alkyl sequences. In addition to high cost, the use of HFIP entails a number of difficulties, such as high volatility, health hazards, incompatibility with a PS–DVB-based stationary phase (particularly with columns of pore sizes <1000 Å), insolubility of PS standards, and the presence of non-steric exclusion effects. Most of these problems have now been largely solved: Calibration can be done with commercially available anionic poly(methyl methacrylate) (PMMA) standards or with "absolute" detection, incompatibility with the stationary phase is minimized with columns specially designed for HFIP (Polymer Laboratories, Shodex, Waters), and closed-loop distillation and the use of narrow-bore columns substantially reduces solvent consumption.

Despite this progress, SEC with HFIP remains an expensive procedure due to extra investment in fluorinated solvent and special columns. Finally, it should be noted that HFIP with a pK_a of 9.3 is sufficiently acidic to react with the nitrogen in aromatic polyimides, resulting in ring-opening solvolysis.

Mixed Eluants

In search of less expensive, less toxic, and lower viscosity eluants, a few authors have proposed diluting the active ingredient with a common SEC eluant such as toluene, dichloromethane, or chloroform. To lower the operating temperature and minimize polymer degradation, mixtures of *m*-cresol with chlorobenzene (50 : 50, v/v, 43°C), dichloromethane (50 : 50, room temperature), and chloroform have been used, with 0.25 wt% benzoic acid added to prevent adsorption. In the same vein, *o*-chlorophenol has been diluted with chloroform (25 : 75) and used at 20°C. The main disadvantage in this latter solvent was a small *dn/dc* for the polymer, which rendered refractive index measurements difficult. In addition, careful purification of the phenol is required to obtain a detection signal. Dichloroacetic acid diluted to 20 vol% with dichloromethane has been proposed as the mobile phase. However, even at this concentration, PA tends to degrade at room temperature.

Among the different solvent combinations, it appears that mixtures based on fluorinated alcohols give the best results in terms of stability of the polymer and compatibility with the stationary phase (conventional silica or PS–DVB columns can both be used). As with pure fluoroalcohols, a salt should be added to suppress polyelectrolyte effects. Toluene, with 20 vol% HFIP, has been used for the SEC fractionation of PA-12 (Fig. 1). However, based on thermodynamic excess properties, this solvent combination should be less efficient in terms of solvation power than mixtures of HFIP with chloroalkanes.

Mixtures of HFIP or TFE with $CHCl_3$ and CH_2Cl_2 have been successfully tested as SEC eluants. HFIP–CH_2Cl_2 mixtures have the advantage of being more stable, of low toxicity, and UV transparent up to 200 nm (an assess for UV-absorption detection) and are better solvents for PA than the other mixtures.[6] On the negative side, HFIP–CH_2Cl_2 forms a 30 : 70 (v/v) azeotrope at 30°C, thus limiting its use to room temperature. HFIP–$CHCl_3$ does not have an azeotrope, whereas TFE–$CHCl_3$ possesses a lower azeotrope at 55°C.

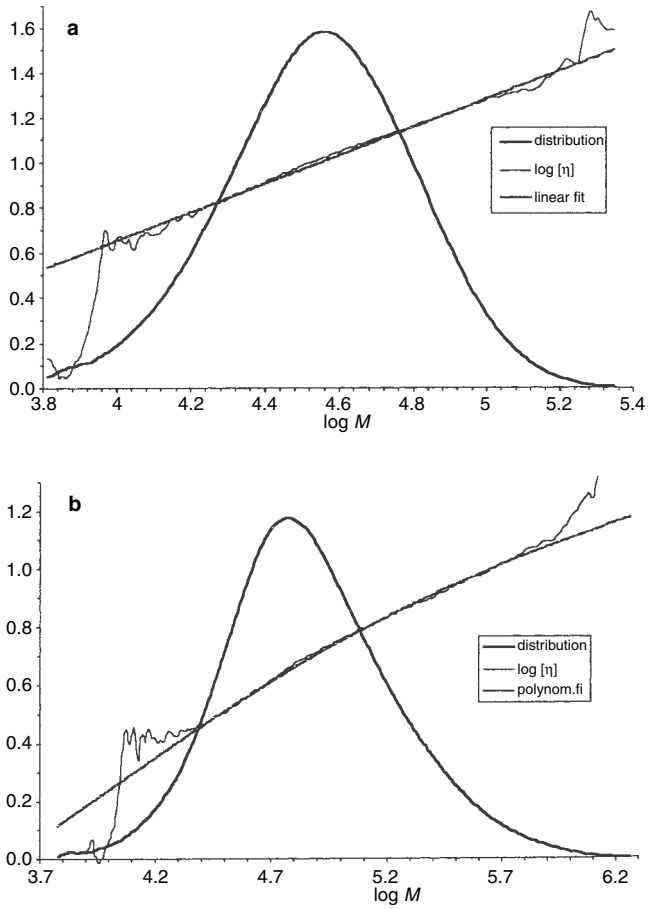

Fig. 1 SEC-viscometry characterization of a linear (a) and a branched (b) PA-12 synthesized by anionic polymerization, with different activators. Analysis conditions: mixed eluant 5:95 v/v; HFIP/CH_2Cl_2 at 30°C; Styragel-HR2/3/4/5 columns.

Problems Associated with Mixed Eluants

The use of mixed eluants in SEC analysis was proposed long ago to take advantage of the desirable properties of both solvent systems. Possible consequences of preferential solvation of the stationary phase and the polymer by one of the eluant components must, however, be critically evaluated: changes in mixture composition with polymer hydrodynamic volume, differences in composition of the mobile phase and of the solvent in the pores, dependence of the refractive index signal on elution volume, and the possibility of interference of the system peak with the oligomer signal in refractive index detection. Solvent recycling is more difficult and the original composition must be readjusted after distillation.

N-TRIFLUOROACETYLATION

N-Trifluoroacetylation remains a common technique to solubilize aliphatic PA for SEC analysis:[7]

$$\text{CONH}- + (\text{CF}_3\text{CO})_2\text{O} \rightarrow -\text{CON}(\text{COCF}_3)- + \text{CF}_3\text{COOH} \quad (1)$$

With a twofold to threefold excess in trifluoroacetic anhydride, reaction 1 is quantitative within 1 day at room temperature. The *N*-trifluoroacetylated polyamides (NTFA–PA) are soluble in many ordinary organic solvents, such as acetone, methylene chloride, chloroform, and tetrahydrofuran. In addition to the change in solubility, another remarkable feature of *N*-trifluoroacetylation is a near-two-orders-of-magnitude increase in the UV-absorption coefficient of the amide band, accompanied by a large bathochromic shift. Trifluoroacetylated polyamides have a rather small *dn/dc* in CH_2Cl_2 and detection was better achieved by UV absorption. Once prepared, the NTFA–PA solutions are unstable in the presence of atmospheric humidity and should be used immediately to avoid reverse hydrolysis, which converts the fluorinated polymer back into the original polyamide. It has been reported that SEC separation of NTFA–PA does not follow the universal calibration in dichloromethane, whereas better agreement was obtained in tetrahydrofuran. Comparative SEC analyses of NTFA–PA in both solvents on Styragel columns show, nevertheless, identical results.[6]

CONCLUSIONS

Size-exclusion chromatography analysis of PAs remains a difficult enterprise in comparison to other amorphous thermoplastics which can be readily dissolved in common solvents at room temperature. To improve MW accuracy, calibration should be performed with absolute detection (online viscometer, light scattering) or with a broad MWD polymer standard of identical chemical composition to the analyzed sample. Among the high-temperature eluants, benzyl alcohol is the less corrosive and seems to give the most reliable results. In low-temperature SEC, HFIP remains the best eluant, provided the necessary extra investment is not a problem. A mixed-eluant based on HFIP is a reasonable alternative to pure HFIP for long alkyl nylons (PA-12, PA-11). For shorter alkyl sequences, the high percentage of HFIP (>10 vol%) required for dissolution of the polymer may interfere with the size-exclusion mechanism of separation.[6] *N*-Trifluoroacetylation of the PA remains an interesting alternative, provided due care is given to prevent contact of the derivatized compound with reagents (water, alcohols, etc.) able to cause scission of the -N-$COCF_3$ bond.

Polycarbonates: GPC/SEC Analysis

Nikolay Vladimirov
Research Center, Hercules Inc., Wilmington, Delaware, U.S.A.

INTRODUCTION

Polycarbonate (PC) polymers are amorphous thermoplastics with excellent toughness, clarity, and high heatdeflection temperatures. They are one of the better thermoplastics where strength and elastic moduli are concerned, offering both excellent impact strength and rigidity. In general, PCs are linear aromatic polyesters of carbonic acid. Polycarbonates can be described as polymeric combinations of bifunctional phenols, or bisphenols, linked together through carbonate linkages.

DISCUSSION

Robertson et al. used gel permeation chromatography (GPC) to examine PCs produced by different synthetic routes. They concluded that this method is superior to end-group analysis. Hoore and Hillman carried out fractionations of PCs by GPC to procure narrow molecular-weight-distribution (MWD) fractions which were used to calibrate the columns of a GPC system and an experimental "*Q* factor" of 23.8 was found. The calibration was further confirmed by membrane osmometry and light-scattering measurements.[1] The "*Q* factor" method is the simplest conversion method for molecular-weight calculations that provides data closer to the real molecular weights while still using polystyrene (PS) standards, but it lacks accuracy because it assumes the extended chain length of the polymer in solution. Most flexible polymers are not extended, but, rather, they are randomly coiled in solution. The more reliable method is to use the concept of the "hydrodynamic volume".[2] A comprehensive listing of Mark–Houwink coefficients *K* and *a* for different solvents and temperatures are published in the *Polymer Handbook*.[3] PC standards for calibration have been commercially available for the past several years from Polymer Standard Service Co. (Mainz, Germany) and American Polymer Standards Co. (Mentor, Ohio, U.S.A.).

The polymerization of trimethylene carbonate (1,3-dioxan-2-one) with a complexation catalyst was studied by Kriecheldorf et al.[4] On the basis of GPC measurements employing a universal calibration, weightaverage molecular weights up to approximately 22,000 were found. A combination of four Ultrastyragel columns was used, with nominal pore sizes of 100, 500, 1000, and 10,000 Å. The detector was a Waters M410 differential refractometer. The molecular weights were estimated from GPC results by means of intrinsic viscosities determined in dichloromethane at 25°C and an universal calibration curve, based on commercial PS standards.

Wang and Gonsalves[5] investigated the enzymecatalyzed synthesis of poly(ethyl phenol) (PEP), which was modified by copolymerization with PCs. GPC was carried out on a system equipped with a differential refractive index detector (DRI) and four Ultrastyragel columns in tetrahydrofuran (THF) with a flow rate of 1 ml/min. A calibration plot, constructed with PS standards, was used to determine the molecular weights. Based on the results, a slight difference between the high- and low-temperature products was observed for the pristine PC. The copolymers PC-*co*-PEP had higher molecular weights when compared to the pristine material, due to the linkage between PC and PEP, which effectively doubled the molecular weights.

GPC was used for the analysis of fullerene-functionalized polycarbonates, achieved by direct reaction of PC and fullerenes with aluminum chloride as a catalyst. THF was used as the eluent and the system was calibrated with PS standards. The working wavelength for the ultraviolet (UV) detector was 340 nm, where the starting PC was hardly detectable, but the reaction product gave two UV peaks, a strong peak in the "normal" molecular weight (MW) region and a weak peak in the very high MW region. Because THF is a non-solvent for fullerenes, the solubility of the polymers in THF and the GPC data served as evidence for the existence of a covalent bonding between the fullerene and PC.[6]

The influence of molecular structure on the degradation mechanism of degradable polymers of poly (trimethylene carbonate), poly(trimethylene carbonate*co*- caprolactone), and poly(adipic anhydride) was explored by Albertsson and Eklund.[7] Measuring the change of the mass and the molecular weight for the 104, 103 polymeric samples during degradation is a good indication of the degradation rate and an initial measure of material deterioration. The value of the molecular weight is not absolute, but, rather, it is relative to PS standards. This is sufficient for this study, which is simply concerned with the change in molecular weight relative to the starting value in order to evaluate the degradation. While the molecular weight decreased, an increase in the polydispersity was observed for some of the samples.

Studies of the thermal decomposition of the products under a nitrogen atmosphere were carried out by combining

LC under critical conditions of adsorption (LACCC) and SEC methods with matrix-assisted laser desorption/ionization–time-of-flight spectrometry (MALDI-TOF) and post-column derivatization. The critical conditions of polymer adsorption in the LC and an optimal matrix system for MALDI-TOF are reported. The changes of molar mass distribution and chemical heterogeneity are said to be due to the simultaneous processes of degradation and recombination.[8]

Branching by reactive end groups, syntheses, and thermal branching of 4-hydroxybenzocyclobutene (BCB-OH)/*p-tert*-butylphenol coterminated bisphenol PC was investigated by Marks et al.[9] Reactive end groups on bisphenol A (BA) PCs allow for significant structural changes in this condensation polymer that are not accessible by direct synthetic routes. Commercially offered branched PCs have improved melt rheological properties, compared to their linear analogues; they are manufactured by incorporation of a trifunctional comonomer in the PC polycondensation process. A GPC system, equipped with a UV detector (GPC-UV), and LC were used for the analyses. A Hewlett-Packard 1047 DRI detector and a LALLS (CMX-100) (low-angle light scattering) photometer were connected in series. Values of *dn*/*dc* were estimated from the DRI responses and sample concentrations. Five TSK MicroPak H-series (3 GMH6, 1 G500H6, and 1 G400H8) columns were used at 30°C with THF as the eluent at 1 ml/min. Heating to 300°C for 20 min causes the BCB-OH/PTBT BA PCs to branch or cross-link. The molecular weight and polydispersity of the branched polymers increase to a value at which the onset of the gel formation is observed. GPC–LALLS (M_w 135,100 and 310,700) was performed on two of the branched samples; it shows, as expected, a significantly higher molecular weight, particularly M_w, than indicated by GPC-UV (M_w 70,600 and 64,600, respectively).

The M_w by GPC-UV of each series of BCB-OH/PTBT BA PCs increases exponentially up to the gel point. The apparent decrease in M_w after the gel point reflects the values of the soluble fraction only, which are, therefore, not representative of the entire sample. LC was applied to investigate the types and distribution of BCB reaction products formed.

Unfortunately, none of the hyperbranched polymers studied to date has demonstrated good mechanical properties. A hyperbranched PC is also expected to be a brittle material, but such a structure may prove interesting as a highly functionalized prepolymer for composites, coatings, and other applications. Hyperbranched PCs were synthesized and characterized by Bolton and Wooley.[10] The products were prepared by the polymerization of an A_2B monomer derived from 1,1,1-*tris*(4′-hydroxyphenyl)-ethane. Silylation of the phenol terminated material with *tert*-butyldimethylsilyl chloride, followed by degradation of the carbonate linkages by reaction with lithium aluminum hydride and analysis of the products by HPLC allowed for the determination of the degree of branching, which was found to be 53%. The molecular weights of the carbonyl imidazolide-, phenol-, and *tert*-butyldimethylsilyl ether-terminated hyperbranched polycarbonates were 16,000, 77,000, and 82,000, respectively, from GPC, based on polystyrene standards, 23,000, 180,000, and 83,000, respectively, from GPC with LALLS, and 24,000, 160,000, and 88,000, respectively, from GPC with SEC software. SEC was conducted on a Hewlett-Packard series 1050 HPLC with a Hewlett-Packard 1047A refractive index detector, a Wyatt MiniDawn laser-light-scattering detector, and a Viscotek Model 110 differential viscometer. Two 5 μm Polymer Laboratories PL gel columns (300 × 7.7 mm), connected in series, were used with THF as an eluent.

Bailly et al. investigated the separation of polycarbonate oligomers by SEC and reversed-phase LC.[11] The separation of PC oligomers was achieved by SEC with styrene–divinylbenzene microparticle gel as a stationary phase and dichloromethane as a mobile phase. Oligomers were separated up to 10 repeating monomer units. SEC is useful for the analyses of the low-molecular- weight content of commercial PC samples. Retention times are significantly influenced by the nature of end groups (O– or OH–O–) (O-phenyl), indicating that adsorption occurs with hydroxy-terminated oligomers. Also, SEC results were compared with reversed- phase HPLC data.

Although the molecular weight of the bisphenol A polycarbonate repeat unit is relatively high, the separation of PC oligomers by SEC is difficult and has, thus, received little attention up to now. The problem is complicated by the existence of three oligomer families resulting from the addition of chain modifiers (monofunctional phenols) during the synthesis of the polymer by the usual interfacial method. The SEC results are compared with those obtained by reversed-phase HPLC for the same systems. Adsorption of phenolic compounds is known to occur on the surface of PS-DVB gels. When several types of oligomers are simultaneously present, interpretation of chromatograms becomes difficult and should be done with caution. This is particularly true when analyzing the oligomer content of commercial PC samples. The resolution obtained by reversed-phase HPLC remains superior, but, in most cases, quantitative result cannot be obtained by this technique because of solubility problems. In contrast with previous claims, the nature of the end groups was observed to significantly influence the retention time of PC oligomers by SEC. The presence of the hydroxy terminal groups induces a reversible adsorption of the compounds onto the columns. This effect is very important for oligomers having two hydroxy end groups.

As a consequence, the precise determination of the number-average molecular weights of PC samples by SEC is possible only if the nature of the oligomers present is taken into account.

Polyesters: GPC/SEC Analysis

Sam J. Ferrito
Analytical Services Department, Cooper Power Systems, Franksville, Wisconsin, U.S.A.

INTRODUCTION

Gel permeation chromatography (GPC), also known as size-exclusion chromatography (SEC), has proved to be an extremely useful analytical technique for characterizing the molecular-weight distribution (MWD) of polyesters. The MWD of a polymer can provide valuable information regarding the molecular composition. For example, along with relative molecular-weight averages, polydispersity, intrinsic viscosity, and branching information can be obtained.

DISCUSSION

Thermoplastic polyesters are popular engineering polymers because they offer excellent chemical and heat resistance, along with desirable electrical properties. When reinforced with glass or mineral fillers, they can be used to replace materials such as metals, ceramics, composites, and other less suitable plastics. In addition, thermoplastic polyesters offer excellent mechanical properties while retaining good processability.[1] Unfortunately, the polyester molecule is readily susceptible to hydrolysis. Hydrolytic degradation of the polymer causes random chain scissions to occur, normally at the ester linkages (R–CO–O–R′), which cause a reduction in molecular weight and, in turn, a reduction in mechanical integrity.[2,3] GPC can be used to monitor the hydrolytic process and predict product performance.[4]

Aromatic polyesters, because of their crystalline structure and polar nature, require the use of aggressive solvents and/or elevated temperatures to dissolve the polymer.[5] Various solvent blends can also be incorporated to aid in the dissolution process.[6,7]

Early work involving high-temperature GPC of polyesters utilized solvents such as meta-cresol and ortho-chlorophenol as mobile-phase solvents. These solvents are very viscous and require system temperatures of between 140°C and 150°C. Both solvents are also very dangerous and difficult to handle.[8,9]

More recently, hexafluoroisopropanol (HFIP) has been used successfully as a mobile phase for both polyesters and polyamides.[4,9,10] Unfortunately, HFIP is very expensive and dangerous to handle. HFIP requires special care and attention due to its extreme corrosiveness to eyes and skin. *Handling should be conducted only by trained professionals equipped with proper splash goggles and face shields for eye/face protection, and appropriate impervious gloves, aprons, and other protective equipments, as noted on the Material Safety Data Sheet for HFIP*. Mobile-phase distillation is necessary due to the extreme cost of the solvent. Some laboratories have reported using blends of HFIP and methylene chloride or HFIP and chloroform successfully in an effort to reduce solvent costs.[7,10–13]

Hexafluoroisopropanol is able to dissolve most polyesters and polyamides (nylons) at room temperature in about 4–8 hr. Sodium trifluoroacetate (NATFAT) is typically added to suppress any polyelectrolyte effects that could occur in HFIP.[9] GPC columns made from cross-linked polystyrene-divinylbenzene are typically used to perform the separation.[14] Calibration is generally performed using poly(methyl methacrylate) standards instead of polystyrene standards, due to solubility constraint.[5,15]

Typical polyesters characterized by GPC include polyethylene terephthalate (PET), polybutylene terephthalate (PBT), and polycyclohexylenedimethylene terephthalate (PCT). Polyphthalamides (PPA) and polyamides are also commonly analyzed.

Polyester detection is normally accomplished by using refractive index detection in conjunction with either viscometry or low-angle laser light scattering (LALLS).

The viscosity data are a quantitative gauge for monitoring the loss of high-molecular-weight chains within the polymer. Because the viscometer detector operates by measuring the pressure drop across a capillary tube, the intrinsic viscosity at a constant flow rate can be measured as follows[11,16]:

$$P = \left(\frac{8}{\pi}\right)\left(\frac{L}{r^4}\right)\eta F$$

where P is the pressure drop across the capillary, L is the capillary length, r is the internal radius of the capillary, η is the viscosity of fluid (GPC column effluent), and F is the flow rate.

Universal calibration incorporates intrinsic viscosity data with molecular-weight information provided by polymer standards of differing composition. Absolute molecular-weight determinations have proved to be inaccurate in HFIP due to non-size-exclusion interactions occurring within the process.[6,17] Typically, *relative* molecular-weight comparisons are reported when using the procedure. However, if *absolute* molecular-weight values are required, light-scattering techniques have been utilized with greater success.[18–20]

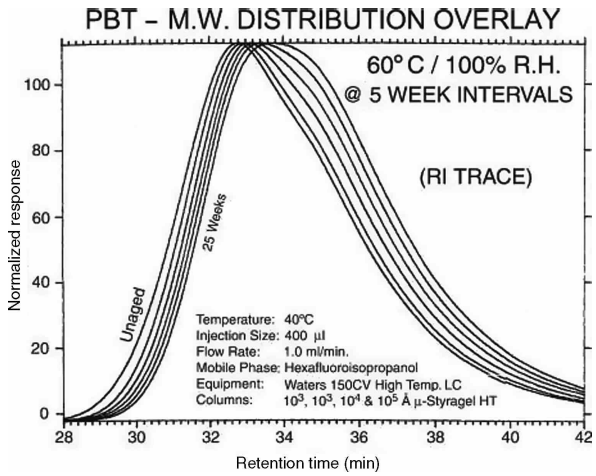

Fig. 1 Degradation of PBT at 60°C and 100% relative humidity; samples for analysis were taken at 5 week intervals.

Data derived from GPC analysis are commonly used to monitor the hydrolytic stability of various thermoplastic polyesters used under conditions requiring exposure to elevated temperatures and humidity. Polyester hydrolysis results in shifts in MWD toward lower molecular weight with a corresponding lowering of the intrinsic viscosity. A reduction in mechanical properties also is evident when hydrolysis occurs. Changes in mechanical properties can also be caused by moisture absorption and by weakening of the glass–fiber bond. GPC can distinguish between the chemical and physical changes occurring in the material.

Fig. 1 compares the changes that occur to PBT due to aging of the polymer at 60°C and 100% relative humidity for a total of 25 weeks. Samples were removed at 5 week intervals, and the molecular-weight distributions were compared. Polymer hydrolysis was evident by regular shifts in molecular-weight distribution toward lower molecular weight.[4]

CONCLUSIONS

Gel permeation chromatographic analysis will serve as a valuable technique for evaluating the newly developed hydrolysis-resistant polyesters and for monitoring the weatherability of polyesters in outdoor applications.

Research Institute of Material Science and Technology (INTEMA), University of Mar del Plata, Mar del Plata, Argentina

Abstract
This entry examines several recent advances in pyrolysis gas chromatography–mass spectrometry (Py–GC/MS). The use of analytical pyrolysis coupled to GC/MS in polymer studies has greatly increased in the past few years because of the hyphenation between a technique permitting a fast thermal program to yield volatile fragments with a powerful tool for their identification. The classical application of Py–GC/MS to thermoplastics has been extended recently to thermosets and even to biopolymers and biocomposites. The use of these techniques to study alternative methods for waste treatment has also been considered as an important and recent feature, showing possibilities for further improvement in the amount of its applications. A brief overview on the identification of polymer additives by Py–GC/MS has also been carried out.

INTRODUCTION

Gas chromatography (GC) is one of the most important instrumental techniques in analytical science. It is fast, sensitive, and allows combination with a wide range of detection methods with good selectivity. However, the application area of GC is limited because the molecules to be analyzed have to be thermally stable and sufficiently volatile. Numerous molecules, in particular macromolecules, do not meet these requirements. Polymers are not volatile; some of them have low solubility in most solvents and/or decompose easily during heating. Therefore, the direct application of powerful analytical tools, such as gas chromatography–mass spectrometry (GC/MS), is difficult on most polymers and composite materials. In such cases, some pretreatment to break polymer macromolecules are necessary to get the adequate chromatographic separation. The strategies exploited include conversion of macromolecules into smaller species and approaches to reduce the polarity of molecules.

Pyrolysis (Py) involves the thermal degradation of organic matter in an oxygen-free environment. There are many applications of analytical pyrolysis, and a large number of them are focused on polymers. From the fingerprints of the pyrolysis products of such macromolecules, valuable information can be obtained about the initial samples. Nowadays pyrolysis in combination with GC/MS is commonly used for the characterization of a wide range of polymeric materials, ranging from synthetic polymers to complex environmental mixtures and biomacromolecules. Some monographs[1,2] and entries[3–7] on this subject have been published in the last few years.

During pyrolysis the polymer sample is subjected to a fast thermal program to yield volatile fragments. Once formed, the highly reactive compounds are rapidly flushed out of the pyrolyzer to avoid secondary reactions. Therefore, the obtained degradation products are characteristic of the polymer and can be used to determine structural parameters of the original material. In addition, pyrolysis of plastics mainly generates oil and gases, which are useful products for energy generation or chemicals. In summary, pyrolysis techniques combined with GC (Py–GC) and GC/MS (Py–GC/MS) have extended the application of GC to materials of low volatility.

Depending on the heating mechanism, pyrolysis systems have been classified into two groups: continuous-mode pyrolyzers (e.g., furnace pyrolyzer) and pulse-mode pyrolyzers (e.g., heated filament, Curie point, and laser pyrolysis). All of them are extensively used in polymer characterization and degradation studies.

Pulse-mode pyrolyzers are the fastest, and they are mostly used in Py–GC/MS devices. The filament type pyrolyzer uses a pulse of a high electric current sent through a resistive piece of metal (frequently platinum). The Curie point pyrolyzer uses a ferromagnetic

metal coil and a high-frequency generator for extremely rapid heating of the samples to a fixed final temperature (it normally takes less than 1 sec to complete a program from room temperature to around 1000°C). The laser pyrolysis or micropyrolysis system consists of the laser and the associated optical devices; the sample chamber and cold trap; and a GC/MS for separation and detailed molecular characterization of the pyrolysis products.

Py–GC/MS techniques have been used in general for thermoplastics and some examples are presented here, but some recent studies on pyrolysis and thermal degradation of thermosets were carried out.[8–10] These resins lose their properties and become brittle solids after curing, and consequently they are neither fusible nor soluble in any solvent. Therefore direct chromatographic analysis of cured resins is not possible, unless Py–GC/MS is used.

POLYMER CHARACTERIZATION

In addition to composition determination, in particular for the gases produced after burning, the polymer microstructure can be explored based on the monomers/oligomers and/or their related fragments.[11] Recently a lot of work has been published in this field, covering fundamental studies as well as advanced applied developments.[12–15] Several copolymers were studied to demonstrate the power of Py–GC in microstructure determination.[16,17] In some circumstances, it was necessary to use a prepyrolysis derivatization technique to alter the sample degradation pathway. This technique can be used in any type of Py–GC method and can be combined with other derivatization procedures to get unique fragments for each polymer analyzed.

One particular and interesting application of the characterization of polymer structures after recycling process in polyesters was developed with the use of Py–GC/MS and Py–GC coupled to Fourier transform infrared spectroscopy (Py–GC/FTIR) techniques in the presence of tetramethylammonium hydroxide.[15] Authors suggested that biphenyl-type cross-linking structures would be considerably formed during the material recycling process of poly(butyleneterphthalate) (PBT) and poly(ethyleneterphthalate) (PET), which might in turn be attributed to the deteriorated properties of the recycled materials of the wasted polyester.

The recent introduction of biopolymer formulations as potential replacements of commodities in some applications has led to a rising interest in the structural studies of such materials. Py–GC/MS has become a very useful technique, as the information obtained can aid in structure elucidation of biopolymers as well as in providing detailed compositional information that can be used to differentiate structurally similar biopolymers. Some studies have recently been published in this area.[16–18]

There are many different approaches to measure the molar mass of polymeric materials. Nevertheless, for most of the traditional methods, such as gel permeation chromatography (GPC), the measurement is performed using dilute solutions of the polymer. Many polymers are not easily diluted in common solvents. In many circumstances, there is a need for a molar mass determination method that could operate under a solid-phase condition. Py–GC has been used to determine the number-average molar mass (M_n) via end-group analysis (EGA). The M_n of several polymers, such as poly(methyl methacrylate) (PMMA),[19] polycarbonate (PC),[20] and phenyl group-terminated polybutadienes (PBDs),[21] has been investigated. More recently, hyphenated systems based on size exclusion chromatography (SEC-Py–GC/MS) have been adapted to allow the use of aqueous solvents as applied in the characterization of water-soluble polymers.[22] The main advantage of these techniques is that no sample preparation is required. The success of these developments elevates the role of Py–GC as an important technique for the determination of number-average molar mass in polymers.

Other polymer properties, such as tacticity, can be studied by Py–GC. One example was the characterization of methyl methacrylate (MMA) sequences in the copolymers of MMA and various acrylates and their cross-linked polymers.[23] Tacticity was determined by Py–GC based on the relative peak intensities of the diastereomeric MMA tetramers in the pyrograms.

Py–GC/MS detection is routinely used to identify intractable polymers including cross-linked rubbers. The presence of characteristic degradation products in the pyrolysate is sufficient to positively identify poly(butadiene-acrylonitrile) rubbers.[24] The method is based on the identification of compounds in the pyrolysate that can be attributed to areas of the copolymer rubber where acrylonitrile and butadiene molecules adjoin.

Another interesting possibility for rapid characterization of synthetic polymers is the combination of laser-based pyrolysis systems (i.e., not linked to a thermal activation but to a photochemical activation) with fast gas chromatography–time-of-flight mass spectrometry (GC/TOF-MS). A combined instrument that was recently developed[25,26] joins the advantages of sampling by the laser, reconcentration of the volatile products, and sample introduction to the GC/TOF-MS. This method uses a UV laser as a fragmentation source, which can create pyrolysis fragments without prior sample pretreatment and with reduced analysis time. The potential for using lasers as a highly directional thermal source in analytical pyrolysis studies of natural biopolymers was further investigated by the laser micropyrolysis GC/MS analysis.[27] It was observed that laser micropyrolysis GC/MS can be used to measure the molecular composition of small ($\geq$50 μm) lignin quantities within complex matrices such as soils and coals by in situ analysis.

Some interesting methods have recently been developed for the very fast identification of compounds in particular samples. For example, direct temperature-resolved mass spectrometry (DTMS) is a fast fingerprinting method suited for the recognition of many classes of compounds, permitting the physical separation of low molar mass compounds by evaporation and polymer cross-linked fractions by a gradual rising of the temperature of the filament probe.[28] The analytical process at high temperature under DTMS conditions is equivalent to in-source pyrolysis mass spectrometry where analytes are analyzed collectively and not as separate fractions. This method has been applied to characterize asphalt samples from painting materials.[29]

PYROLYSIS OF POLYMER WASTES

Pyrolysis techniques have also shown a great potential for the study of thermal degradation of polymer wastes, which are common in urban and industrial residues. Commodity polymers in general are not biodegradable when buried in landfills. They can be the source of undesirable emissions [e.g., HCl in poly(vinyl chloride) (PVC) incineration]. An attractive solution to this problem is recycling by pyrolysis.[15,30–32] For example, some research was carried out to obtain the separation of PVC and PET.[33] This method permitted an easy separation of both materials at high temperatures, avoiding the formation of large amounts of HCl inherent to the PVC thermal degradation. A vacuum pyrolysis technology, known as the Pyrocycling™ process, which produces pyrolysis under vacuum conditions and reduces the incidence of secondary reactions in comparison to slow pyrolysis at atmospheric pressure, has been proposed.[34] GC/MS has been used to detect and determine all volatiles generated in this process.

Significant effort has recently been put in for the elimination of polymer wastes from electric and electronic equipment (WEEE) by pyrolysis. WEEE includes mainly epoxy resins and styrene polymers. They often contain brominated aromatics, which are highly contaminant. However, their elimination by simple thermal treatments is no longer possible as one of the most important drawbacks in dealing with thermal treatment of WEEE is the likely production of supertoxic halogenated dibenzodioxins and dibenzofurans. A pyrolysis method at low temperature range was developed, which limited the formation of such toxic by-products and reduced pyrolysis costs, even at relatively long residence times in the reactor.[30,35]

Copyrolysis of municipal solid waste (MSW) has led to a good separation when coupled to GC/MS. MSW is usually mainly composed of plastic residues (e.g., from packaging) and organic matter. During incineration of MSW each component may have a positive or negative influence on the thermal behavior of the others. Therefore, pyrolysis can also be envisaged as a tool for analyzing these effects. Some studies have approached this process, e.g., with the use of blends based on carbon and polymeric residues.[36] Another possibility is the study of the thermal decomposition of polystyrene as a way to separate this polymer from others during MSW treatment.[37]

Some effort has recently been made to study copyrolysis of wood biomass and polyolefins.[38] The effects of reaction temperature, wood–polymers mixture composition, and catalysts on the mixture's conversion into liquids and gases were established and discussed. The optimum temperature of wood–plastic mixture conversion, which corresponded to the maximum total liquid products yield, was close to 400°C. In the cohydropyrolysis processes the non-additive increase of the wood–plastic mixture conversion degree and of the distillable fractions yields took place as a result of the chemical interaction between radical fragments of wood and the thermal decomposition of polyethylene.

More work was carried out to study the effect of wood, cellulose, lignin, and activated charcoal on the thermal decomposition of polystyrene (PS) and polyethylene (PE) occurring in municipal waste.[39] Py–GC/MS revealed that these materials had a similar influence on PS and PE thermal decomposition under slow and fast heating conditions. The effect is related to the char-forming capability of the wood-derived additives; thus cellulose had the least and pure charcoal had the greatest influence on the decomposition of the polymers studied. The yield of monomers, dimers, and trimers decreased, and the formation of other products (e.g., toluene, ethyl benzene, and α-methyl styrene) was detected in the obtained pyrograms.

Chromatographic techniques can also be used to evaluate the performance of pyrolysis of waste products and the possibilities for recycling to give residues such as tires, automobile shredder residues, or commingled plastics an added value for further use. Some studies have considered the potential of Py–GC/MS as a tool for investigating the possibilities and limitations of pyrolysis as a means of recycling of polymers.[40,41] Through monitoring by GC, the kinetics of formation of hydrocarbon products can be determined. These products are interesting as raw materials for the petrochemical industry (mainly light olefins and aromatics) and for the synthesis of basic materials in tire manufacturing (isoprene and 1,3-butadiene). Some of the results obtained in these studies were used to determine the composition by GC/MS analysis of the composite derived oils, to establish the possibilities of reusing or treating and reusing.

Many studies were carried out for the pyrolysis treatment of residues obtained from particular sectors, such as automotive[42] and electronic industries.[43] Because pyrolysis involves the thermal degradation of plastic materials in the absence of air, it could yield valuable hydrocarbon products, while at the same time facilitating the recovery of the metal components. Pyrolysis would facilitate the recovery of both chemical hydrocarbons and metals embedded or mixed with

the plastic waste stream. The fractionation and identification of each component is easily carried out by GC/MS. Special attention has recently been given to the recovery of paint residues from automotive industry wastes.[44,45] It was shown that using Py–GC/MS it was possible to distinguish between members of a series of modified alkyl resins used in paint manufacture including those that were indistinguishable by FTIR. The identification of paint pyrolysis products enables easy discrimination of samples on the basis of their composition.

Another important application of Py–GC/MS techniques is the evaluation of contamination caused by industrial wastes consisting of usual polymers such as PVC, PS, poly(vinyl acetate) (PVA), polybutadiene (PB), poly(acrylonitrile-*co*-styrene-*co*-butadiene) (ABS), styrene-butadiene random (SBR) and styrene-butadiene-styrene block (SBS) copolymers. The presence of synthetic polymers in environmental samples is indicated by anomalously high levels of styrene and benzene in the pyrograms, and by the detection of selected markers (e.g., chlorobenzene for PVC, acetic acid for PVA, benzenebutanenitrile for ABS, cyclohexenylbenzene for styrene-butadiene rubbers), which are useful for better identification of individual polymers. This method was applied to a particular case of contamination in an Italian lake near an industrial area.[46,47]

THERMAL DEGRADATION OF BIODEGRADABLE POLYMERS AND BIOCOMPOSITES

Eco-friendly biodegradable polymers and biocomposites are relatively novel materials that can contribute to reduce the dependence on fossil sources. Because of their renewable nature and biodegradability, environmentally benign composite materials with properties comparable to those of some widely used commodities can be produced. Py–GC/MS has developed as a useful tool for the study of thermal degradation of such polymers and composites, and many studies have recently been published for biodegradable polymers, such as polycaprolactone (PCL),[48,49] polyhydroxyalcanoates (PHAs) and their copolymers,[50–52] poly(lactic acid) (PLA),[53,54] and carbohydrates, including starch and cellulose.[55,56]

In all cases Py–GC/MS proved to be a rapid and highly sensitive method to determine thermal degradation of biodegradable polymers by determining the evolved reaction products without using any time-consuming pretreatment. Py–GC/MS elucidates the microstructure of polymers, and in life time studies of polymers it was shown to be a versatile tool to study the extent of degradation. In addition and because this technique requires only trace amounts (about 0.1 mg or less) of the sample, the small difference in the composition of the residual polymer film recovered during a biodegradation test can be analyzed.

IDENTIFICATION OF POLYMER ADDITIVES BY PY–GC/MS

Polymer additives are essential in polymer processing and they determine end-use properties. A polymer additive is supposed to give some particular characteristics to the polymer. There are a large variety of additives depending on the desired properties, and their chemical structure can be very complex. Sometimes the identification and/or determination of such additives is difficult to be carried out by a single technique, and to establish the feasibility of environmentally and economically interesting plastic components it is necessary to determine their additive content. Some work was carried out to get a fast method for the identification of plastic additives by Py–GC/MS.[57,58]

Analytical determination of polymer additives is sometimes complicated, as evaporation of volatile fractions and degradation can occur simultaneously. Py–GC/MS has shown the potential to separate and finally identify volatiles in liquid polymers or oils, which are usually charged with additives. The onset temperature of thermal degradation of a liquid polymer and the characteristics of the pyrolysis at higher temperatures can be assessed by studying the volatiles produced. However, this approach requires that the true thermal degradation products be identified and not just any components that are simply evaporated from the sample. An innovative method, called the temperature-sequence GC method, was proposed.[59,60] In this method the same sample is subjected to a sequence of 10 sec pyrolyses at increasing temperatures, and for each temperature the complete chromatogram of the volatile products is recorded. This method has the potential to provide good characterization of the volatile products, but its disadvantage is that not enough temperature steps can be taken to allow the onset temperature of degradation.

Many studies on the identification of polymer additives by Py–GC/MS have been published recently; for example, an innovative method based on direct analysis of polymers containing polymeric hindered amine light stabilizers (HALS) by using pyrolysis coupled to GC/MS was applied successfully for fast and straightforward identification of these additives.[61] Each of the HALS showed different pyrolysis gas chromatograms containing characteristic pyrolysis products. As a result, HALS additives with very similar chemical structures, e.g., Chimassorb® 944 and Chimassorb® 2020, could be distinguished.

Alfonso Jiménez
Department of Analytical Chemistry, Nutrition and Food Sciences, University of Alicante, Alicante, Spain

Abstract
Polymer additives fulfill several functions, both in processing the material and in improving the properties of the product, and can act, for example, as antioxidants, light stabilizers, antistatic agents, flame retardants, or plasticizers. There are hundreds of chemical compounds that are currently used as additives in polymer formulations. However, some of them are currently under discussion because of toxicological and environmental issues. Identification and eventual determination of polymer additives is an important issue in many fields, mainly in the area of packaging materials where additive migration from food contact materials may have potential toxic effects in humans. International regulations require that pharmaceutical, biomedical, cosmetic, and packaging materials do not interact physically or chemically with their contents or environments. Direct analysis of additives in the polymer matrix is difficult due to the small amounts usually added. Chromatographic techniques, either on their own or hyphenated to powerful analytical detection techniques, have shown a great potential to determine and eventually identify many of these compounds. This entry analyzes the recent advances in extraction, sampling, separation, as well as detection methods for the identification and analysis of a variety of typical polymer and biopolymer additives.

INTRODUCTION

During the past 50 years polymers have essentially changed human life, and the plastic industry has developed materials increasingly adapted to specific uses.[1] Processing, durability, and end-use response of plastic items result from an adequate and precise combination of the desired polymer and additives. Both technically and economically, additives form a large and increasingly significant part of the polymer industry. Additives such as lubricants, plasticizers, antioxidants, light stabilizers, colorants and dyestuffs, antistatic agents, surfactants, and preservatives are all commonly encountered in various polymer formulations, including synthetic polymers, biopolymers, composites, and biocomposites.[2–11]

There are hundreds of chemical compounds that are currently used as additives in polymer formulations. However, some of them are currently under discussion because of toxicological and environmental issues.[12,13] The increasing use of biopolymers and biodegradable polymers in commercial applications has encouraged the search for compatible and safe additives. A major portion of additive research is nowadays focused on compounds that are on the Food and Drugs Administration's (FDA's) Generally Regarded as Safe (GRAS) list.[14] Table 1 summarizes some of the most common and new additives used in polymer and biopolymer formulations.

For some decades plasticizers have gained industrial importance because their primary role is to improve flexibility and processability of polymeric materials. In general, plasticizers are low-molar-mass compounds (LMMC) that can disrupt polymer chain interactions by forming secondary bonds with polymer chains.[2,9] Lubricants increase the overall rate of processing or improve the release properties during processing and molding operations.[10]

Antioxidants are one of the main families of additives where much work has been carried out during the past few years. They preserve chemical and physical-mechanical properties of polymers both during processing and under in-use conditions.[11] In particular, natural antioxidants, mostly hindered phenols, are chosen to replace synthetic ones mainly in biopolymer and biocomposites formulations to render them completely compatible with different biologically active environments (e.g., natural environments and human body). Side effects of some synthetic antioxidants, such as butyl hydroxytoluene (BHT) and butyl hydroxyanisole (BHA), have been documented, and this has stimulated the substitution of synthetic antioxidants by natural ones.[15,16] Among them, tocopherol,[17] ferulic acid,[18] sorbic acid,[19] ascorbic acid,[20] and vegetable oil with essential fatty acids[21] are those most commonly found in biopolymer formulations.

Light stabilizers are able to reduce photo-oxidation and protect polymers from UV radiation damage. In general,

Table 1 Some common polymer and biopolymer additives.

Additive	Chemical name	Acronym/commercial name
Lubricants	Stearic acid	SA
	Stearamide	STA
	N,N′-ethylene-*bis*-stearamide	EBS
Plasticizers	Di(2-ethylhexyl) phthalate	DEHP; DOP
	Dibutyl phthalate	DBP
	Di(2-ethylhexyl) adipate	DOA
	Trioctyl trimellitate	TOTM
	Triethyl citrate, tributyl citrate, acetyl butyl citrate	TeC, TbC, ATBC
	di(propylene)(glycol)dibenzoate	Benzoflex 9–88
	Polyadipates	PAD
	Triethyleneglycol	TEG[a]
	Poly(ethyleneglycol)s	PEGs
	Poly(propyleneglycol)s	PPGs
	Sorbitol	SOR[a]
	Glycerol	GLY[a]
	Diethanol amine, triethanolamine	DETA, TEA
Antioxidants	Di-*t*-butyl-*p*-cresol	Bisphenol A
	Dioctadecyl (3,5-di-*t*-butyl-4-hydroxy benzyl) phosphate	Irganox 1093
	2,2′-methylene bis-(4-methyl-6-tert- butylphenol)	Irganox 2246
	Tris(2-methyl-4-hydroxy-5-*t*-butylphenyl)-butane	Irganox 1076
	α-tocopherol	Vitamin E[a]
	Ascorbic acid	AA[a]
	Sorbic acid	SA[a]
	Butylhydroxytoluene	BHT
	O-butylhydroxyanisole	BHA
	Ferulic acid	FA
	Essential oils and plant extracts	Rosemary extract
		Oregano extract
		Aloe vera
Light stabilizers	2-(2′-hydroxy-3,3,5-di-tert-amylphenyl) benzotriazole	Tinuvin 328 (Ciba)Tinuvin 928
	2-Hydroxy-4-*n*-octoxybenzophenone	Chimassorb (Ciba)Chimassorb 81
	Poly-{[6-[(1,1,3,3-tetramethylbutyl)-imino]-1,3,5-triazine-2,4-diyl] [2-(2,2,6,6-tetramethylpiperidyl)-amino]-hexamethylene-[4-(2,2,6,6-tetramethyl piperidyl)-imino]}	Chimassorb 944
	Benzophenone-type ultraviolet absorbers1,3-*bis*-[(2′-cyano-3′,3′-diphenylacryloyl)oxy]-2,2-*bis*-{[(2′-cyano-3′,3′-diphenylacryloyl)oxy]methyl}-propane-*N,N′-bis*-formyl-*N,N′-bis*-(2,2,6,6-tetramethyl-4-piperidinyl)-hexamethylenediamine	Univul (BASF); Uvinul 3030[a]; Uvinul 4050 H[a]
	Titanium dioxide (Rutilo)	TiO_2[a]
Organic flame retardant	Tetrabromobisphenol A	TBBA
	Hexabromocyclododecane	HBCD
	1,2,3,4,7,8,9,10,13,13,14,14-dodecahydro-1,4,4α,5,6,6α,7,10,10α,11,12,12a-dodecahydro-1,4,7,10-dimethanodibenzo[αε] cyclooctene	Dechlorane Plus

[a]Generally recognized as safe—a term used by the FDA.

they respond to the structure of the hindered amine and are known as hindered-amine light stabilizers (HALS).[5] Owing to their high molar mass, these additives have the advantage of limited mobility, and therefore their loss during processing or use is negligible.

Food preservation requires the use of integral solutions where the packaging plays a more active role. In this context, active packaging strategies aimed at the integration and/or controlled release of active molecules in conventional or renewable packaging systems, giving them an added value, are being developed. Evidences in the literature widely support the incorporation of antimicrobial food components and additives into packaging materials to reinforce the hurdle concept in the food production chain.[22] These compounds have proven to have an antimicrobial or bacteriostatic effect on spoilage of foods by pathogenic microorganisms, yeasts, and fungi. Several strategies intended to incorporate low-molecular-weight antimicrobial food components and bacteriocines to different films used for food packaging applications are described in the literature.[22–27] In this framework, the formulation of active packaging systems with controlled migration of natural antioxidants to foodstuff may result in prolonged shelf life and preservation of quality of the product.[27] Active substances like plant extracts and essential oils are being added to biopolymer formulations to produce biodegradable active films with antimicrobial and/or antioxidant properties.[28,29] On the contrary, aromatic ketones are being used to modify stable polymers commonly used in the manufacture of packaging materials such as polystyrene (PS) and poly(vinyl chloride) (PVC), in an attempt to make them degradable in natural environments.[30]

Flame retardants are a class of materials that are compounded into plastics to have certain defined reactions during combustion.[31] Brominated flame retardants (BFR) (Table 1) are widely used in many applications because of their low cost and high efficiency. However, the effect of such compounds on health has been studied and some of them such as octabromodiphenyl ether (octa-BDE), a type of BFR, are highly toxic, and its production has therefore been banned by the European Union. Therefore, there is a desire in the general flame retardant market to replace halogenated flame retardants with halogen-free alternatives. New phosphorus-based flame retardants seek to solve drawbacks of these more traditional non-halogens.[32] Nanoclays and carbon nanotubes are beginning to find use as antidripping agents in flame retardant packages.[33]

Identification and eventual determination of polymer additives is an important issue in many fields, mainly in the area of packaging materials where additive migration from food contact materials may have potential toxic effects in humans.[3,34–37] In biomedical applications, plasticizers present in the polymer [e.g., Di(2-ethylhexyl) phthalate (DEHP) in PVC] will readily leach into the liquids passing through it, particularly for lipid-containing fluids, e.g., blood. There is a great concern about the toxicity of DEHP, especially for risk groups such as patients in hemodialysis.[38] International regulations require that pharmaceutical, biomedical, cosmetic, and packaging materials do not interact physically or chemically with their contents or environments. Therefore, the possible release of polymer additives by plastic containers should be monitored, controlled, and minimized. Chromatographic techniques, either on their own or hyphenated to powerful analytical detection techniques, have shown a great potential to determine and eventually identify many of these compounds.

As was pointed out above, it is evident that the new reliable and rapid analysis method for polymer additives is a challenging task for several reasons: quality control, additive depletion/stability during processing and lifetime, litigation, migration studies, contamination, government regulations, and the development of new materials.

EXTRACTION AND SAMPLING METHODS

Techniques currently in use for the analysis of polymer additives have been extensively reviewed.[9,34–36] The most common analytical procedures on solid materials usually involve sample preparation and discontinuous and continuous extraction procedures[37,39] prior to the determination step, which is usually carried out by chromatographic techniques coupled to a variety of detection systems. Some innovative approaches have recently been proposed as alternatives to conventional extraction methods such as liquid–liquid extraction, liquid–solid extraction, and sonication. One example is the use of dispersive liquid–liquid microextraction (DLLME), which uses microliter volumes of extraction solvents along with a few milliliters of dispersive solvents such as methanol, acetonitrile, acetone, or tetrahydrofurane. This strategy was applied for preconcentration of organophosphorus pesticides from aqueous samples.[40] This method was very efficient and repeatable when applying for the concentration of three commercially available polymer additives, Irganox® 1076, Irganox® 1010, and Irgafos® 168, from aqueous solutions.[41]

For environmental reasons, direct examination of polymers by spectroscopy and/or by non-destructive methods is preferred over solvent-consuming techniques.[35] Poleunis et al.[42] reported the use of time-of-flight secondary ion mass spectrometry (ToF-SIMS) to analyze additive migration toward polymer surface in thin films of amorphous polyester containing variable quantities of an antioxidant (Irgafos® 168) and a UV stabilizer (Hostavin® N30). The results obtained were promising, but authors stated that ToF-SIMS data can be compared quantitatively only if the surfaces have undergone identical treatments.

Other analytical procedures, such as supercritical fluid extraction (SFE) and microwave-assisted extraction (MAE), are gaining significant attention. SFE is commonly applied to many analyses that require extraction from solid matrices and has found important applications in the

extraction of aromatic amines, organotin stabilizers, light stabilizers, and antioxidants from different polymers.[43–45] In general, compared with Soxhlet extraction, SFE ensures higher extraction efficiencies. New and improved SFE-based methods are being developed nowadays. SFE coupled to supercritical fluid chromatography (SFE–SFC) is a promising method and is believed to have a great potential in determining polymer additives.[46] In MAE, sample and solvent (or a mixture of solvents) are allocated in a vessel and microwave radiation is applied at adequate temperature. Samples are then recovered, filtered, and analyzed, generally, by a chromatographic technique. This method was successfully applied to extract commercial antioxidants (present in concentrations varying from 0.05 to 0.35 wt%) from pharmaceutical and cosmetic polyolefinic-based packaging materials.[47] For insoluble or highly cross-linked polymers, these approaches are difficult to apply; thermo-analytical extraction techniques that consist of liberating the additive by heating are required in these instances. Some thermo-analytical techniques, such as thermo-gravimetric analysis (TGA) or temperature programed pyrolysis (TPPy), specifically take advantage of relatively slow heating, in particular in combination with appropriate detection modes such as mass spectrometry (MS) (e.g., TG–MS, TG–FTIR, TPPy–MS). In such volatile removal techniques, the additives are usually detected at temperatures below the decomposition temperature of the polymer.

Other emerging environmentally-friendly extraction technique is liquid-phase microextraction assisted by porous membranes, especially hollow fiber liquid-phase microextraction (HFLPME).[48] This method is versatile and can be adapted to many analytical instruments. Dynamic HFLPME coupled with gas chromatography (GC) was applied for determining essential oils (ginger, oregano, and cinnamon) as migrants from several active films [ethylene-vinyl alcohol copolymers (EVOH)] with potential antioxidant and antimicrobial activity. Results indicate that active films containing ginger can be directly marketed without problems. Authors stated that the proposed method opens new perspectives to a technique limited until now to biomedical and environmental applications.

SEPARATION AND DETECTION

Among all chromatographic techniques that can be applied for the separation and identification of polymer additives after the extraction step, high-temperature capillary gas chromatography (CGC),[49,50] high-performance liquid chromatography (HPLC),[45,51–54] supercritical fluid chromatography (SFC),[26] size-exclusion chromatography (SEC),[55] capillary electrophoresis (CE),[56] and thin-layer chromatography (TLC),[57] are the most frequently used. In general, these techniques are coupled to different detection systems such as mass spectrometry (MS), matrix-assisted laser desorption ionization (MALDI) in combination with ToF mass spectrometry (MALDI-ToF), and Fourier transform infrared (FTIR) spectroscopy and microscopy.[57]

The separation and determination of antioxidants in polymers showed the potential use of LC for the separation and isolation of tocopherols in polymers and biopolymers.[17] It was shown that, although a large number of LC peaks were formed, they mainly corresponded to different stereoisomeric forms of only a small number of oxidative coupling products of tocopherol. Compared to classical LC, nano-LC[51] is advantageous because it is more efficient and less volume of the mobile phase is required, which in turn increases the sensitivity and reduces waste. On the contrary, this technique requires extraction procedures prior to analysis and currently the instrumentation and packed columns used are very expensive. SFE commercial system with the addition of a single six-portion valve and coupled to a reversed-phase LC system to perform online SFE–LC analysis was used for the quantitative determination of Irganox® 1010, Irganox® 1076, and Irgafos® 168 in poly(methylmethacrylate) (PMMA).[45] This SFE–LC online method was demonstrated to be more accurate because the analytes could be extracted at relatively low temperatures in the absence of light and under anaerobic conditions.

Flame retardants in polymer electronic waste were also identified by HPLC–UV/MS, and a comparison with GPC–HPLC–UV was carried out.[52] Brominated and phosphate-based flame retardants were determined. Pressurized liquid extraction followed by HPLC–UV/MS proved to be a powerful tool and covered all the compounds studied. GPC–HPLC–UV could be part of a routine quality control as reproducibility and limit of quantification are sufficient to give accurate results at levels around 0.1% dry mass.

HPLC–MS with atmospheric pressure chemical ionization (APCI) was recently used to evaluate the potential for the analysis of radiolysis products in polyethylene terephthalate (PET) irradiated with ^{60}Co gamma rays in order to evaluate the effect of such radiation on this polymer.[53] Results indicate that highly radiation-resistant polymers, such as PET, form measurable amounts of low-molar-mass degradation compounds, with their yield depending on the radiation conditions (presence or absence of air).

A new method for determining *N,N′*-ethylene-*bis*-stearamide (EBS), which is used as a high melting point lubricant for a variety of polymers, was developed by using normal-phase HPLC with evaporation-light scattering detection (ELSD).[54] First, EBS structure was characterized by GC–MS. EBS was identified, but two other molecular species (C16/C18 and C16/C16) were also present in large amounts. EBS in ethylene-vinyl acetate (EVA) was determined by dissolution/precipitation extraction method prior to HPLC procedure. Gel permeation chromatography (GPC) was envisaged in order to separate low-molar-mass compounds, despite the poor resolution. NP-HPLC with apolar solvent was used and EBS was quantified as the

unique peak as different molecular species could not be separated by NP-HPLC. This method turned out to be rapid and efficient for quantitative determination of EBS.

A food/antimicrobial coating system with sorbic acid as active compound, agar gel as model food, and wheat gluten or beeswax film as edible coating was studied by Guillard and coworkers.[14] The change in sorbic acid concentration with time, in the film and in the model food, was determined by measuring its concentration in agar gel after extraction with water by HPLC–UV. HPLC was also used recently to evaluate the kinetics of thymol (biopreservative) release from zein films.[23] Samples were immersed in water and the release of thymol was evaluated by measuring the concentration of the surrounding solution until an equilibrium value was reached. HPLC was used with a C18 reverse-phase column and detection at a wavelength of 277 nm. In all these applications, the separation step is one of the most critical during the whole analytical process.

GC combined with different extraction and detection techniques, such as Py–GC, Py–GC/MS, SFE–GC, thermodesorption cooled injection system (TD-CIS)–GC/MS among others, has been widely applied to the analysis of many additives. The use of Py–GC and Py–GC/MS in the determination of lubricants, antioxidants, plasticizers, and flame retardants was discussed in depth by Wang and coworkers.[9–11] In the case of antioxidants, Py–GC seems to provide an approach that minimizes sample preparation and follows it with a one-step effective separation and identification. A fast identification of low-molecular-weight antioxidants, which desorbed better before the polymer chain underwent decomposition, was achieved using MS detection.[49] Lubricants, which can be classified into fatty acids, their esters and amide derivatives, and waxes with a high number of carbon atoms, can be identified by Py–GC.[10] The most important advantage of Py–GC in plasticizer analysis is the elimination of sample preparation and the fact that all information can be obtained in a single experiment. The analysis of organic flame retardants requires the use of MS detection owing to the presence of halogen atoms in their structure. Off-line SFE–GC/MS was used to determine phenol, citrates, and phthalates in PVC with efficiencies of around 100%.[43,44]

Quite recently Bonini et al.[37] reported an easy method to control the migration of common plasticizers used in polymeric films for food contact packaging. The method they proposed is the result of the adaptation and optimization of the method used for determining phthalates in soft plastics for toys. The procedure comprises a Soxhlet extraction followed by a multiresidue gas chromatography analysis with flame ionization detector (FID) to evaluate the real content of plasticizers and their migration into food simulants. The procedure was applied to commercially available films for food packaging (not identified in the study). The average extraction yield was about 95%, and the chromatographic analysis was able to determine and clearly separate 16 compounds with detection limits ranging from 0.07 to 0.7 wt%. However, it is not clear whether the application of this method for the determination of these additives in biopolymers would be easy, because of the potential problems in the extraction of analytes prior to GC analysis. Therefore, the potential application of this sensitive method to biopolymers is a matter of research.

Despite its high resolution, conventional GC/MS encounters problems in solving all components in samples such as elastomers, particularly when they contain large amounts of multicomponent species. The use of two consecutive GC columns could be the solution. The method uses a non-polar column that concentrates the retained compounds for a short time and then sends them to a second shorter and narrower polar column situated in its own compartment within the main oven. The mass spectrometer is located at the end of the second column. The result of having two columns coupled in this way is that compounds can be separated by their volatility in the first column and by polarity in the second one. This strategy has been demonstrated to provide good results for additives in elastomers with a considerable increase in resolving power.[50]

SEC is usually applied to characterize complex mixtures of low-molecular-weight additives with molar masses between 150 and 1000 Da. This technique allows the classification of individual components in complex mixtures based on molar mass or hydrodynamic volume, and not on boiling point (like in GC) or polarity (in HPLC). This technique provided a reasonable separation for methylene-bridged hindered phenols and alkylated diphenylamines.[58] Compared with HPLC, SEC shows high reproducibility and simplicity in the chromatogram, which makes identification easier.

TLC remains one of the most widely used techniques for a simple and rapid qualitative separation.[57] The combination of TLC with spectroscopic detection techniques, such as FTIR or nuclear magnetic resonance (NMR), is a very attractive approach to analyze polymer additives. Infrared microscopy is a powerful technique that combines the imaging capabilities of optical microscopy with the chemical analysis abilities of infrared spectroscopy. FTIR microscopy allows obtaining of infrared spectra from microsized samples. Off-line TLC–FTIR microscopy was used to analyze a variety of commercial antioxidants and light stabilizers.[57] Transferring operation and identification procedure by FTIR takes about 20 min. However, the main drawbacks of TLC–FTIR are that TLC is a time-consuming technique and usually needs solvent mixtures, which makes TLC environmentally unsound, analytes must be transferred for FTIR analysis, and TLC–FTIR cannot be used for quantifying purposes.

Microemulsion electrokinetic chromatography (MEEKC) is an electrophoretic method that can be classified as an extension of micellar electrokinetic chromatography (MEKC) where the micelles are substituted by oil droplets. The high solubilizing ability of MEEKC allows the analysis of highly hydrophobic and aromatic polymer additives, such

as antioxidants. This technique was applied in the separation of commercial antioxidants from polypropylene (PP).[56] Two different approaches were investigated. When an acidic buffer and a negative separation voltage were used, incomplete separation of the analytes resulted. However, by using an alkaline buffer joined to a positive separation voltage the baseline separation of all analytes was achieved in less than 25 min. MEEKC is a superior separation method for these analytes, with respect to separation time, selectivity, and efficiency.

Finally, it is important to mention that huge efforts are being carried out for the development of more powerful extraction/chromatographic techniques/detection systems combinations. In this sense, highly specific stationary phases are being designed by molecular imprinting (MI).[59] MI is known as a technique that allows the fabrication of artificial receptors with recognition properties. Compounds of similar structure, like a group of β-lactam antibiotics, can be separated based on the application of molecularly imprinted polymers (MIP) as highly specific stationary phases in HPLC or capillary electrochromatography. Synthetic antioxidants, such as BHA and BHT, have been selected as templates for generating an MIP (BHA–MIT and BHT–MIT), as well as a control polymer (CP) in the absence of any template. BHA-MIT was successfully applied as the stationary phase in liquid chromatography and showed a higher affinity as compared to its CP.

CONCLUSION

The improvement in the number of published works in this area during the last years is a clear sign of the importance of the methods based on chromatography for the qualitative and quantitative analysis of polymer and biopolymer additives. This trend is expected to continue in the coming years as a response to the more stringent international regulations about additives for plastic materials and the need for more specific properties of polymer materials.

Polymers and Particles: ThFFF

Martin E. Schimpf
Chemistry Department, Boise State University, Boise, Idaho, U.S.A.

Abstract
Thermal field-flow fractionation (ThFFF) can be applied to the analysis of virtually any polymer or copolymer that can be dissolved in an organic solvent, subject to low-molecular-weight limitations discussed in this entry. Water-soluble polymers are more difficult to separate because thermal diffusion, and therefore retention, is weak in water and other protic solvents. Still, certain non-ionic polymers can be separated, and with the use of mobile phase additives, even charged materials have been retained. Proteins, on the other hand, have not been successfully separated by ThFFF.

POLYMERS

For a detailed discussion of the application of ThFFF to the analysis of various polymers see Ref. 1. Although ThFFF is mostly applied to lypophilic polymers due to their strong thermal diffusion (hence, high level of retention), other significant applications exist. For example, polyethylene oxide and polyethylene glycol show strong retention in a range of aqueous solvents, including deionized water, while polystyrene sulfonate is moderately retained in 5 mM tris-Na_2SO_4 buffer.[2] Other hydrophilic polymers that could not be retained in water have been separated in aprotic solvents. For example, a variety of polysaccharides, including pullulans, dextrans, various starches, and Ficoll™, have been separated in dimethyl sulfoxide (DMSO).[3] Ficoll is a highly branched copolymer of sucrose and epichlorohydrin. Dextrans have been separated in mixtures of water and DMSO.

ThFFF can also be combined with instrumentation that yields information on molecular weight directly, such as multiangle light scattering[4] and mass spectrometry.[5,6] Such combinations are powerful because ThFFF can greatly enhance the precision of the molecular weight information by separating the analyte into more monodisperse fractions prior to molecular weight analysis.

The major limitation of ThFFF occurs in the separation of low-molecular-weight materials. Thus, the technique is not widely applicable to molecular weights below about 10^4 g/mol. This limit can be somewhat reduced by the use of solvent mixtures.[7,8] For example, polystyrene components as small as 2500 g/mol were resolved in a mixture of tetrahydrofuran and dodecane.[4] Even lower molecular weights than 2500 g/mol have been retained, but only through the use of special channels, which were highly pressurized to increase the temperature gradient without boiling the solvent.

ThFFF has virtually no upper limit to the molecular weights that can be resolved. The channel is not packed with a stationary phase, and the flow of carrier liquid through the channel is laminar. As a result, large materials can be eluted without plugging the channel, and fragile materials are eluted without being damaged. In a comparison of ThFFF and size exclusion chromatography (SEC),[9] for example, it was found that SEC consistently underestimates the molecular weight of ultra-high-molecular-weight polymers, even when extremely low flow rates are employed and a multiangle light scattering detector is used to directly measure the molecular weight of the eluting components.[4] In addition to the problem of shear-induced damage, SEC suffers from anomalous retention effects due to adsorptive interactions between the high-molecular-weight polymers and the stationary phase. Although not completely absent, surface interactions are minimized in ThFFF because there is no packing material. Finally, the resolution of ThFFF for ultra-high-molecular-weight polymers is vastly superior to that of SEC. As a result, ThFFF enjoys a unique niche in the separation of these materials.

Another application in which ThFFF enjoys an advantage over SEC is the analysis of high-temperature polymers. The operating temperature is limited only by the degradation temperature of the spacer used to form the channel, which for polyimides can be as high as 600 K. In the analysis of high-molecular-weight polyethylene,[10] for example, temperatures in excess of 400 K are required for the samples to be soluble. Under these conditions, column stability and separation efficiency limit the application of SEC. In contrast, such samples can be routinely analyzed with commercially available ThFFF channels.

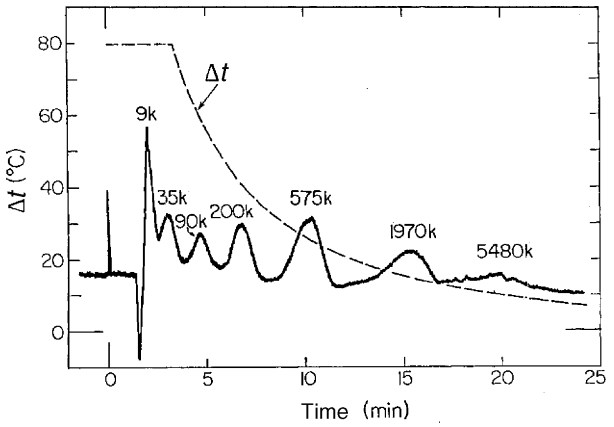

Fig. 1 Separation of seven polymers of indicated molecular weights by programed ThFFF.

Retention times in FFF are affected by the magnitude of the applied field, which can therefore be optimized for a particular molecular weight range. For extremely broad-molecular-weight distributions, the field can be programed. Fig. 1 illustrates the separation of polystyrene standards ranging in molecular weight from 9000 to 5.5 million g/mol in a single run.[11] Note that the elution order is from low- to high-molecular weight. The field, which is expressed in Fig. 1 by the temperature difference (ΔT) between the hot and the cold walls, was programed to exponentially decay from 80 to 10 K over the course of the 25 min separation.

POLYMER GELS

ThFFF is also unique in its ability to handle gel-containing polymers. To analyze such materials by SEC, the sample solution must first be filtered to prevent damage in the form of contamination or even blockage in the column. With ThFFF, such samples can be directly injected into the channel, and the gel content can even be characterized. The advantage of ThFFF for analyzing samples in which the gel contains information that is critical to the analysis has been demonstrated with acrylate elastomers.[9] ThFFF was used to correlate the gel content of such elastomers to mechanical properties after SEC combined with viscometry and light scattering failed to elucidate any difference among the samples. In a related application, ThFFF also proved superior in the analysis of natural rubber,[4,12] where the ability to analyze unfiltered samples was a clear advantage.

POLYMER BLENDS AND COPOLYMERS

The driving force for polymer retention in ThFFF is thermal diffusion, which varies with polymer composition. As a result, polymer blends and copolymers can be separated even when the molecular weights or diffusion coefficients of the components are identical. Furthermore, as thermal diffusion can be measured quantitatively by ThFFF through the thermal diffusion coefficient (D_T), the compositional distribution can, in principle, be directly obtained from elution profiles, provided the dependence of D_T on composition is known. In practice, however, there are several complications. First, retention does not yield D_T directly, but rather the Soret coefficient, which is the ratio of D_T to the ordinary diffusion coefficient (D). As compositional information is contained in D_T alone, an independent measure of D must be available. Second, a general model for the dependence of D_T on composition has not been established; therefore the dependence must be empirically determined for each polymer–solvent system. Fortunately, D_T is independent of molecular weight,[13] and for certain copolymers, the dependence of D_T on chemical composition has been established. With random copolymers, for example, D_T is a weighted average of the D_T values for the corresponding homopolymers, where the weighting factors are the mole fractions of each component in the copolymer.[14] For block copolymers, solvent mixtures can be used to obtain a linear dependence of D_T on composition.[15] As a result, the composition of random copolymers can be determined by combining ThFFF with methods either for calculating or measuring D. For example, dynamic light scattering can be directly used to measure D, while SEC can be used to measure D through calibration curves that relate log$D$ to the retention volume.[13] Mark–Houwink coefficients can also be used to calculate D.[16] Once the value of D is obtained for a separated component, the D_T value of that component can be calculated from its ThFFF retention and used to obtain compositional information.[17–19] The method was first demonstrated in the determination of both molecular weight and composition of styrene–isoprene copolymers, where an online viscometer was used to obtain both D and viscosity-average molecular weight of the components separated by ThFFF.[19] Even more powerful is the combination of ThFFF and SEC in producing 2-D separations. Here, the components are first separated by SEC; fractions from the SEC elution profile, which have similar D values, are further separated according to chemical composition by ThFFF.[15,20]

COLLOIDS AND PARTICLES

Historically, the application of FFF to colloids and particles has been limited to flow and sedimentation FFF. However, the ThFFF channel is not only capable of separating these materials, it is also simpler in design and can be used with both aqueous and organic solvents. Furthermore, the dependence of retention on chemical composition

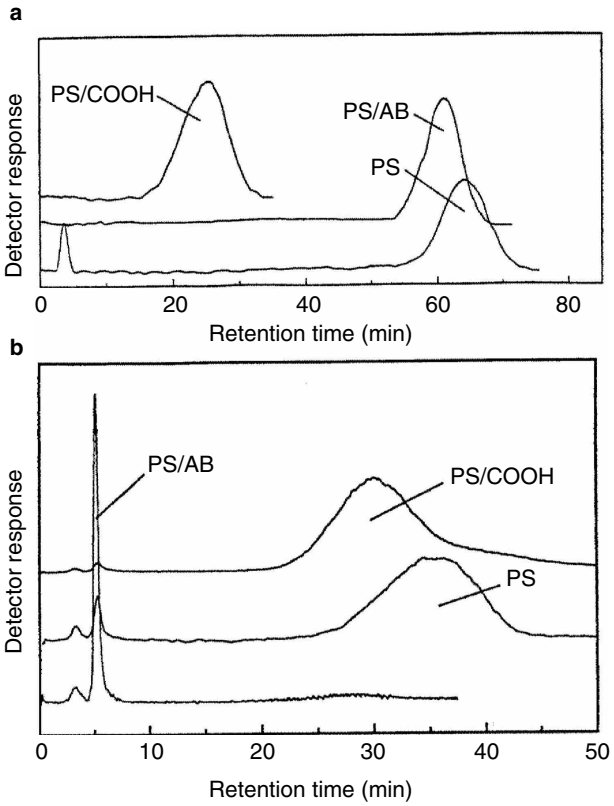

Fig. 2 A comparison of ThFFF elution profiles for 0.2 μm particles of polystyrene (PS), carboxylated PS (PS/COOH), and (aminated PS (PS/AB): a) in an aqueous solution containing 9 m*M* NaN_3 and 0.05 wt% FL-70 surfactant (pH 8.5); b) in 10 m*M* phosphate buffer (pH 4.7). Differences in retention are due to differences in thermal diffusion, which is governed by the composition and energy of the particle surface.

presents unique opportunities for the separation of such materials.

The application of ThFFF to a variety of colloids and particles has been demonstrated in both aqueous and organic carrier liquids.[21–25] Fig. 2 illustrates the dependence of retention on the surface composition of polystyrene particles. The three particles are similar in size, but the surface of one of the samples has been carboxylated, while that of another has been aminated. The relative order of elution of the three particles can be changed by modifying the carrier liquid.[21] Increasing the strength of the carrier liquid generally leads to an increase in retention up to a certain point, beyond which a plateau value is reached.[21–23]

Finally, in the separation of micron-sized particles the elution order is reversed, with larger particles eluting ahead of smaller ones due to negligible diffusion. In this case, particles are "lifted" into the faster-moving flowstreams by hydrodynamic forces that increase with particle size. In this so-called hyperlayer mode, particle retention tends to decrease with the flow rate of the carrier liquid, as well as with particle size.[25]

EXPERIMENTAL CONSIDERATIONS

One of the most common mistakes made in the analysis of polymers by ThFFF and SEC is the injection of too much sample; this is often referred to as overloading. It is important to understand that *D*, and therefore retention volume (V_r), varies strongly with polymer concentration above the so-called critical concentration (c^*), where polymer solutions undergo an abrupt transition from "dilute to semidilute" behavior. In the semidilute regime, polymer coils tangle with one another and the magnitude of *D* dramatically drops. Therefore, it is important to keep the polymer concentration below c^* to avoid overloading effects, which manifest as peak "fronting" and an increase in V_r. With excessive overloading, additional peaks appear in ThFFF due to the formation and separation of aggregates.

Although experienced users of SEC are aware of overloading effects, they are not always aware that overloading occurs with a smaller sample load in ThFFF. First, the channel has a relatively small volume (1–2 ml); therefore, injection volumes are smaller (3–30 μl) as compared to those in SEC. More importantly, the sample is initially concentrated against one wall by the field. The extent of concentration varies with the sample and the magnitude of the applied field. A general rule that should be used to avoid overloading when a new method is being developed is to prepare the sample with a concentration that is one-tenth of the expected critical concentration. Of course, the critical concentration varies with molecular weight and other factors. In general, it is typical to use a sample concentration that is between one-fourth and one-tenth of that used in SEC. Sample concentrations between 0.01 and 1 mg/ml are typical. When one is uncertain of the critical concentration, the injected concentration should be varied and the elution profiles examined for indications of sample overloading. Otherwise peak shape and reproducibility will be compromised. With recent advances in the sensitivity of detectors used for polymer analysis, sample overloading is less of a problem because even highly dilute samples can be analyzed, but overloading can still occur if the user is not aware of the potential.

CONCLUSION

ThFFF is a separation technique that complements SEC in two primary ways. First, its resolving power increases with the molecular weight of the sample, and it virtually has no upper-molecular-weight limit. Second, it separates polymers depending on their chemical composition and their molecular weight. ThFFF can also be used to separate colloids and particles by size and surface composition. Because the shear forces in the FFF channel are less,

ThFFF has found a unique niche in the separation of ultra-high-molecular-weight polymers and other fragile materials, as well as polymer gels and particles that tend to clog chromatography columns.

Universal calibration of ThFFF channels can be achieved, but one additional piece of information is required for each polymer–solvent system under consideration, which is the thermal diffusion coefficient. Fortunately, this coefficient is independent of molecular weight, so only one such coefficient is required for each system. Such coefficients are available in the literature for many systems, or they can be measured using ThFFF. Once the thermal diffusion coefficients are obtained, universal calibration plots are based on the same principles as those used in SEC, and utilize intrinsic viscosity measurements. A thorough discussion of ThFFF and its applications can be found in the *Field-Flow Fractionation Handbook.*[1]

Polymers: Additives

M.L. Marín
Alfonso Jiménez
Department of Analytical Chemistry, Nutrition and Food Sciences, University of Alicante, Alicante, Spain

INTRODUCTION

The need for developing methods of analysis for additives in plastics materials is increasing day by day because of several aspects. First, as toxicological studies are developed, there is the presence of some substances which have been banned in specific products. Second, in production, it is necessary to carry out a quality control for additive levels. It is also necessary to determine the stability of the additives when the polymer is processed. In this case, some additional compounds, often undesirable, can be generated and their control becomes necessary. Finally, the analysis will let us know the composition of a plastic product.

It is possible to use techniques in which the additives can be determined by direct analysis of the sample, such as nuclear magnetic resonance (NMR) spectrometry, ultraviolet (UV) spectrometry, and UV desorption–mass spectrometry (MS). These techniques are very useful when the concentrations of additives in the polymer are high. However, when additives are present in trace levels, it is necessary to carry out a preliminary extraction/concentration step before analysis. Some of the most common additives used in plastics materials are presented in Table 1.

SAMPLE PREPARATION

As was previously mentioned, a preliminary extraction step is necessary for samples in which a low level of organic compounds of interest must be determined. The extraction presents advantages when compared to the direct plastics analysis solution. In this case, the polymer is dissolved directly in an organic solvent and then precipitated. This procedure is not selective and the polymer residues can affect the analysis of the additives. When an extraction is carried out, higher selectivities can be obtained when the appropriate extraction conditions are used.

Traditional methods of extraction, such as Soxhlet, have been replaced by modern techniques as supercritical fluid extraction (SFE), microwave-assisted extraction (MAE), ultrasonic extraction, and accelerated solvent extraction (ASE) during recent years. The application of specific methods to these kinds of samples has permitted the development of a great number of other extraction methods. In the following list, a brief description is given:

- SFE: This method uses pressure and temperature for fluids above their critical points. Under these conditions, the density and diffusivity of a supercritical fluid are between those of liquids and gases, resulting in an increase of the solvent power.
- MAE: In this case, the sample and solvent are placed in a vessel and microwave radiation is applied. The solvent is heated under pressure above its normal boiling point so it remains in the liquid state.
- ASE: Common solvents are used, at elevated temperatures and pressures, to increase the speed and efficiency of the extraction process.

In general, each of these procedures presents advantages: They are faster, an extract concentration step is not necessary, a minimal amount of solvents is used, so they are environmentally friendly, and cleaner extracts are obtained. Thus, when the extract is obtained, a separation technique such as chromatography, can be applied in order to analyze the sample qualitatively and quantitatively.

There are many publications showing the applications of SFE to the determination of polymer additives. Antioxidants such as Irganox 2246, BHT and others, as well as UV stabilizers such as Tinuvin P, have been effectively extracted with supercritical CO_2. Extraction conditions varied from 15 to 25 MPa at 60°C and with a total time of 30 min.[1] If microwaves are applied to extract these compounds, a mixture of solvents can be used (acetone–heptane, for example) and time is considerably reduced (from 3 to 6 min).

Phthalate plasticizers are extracted with the same supercritical fluid at a pressure of 48 MPa at 95°C for the same amount of time.[2] Other phthalate plasticizers, such as TOP and TOTM are extracted from poly(vinyl chloride) (PVC) by ASE with ether at 100°C for 20 min.

CHARACTERIZATION OF POLYMER ADDITIVES WITH CHROMATOGRAPHIC TECHNIQUES

There are several techniques that can be used for the determination of polymer additives after extraction;

Table 1 Common additives used in plastic products.

Additive type	Chemical name	Commercial name
Antioxidants	Di-*t*-butyl-*p*-cresol	Bisphenol A
	Dioctadecyl (3,5-di-*t*-butyl-4-hydroxybenzyl)phosphate	Irganox 1093
	2,2′-Methylene bis (4-methyl-6-*t*-butylphenol)	Irganox 2246
	Tris(2-methyl-4-hydroxy-5-*t*-butylphenyl)-butane	Topanol CA
	4,4′-Thio-bis (6-*t*-butyl-*m*-cresol)	Santonox
Light stabilizers	2-(2′-hydroxy-3,3,5-di-*t*-amylphenyl)benzotriazole	Tinuvin 328
	Bis(2,2,6,6-tetramethylpiperidin-4-yl)sebacate	Tinuvin 770
	2-(2-Hydroxy-5-methylphenyl)-2*H*-benzotriazole	Tinuvin P
	2-Hydroxy-4-*n*-octoxybenzophenone	Chimassorb 81
Plasticizers	Di(2-ethylhexyl) phthalate	DEHP
	Disononyl phthalate	DINP
	Di(2-ethylhexyl) adipate	DOA
	Dipropylene glycol dibenzoate	Benzoflex 9–88
	Tributyl-*O*-acetylcitrate	Citroflex A
	Tris(2-ethylhexyl) phosphate	TOP
	Trioctyl trimellitate	TOTM
Colorants	Monoazo benzimidazole pigment	
	Pigment Red 176	
	Solvent Blue 97	
Flame retardants	Tetrabromobisphenol A	TBBA
	Hexabromocyclododecane	HBCD

for example, high-performance liquid chromatography (HPLC), supercritical fluid chromatography (SFC), and high-temperature capillary gas chromatography (GC) are the most widely used. Capillary gas chromatography is especially useful because it combines high resolution with the possibility of coupling the instrument with some sophisticated detection techniques, such as mass spectrometry (MS), Fourier transform infrared (FTIR), or atomic emission detection (AED). MS is the most suitable detector for GC; it is very easy to prepare a personal spectral library for identification of separated species. There are also commercially available spectral libraries. Apart from the fact that the versatility of GC is due to its detectors, the injection systems provide a higher number of applications; for instance: on-column, split/splitless, and headspace techniques, among others. Today, almost every organic substance can be analyzed by gas chromatography, because of the development of high-temperature injectors. The combination of SFC with MS is also useful. In some cases, an online extraction is used, such as SFE–SFC.[3]

The case of HPLC is quite different, because of the peak broadening or, sometimes, when the additives cannot be eluted from the stationary phase. However, it is a very useful technique when analyzing high-molecular-weight additives and, in combination with diode-array detection, provides an important tool for qualitative analysis. An important application is the determination of organic colorants in cosmetics.[4] HPLC is also applicable for the determination of linear and cyclic derivatives from poly(ethylene terephthalate), extracts of which were obtained using supercritical CO_2.[5]

OTHER DETECTION SYSTEMS

The analysis of extracts is also possible by using other techniques, such as infrared spectrometry. This kind of detector is very useful because it provides a total spectrum for the analyte. For example, a method for analyzing poly(dimethylsiloxane) oil from polymer samples was developed by Kirschner et al. [6] In this case, the extractor is directly coupled to the spectrometer. However, it is also possible to carry out offline analyses with high recoveries. This combination was also used by Raynor et al.[7] in order to analyze some UV stabilizers such as Tinuvin 770, Irganox 1010, and Topanol OC. In this case, a preliminary separation was carried out by supercritical fluid chromatography.

Polymers: Concentration Effects on ThFFF Separation and Characterization

Wenjie Cao
Mohan Gownder
Huntsman Polymers Corp., Odessa, Texas, U.S.A.

INTRODUCTION

The understanding of the effects of sample concentration (sample mass) in field-flow fractionation (FFF) has being obtained gradually with the improvement of the sensitivity (detection limit) of high-performance liquid chromatography (HPLC) detectors. Overloading, which was used in earlier publications, emphasizes that there is an upper limit of sample amount (or concentration) below which sample retention will not be dependent on sample mass injected into the FFF channels.[1] Recent studies show that such limits may not exist for thermal FFF (ThFFF) (may be true for all the FFF techniques in polymer separation), although some of the most sensitive detectors on the market were used.[2]

Experimental results indicate that the effects of sample mass include, but not exclusively, the following aspects.

Increased Polymer Retention

Fig. 1 shows the fractograms of ThFFF to show the concentration effects for poly(methyl methacrylate) (PMMA) in tetrahydrofuran (THF), where M_p is the peak average molecular weight, m is the sample mass in micrograms injected into the ThFFF channel, and t^0 is the retention time of a nonretained species such as toluene. When the molecular weight (MW) of a polymer is moderate or higher, say above 300×10^3 g/mol for PMMA in THF, a moderate increase in concentration will result in longer retention. As reported in Ref.,[2] the detector limits for the study was 0.09 μg of sample mass for 1000×10^3 g/mol polystyrene using an ultraviolet (UV) detector and 1 μg for 570×10^3 g/mol PMMA with an evaporative light-scattering detector. The retention was measured for sample masses ranging from these limits to more than 20 μg and was consistently found to increase with the increase in sample mass. The high limit, below which polymer retention is not dependent on concentration, was not found.

Broader Polymer Peaks

Increased concentration will increase band broadening in all chromatographic techniques, but it seems that the effect of concentration on band broadening is more serious in FFF, due to its concentration enhancement as shown by Fig. 1, and by Fig. 5 of Ref.[1] More details will be discussed in the next section.

Distorted Peaks and Double-Topped Peaks (Ghost Peaks)

When the amount of sample mass injected into the ThFFF channel is moderate, say 1–10 μg for a typical channel, the peaks are pretty symmetrical and not much distortion may be observed for small polymers, as shown by Fig. 1. Increased retention may be observed for high-MW polymers.[2] When sample mass is further increased, say more than 20 μg, distorted peaks, even double-topped peaks or ghost peaks, may be observed for high-MW polymers as shown by Fig. 1, Fig. 6 of Ref.,[1] and Fig. 3 of Ref.[2] The detailed report and discussion of double-topped peaks can be found in both Refs.[1,2]

ENHANCED VISCOSITY IS BLAMED FOR THE SAMPLE CONCENTRATION EFFECTS

The viscosity of a polymer solution is highly dependent on concentration, temperature, and MW, as discussed below.

Concentration and Viscosity Enhancement in FFF

The amount of sample injected into the FFF channels can affect the retention time, primarily by influencing the viscosity of the solute–solvent mixture in the sample zone.[1,2] Unlike other chromatographic polymer separation methods [e.g., gel permeation chromatography–size-exclusion chromatography (GPC–SEC) and temperature rising elution fractionation (TREF), etc.], the viscosity of the fluid is not homogeneous at a given channel (column) cross section. In order for the samples to be retained by FFF, the concentration must be larger near the accumulation wall than that near the depletion wall.[3,4] In chromatography, sample concentration changes only along one dimension (i.e., the flow axis) whereas in FFF, sample concentration varies along two dimensions, one being the flow axis and the other one is across the channel thickness, which is

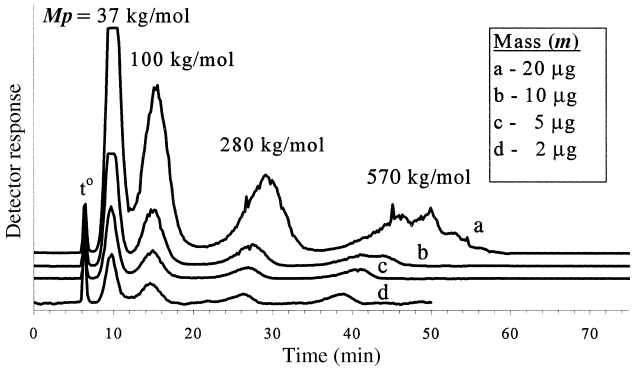

Fig. 1 Fractograms of PMMA in THF showing the effect of sample concentration on retention. Experimental conditions: cold-wall temperature, 25°C, *T*, 50°C; flow rate, 0.1 ml/min.

perpendicular to the flow axis. The concentration across the channel thickness varies due to the migration of the molecules under the influence of the temperature gradient across the ThFFF channel.[3] The concentration distribution is approximately exponential as given by

$$c(x) = c_0 \exp\left(\frac{-x}{\lambda w}\right) \tag{1}$$

where $c(x)$ is the concentration at distance x across the channel thickness measured from the accumulation wall, c_0 is the concentration at the accumulation wall, w is the channel thickness, and λ is the retention parameter or reduced mean thickness of the sample zone. Shortly after injection, the sample zone is assumed to broaden into a Gaussian distribution along the z axis, corresponding to the direction of flow down the channel. The two-dimensional concentration becomes[5]

$$c(x,z) = c_{00} \exp\left(\frac{-(z-Z)^2}{2\sigma^2}\right) \exp\left(\frac{-x}{\lambda w}\right) \tag{2}$$

where Z is the distance traveled by the center of the zone down the channel. The concentration at the accumulation wall at the center of the zone, c_{00}, is found from[6]

$$c_{00} \simeq \frac{V_{\text{inj}} c_{\text{inj}} L}{(2\pi\sigma^2)^{1/2} V^0 \lambda} \tag{3}$$

where V_{inj} is the volume of sample injected, V^0 is the void volume (channel volume), c_{inj} is the concentration of the injected sample, L is the length of the channel, and σ is the sum of the variances contributing to the zone breadth.

A rough calculation using Eq. 3 indicates that the concentration of c_{00} can be as high as 20 times the concentration of the original polymer solution. The concentration of the sample zone, therefore, can be enhanced dramatically in FFF.

The relationship between viscosity and concentration of polymer solution is very complex. Several empirical equations are necessary to describe the viscosity behavior of a polymer solution's dependence upon concentration. As an example, the following equation can be used for dilute solutions:[7]

$$\eta = 0.54 + 1.3374C + 1.1593C^2 \tag{4}$$

where η is viscosity in centipoise and C is the concentration in grams per deciliter.

For the concentration where a microgel may be formed, the following equation is proposed:[8]

$$\eta = BM^3C^{3.7} \tag{5}$$

where B is a constant and M is the polymer's molecular weight.

Although various empirical equations can be found in the literature, the common aspect is that the viscosity of a polymer solution is highly dependent on concentration and molecular weight.

Temperature Dependence of Viscosity

The effect of temperature on the viscosity of the carrier can be expressed as[5]

$$\frac{1}{\eta} = a_0 + a_1T + a_2T^2 + a_3T^3 \tag{6}$$

where a_0, a_1, a_2, and a_3, are empirically obtained coefficients.

As Eq. 6 shows, the viscosity of a polymer solution is highly dependent on temperature. The sample zone of a high-MW polymer is pressed much closer to the cold wall in ThFFF. Its viscosity is more enhanced than with a low-MW polymer. The concentration effect, therefore, is more serious for high-MW polymers in ThFFF.

Molecular-Weight Dependence of Viscosity

If the temperature and concentration are kept the same, the viscosity of higher-MW polymer solution is higher, as shown by Eq. 2; thus, more distortion of its peak is expected, as shown by Fig. 1.

Unlike most of the elution separation methods, such as HPLC, GPC/SEC, gas chromatography (GC), and so forth, where the concentration of the sample zone will never be higher than the stock solution before injection, FFF will concentrate the samples, that is to say that sample concentration will be enhanced near the accumulative wall of FFF and the cold wall in ThFFF. The higher the MW of the polymer, the more the concentration will be enhanced and the lower the temperature of the sample zone will be. All three factors, concentration, temperature, and MW, contribute

simultaneously to enhance the viscosity of the sample zone of the polymers in ThFFF. The viscosity of the sample zone can reach such extension that there is a tendency for the carrier fluid to flow over the top of the zone, with increased velocity in the region above the sample zone. The moving fluid will go over the sample zone, thus resulting in a longer retention for the sample zone; this is like a sticky slump going slowly on the floor of a river. A longer retention will be observed even if the flow rate of the carrier is constant.

When the MW of the polymer is so large that its zone is compressed close to the cold wall, the temperature of the sample zone becomes, essentially, the temperature of the cold wall, 25°C in many experiments. The viscosity is enhanced so much that the flow velocity of the carrier fluid is further distorted, so that deformed or double-topped peaks will be produced.

For the double-topped peaks, pseudo-gel, formed near the cold wall, is also proposed due to the low temperature and high concentration of the sample zone in ThFFF.[2,9] The behavior of a pseudo-gel solution is quite different from the polymer solution from which it is formed. The diffusion coefficient of a pseudo-gel is much smaller than that of the original polymer, and the viscosity of the pseudo-gel solution will be much larger than that of the original polymer solution. The pseudo-gel, in theory, will be compressed closer to the cold wall and will elute out of the channel later than the parent molecules. However, as the size of the pseudo-gel cluster increases, hydrodynamic effects will result in an earlier emergence from the channel.[3] If either of these scenarios occurs in the ThFFF channel, double peaks might be observed for a sample of a single peak without "overloading."[10]

CONCLUSIONS

Any attempts to obtain the parameters of the chromatograms and the physicochemical constants which are measurable in theory, by FFF, will be affected by the sample mass injected into the FFF channel. All of the concentration effects on the chromatograms discussed in the previous sections will be transferred, in turn, to those measured parameters and the physicochemical constants, such as the mass selectivity (S_m), the common diffusion coefficient (D), the thermal diffusion coefficient (D_T) and so forth. The increased retention of large polymers will result in enhanced mass selectivity in ThFFF. For a long time, this enhanced selectivity, in turn, the enhanced ThFFF universal calibration constant n, has led to confusion concerning the accuracy and repeatability of FFF, because different research groups have reported different data for selectivity and physicochemical constants measured by FFF for a given polymer–solvent combination.[2,11] Recent studies show that the enhanced selectivity and the different values of the physicochemical constants reported by different laboratories, measured by ThFFF, may be caused by different concentrations (sample mass) used by different laboratories.

Polymers: Degradation in GPC/SEC Columns

Raniero Mendichi
Institute of Macromolecular Chemistry, National Research Council (CNR), Milan, Italy

INTRODUCTION

Size-exclusion chromatography (SEC) is a well-established method for the determination of the molar mass distribution (MMD) of polymers. However, the determination of the MMD by SEC substantially excludes ultrahigh-molar-mass (UHMM) polymers. Actually, it is well accepted that UHMM polymeric samples degrade, by shearing or elongational forces, in the SEC columns. The upper limit of the molar mass for a successful SEC fractionation without degradation of the sample depends on the broadness of the MMD of the sample from the SEC columns used and, obviously, from the experimental conditions. Successful SEC fractionations of narrow MMD standards up to 1×10^7 g/mol of molar mass have been reported. Instead, when the MMD of the sample is broad, rarely does the molar mass of the polymeric samples exceed the upper limit of 1×10^6 g/mol.

DISCUSSION

Whenever SEC fractionation has been applied to UHMM polymers, severe problems, strongly interrelated, have been invariably reported. The degradation of UHMM polystyrene during SEC fractionation in a good solvent has been often reported. The degradation of some other UHMM synthetic polymers [polyethylene, polyisoprene, polyacrylamide, polyisobutylene, poly(methyl methacrylate), etc.] has been reported. Besides, the degradation of some natural polysaccharides such as hyaluronic acid has been reported. The possible degradation of the polymeric sample is not the only problem of the SEC fractionation of UHMM polymers. The degradation of the UHMM sample in the SEC columns is often accompanied by some other important problems, such as (a) concentration effects, (b) anomalous flow, (c) poor column resolution (band broadening), and (d) very poor reproducibility.

Generally, the practical difficulties in the SEC fractionation exponentially increase with the polymer molecule's dimension, hydrodynamic volume, hence with the molar mass and the conformation, stiffness, of the polymer. For many years, SEC has been considered inadequate for the fractionation of UHMM polymers. In the past, there have been many theoretical and experimental studies[1,2] to elucidate a better knowledge of the degradation of UHMM polymers. Furthermore, there have been notable improvements in the SEC column's performance. At this time, there are commercially available SEC columns specifically designed for the fractionation of UHMM polymers.

Evidence of the degradation of the polymeric sample may be found by using qualitative and quantitative methods. From a qualitative point of view, an accurate analysis of the chromatogram of a series of narrow MMD standards with increasing molar mass, under identical analytical conditions, would be self-evident. The resolution of the SEC columns, almost in the low-molar-mass range, generally is very good. In the high-molar-mass range, $M > 1 \times 10^6$ g/mol, the resolution of the SEC columns quickly decreases. In the presence of the degradation of the sample, the resolution of the SEC columns is poor or absent. Furthermore, the peak shapes of degraded UHMM narrow standards is abnormally broad with a severe tailing. Obviously, we assume the absence of non-steric fractionation. To find evidence of the degradation of broad MMD samples is more difficult. The analysis of the peak shape of a broad MMD sample requires experience. Generally speaking, a chromatogram that presents too steep slopes, shoulders, excessive tailing, or multipeaks is suspect from the point of view of the degradation of the sample. Obviously, the origin of these anomalous shapes of the chromatogram could be different. Concentration effects and anomalous flow often accompany the degradation of the sample. The qualitative analysis is used only to identify the problem.

A quantitative analysis of the degradation of the sample substantially requires the use of an online absolute detector such as light scattering (SEC-LS). In this case, the online LS detector directly measures, without calibration, the molar mass of the sample. The characterization of a series of narrow MMD standards with increasing and known molar mass evidences the degradation of the sample. The simple direct comparison of the known molar mass of the standards and the molar mass value obtained from the LS detector provides an estimate of the extent of the degradation under the experimental conditions used. Furthermore, if the dispersity D of the standards is very narrow (i.e., $D \leq 1.05$), the central part of the $M = f(V)$ plot, where M is the molar mass and V the elution volume, of each standard from the LS detector could be substantially flat. In fact, the central part of the peaks of the standards could be considered homogeneous in molar mass and the residual broadness of the peak is substantially due to the band broadening of the system. In the presence of degradation of the sample, the $M = f(V)$ plot of a narrow

standards is not flat (M = constant) but steep. The method could be used to set up the experimental condition (columns set, flow rate, sample concentration) to avoid the degradation of the sample.

Fig. 1 shows the experimental $M = f(V)$ plot of a narrow MMD polystyrene (PS) standard ($M = 1.15 \times 10^7$ g/mol, $D = 1.03$) from an online LS detector. The experimental conditions were as follows: one column, packed with 16 μm spherical particles of porous silica; tetrahydrofuran as the mobile phase; 0.8 ml/min flow rate; 0.1 mg/ml of sample concentration; 100 μl injection volume. Fig. 1 evidences the quick decrease of the molar mass of the sample due to the degradation of the UHMM PS sample in the column. A fractionation with the identical experimental conditions, column, and concentration and a 0.2 ml/min flow rate shows a constant $M = f(V)$ plot (i.e., the absence of degradation).

The origin of the degradation of the sample could be in the SEC columns and, for UHMM polymers, also in some other critical part (detector cell, long narrow capillary tube, injector, etc.) of the fluidic system. The extent of degradation also depends on the experimental conditions, particularly the flow rate and the concentrations of the polymeric solutions. In an SEC column, there are three parameters that have to be optimized for a successful fractionation of UHMM polymers. Two parameters are related to the packing of the column: particle size and pore size. The last parameter, often incorrectly ignored, is the dimension of the pores of the inlet and outlet frits of the column. It is well accepted that for a successful fractionation of UHMM polymers, one must use SEC columns with the diameter of the particles larger than 10 μm. In organic solvents, 20 μm particle columns are customarily used. However, in aqueous solvent, there are commercially available 15 μm nominal, maximum 17 μm particle columns. Obviously, the efficiency of the column quickly decreases with the increase of particle size. As usual, one needs to find a reasonable compromise between discordant effects.

The influence of the pore size on the degradation of the sample is not generally accepted. However, to obtain a meaningful fractionation on the basis of the dimension of the macromolecules, it is necessary that the pore size be higher than the dimensions of the molecules. The maximum dimension of UHMM macromolecules could be of several hundreds of nanometers. Polymer degradation strongly decreases with the large pore size of the frits of the columns. The commercially available 20 μm-particle SEC columns commonly use 10 μm inlet and outlet frits. Finally, it is very important to remember that partially obstructed frits could cause strong polymer degradation.

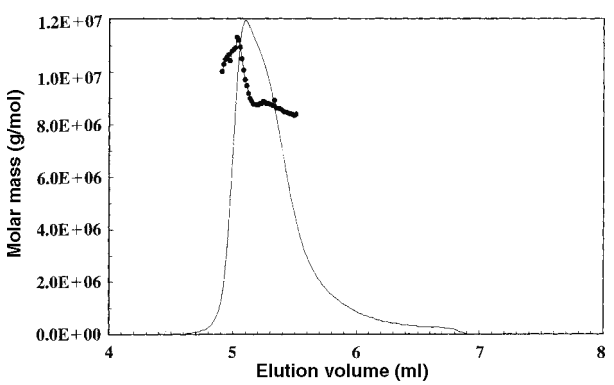

Fig. 1 Experimental $M = f(V)$ plot from an online LS detector.

Also, the experimental conditions have to be optimized to avoid the degradation of UHMM samples. Particularly, the flow rate and concentration of the sample are two critical parameters. Polymer degradation strongly increases with the increase of the flow rate. For a successful fractionation of UHMM macromolecules, it is necessary to use a very low flow rate. With UHMM macromolecules, it is not unusual to use a flow rate of 0.2 ml/min or less.

The influence of the polymer concentration is well known in SEC. Theoretically, SEC assumes independence of the elution volume with regard to the concentration of the molecular species. Practically, it is well known that a high concentration of the sample solution leads to distortion of the polymer peak and dependence of the elution volume on the concentration of the sample. The "concentration effect"[3] depends on the difference in molecular mobility between the pure solvent and the viscous polymeric solution. This difference causes nonuniform flow, often called "viscous fingering," and, as a result, multiple peaks. In addition, it is well known that a high sample concentration decreases the hydrodynamic volume of the macromolecules. SEC fractionation is based on the hydrodynamic volume of the macromolecules; hence, this effect causes the dependence of the elution volume on the concentration, at least for high-molar-mass polymers.

The concentration, with UHMM macromolecules, also influences the degradation of the sample. Hence, in the fractionation of UHMM polymers, the concentration is very critical and has to be as low as possible. A sample concentration of 0.1 mg/ml or less is not unusual with UHMM polymers. In this case, it is necessary to use the minimal sample concentration that is consistent with the sensitivity of the concentration detector.

To avoid the degradation of the sample, some authors suggest the use of an ideal "theta" solvent as the mobile phase.[4] It is well known that the dimension of the macromolecules depends on the expansion factor α (excluded volume). For an ideal theta solvent, $\alpha = 1$ and the dimension of the macromolecules is minimal. For many polymers, an ideal theta solvent is known. For example, cyclohexane at 34.0°C is an ideal solvent for polystyrene polymers. For a polyelectrolyte polymer, ideal solvent means infinite ionic strength. Obviously, this condition is impracticable. Nevertheless, for example, the dimension of the macromolecules of an hyaluronic acid, anionic polymer, sample ($M = 7.4 \times 10^6$ g/mol) approximately

decreases 20% when the solvent is changed from 0.15 *M* to 0.5 *M* NaCl. The use of ideal solvents to avoid the degradation of the sample is not generally accepted. In fact, using ideal solvents as the mobile phase could cause absorption of the polymer onto the column's packing. Also, some authors hypothesize that the degradation of the sample could also increase with ideal solvents.

At equilibrium conditions, at very low concentration, the elution volume of a macromolecule should be independent of the flow rate. However, with increasing molar mass in the UHMM range, in the absence of degradation, the elution volume strongly depends on the molar mass of the sample. This result does not depend on the concentration of the sample. This "retardation" effect occurs also at very low concentrations below the overlapping concentration c^*. The "retardation" of UHMM macromolecules has been studied by several workers;[5,6] it is a very complex effect and substantially still not well understood. The "retardation" effect is particularly meaningful in proximity to the exclusion limit of the columns and when the pore size approximately equals or is lower than the sizes of the macromolecules. A trivial conclusion is that for a successful fractionation of UHMM macromolecules without "retardation" effects, one must use SEC columns with ultralarge pore sizes.

Degradation of the sample and related problems, such as the "concentration effect" and anomalous flow, are the more important problems in the fractionation of UHMM polymers. The critical point in the characterization of the UHMM polymers is the fractionation in the SEC columns. For a successful fractionation of UHMM macromolecules, one must use specifically designed SEC columns with large particle sizes and ultralarge pore sizes. Furthermore, many aspects of the experimental protocol, such as flow rate and sample concentration, which is not critical in the usual molar mass range, become determining with UHMM polymers. A successful characterization of UHMM polymers requires optimization of the experimental protocol. Each step of the experimental protocol should be performed methodically to achieve the absence of sample degradation and reliable results.

Polymers: GPC Determination of Intrinsic Viscosity

Yefim Brun
Waters Corporation, Milford, Massachusetts, U.S.A.

INTRODUCTION

The intrinsic viscosity is a widely used measure of molecular weight, M, and size (dimensions) of macromolecules in dilute solution. Important information about macromolecular architecture and conformations can be obtained from the molecular-weight dependence of intrinsic viscosity for a homologous series of polymers. Size exclusion chromatography (SEC) provides a unique opportunity to measure this dependence in a single chromatographic run. Another striking coincidence is that the dimensions of a macromolecule associated with its frictional properties in dilute solution (i.e., with the intrinsic viscosity) determine the elution time (volume) in size-exclusion separation. This allows one to use the intrinsic viscosity measurement as a crucial intermediate step in the determination of molecular weights and molecular-weight distributions of polymers. From the above, it might be assumed that online intrinsic viscosity measurements represent an important aspect of contemporary gel permeation chromatography (GPC).

SOLUTION VISCOSITY

There are several dilute solution viscosity quantities used in the determination of the intrinsic viscosity. The size of macromolecules in solution is associated with an increase in viscosity of the solvent brought about by the presence of these molecules. Relative viscosity is a dimensionless quantity representing a solution/solvent viscosity ratio, $\eta_r = \eta/\eta_0$, where η and η_0 are the solution and solvent viscosities, respectively. The specific viscosity $\eta_{sp} = \eta_r - 1$ is the fractional increase in viscosity between the solution and solvent. The effect of the concentration can be normalized by division of η_{sp} by the concentration C, expressed in grams per deciliter (g/dl). This concentration-normalized viscosity is termed the reduced specific viscosity or η_{sp}/C (the International Union of Pure and Applied Chemistry (IUPAC) preferred term is viscosity number). Another related term, the inherent viscosity, is expressed as $\eta_{inh} = (\ln \eta_r)/C$ (the IUPAC preferred term is logarithmic viscosity number).

In order to relate viscosity to molecular weight, the value of reduced (or inherent) viscosity is extrapolated to zero concentration. This parameter is called the intrinsic viscosity $[\eta]$, and is usually expressed in deciliters per gram (dl/g) (the IUPAC preferred term is limiting viscosity number, ml/g):

$$[\eta] = \lim(\eta_{sp}/C) = \lim \eta_{inh}(C \to 0) \quad (1)$$

Practically, the limit in Eq. 1 is achieved when the concentration is so low that the frictional interactions between an individual macromolecule and a solvent are not affected by the presence of other macromolecules in the same solution. Under these conditions, which are typical for the GPC/SEC experiments, the difference between the reduced and intrinsic viscosities is negligible.

CALCULATION OF INTRINSIC VISCOSITY IN GPC

The opportunity to measure the dilute polymer solution viscosity in GPC came with the continuous capillary-type viscometers (single capillary or differential multicapillary detectors) coupled to the traditional chromatographic system before or after a concentration detector in series (see *Viscometric Detection in GPC/SEC*, p. 2411). Because liquid continuously flows through the capillary tube, the detected pressure drop across the capillary provides the measure for the fluid viscosity according to the Poiseuille's equation for laminar flow of incompressible liquids.[1] Most commercial online viscometers provide either relative or specific viscosities measured continuously across the entire polymer peak. These measurements produce a viscometry elution profile (chromatogram). Combined with a concentration-detector chromatogram (the concentration versus retention volume elution curve), this profile allows one to calculate the instantaneous intrinsic viscosity $[\eta]_i$ of a polymer solution at each data point i (time slice) of a polymer distribution. Thus, if the differential refractometer is used as a concentration detector, then for each sample slice i,

$$[\eta]_i \approx \frac{\eta_{sp,i}}{C_i} = \frac{\nu \eta_{sp,i}}{n_i} \quad (2)$$

where Δn is the refractive index change due to the polymer in solution, detected by the refractometer and $\nu = dn/dc$ is the refractive index increment of the polymer. The quantity calculated from Eq. 2 is often designated as "observed" intrinsic viscosity, $[\eta]_{obs}$.

As can be seen from Eq. 2, the observed intrinsic viscosity for each slice is proportional to the ratio of two detectors' responses. It follows that detector noise,

which is an irreducible component of the measurement process, introduces noise in the intrinsic viscosity that depends on this ratio. However, two detectors have different sensitivities at the tails of polymer distribution: the concentration detector is less sensitive to the high-molecular-weight end and the viscometer is less sensitive to the opposite end. Thus, the noise increases dramatically on both tails of the distribution, where the ratio (2) does not produce physically meaningful values. For example, the logarithm of intrinsic viscosity computed from the slice ratios (2) sometimes does not increase monotonically with molecular weight (i.e., with decreasing elution volume V) even for the flexible coillike polymers (curves 2 in Fig. 1).

Fitting a smooth, multivariate model to a time series of noisy data is an effective way to produce a more precise estimate of the measured quantity at each sample time. Typically, the logarithm of intrinsic viscosity is modeled as a low-order polynomial in elution volume V using a least-squares fitting to the experimental data.[2–4] The intrinsic viscosity calibration curve ($\log[\eta]_{\text{fit}}$ vs. V) obtained this way depends on properties of the polymer as well as that of the chromatographic system (e.g., columns). It can be used for diagnostic information concerning the GPC–viscometry system[5] and also to refine such system parameters as interdetector volume and band broadening (see *Band Broadening in GPC/SEC*, p. 147).

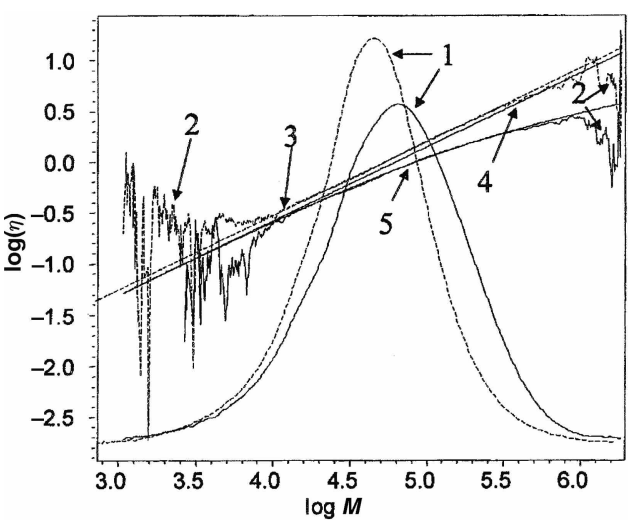

Fig. 1 Molecular-weight-distribution (MWD) and viscosity-law plots for NIST PE1475 high-density polyethylene (dashed lines) and NIST PE1476 low-density polyethylene (solid lines). The curves are (1) MWD, (2) observed viscosity, (3) fitted viscosity for linear polyethylene, (4) extrapolated fitted viscosity for polyethylene with short-chain branches only, and (5) fitted viscosity for branched polyethylene.

APPLICATION OF INTRINSIC VISCOSITY IN GPC TO POLYMER CHARACTERIZATION

Molecular Weight and Molecular-Weight Distribution Determination

The most important feature that has been added to conventional GPC by the viscometer detector through the intrinsic viscosity calculation is the ability to determine the "absolute" molecular weight distribution (MWD) without any additional assumptions about the polymer chemical structure. This goal is accomplished by applying the universal calibration concept, which establishes the hydrodynamic volume $H = [\eta]M$ as a universal parameter governing the size-exclusion separation. The MWD can be determined in three steps. First, the set of narrow polydispersity polymers with known molecular weights (narrow standards) covering the entire region of column size-exclusion separation is selected to construct the universal (or hydrodynamic volume) calibration curve, $\log H$ vs. elution volume V (see *GPC/SEC: Calibration with Universal Calibration Techniques*, p. 1006). This curve is then used to calculate the molecular-weight calibration curve via the relationship $\log M = \log H - \log[\eta]_{\text{fit}}$, where these quantities are obtained from the (smooth) hydrodynamic and intrinsic viscosity calibration curves. Finally, the MWD is constructed by plotting the concentration C as a function of $\log M$ across the polymer distribution (curves 1 in Fig. 1). Different statistical moments of this distribution (i.e., average molecular weights, including viscosity-average molecular weight M_v) can be calculated by appropriate summation over the slice data and compared with the values obtained by bulk measurements.[6]

Intrinsic Viscosity Distribution

The intrinsic viscosity is a fundamental property of the polymer sample in solution, and thus the intrinsic viscosity distribution (IVD) (C vs. $\log[\eta]$) with associated statistical moments may be used to characterize polymers without converting this distribution into a MWD.[7] The IVD can be determined in GPC–viscometry directly, without resorting to universal calibration. This distribution depends not only on the polymer sample itself but also on the solvent and the temperature, and hence does not possess the versatility of the MWD. Nevertheless, the IVD measurement in GPC–viscometry is much less sensitive to experimental conditions than any calibration curve and, hence, can be successfully used in industry (e.g., for quality control of polymers in production).

Size and Molecular Structure of Polymers

The GPC–viscometry with universal calibration provides the unique opportunity to measure the intrinsic viscosity as a function of molecular weight (viscosity law, $\log[\eta]_{\text{fit}}$

versus log M) across the polymer distribution (curves 3 and 4 in Fig. 1). This dependence is an important source of information about the macromolecule architecture and conformations in a dilute solution. Thus, the Mark–Houwink equation usually describes this law for linear polymers: $\log[\eta] = \log K + \alpha \log M$ (see *Mark–Houwink Relationship*, p. 1429). The value of the exponent α is affected by the macromolecule conformations: Flexible coils have the values between 0.5 and 0.8, the higher values are typical for stiff anisotropic ("rod"-like) molecules, and much lower (even negative) values are associated with dense spherical conformations.

The determination of the viscosity law in GPC–viscometry is even more important for branched polymers. Branches reduce the sizes of a macromolecule, including its hydrodynamic volume H. This size reduction is reflected by the changes in the shape and position of the viscosity law plot for a branched polymer. Short-chain branches usually do not change the linearity and slope of the Mark–Houwink plot and just decrease the value of parameter K, whereas the long-chain branches cause bending of the corresponding plot.

These features of the viscosity-law plots for branched polymers are demonstrated in Fig. 1 with two NIST (National Institute of Standards and Technology, U.S.A.) polyethylene standards as examples: high-density linear polyethylene PE1475 and low-density branched polyethylene PE1476. This last one contains both short- and long-chain branches. Dashed straight line 3 represents the Mark–Houwink plot for linear polyethylene, parallel solid line 4 takes into account the short-chain branches, and polyethylene with both types of branches (PE1476) is described by solid curve 5.

For further information on the intrinsic viscosity determination in GPC, including the use of the light-scattering detector, see Ref.[8] and *GPC/SEC Viscometry from Multiangle Light Scattering*.

Polymers: Solvent Effects in ThFFF Separation

Wenjie Cao
Mohan Gownder
Huntsman Polymers Corp., Odessa, Texas, U.S.A.

INTRODUCTION

The early research of Myers et al.[1,2] shows that polymer thermal field-flow fractionation (ThFFF) retention and thermal diffusion are solvent dependent. Recently, Sisson and Giddings[3] indicated that polymer ThFFF retention could be increased by mixing solvents. Rue and Schimpf[4] extended the molecular-weight range that can be retained by ThFFF to much lower molecular weights (<10 kDa) by using solvent mixtures without using extreme experimental conditions. There are several other reports on the effect of solvents on polymer retention, selectivity, and the universal calibration in FFF in last few years.[5]

DISCUSSION

The dissolving of a polymer into a solvent is governed by the free energy of mixing,[6]

$$\Delta G_m = \Delta H_m - T\Delta S_m \tag{1}$$

where ΔG_m is the free-energy change of the solution, ΔH_m is the enthalpy change of the solution, and ΔS_m is the entropy change of the solution.

The enthalpy change is given by

$$\Delta H_m = V\left(\left(\frac{\Delta {E_1}^v}{V_1}\right)^{1/2} - \left(\frac{\Delta {E_2}^v}{V_2}\right)^{1/2}\right)^2 \phi_1\phi_2 \tag{2}$$

where V is the volume of the mixture, ΔE_i^v is the energy of vaporization for species i, V_i is the molar volume of species i, and ϕ_i is the volume fraction i in the solution.

The solubility parameter, δ_i, has been defined[6] as the square root of the cohesive energy density (CED), $\Delta E_i^e/V_i$, and describes the strength of attraction between molecules:

$$\delta_i = \left(\frac{\Delta {E_i}^v}{V_i}\right)^{1/2} \tag{3}$$

Eq. 1 may be rewritten as

$$\Delta G_m = V(\delta_1 - \delta_2)^2\phi_1\phi_2 - T\Delta S_m \tag{4}$$

Because the second term, the entropy term, is always positive for the process of polymer dissolution, the deciding factor in determining the sign of the Gibbs energy change in Eq. 4 is the first term, which contains the solubility parameters of the polymer and the solvent. In general, $(\delta_1 - \delta_2)^2$ must be small for the polymer and the solvent to be miscible. A polymer dissolves most easily in a solvent whose solubility parameter matches it or is close to its own. This is consistent with the "like dissolves like" rule.

If a polymer is easily soluble in a solvent, by convention, the solvent is called a good solvent, and the converse, it is a poor solvent.[6] Therefore, a solvent whose δ value is close to the δ value of a polymer family is a good solvent for this polymer family. As examples, the δ value of polystyrene (PS) is about 18, which is closer to the δ value of 18.6 of tetrahydrofuran (THF) than the d value of 16.8 of cyclohexane (CH). Therefore, THF is expected to be a better solvent for PS than CH. For polyisoprene (PIP), the situation is reversed; CH is a better solvent than THF.

Polymer molecules tend to spread out to a larger hydrodynamic size in a good solvent than they do in a poor solvent, which results in a reduced diffusion coefficient D as the Stoke–Einstein equation shows:

$$D = \frac{kT}{6\pi\eta R_h} \tag{5}$$

where k is the Boltzmann constant, T is the absolute temperature, η is the solvent viscosity, and R_h is the hydrodynamic radius of the polymer molecules in a solvent.

The retention of polymer molecules in ThFFF is determined by the diffusion coefficient and the thermal diffusion coefficient D_T illustrated approximately by[8]

$$\frac{t_r}{t^0} \approx \frac{1}{6\lambda} = \frac{\Delta T}{6}\frac{D_T}{D} \tag{6}$$

where λ is the reduced mean layer thickness of a sample zone in the ThFFF channel, is the polymer retention time, t^0 is the elution time of the non-retained species, and ΔT is the temperature difference across the channel thickness.

From the point of view of diffusion, the reduced D, obtained by replacing a poor solvent with a good solvent, will result in smaller λ if ΔT and other experimental conditions are kept unchanged. The reduced λ (sample zone is closer to the accumulation wall) will cause the polymer molecules to elute out of the ThFFF channel later because of the parabolic flow inside a ThFFF channel.[8] Higher retention, therefore, should be expected for polymers eluted by good solvents in ThFFF.

D_T for the polymer solution is not well understood. There are several theories of polymer thermal diffusion in liquids. Extensive reviews have been done by Schimpf and colleagues in several publications.[4,9] As an example, the radiation pressure theory of Gaeta and Scala shows that D_T is proportional to the cross-sectional area of the solute molecules:[10]

$$D_T = Z_A\left(\frac{\kappa_s}{U_s} - \frac{\kappa_p}{U_p}\right)\frac{\sigma}{f} \tag{7}$$

where Z_A is the acoustical impedance, a quantity related to the density and velocity of sound waves in the polymer and solvent, κ_p and κ_s are the thermal conductivity of the polymer and solvent, respectively, U_p and U_s are the corresponding velocities of sound in the two media, f ($f \propto \eta R_h$) is the frictional coefficient, and σ ($\sigma = \pi R_h^2$) is the cross-sectional area of the polymer molecules.

As discussed earlier, the sizes, or cross-sectional areas, of polymer molecules dissolved in a good solvent are larger than that in a poor solvent. Therefore, the D_T of a polymer in a good solvent is predicted to be larger than that in a poor solvent according to Eq. 7.

From the point of view of both diffusion and thermal diffusion (assuming Gaeta's theory is correct in this case), ThFFF retention of a polymer should be larger in a good solvent than in a poor solvent.

The study of Sisson and Giddings[3] shows that polymer retention in some binary solvents can be enhanced while retention is relatively unaffected or even diminished in other cases. In the case of a mixture of 30% dodecane and 70% THF, polymer retention was enhanced by 35% relative to pure THF. The low end of the molecular-weight range, which can be analyzed by ThFFF, therefore, can be expanded further down by using binary carriers.

Rue and Schimpf[4] investigated component partition of a solvent mixture under thermal gradient. It is indicated that when one solvent is a significantly better solvent for a polymer, then the gradient of this solvent will cause the polymer to migrate in the same direction as the thermophoretic motion of this solvent. This is called solubility-based migration as a partitioning effect. When the better solvent partitions to the cold wall of the ThFFF channel, polymer retention is enhanced; when the better solvent partitions to the hot wall, retention is diminished. Five polystyrene samples, ranging in molecular weight from 2500 to 179,000, were separated in a mixture carrier containing 45 vol% THF in *n*-dodecane. This separation was the first time that polymers of molecular weight below 2500 become separated from the void peak without using extreme experimental conditions such as channel pressurization, ultrahigh ΔT, and so forth.

If the solvent effect is the same for both small and large polymer homologs, the selectivity will not be changed by switching solvents. This might not be the case, because small polymer molecules tend to be spread out to the maximum length of the flexible chain, even in a relatively poor solvent, whereas larger polymer molecules may need better solvents to spread out to their maximum. A different solvent effect might, therefore, be expected when a poor solvent is replaced by a good solvent for a homologous polymer series, and vice versa. It is possible, therefore, to manipulate the selectivity of polymer separation by ThFFF through solvent selection. Any dependence of D_T on molecular weight may be different for different solvents, and this may also contribute to changes in selectivity. Better retention and,

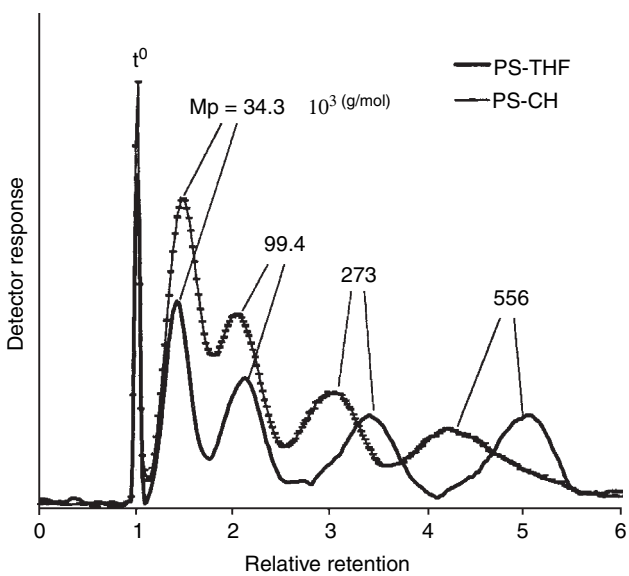

Fig. 1 Fractograms of PS in THF and CH. $\Delta T = 50°C$; $T_c = 25°C$. Flow rate is 0.1 ml/min and sample mass is 1 μg.

probably, better selectivity are expected for PS in THF and PIP in CH among the possible four polymer–solvent pairs, as an example.

Fig. 1 shows the overlaid fractograms of PS eluted by THF and CH under the same experimental conditions of cold-wall temperature, temperature drop, flow rate, and sample mass (1 μg).[5] The fractograms show that a small PS of molecular weight 34,300 is retained approximately the same in both THF and CH, whereas the retentions of larger polymers show significant differences in the two solvents, with the larger PS retained longer in THF. This indicates that using better solvents may enhance both retention and selectivity.

INTRODUCTION

Thermal field-flow fractionation (FFF) is an elution-type separation technique applicable to the characterization of various synthetic organic polymers with molecular weights higher than about 10^4.[1] In thermal FFF, a dilute solution of polymer sample is injected into a thin ribbon-shaped flow channel across which an external "field" (in the form of a temperature gradient) is applied. Under the influence of the temperature gradient, different components of the sample are carried down the channel at different velocities, leading to the elution of different components at different times—separation is obtained.

MOLECULAR WEIGHT-BASED SEPARATION

In thermal FFF, retention time t_r is given by[2]

$$t_r = \frac{t^0 \Delta T}{6}\left(\frac{D_T}{D}\right) \tag{1}$$

for well-retained components. Here, t^0 is the channel void time (a constant for a given channel dimension), ΔT the temperature drop across the channel, D_T the thermal diffusion coefficient, and D the mass diffusion coefficient. For most polymeric materials, D is related to the molecular weight M by

$$D = \frac{A}{M^b} \tag{2}$$

Combining Eqs. 1 and 2 yields

$$t_r = \frac{t^0 \Delta T D_T}{6A} M^b \tag{3}$$

It has been shown that D_T is independent of branching configuration and molecular weight for homopolymers (such as polystyrene) in a given solvent.[3] Thus, under fixed experimental conditions, the retention time of polystyrene depends only on the molecular weight, resulting in a molecular weight-based separation: The retention time increases as the molecular weight increases.

EFFECT OF ΔT IN POLYSTYRENE SEPARATION

It is seen from Eq. 3 that dt_r/dM (the difference in retention time for the same molecular weight difference) increases with ΔT, indicating that the separation (and thus the resolution) between two polystyrene components increases with ΔT. However, the gain in resolution comes at the cost of time, as the use of higher ΔT requires longer analysis time. An optimum condition for ΔT must be determined for each sample by observing the time and the elution profile at various ΔT. Finding the optimum ΔT is relatively easy for samples having narrow molecular weight distributions. However, for samples having broad distributions, finding the optimum ΔT may not be trivial. Field programming may be required for samples having broad molecular weight distributions to prevent excess retention of late-eluting high-molecular-weight components.[4] In a field-programmed thermal FFF, ΔT generally starts at high and is gradually decreased during a run. Fig. 1 shows a separation of four polystyrene standards having nominal molecular weights ranging from 47,000 to about 1 million daltons.

DETERMINATION OF PHYSICOCHEMICAL PROPERTIES

The simplicity of both retention mechanism and the channel geometry of thermal FFF allows one to theoretically predict the degree of retention of a sample, provided certain physicochemical properties of the sample are known. Conversely, one may determine the physicochemical properties of a sample by measuring its retention time (or volume).

Determination of Diffusion Coefficients

As seen in Eq. 1, retention time in thermal FFF is a function of the ratio of two diffusion coefficients, D_T/D. If one of the two diffusion coefficients is known, the other

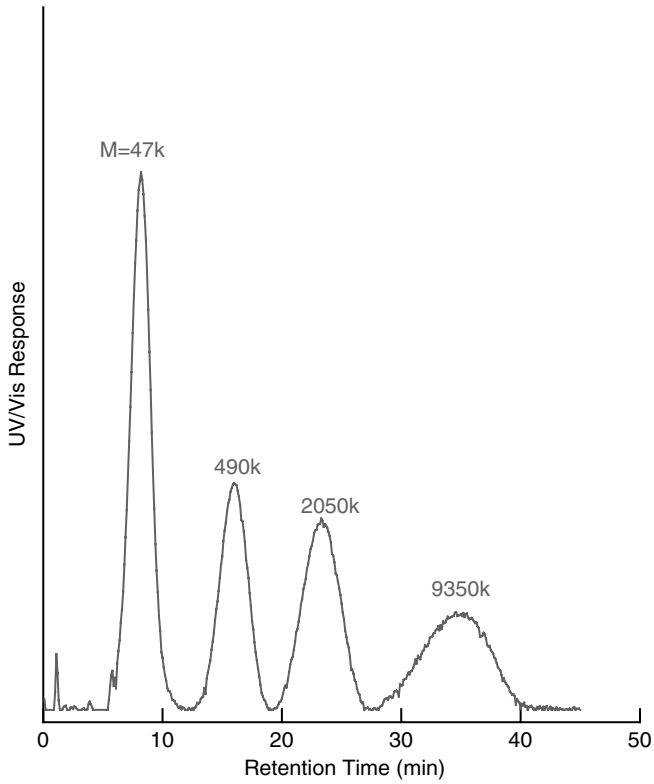

Fig. 1 Thermal FFF separation of polystyrene standards having nominal molecular weights as indicated. Power programming was used with initial $\Delta T = 80°C$, predecay time $t_1 = 3$, $t_a = -6$, and hold $\Delta T = 10°C$. The solvent/carrier was tetrahydrofuran and the flow rate was fixed at 0.2 ml/min.

can be determined directly from the retention time using Eq. 1. It is noted that the values of the diffusion coefficients may vary in various solvents.

Determination of Molecular Weight

If the values of A, b, and D_T are available, the molecular weight of a polymer can be directly determined from its retention time using Eq. 3. If D_T is not available, one may use a calibration curve [$\log(D/D_T)$ vs. $\log M$] constructed with a series of narrow polystyrene standards of known molecular weights. For the molecular weight analysis of an unknown, the D/D_T value of the sample is first calculated from its measured retention time, and then the molecular weight is determined from the calibration curve.

Use of molecular weight-sensitive detectors (e.g., differential viscometer or light-scattering detector) eliminates the need for calibration. With a differential viscometer used as a detector for thermal FFF, the intrinsic viscosity is first measured for each retention time and then converted to molecular weight using Mark–Houwink constants.[5] The use of accurate values of Mark–Houwink constants is essential in this method. Unlike the viscometer, the light-scattering detector measures the absolute molecular weight of the polymers directly. In multiangle light scattering, the scattered light intensity is measured over a broad range of scattering angles, allowing the determination of molecular size (radius of gyration) as well as molecular weight.[6]

ANALYSIS OF HIGH-MOLECULAR-WEIGHT POLYSTYRENE

Thermal FFF is often compared with size-exclusion chromatography (SEC) as both can be used for the same application, that is, the molecular weight determination of polymers. In SEC, the elution volume of the sample in a column (or in a column set) is limited to values between the interstitial volume of the column ("total exclusion limit") and the total liquid volume ("total permeation limit"). The resolving power of SEC quickly drops as the elution volume approaches these limits. By contrast, there is no theoretical limit in thermal FFF, and the applicable molecular weight is virtually unlimited in the high molecular weight range. Also, the openness of the channel minimizes the shear degradation and adsorption of polymers. Thermal FFF is thus useful for characterizing high-molecular-weight polymers, including samples containing microgel, that are difficult to analyze using SEC.[7]

It is noted, however, that for polymers of molecular weight below about 10,000 Da, SEC may be more useful than thermal FFF. Analysis of such low-molecular-weight samples using thermal FFF requires the application of very high ΔT, which may require the use of a pressurized system to avoid boiling of the solvent.

Porous Graphitized Carbon Columns in LC

Irene Panderi
School of Pharmacy, Division of Pharmaceutical Chemistry, University of Athens, Athens, Greece

INTRODUCTION

Liquid chromatography (LC) is a separation technique which is used widely in many different areas of analytical chemistry and provides a powerful tool for the separation and quantification of substances in various matrices. Nowadays, the majority of the high-performance liquid chromatography (HPLC) methods are carried out in reversed-phase mode using a non-polar stationary phase and a polar-mobile phase.

The most popular reversed-phase columns are manufactured from silica-based bonded phases, and, among those, the C_{18}-type bonded phase is most frequently used. These bonded phases are prepared by reacting silica with a reactive silane that carries the hydrophobic ligand after which the phase is named. However, the poor stability of silica at extreme pH values, along with the presence of underivatized silanol groups that most frequently cause secondary interactions, limits the application of silica-based supports in LC.

POROUS GRAPHITIZED COLUMNS

Over the years, serious efforts have been devoted to the development of new reversed-phase packing materials in attempts to overcome the drawbacks of silica-based bonded phases. Thus reversed-phase separations can also be performed on polymeric columns. The great majority of these columns consist of styrene-divinylbenzene-, methacrylate-, or polyvinylalcohol-based phases and appear to be more stable over a wide pH range. Divinylbenzene packings are stable over the whole pH range, while the other two substrates (methacrylate and polyvinylalcohol) are hydrolytically stable between pH 2 and 12. Thus these polymer-based packings can be used at extreme pH values where silica-based columns degrade rapidly. However, silica-based columns are still more efficient and provide a much greater choice of different silica-based packings than polymeric columns.

The expectation that graphitized carbon-packing material would show high chemical stability over the entire pH range (pH = 0–14), and ultimate hydrophobic properties, led to a number of investigations in this area.[1] There have been many attempts to manufacture reversed-phase carbon-based packings by the use of carbon black[2] and led to the development of graphitized carbon black (GTCB) supports. Unfortunately, these supports were unsuitable for routine chromatographic analyses because of their extremely poor mechanical stability. Several trials have been made to overcome this limitation until the successful preparation of porous graphitized carbon (PGC) packing material.[3]

Porous graphitized carbon packing material was developed by Knox et al.[4–6] to provide a reversed-phase support that could have sufficient hardness to withstand high pressures, such as those encountered in HPLC, and would not suffer from the disadvantages of silica-based bonded supports. This packing material was produced by the templation method using silica gel as template. Actually, a 7 μm spherical porous silica gel template was impregnated with a phenol hexamine mixture and then heated to 150°C to form phenol-formaldehyde resin within the pores of silica gel. This polymer was further heated slowly to 900°C under a stream of oxygen-free nitrogen. The silica–carbon particles were then treated with potassium hydroxide to dissolve the silica template, and the remaining porous carbon was heated to a high temperature in the range of 2000–2800°C to anneal the surface, remove micropores, and, depending upon the temperature, produce some degree of graphitization. The particle size, shape, porosity, and pore size are determined by the choice of template material. It is thus possible to produce porous graphitized carbons with a range of pore and surface properties.[7]

The surface characteristics of the porous graphitized carbon have been extensively investigated.[8] X-ray diffraction provides useful information about the degree of graphitization. The Bernal structure of perfect three-dimensional graphite is one of the forms of carbon atoms to which the term graphitization can be applied and is clearly presented in Fig. 1a. However, perfect graphite is rarely formed synthetically from amorphous solid carbon because the bonding between the carbon atoms within the graphitic layers is extremely strong, while the interlayer bonding is weak. Graphitization tends to develop by the formation of graphitic layers, which are initially randomly oriented. The reorganization of these layers into ordered three-dimensional graphite requires high activation energy (above 3000°C). Thus most synthetic carbons, when heated to about 3000°C, lead to a two-dimensional graphite structures. The atomic-molecular structure of PGC is clearly presented in Fig. 1b; it is a two-dimensional graphite molecular structure (Warren structure), otherwise termed turbo static carbon structure, in which graphitic

layers are randomly oriented and, unlike three-dimensional graphite, there is no ordering of the atoms between layers. The high-resolution electron micrograph of PGC supports is presented in Fig. 2 and reveals a structure that is composed entirely of flat graphitic layers of hexagonally arranged carbon atoms showing sp^2 hybridization. The graphitic layers are randomly twisted and interleaved in a complex way, and, unlike silica gel, there are no surface functional groups.

It is important to mention that attempts have been made to construct porous carbon supports using entirely different carbonization procedures.[9,10] One involved the carbonization of hydrocarbons on porous zirconia microplates.[11] The type of chromatographic support that is obtained by this procedure is highly dependent upon the type of hydrocarbons used. In particular, when saturated hydrocarbons are used as the carbon source, the loading capacity and efficiency of the carbon supports are much greater than those obtained by unsaturated hydrocarbons. In other carbonization attempts, the three-dimensional channels of zeolites were used as templates to prepare porous carbon.[12] The nanospaces in zeolites are packed with carbon and then the carbon is extracted from the zeolite framework. The resultant carbons are highly porous with surface areas greater than 2000 m^2/g.

Nowadays, PGC are one of the most new reversed-phase packing materials with a homogenous hydrophobic surface, but they can also be used in the normal-phase mode.[13] At the end of the 1980s, PGC packing materials were made available, the most common one under the trade name Hypercarb. This packing material exhibits a well-defined pore structure, allowing a good mass transfer of a large number of solutes and a specific surface area in the range 150–200 m^2/g that gives improved retention possibilities of solutes and maintains a linear sample capacity over a large concentration range. It is totally unaffected by aggressive eluents as it exhibits high chemical stability, probably because of the lack of ordering between the graphitic layers, and can withstand high temperature. Moreover, it does not suffer from swelling or shrinking and it is hydrolytically stable across the entire pH range 0–14. Its retention and selectivity behavior is quite different from that of reversed-phase bonded phases. Porous graphitized carbon is recommended for the separation of highly polar and ionized compounds, and it gives an unrivaled stereoselective surface with unique ability to resolve isomeric and closely related compounds.[14,15] It is thus suitable for large, fairly rigid molecules with a multitude of polar groups, such as many natural compounds and new drugs.[16]

CHROMATOGRAPHIC CHARACTERISTICS AND RETENTION BEHAVIOR OF POROUS GRAPHITIZED CARBON COLUMNS

The chromatographic retention on PGC columns has been extensively investigated.[17] Results indicate that PGC offers a unique retention mechanism that could be explained by a combination of various kinds of selective interactions between solutes, mobile phases, and PGC packing material.[18] These supports are not only strongly hydrophobic in comparison to the other traditional reversed-phase packing materials such as silica-based packings, but they also retain solutes through electronic (π–π) interactions. The delocalization of the π-electrons in the large graphitic layers and the high polarizability of the carbon are responsible for strong dispersion interactions. In addition, charge-induced interaction between the graphite surface and the polar substituents of the solutes, steric effects, along with hydrophobic interactions, affect the mechanism of retention onto PGC.

It was observed that, where purely hydrophobic surface–solute interactions are present, it will require higher concentrations of organic modifier to elute such solutes.[8] Several efforts have been made to categorize solvent strength data for PGC supports into an eluotropic series using various types of solutes. Although the choice of organic modifier offers a route to modify the retention of solutes on PGC columns, the results indicated that organic modifiers did not show common eluotropic behavior and that their effects on retention are mainly dependent on the type of solutes.[19] Thus it is possible to arrange solvents in an order of eluotropic strength for particular types of solutes. Solvent strength data for aniline, naphthalene, ethyl benzene, and phenol are presented in Fig. 3; they indicate that methanol and acetonitrile show low eluotropic strengths for aniline, naphthalene, and ethyl benzene, while for phenol, the same solvents have higher values of eluotropic strength. On the other hand, dioxane and tetrahydrofuran have higher eluotropic strengths for the majority of solutes.

A study of the retention characteristics of several aromatic hydrocarbons on PGC, using methanol as the mobile phase, showed that this graphite packing is an extremely strong adsorbent in comparison to other silica-based packing materials.[20] Studies on the effect of eluent pH on the retention of isomers of ionizable substituted benzene compounds, including isomers with electron-donating and electron-withdrawing substituents, on PGC and ODS packings, provided valuable information on how the surface structure of the stationary phase can affect solute retention and selectivity.[21] The retention factors of unionized solutes were generally greater on PGC than those on ODS, confirming previous observations that neutral compounds are more strongly retained on the PGC packing material. The fact that ionic interactions with ionized solutes were essentially absent on the surface of PGC implies that the retention order is probably governed by a solute molecular orientation effect induced by competing interactions of solute between the stationary phase and the mobile phase. Fig. 4 shows the effect of eluent pH and hence ionization on the retention of the zwitterionic aminobenzoic acid isomers. The greater retention is achieved where neither acid nor basic substituent is ionized. In particular, as the mobile phase pH increased, the retention factor rose initially to a peak value and then began to fall again.[22] The homogeneous and flat crystalline surface of PGC packing is thought to be responsible for its unique selectivity toward the discrimination of ionizable aromatic isomers compared with an ODS packing material. Thus adsorption onto a graphite surface depends on how well many of its atoms can fit onto the flat surface. Thus planar molecules and straight chain hydrocarbons can fit onto the graphite surface, whereas, as the planarity of such molecules is destroyed by the presence of non-planar rings, the adsorption is deteriorated and a parallel decrease in retention is observed. An excellent example that reflects the unique surface properties of the graphitic carbon is the reversal of the elution order of isomeric xylenes when separated on PGC columns in comparison to the elution order of these isomers on reversed-phase silica-based packing.[8] The methyl groups are sufficiently large that adjacent carbon atoms in the ring are just above the graphite surface and so are not as strongly retained as they would be in a totally planar molecule such as benzene. In the case of *o*-xylene and *p*-xylene, four carbon atoms

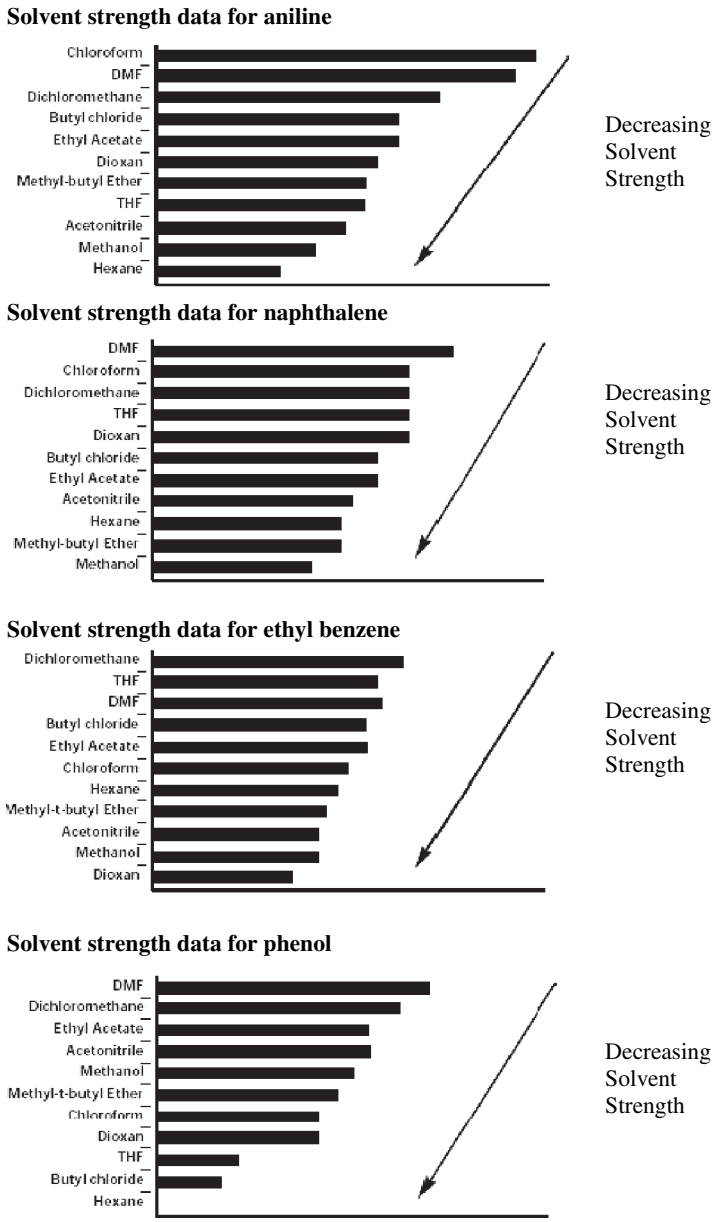

Fig. 3 Solvent strength data on porous graphitized carbon columns for the retention of aniline, naphthalene, ethyl benzene, and phenol.
Source: Reproduced by kind permission of Thermo-Hypersil-Keystone.

contact the graphite surface (two from methyl groups and two from the ring), whereas, in the case of *m*-xylene, only three carbon atoms contact the surface (two from methyl groups and one from the ring). Therefore *m*-xylene elutes first on PGC supports, while the isomers elute later.

The retention of polar compounds (mono-, di-, and tri-substituted benzenes) on PGC, silica-based, and apolar copolymer supports[14] was performed using unbuffered methanol water as eluent. The relationship between log k and the volume fraction of methanol was calculated separately for each solute. It was found that porous graphitic carbon retains polar compounds fairly well under reversed-phase conditions, while the retention factor increased with an increase in the number of polar substituents. In particular, the retention behavior of polar solutes on PGC supports is mainly governed by several polarity parameters (Hammett's constant, proton-donor capacity, and steric effects of substituents) and is quite different from that observed with other reversed-phase supports. Thus it was concluded that charge-induced interactions between the graphite surface as well as steric effects force the polar groups close to the graphite surface. This type of interaction is called "polar retention effect on graphite," (PREG),[23] and proved to be more important than hydrophobic interactions in the retention mechanism of polar compounds.

Separation of various cationic and anionic compounds on PGC columns with a mobile phase containing an electronic modifier (e.g., trifluoroacetic acid) and an organic modifier (e.g., acetonitrile) in the eluent has also been demonstrated.[24] In the same study, positively and negatively charged ions were well separated in the same

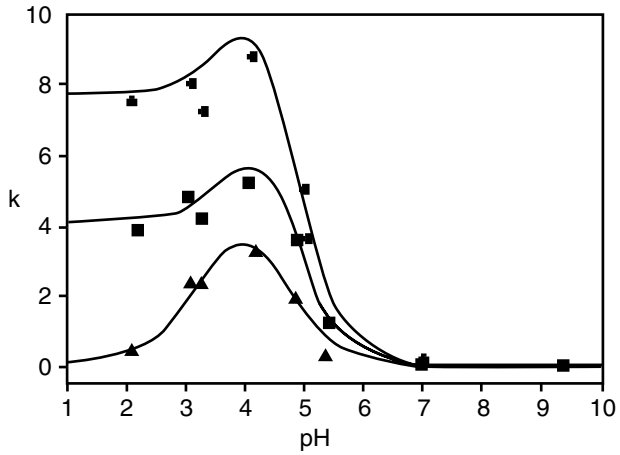

Fig. 4 Effect of the pH of the mobile phase on the retention of aminobenzoic acid isomers. (●): *o*-isomer, (▲): *m*-isomer, and (■): *p*-isomer.

chromatogram. Thus PGC seems to behave equally as an electron donor and electron acceptor and proved to be an important stationary phase for the separation of ionized solutes by a mechanism other than ion exchange. It was concluded that the retention of anionic compounds is mainly dominated by electronic interaction between the solute and the delocalized electron clouds on the graphitized carbon surface, while cationic compounds are mainly retained by ion suppression or ion pairing consistent with a reversed-phase interaction with the hydrophobic carbon surface.

Another example of electronic interaction between the graphite and ionic solutes is the retention of metal ions on PGC supports.[25,26] Such electronic interaction, either electron donation or acceptance, is presumably between the available orbitals of metal ions and the electronic cloud of the flat graphite surface. The addition of a small concentration of oxalic acid into aqueous mobile phase tends to modify the graphite surface and to increase, through complexation, the range of metal ions retained.

It is extremely important to understand the interactions that govern retention on the graphite surface to better utilize this material and begin to predict how changes in the system will influence carbon-based separation processes.[27] A qualitative insight into the chemical interaction that is involved in the retention process on graphite has been recently achieved through solvatochromic linear solvation energy relationships (LSERs).[28] A variety of solute descriptors were used to correlate retention on graphite. Multiple linear regression of log k' values of 26 solutes against the LSER solute parameters indicated that all parameters were significant. Data of the fitting coefficients indicate that a combination of three solute parameters, size, dipolarity/polarizability, and hydrogen bond basicity, dictates a solute's retention. A spectral mapping technique (SPM) was also employed[29] for the evaluation of the retention mechanism of solutes on PGC; barbiturates were chosen as probe solutes in this study, while mixtures of dioxane-water were used as eluents.[30] Spectral mapping technique proved to be a valuable tool to separate retention strength and the selectivity of solutes and organic modifiers and thus promote a better understanding of the separation process. In particular, through SPM, it was concluded that the retention strength of organic modifiers depends on the electronic parameter characterizing the resonance effect, suggesting that electronic interaction exerts a considerable impact on the elution strength of organic modifiers on PGC. The fact that the calculated lipophilicity of the drugs had no significant role in the chromatographic characteristics indicates, again, that the retention mechanism differs from that of octadecylsilica phase where lipophilicity is the most important parameter influencing the retention. The interaction between the graphite surface and the planar ring of the solute molecules contributes to the retention.

APPLICATION AREAS

Porous graphitized carbon columns have successfully been applied for the analysis of various compounds by HPLC. As already mentioned, PGC shows a highly ordered crystalline structure with large bands of delocalized electrons, so that the retention mechanism is a mixture of hydrophobic and electronic interactions and is very different from that observed with silica-based bonded phases and apolar copolymers.[31] Thus the following criteria must be taken into consideration during the development of a chromatographic separation on PGC columns: 1) strength of organic modifier for particular type of analytes; 2) ionization of the analytes and pH dependence as well as the effect of organic modifiers on control of ionization and pH dependence; 3) effect of the electronic modifier on analytes retention; and 4) effect of analyte shape.

Pharmaceuticals

HPLC has become the most popular chromatographic technique in drug analysis. A literature survey reveals a number of papers that take advantage of the benefits of porous graphitized carbon columns for the separation and determination of several compounds of pharmaceutical interest.[32] In particular, this material possesses several advantages, most notably its physical and chemical stability, as well as a highly stereoselective surface able to resolve diastereomers and geometric isomers; also, it is most applicable to the separation of small ionizable molecules that are not retained with octadecylsiloxane (ODS) columns.

Two different LC systems, equipped with porous graphitized carbon and silica-based RP-8 columns, respectively, were used for the assay of alprenolol and its related substances in quality control.[33] The ability of the PGC system to separate metoprolol and closely related substances was also tested; baseline separations with high column efficiencies were obtained. The robustness of the proposed methods was investigated using experimental design and evaluation with multivariate calculations. The results indicated that the PGC column, with its unique selectivity, excellent stability against alkaline mobile phases, and high column efficiency, is a proper complement to the traditional silica-based reversed-phase supports. Another method describes the simultaneous determination of paracetamol and its related compounds, 4-aminophenol and 4-chloroacetanilide, in pharmaceutical preparations, using PGC column.[34] The chromatographic behavior of the three compounds under variable mobile phase compositions was thoroughly investigated, and the results indicated that retentions were dependent upon organic phase nature, concentration, and pH. Stronger eluents with dipolar properties, such as tetrahydrofuran, could be used with PGC to avoid long retention times for late eluting compounds. The retention selectivities of these compounds on PGC were compared with those on octadecylsilica (ODS) packing materials in reversed-phase liquid chromatography. Porous graphitized carbon columns showed high retention selectivity, rapid equilibrium, and a high stability during the analysis than commercially used ODS columns.

Several amines of pharmaceutical interest (e.g., alprenolol, sotalol, terbutaline, promethazine, and trimipramine) have been well separated with high enantioselectivity using, mainly, *N*-benzyloxycarbonylglycyl-L-proline (L-ZGP) and also *N*-benzyloxycarbonylglyclglycl-L-proline (L-ZGGP) as chiral selectors on PGC column with methanol containing bases as mobile phase.[35] The retention of the enantiomeric amines was found to increase with increasing concentration of the anionic form of L-ZGP. Previous investigation[36] showed an improvement in peak symmetry in the presence of a mobile phase amine. Hence the addition of an alkylamine in the mobile phase in excess of L-ZGP was also investigated and led to a decrease in retention and enantioselectivity. The unique adsorption properties of porous graphitic carbon were also used for separation of racemic amines using chiral counterions dissolved in mobile phases; it was found that a column temperature below 0°C improved the enantioselective resolution.[37] Recently, two newly synthesized chiral di-anionic ions were tested as additives for enantiomeric resolution of a set of amino alcohols on a Hypercarb porous graphitized carbon column.[38] Z-L-Aspartyl-L-proline was used as a di-anionic counterion and resolved 9 of 12 tested racemates. One of its diastereoisomers, Z-L-Aspartyl-D-proline, was also tested, but resulted in low separation factors. The study showed the necessity to titrate the counterion with sodium hydroxide to its di-anionic form to optimize the resolution. Increased retention and enantioselectivity were observed with decreased column temperature.

Stepwise regression analysis and principal component analysis were used to examine the effect of various physicochemical parameters on the retention of 16 monoamine oxidase inhibitory drugs (proparlgylamine derivates) on a PGC column, using ethanol–water mixtures as eluents.[39] Both steric and electronic parameters were found to affect the retention of monoamine oxidase drugs on the graphite surface. An investigation was also carried out on the retention characteristics of 11 steroidal drugs on PGC using water–tetrahydrofuran mixtures as eluents.[40] The logarithm of the capacity factor of each compound was linearly related to the percentage of tetrahydrofuran in the eluent. Principal component analysis was also used to correlate the retention characteristics and the physicochemical parameters of the steroidals. Steric conditions and electrostatic interactions were also found to be responsible for the retention of these compounds onto PGC packings. The porous graphitized carbon column proved to be suitable for the separation of the anticancer drug, taxol, a highly functionalized taxane diterpene amine, in bark and foliage of different Taxus species using water dioxane as eluent.[41,42]

Bio-organic Substances

Because of the considerable importance of the analysis of bio-organic compounds in biochemical and biophysical research, many LC methods have been developed and applied for their separation and purity control. There is now growing evidence that PGC columns can contribute considerably to this application area. The flat graphite surface is able to differentiate between closely related compounds such as the structures of several carbohydrates found in nature.

The chromatographic behavior of oligosaccharide alditols containing two to five monosaccharides has been reported on a Hypercarb porous graphitized carbon column using gradient elution from water to acetonitrile in the presence of 0.05% trifluoroacetic acid.[43] Elution patterns were based on size, charge, and linkage such that isomeric compounds could be separated from each other. In particular, the nature of the linkage appeared to play an important role with (1,3)-linked compounds eluting before the (1–4) linkage.

The chromatographic characteristics of 14 peptides have been determined on a PGC column, using acetonitrile–water mixtures as eluents.[44] The majority of peptides showed irregular retention behavior; their retention decreased with increasing concentration of acetonitrile, reached a minimum, and increased again with increasing concentration of acetonitrile. For the elucidation of the relationship between the various physicochemical parameters and retention characteristics, principal component

analysis (PCA) was employed. Calculations indicated that the impact hydrophobicity, steric, and electronic parameters on the retention of peptides on a PGC column are similar, yet the steric parameters of substituents exert the highest impact on retention.

Porous graphitized carbon has also been explored for HPLC of monosaccharides and disaccharides released from proteoglycans and fluorescently labeled oligosaccharide derivatives for fluorescence detection.[45] Sulfated oligosaccharides show good retention and separation behavior on PGC columns. Gradient elution using mixtures of water with acetonitrile containing trifluoroacetic acid was used to perform the separation on a PGC column. The disadvantage of the anion exchange and reversed-phase ion-pair chromatography is that they require high salt concentrations that are not readily removed when compared with PGC which employs low concentrations of trifluoroacetic acid. Therefore PGC-based chromatography may be useful for two-dimensional sugar mapping and preparation of pure oligosaccharides, including the monitoring of derivatization efficiency with 2-aminobenzamide labels for reagent array analysis method sequencing, mass spectrometry (MS), and NMR. In particular, LC/electrospray MS was used as a tool for the analysis of sulfated oligosaccharides from mucin glycoproteins prepared from pig stomach and colon.[46] A PGC column, along with an amino-bonded column, were used and oligosaccharides were eluted with linear gradients of acetonitrile and water containing 5 m*M* ammonium hydrogen carbonate or formate buffers at basic pH values. Results indicated the benefits of both the amino-bonded and PGC-type chromatography in LC/electrospray ionization–mass spectrometry (ESI–MS) to achieve separations of mixtures of sulfated oligosaccharide alditols. Compounds co-eluting on one column could be separated on the other, indicated by the differing number of isomers separated in each system. The elution order of sulfated oligosaccharides does not appear to be pH-dependent on the PGC column. Various linear and branched oligosaccharides were labeled with 9-aminofluorene and further analyzed on a porous graphitized carbon column using acetonitrile water in 0.05% trifluoroacetic acid as eluent with MS detection.[47]

Ten guanidino compounds were analyzed in the serum of nephritic patients using a porous graphitized carbon column in combination with ion-pair LC and a postcolumn derivatization procedure using ninhydrin as a reagent.[48] The retention mechanism of guanidino compounds on PGC was thoroughly investigated by computational chemical calculation using molecular mechanism (MM2). The retention mechanism of cationic compounds on PGC proved to be electrostatic interaction for cationic guanidino compounds and hydrophobic interaction for molecular-form compounds. It was found that the micelle formation of hydrophobic ion-pair reagents reduces the retention of guanidine compounds. The successful separation of guanidino compounds was achieved by the addition of octanesulfonate in citric buffer. The authors suggest the use of a small precolumn packed with octadecyl-bonded silica to eliminate small particles and hydrophobic compounds from the analyzed samples.

Residue Analysis

The development of methods for the chromatographic separation and quantitation of trace levels of environmental pollutants is always in demand. However, these polar analytes cannot be easily retained on the most commonly used silica-based columns. It has been shown that, for some polar compounds, the retention in water can be very high using PGC columns.[31]

An online technique coupling preconcentration via a precolumn packed with PGC and LC with a PGC analytical column has been applied to the trace-level determination of some polar and water-soluble organic pollutants from environmental waters.[49] As these analytes are much more retained by the graphite surface than by silica C_{18}, preconcentration on the PGC precolumn cannot be coupled online with a widely used and more efficient C_{18} silica analytical columns. In this study, applications were presented for the trace-level determination of 2-chloro-4-aminophenol, chloroanilines, aminophenols, and cyanuric acid; these organic compounds are included in the EC environmental priority pollutant list. The influence of the sample matrix was investigated with drinking and river water samples.

The environmental pollutants 3,4-dimethoxybenzaldehyde (DMB) and 3,4-dimethoxyphenylacetone (DMPA) were separated and quantitated in treated and untreated industrial wastewaters on PGC columns using HPLC and diode array detection.[50] The effect of aerobic and anaerobic treatments on the decomposition rate of DMB and DMPA was also investigated; both techniques were found to be suitable for the decomposition of these pollutants in wastewaters. Furthermore, the chromatographic behavior of 16 environmental pollutants has been investigated on alumina and porous graphitic carbon columns using *n*-hexane as eluent.[51] The fact that solutes were not retained on PGC surface using *n*-hexane as mobile phase indicates the greater polarity of the alumina stationary phase compared with that of PGC.

A further example for the analysis of trace levels of pollutants is the determination of polychlorinated dibenzodioxins and polychlorinated dibenzofurans in milk.[52] The method includes gel permeation chromatography, alumina cleanup, and porous graphitized carbon chromatography, followed by analysis by GC/high-resolution MS. Moreover, the potential of porous graphitic carbon as an HPLC adsorbent for the isolation of halogenated aromatic compounds has been demonstrated by the fractionation of polychlorinated biphenyls (PCBs), chlorinated pesticides, polychlorinated dibenzo-*p*-dioxins (PCDDs), and

polychlorinated dibenzofurans (PCDFs).[53,54] The proposed procedures can be used in routine bases for the determination of PCDDs and PCDFs in soil extracts because of the reproducible behavior of PGC compared with activated carbons and the convenience of a single solvent elution method.

CONCLUSIONS

Porous graphitized carbon as a packing material meets all the requirements necessary for selective and effective stationary phases, such as rigidity of microparticles, adequate surface area, and uniformity of the surface. The development of this highly pH-stable column was motivated by the fact that the use of silica-based supports in HPLC is limited by the low stability of silica at extreme pH values and by the undesirable electrostatic interactions that occur in silica-based columns between the polar substructures of solutes and the free silanol groups not covered by the hydrophobic ligand. Porous graphitic carbon is extremely hydrophobic, and the retention of ordinary compounds is quite long compared with that of the commonly used silica-based columns. Thus the high adsorption properties for polar compounds make PGC a most interesting complement to traditional silica supports. Moreover, the unique surface makes the PGC material suitable for separation of closely related structures, e.g., positional isomers and diastereomers. It has also been used to separate enantiomers using chiral mobile-phase additives.

ACKNOWLEDGMENT

Potential Barrier FFF

George Karaiskakis
Physical Chemistry Laboratory, Department of Chemistry, University of Patras, Patras, Greece

INTRODUCTION

Potential barrier field-flow fractionation (PBFFF), developed by Karaiskakis, is a combination of potential barrier chromatography and field-flow fractionation (FFF). It can be applied to separate colloidal particles and is based on differences in size or in any physicochemical parameters involved in the potential energy of interaction between the particles and the material of the FFF channel wall. Of the various quantities which affect the total potential energy (surface potential, Hamaker constant, and Debye–Huckel reciprocal distance), none is as accessible to empirical adjustment as the ionic strength of the suspending medium. This quantity depends on both the concentration and the cationic or anionic charge of the indifferent electrolyte added to the carrier solution. In its simplest form, the PBFFF technique consists in changing the ionic strength of the carrier solution from a high value, where only one of the colloidal components of the mixture subject to separation is totally adhered at the beginning of the FFF channel wall, to a lower value, where the total number of adhered particles is released.

The method has been applied to the separation of hematite and titanium dioxide submicron spherical particles, to the separation of submicron hematite spherical particles with different sizes, to the separation of various mixed sulfides with supramicron polydisperse irregular particles, and to the concentration of dilute colloidal samples, in both the normal and the steric modes of operation of sedimentation FFF.

PRINCIPLE OF PBFFF

Field-flow fractionation is a family of high-resolution techniques capable of separating and characterizing colloids and macromolecules. In normal FFF, the particles form a Brownian-motion cloud that extends a short distance into the channel. Separation is possible because the solvent flows at different velocities at various points within the channel. The smaller particles, whose cloud protrudes out into the faster laminae, are transported more rapidly than the larger particles, so that the two populations are soon separated. In the steric mode of operation, which happens when the protrusion of particles into the flow stream is determined by their physical bulk instead of by diffusion, the larger particles are elute earlier than the smaller ones.

In normal sedimentation FFF (SdFFF) the retention volume, of a spherical particle is immediately related to its diameter, d, via

$$V_r = \frac{\pi G w \Delta\rho V_0}{36kT} d^3 \tag{1}$$

where G is the sedimentation field strength expressed in acceleration, w is the channel thickness, $\Delta\rho = | \rho_s - \rho |$ is the density difference between the particle (ρ_s) and the carrier liquid (ρ), V_0 is the void volume of the channel, k is Boltzmann's constant, and T is the absolute temperature.

In the sedimentation steric FFF (Sd/StFFF), the retention volume of a spherical particle is immediately related to the diameter via

$$V_r = \frac{wV_0}{3\gamma}\frac{1}{d} \tag{2}$$

where γ is a dimensionless factor that accounts for the drag-induced reduction in velocity, as well as for the increase in velocity due to the activity of lift forces. To find γ, it is necessary to have a linear calibration curve of log V_r vs. log d for standard particles of known size and nature (e.g., polystyrene latex beads). The easier way of working in the steric mode of FFF is that using the Earth's gravity as the external field (gravitational FFF = GFFF).

In the normal mode of the SdFFF operation, the potential energy, $\varphi(x)$, of a spherical particle is given by

$$\varphi(x) = \frac{\pi d^3}{6} \Delta\rho G x \tag{3}$$

where x is the coordinate position of the center of particle mass.

When the colloidal particles interact with the SdFFF channel wall, the potential energy given by Eq. 3 must be corrected, so as to include the potential energy of interaction, $\varphi(h)$. The latter can be estimated by the sum of the contributions of the van der Waals, $\varphi_6(h)$, and double-layer, $\varphi_{DL}(h)$, forces, and the total potential energy, φ_{tot}, of a spherical particle in PBSdFFF is given by the relation

$$\begin{aligned}\varphi_{\text{tot}} &= \varphi(x) + \varphi(h) \\ &= \varphi(x) + \varphi_6(h) + \varphi_{\text{DL}}(h) \\ &= \frac{4}{3}\pi a^3 \Delta\rho G x + \frac{A_{132}}{6}\left[\ln\left(\frac{h+2a}{h}\right) - \frac{2a(h+a)}{h(h+a)}\right] \\ &\quad + 16\varepsilon a\left(\frac{kT}{e}\right)^2 \tan h\left(\frac{e\psi_1}{4kT}\right)\tan h\left(\frac{e\psi_2}{4kT}\right)e^{-\kappa h}\end{aligned} \tag{4}$$

where h is the separation distance between the sphere and the channel wall, a is the particle radius, A is the effective Hamaker constant, ε is the dielectric constant of the liquid phase, e is the electronic charge, ψ_1 and ψ_2 are the surface potentials of the particle and the wall, respectively, and κ is the reciprocal Debye length.

The last equation shows that the energy in PBSdFFF is a function of the size and of the surface potential of the particle, of the Hamaker constant, and of the ionic strength of the carrier solution, as the reciprocal double-layer thickness is immediately related to the ionic strength of the suspending medium. Thus, selectivity in PBSdFFF results from differences in particle size or chemical composition of the particles and of the suspending medium, where the latter will affect the surface potential and the Hamaker constant of the particle, as well as the medium's ionic strength.

APPLICATIONS OF PBFFF

As model samples for the verification of the PBFFF as a separation technique, colloidal samples of hematite and titanium dioxide with submicron monodisperse spherical particles were used. In the first example, the fractionation of titanium dioxide [TiO_2 with the nominal diameter obtained by a transmission electron microscope (TEM) of 0.298 μm] and hematite-I [α-Fe_2O_3(I) with nominal diameter obtained by TEM of 0.148 μm] spherical particles was succeeded by the PBSdFFF technique. Fig. 1a shows the fractionation of the TiO_2 and α-Fe_2O_3(I) particles by the normal SdFFF mode of operation, and Fig. 1b shows the fractionation of the same particles by the potential barrier mode of SdFFF. The latter is based on the difference of the total potential energy of interaction between the colloidal particles and the channel wall due to the variation of the ionic strength of the suspending medium.

In the PBSdFFF technique, the mixture was introduced into the channel with a carrier solution containing 0.5% (v/v) detergent FL-70, 0.02% (w/w) NaN_3 and 3×10^{-2} M KNO_3. At this high electrolyte concentration, all of the TiO_2 colloidal particles adhered at the beginning of the SdFFF Hastelloy-C channel wall, whereas all of the α-Fe_2O_3(I) particles were eluted from the channel. The average diameter of the eluted α-Fe_2O_3(I) particles determined by Eq. 1 was found to be 0.143 μm, in good agreement with that obtained

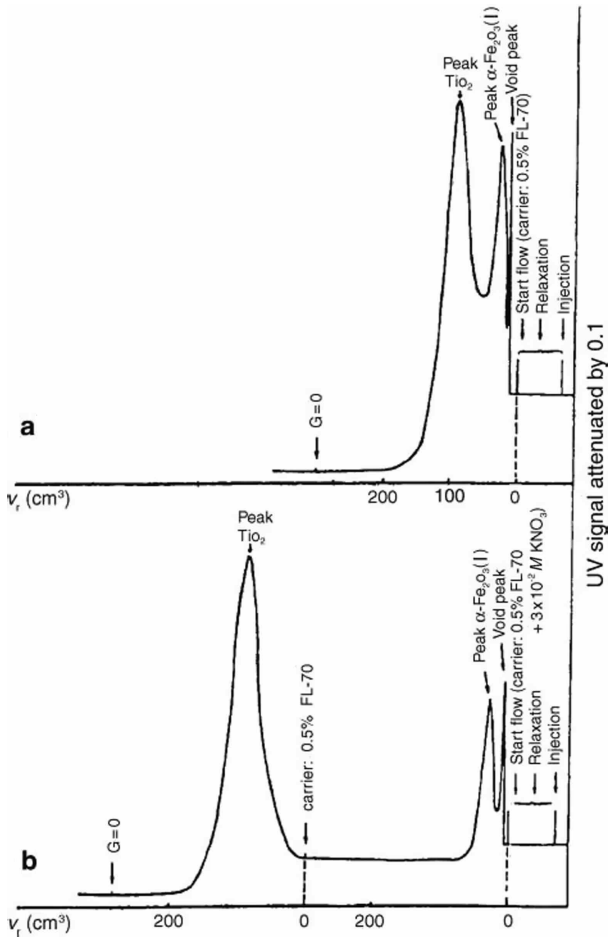

Fig. 1 Fractionation of α-Fe_2O_3(I) (with nominal diameter 0.148 μm) and TiO_2 (with nominal diameter 0.298 μm) colloidal particles by (a) the normal SdFFF and (b) the PBSdFFF technique. The experimental conditions, except for those given in the scheme, were as follows: field strength = 15.5 g, flow rate = 150 cm^3/hr, void volume of the channel = 2.06 cm^3.

by TEM (0.148 μm) or determined by normal SdFFF (0.150 μm). Changing the carrier solution to one containing only 0.5% (v/v) detergent FL-70, whose ionic strength is 1×10^{-3} M, released all the adhered TiO_2 particles and gave a particle diameter (0.302 μm) in good agreement with that obtained by TEM (0.298 μm).

In order to show whether the size of the particles and not their nature is responsible for the variation of the total interaction energy between the colloids and the channel wall, a second example of fractionation was performed by using two samples of hematite with different particle diameters [α-Fe_2O_3(I) with nominal diameter 0.148 μm and α-Fe_2O_3(II) with nominal diameter 0.248 μm]. In the present case, the separation is based only on the particle size difference, as the Hamaker constants and the surface potentials of the two samples are identical. That obtained by the PBFFF

technique fractogram had the same form as that of Fig. 1b, except for the fact that the peak of α -Fe_2O_3(II) was in the position of TiO_2. The critical electrolyte (KNO_3) concentration for the adhesion of α-Fe_2O_3(II) particles at the beginning of the SdFFF channel wall was found to be 3×10^{-2} *M*, whereas at this high concentration of KNO_3, the whole number of α-Fe_2O_3(I) particles are eluted from the channel. Variation of the carrier solution to one containing only 0.5% (v/v) detergent FL-70 and 0.02% (w/w) NaN_3 without any amount of KNO_3 released the total number of adherent α-Fe_2O_3(II) particles. The particle diameters obtained by the PBFFF technique [0.151 μm for α-Fe_2O_3(I) and 0.244 μm for α-Fe_2O_3(II)] are in excellent agreement with those found by normal SdFFF [0.145 μm for α-Fe_2O_3(I) and 0.237 μm for α-Fe_2O_3(II)] or determined by TEM [0.148 μm for α-Fe_2O_3(I) and 0.248 μm for α-Fe_2O_3(II)].

In PBFFF, the variation of the potential energy of interaction between the colloidal particles and the channel wall can be succeeded, except for the variation of the ionic strength, by changing also the pH and the nature of the suspending medium. Polydisperse, irregular supramicron colloidal particles of the mixed sulfides $Cu_xZn_{1-x}S$ ($0 < x < 1$) were used as model samples to verify the applicability of the potential barrier gravitational field-flow fractionation (PBGFFF), based on the variation of the above parameters, to fractionate colloidal particles.

A general methodology for the analysis of a colloidal mixture by PBSdFFF consists in injecting into the column the mixture with a carrier solution in which the ionic strength is too high to assure total adhesion of all the components of the mixture, except for the one with the lower attractive force with the channel wall. Then, a programmed decrease of the ionic strength of the carrier solution is applied to release, *in time*, the adherent particles according to their size and/or surface characteristics. As the PBSdFFF technique is based on particle–wall interactions, its applications can be extended by using different from Hastelloy-C materials, such as stainless steel, Teflon, and polyimide. PBSdFFF is also a convenient and accurate method for the *concentration* and analysis of *dilute* colloidal samples. The major advantage of the proposed concentration procedure is that the method can concentrate particles even of the same size but with different surface potentials and/or Hamaker constants. The method has considerable promise for the separation and characterization, in terms of particle size, of dilute complex colloidal materials, such as those of natural water, where particles are present in low concentration.

FUTURE DEVELOPMENTS

Looking to the future, it is reasonable to expect continuous efforts to improve the theoretical predictions and to expand the applications of the potential barrier methodology of FFF to more complex and dilute colloidal samples. The latter can be easily succeeded by constructing FFF channels from various materials of well-defined composition.

Preparative HPLC Optimization

Michael Breslav

INTRODUCTION

Preparative high-performance liquid chromatography (PHPLC) has assumed an increasingly important role in chemical and pharmaceutical research and development. Earlier, in the 1980s (and even the mid-1990s), this technique was avoided in the industry. However, nowadays preparative chromatography has become an essential part of common practice at both laboratory and production scale. This tendency is favored by the considerable progress achieved recently in developing selective and stable stationary phases for a large variety of separation problems, as well as new techniques and instrumentation.

General comparison of the goals and targets of analytical and preparative chromatography demonstrates some similarities, but also major differences. In analytical HPLC, the ultimate goal is to extract information, while preparative applications are designed to isolate pure compounds. Analytical methods often target resolution of all compounds in the mixture, whereas preparative separations are planned for isolation of one or only a few compounds present in a mixture. In analytical chromatography, the emphasis is on resolution, while the critical parameters in preparative chromatography are the amount of compound produced per unit of time, product purity, recovery, and separation cost.[1] Optimization of all these parameters is always a compromise (Fig. 1).

The approach used for PHPLC optimization depends on the scale of a particular laboratory or industrial chromatographic separation. Large-scale PHPLC optimization goals that ultimately lead to a product with a given minimum purity may include targeting for a maximum amount of the purified material per weight unit of stationary phase per time unit (g/kg/day), maximum amount of the purified material per mobile phase unit per time unit (g/L/day), maximum production rate (g/day), lowest cost ($/kg), and/or maximum recovery (%). Separation expenses (cost of solvents, stationary phase, labor, and equipment usage) should be compared to the value of the product being purified. Overall production cost is a function of purification expenses and production rate. Rapid development of continuous processes, such as simulated moving bed (SMB)[2] and Varicol,[3] has led a growing body of theoretical work to describe and predict separation parameters for a large scale of PHPLC. These techniques are designed to improve the production rate and cost by continuous feed injection and product collection, thus decreasing solvent consumption compared to conventional batch PHPLC. As a result, the solvent usage is greatly reduced, production rate increases, and products are obtained in higher concentrations. However, development of the continuous processes is longer and requires special hardware.

When dealing with large-quantity production of a selected material, it is worthwhile to invest a substantial effort in mathematical modeling of the non-linear chromatographic process.[4] In contrast, when preparing small amounts of material, optimization principles can be applied qualitatively since time becomes the most crucial parameter for the delivery of the pure compounds for the initial testing. Economic aspects are less critical for laboratory scale PHPLC compare to production scale purifications.

This entry focuses mainly on practical aspects of PHPLC optimization for the most common bench scale chromatography.

SPECIFIC ASPECTS OF PHPLC OPTIMIZATION PROCESS

The success of preparative chromatography is strongly related to the way the analytical separation is optimized. As for analytical applications, a resolution of about 1.5–2 is considered to be satisfactory; however, optimization of preparative separations is more difficult due to non-linear effects under overloading conditions and some specific aspects that are discussed below.

Unlike analytical separations, preparative methods may have a number of specific constraints related to the stability of the compound in solution, cost and handling of the large volumes of mobile phase, bulk stationary phase, and special hardware. Preparative chromatography also has the added complication of demanding maximum solubility of the sample in the mobile phase as well as buffer limitations. Lack of solubility causes problems in achieving desired load and also raises concerns about the possibility of

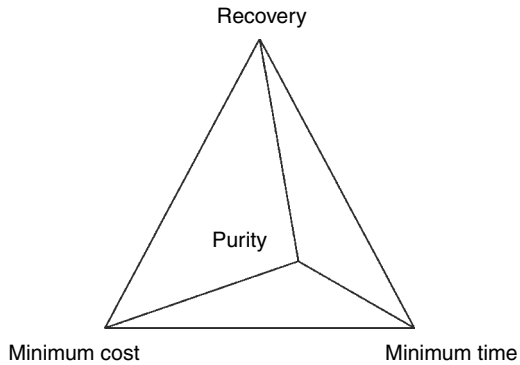

Fig. 1 Purity, recovery, time, and cost of purification can be optimized, but not maximized simultaneously.

sample precipitation inside the injector, solvent lines, and column. Since the ultimate goal of any preparative run is the isolation of a certain amount of pure material, the mobile phase as well as its additives should be easily removable at the end of purification. Therefore, the solvent and modifiers (buffers, acids, and bases) used in the process should be volatile. Factors such as safety hazards associated with large-volume solvent usage, non-specific adsorption on a column, and potential contamination of the product through the leaching of the stationary phase need to be considered as well. Most of these concerns should be addressed during the optimization process prior to scale-up.

Regardless of differences in scale and application, a number of variables are critical in PHPLC optimization strategy and have a pronounced effect on the purity and recovery of the product as well as the time and cost required for the separation. Some of these parameters are discussed below.

RETENTION

It is advantageous to use the minimum retention factor (k) necessary for isolating the product and providing the desired purity, since cycle time is decreased and the production rate is increased. In both normal phase and reversed-phase modes, the concentration of the product in collected fractions decreases when retention increases. In displacement chromatography, longer sample retention provides a more concentrated product fraction. As retention increases, column efficiency increases, but the cycle time and solvent consumption are increased as well. The optimum retention is in the range of $k = 1.2$–2.0 for isocratic separations and $k = 3$–4 for gradient separations. If the difference in retention of impurities and the desired material is large enough, the separation should be optimized, e.g., weakly retained impurities eluted from the column in the void volume. Impurities that are retained significantly longer than the product need to be washed off from the column at the end of the run cycle using a step gradient with a strong eluent; this step may include flow reversal.

SELECTIVITY

Separation of the material of interest and closely retained impurities is greatly affected by changes in selectivity (α, separation factor). Selectivity is described as $\alpha = k_2/k_1$, where k_1 and k_2 are the retention factors for adjacent peaks. Whether a touching band or an overlapping band strategy is adopted, the production rate that can be achieved with a given column is proportional to at least the square of $(\alpha - 1)/\alpha$ and sometimes to the cube of this ratio.[5] Therefore, selectivity is among the factors that have a great effect on the throughput and overall cost of purification. Optimization of the analytical separation for further scale-up should be targeted for a selectivity value at least 1.2 or greater to maintain reasonable cost of preparative purification process. Increasing the selectivity value up to 2 or 3 significantly improves the throughput of separation. Selectivity can be optimized by changing the solvent composition as well as pH and nature of buffer added to the mobile phase.[6] It is also dependent on the chemistry of the stationary phase being used. Therefore, a careful screening of mobile and stationary phase combinations is necessary to select the best method for scale-up.

MOBILE PHASE

When choosing an optimum mobile phase composition, along with the search for the best selectivity value, a number of considerations should be kept in mind. These include parameters such as solvent viscosity, sample solubility in the mobile phase, pH, volatility of solvents/buffers, solvents cost, and safety hazards.

The viscosity of the mobile phase influences the backpressure and efficiency of the separation. The higher the backpressure, the lower the flow rate that can be used, and consequently the longer the run time. Lowering the viscosity increases mass transfer, and hence the efficiency of the separation is improved (the peaks are narrower).

The solubility of the product in the mobile phase is an important parameter. Low solubility of the crude material in a mobile phase may require alterations in the method to prevent on-column precipitation of the material. If a number of different mobile phase mixtures provides similar selectivity, the one in which the product is most soluble should be selected.

Peak shape and preparative loadability are improved for neutral or non-ionized forms of purified compounds. Thus, loading of acidic compounds is improved with low-pH mobile phases, and loadability of basic compounds is higher with basic-pH mobile phases.[7]

Isolation of the product after separation is easier if the solvents and additives to the mobile phase are volatile. Concentration of the product in reversed-phase PHPLC fractions requires evaporation, lyophilization, or dialysis of water-containing mobile phase. Acetonitrile/water but not methanol-containing solutions can be lyophilized. Another approach is to concentrate the fraction by diluting it with water and injecting and concentrating the product on a separate column followed by elution using a pure organic solvent. This method provides a concentrated solution of the product in an organic phase. In normal phase PHPLC, non-aqueous solvents are easily removed from the product by evaporation and are less expensive to dispose of than water-containing mobile phases. At the same time, the use of high volumes of low-boiling flammable organic solvents may represent a safety concern. Accordingly, a less volatile solvent, heptane, for example, rather than hexane, should be used.

Usage of low-boiling organic acids as mobile phase modifiers simplifies workup due to their high volatility. It is common to add trifluoroacetic acid (TFA) to water/organic mobile phases as an ion-pairing reagent in reversed-phase PHPLC. It is important, however, to maintain a sufficient concentration of TFA, especially during loading of the sample, in order to insure adequate concentration of the counter-ion. Any residual TFA can be effectively removed by freeze–drying and/or anion-exchange chromatography. Neutral and basic pH are achieved using ammonium acetate, ammonium, and ammonium bicarbonate additives. These buffers are easily removable at the end of purification as well.

Since the cost of the mobile phase often represents more than half of the total cost of the separation (except the lower cost of carbon dioxide in supercritical fluid chromatography, SFC), it is worthwhile to minimize the solvent consumption and also to increase the concentration of the product in the eluted fractions. Regeneration of the mobile phase is an economical choice at high solvent consumption rates. Regeneration may include distillation of the used mobile phase followed by adjustment of the mobile phase composition if necessary.

STATIONARY PHASE

A number of factors should be considered when choosing a stationary phase for a particular separation task. The chemistry of the stationary phase controls selectivity and therefore production rate. Packing efficiency and loading capacity have a great impact on the throughput, i.e., the amount of mixture injected into the chromatograph per unit time. Mechanical stability of the stationary phase under packing conditions is also an important consideration.

Chemistry of the Stationary Phase

Depending on a particular separation task and combining the knowledge of the analyte's physicochemical properties with that of the phase's characteristics, it should be feasible to weigh the column selection accordingly. Reversed-phase types of stationary phases are widely used in PHPLC due to availability in bulk quantities, easy regeneration, and reliability when scaled up from analytical to preparative conditions. In reversed-phase PHPLC, the choice between stationary phases with longer or shorter alkyl chains (C_3, C_8, and C_{18}) depends mainly on the lipophilicity of the compounds to be separated. In order to assure that retention times are not too long for highly lipophilic compounds, a shorter alkyl chain length is preferred. This allows for faster separation and consequently less organic solvent in the mobile phase, thereby cutting down on solvent costs. However, if evaporation of the collected fractions is critical, then using a longer alkyl chain length stationary phase with a more volatile mobile phase may be advantageous.

A number of novel stationary phases are commercially available now in bulk quantities for in-house packing or in prepacked preparative size columns. These media can be used to meet different separation needs, such as separation of compounds with polar functional groups, highly hydrophilic compounds, basic analytes, etc. The newest additions to the selective packing materials include custom-tailored molecular imprinted polymers.[8]

While regeneration is a regular procedure in reversed-phase chromatography, normal phase chromatography has disadvantages associated with strong binding of polar impurities to the silica surface. However, because of the low price of the bare silica, the stationary phase is often discarded after one or several runs. Normal phase separations are widely used in flash chromatography due to the low price of disposable silica-gel-containing cartridges and easy scale-up from thin-layer chromatography (TLC). Improvements in selectivity and production rate in this case can be achieved by increasing the difference in a number of column volumes eluted between the product and a closely retained impurity (ΔC_v).

$$\Delta C_v = 1/R_{f1} - 1/R_{f2}$$

where R_{f1} and R_{f2} are mobility coefficients of the separated compounds obtained using TLC.

Efficiency of the Packing Material

Efficiency of the packing material is an important consideration in the PHPLC optimization process. When the load is kept sufficiently small, not exceeding the value corresponding to the touching band, it is obvious that the higher efficiency allows injection of more feed. Scale-up of "better than baseline" analytical separation often benefits from increased production rate of the target material. However,

under overloading conditions, pure products may still be recovered with a "less than baseline" separation, although with a lower yield. When a pure compound is injected at a sufficiently high load, there is no effect of the column efficiency on the peak profile. When a mixture is injected, the region where the band interferes is strongly dependent on the column efficiency due to the displacement effect. Therefore, it is preferable to work with highly efficient columns in PHPLC. Using stationary phases with smaller particle size can increase efficiency. Another factor that influences efficiency is flow rate.

Particle size

Decrease in particle size results in increased column efficiency. In preparative chromatography, in practice it is not possible to increase the column efficiency indefinitely, for both practical and economical reasons. Pressure drop is inversely proportional to the square of the particle diameter. Ease of packing of columns decreases with decreasing particle size. Current average particle sizes for reversed-phase PHPLC are in the range of 7–20 μm. In preparative liquid carbondioxide-based SFC, smaller particles in the 5–10 μm range are used due to the low viscosity of the mobile phase.

If the stationary phase contains particles of different sizes, the fraction of larger particles controls the efficiency and the fraction of smaller particles controls the backpressure. The use of high-quality packing with a narrow particle size distribution allows for increased production rates with less backpressure and higher flow rates.

Column length

Production rate (g/day) in batch chromatography increases with increased size of the column. However, backpressure also increases with longer column length. Columns of different lengths, packed with particles of different sizes of the same material, may have a similar production rate provided that the ratio of d_p^2/L is the same, where d_p is the diameter of the particles and L is the length of the column.

Flow rate

Production rate increases at higher flow rates; however, some decrease in separation efficiency occurs. The upper limit of the flow rate depends on the ability of the stationary phase and hardware of the PHPLC system to withstand the higher backpressure. Many non-covalently bonded large-pore fragile enantioselective stationary phases may not be able to withstand higher flow rates and pressure.

Loading Capacity

The total capacity of the column may be found using frontal analysis.[9] A loading factor that represents the percentage of the loaded amount vs. total capacity of the column is one of the major parameters of optimization. The loadability of the stationary phase, and hence the throughput and production rate, is proportional to a specific surface area of a stationary phase. Most of the specific area is located within the pores and therefore can be controlled by the pore size and the pore volume. The pore size of the particles should be large enough to allow the molecules to readily diffuse into and out of the pores. The choice of optimum pore size is dictated by the size of the analyte molecules. Pore sizes usually vary from 60 to 80 Å for small molecules to 150 Å for proteinlike molecules. Larger pores (>150 Å) may give fragile particles that cannot be compressed.

Mechanical Stability

Small particle size material requires a high-pressure slurry packing procedure. It is preferable to work with spherical particles since they have better mechanical stability and thus longer life than irregular ones. Axial compression columns allow for efficient in-house packing of columns with bulk stationary phases. Systems utilizing radially compressed, preloaded disposable cartridges are commercially available.

TEMPERATURE

Increase in temperature usually improves resolution and solubility and decreases the viscosity of the mobile phase. Consequently, the production rate increases, provided that the selectivity of separation or stability of the separated compounds and stationary phases is not compromised. In contrast, resolution in chiral chromatography often improves at lower temperatures.

GRADIENT PROGRAM

Gradient elution provides a better production rate and higher recovery than using isocratic conditions. The gradient profile decreases peak tailing compared to isocratic elution. After sample injection in reversed-phase PHPLC, gradient elution starts with a slightly weaker mobile phase (lower percentage of organic) than required to elute the product with a desired retention and then increases slowly in order to decrease the tailing. The gradient used is shallower when the target compound is the late-retained peak of the two peaks separated. The slope of the gradient should be steep enough to avoid dilution of the product fraction. Too shallow a gradient decreases production rate and complicates isolation of the product. After most of the product has eluted, the gradient is raised stepwise in order to elute all late-retained impurities from the column. The

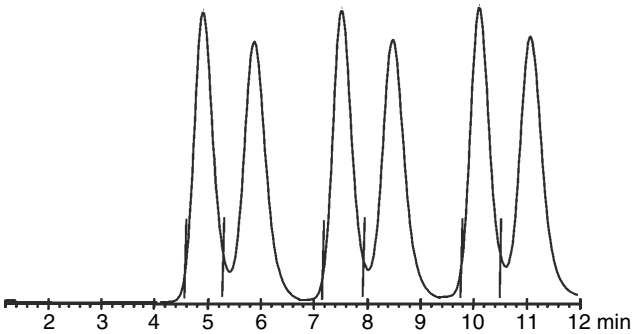

Fig. 2 Stacked injections.

column is equilibrated again with at least one column volume before the cycle is repeated.

Isocratic elution is preferable in batch mode for the separation of closely related analytes to enhance selectivity and allow automation and short injection cycle. Automated injections provide an opportunity for repetitive unattended operation. In isocratic separations, sample injection is often done before the previously injected product elutes from the column, thus reducing cycle time and solvent consumption (Fig. 2). This technique is especially useful in chiral chromatography, where automated processes are used to decrease the required amount of expensive stationary phases, lowering the overall separation expenses.

ELUTION ORDER

If a compound is the major component in a mixture, the production rate increases if the impurities are eluted first. However, it is preferable for the product to be eluted prior to any closely retained impurity if a compound is not the main component in the mixture.[4] Under self-displacement conditions, the product can actually be separated in a more concentrated solution than in touching-band separation, especially if a later-retained impurity is in high concentration. The production rate in this case can be improved by an increase in loading despite some decrease in recovery.

SAMPLE-LOADING PROCEDURE

Unlike conventional small volume injections in analytical HPLC, preparative chromatography often requires loading larger sample quantities in larger volumes and/or strong solvents in order to increase separation throughput, which, in turn, may compromise resolution. Obviously, the narrower the zone of the sample during and after loading, the better the separation results. This is particularly difficult to achieve for low-soluble samples, and, in normal phase chromatography, the problem is usually overcome by using the column impregnation (dry injection) technique. In this case, a suspension of silica in the sample solution is concentrated to dryness and placed in a separate sample injection module before the actual column.

Recently, the at-column dilution technique has been designed in reversed PHPLC to decrease the size of the loading zone by concentrating the sample on the top of the column before separation starts.[10,11] This is achieved by mixing the sample solution stream with a "weak" mobile phase flow at the top of the chromatographic column so that the resulting composition of the mobile phase provides adsorption of the sample on the top of the column. During at-column dilution loading, the sample is first absorbed on the top of the column while the sample solvent is separated and completely eluted from the column. Separation then continues using selected gradient or isocratic methods. Variations in loading design may include injection of the sample solution in the stream of the strong mobile phase component or separate injection pump.[a] The resulting composition of the mobile phase and sample solution combined flow during at-column dilution loading (percentage organic in water/organic mixture) depends on the composition of the mobile phase, composition of the sample solution, and flow rates of the mobile phase and sample solution:

$$\%\,\text{organic} = A * B/(B + C) + C * D/(B + C)$$

where A is the % organic in a sample feed solution at loading, B the feed flow rate at loading, C the mobile phase flow rate at loading, and D the % organic in mobile phase at loading.

At-column dilution allows for processing of low-soluble samples often in large volumes of strong or aggressive solvents and reprocessing of the chromatographic fractions enriched with the target material.

SCALE-UP ISSUES

Direct scale-up of an analytical HPLC method at touching-band conditions is feasible only when there is a need for small (mg) amounts of the isolated material or repetitive automated injections are used to isolate larger quantities of the desired compound. When using a touching-band optimization technique, the amount of material loaded may be increased until visible peak broadening occurs and the first sign of overlapping between the product peak and closely retained impurities is observed. The amount of product that may be loaded onto a column under touching-band conditions can be estimated as[12]

$$w \approx 1/9 w_s[(\alpha - 1)/\alpha]^2$$

[a]Breslav, M. Author's laboratory practice.

where w_s is the column capacity, which may be experimentally found by frontal analysis or less accurately estimated as w_s (mg) ≈ 0.4 (column surface area, m^2).

Overloading of the column provides a better production rate than the touching-band technique. In general, Gaussian peak shape and base-line resolution are not a requirement in PHPLC. Overloading causes interaction between the compounds during chromatography, which creates a sample self-displacement effect. This reduces peak tailing of the earlier eluting peak of the product and leads to increased purity and concentration of the eluted band. In contrast, if the concentration of the closely retained earlier eluted compound is higher than that of the product, the tag-along effect compromises separation.

FRACTION COLLECTION

Automated fraction collection with optimized cut points can contribute significantly to the overall efficiency of preparative separation. Until recently, ultraviolet (UV) directed fraction collection has been commonly used. However, with the necessity to purify a large number of combinatorial libraries consisting of thousands of crude reaction mixtures, the amounts of fractions that need to be collected, analyzed, combined, and tracked is enormous. To address the above issues, a number of commercial high-throughput PHPLCs coupled to tandem mass spectrometry have been developed recently. These automated HPLC/MS systems allow purification of combinatorial libraries at a 50–100 mg scale with a throughput of 250–500 samples/instrument/day.[13] Along with UV detection, the method uses real-time ion signals to trigger fraction collection, and only the masses of the compounds of interest are collected. This format avoids the problem of large fraction collector arrays and eliminates the need for post-purification analysis or pooling of fractions collected. Along with the preparative-scale purifications of combinatorial libraries, preparative liquid chromatography/mass spectrometry (LC/MS) is successfully used in drug discovery to isolate minor compounds from complex mixtures for further structure elucidation or to prepare reference standards.

DESIGN OF THE OPTIMIZATION EXPERIMENT

Nonlinearity of the Langmuir adsorption isotherms is observed even in non-competitive chromatographic processes. Individual adsorption isotherms can be found experimentally using frontal analysis at overload conditions; however, the adsorption isotherms in the separation of mixtures are different because of the interference with other compounds. In PHPLC method development efforts to optimize preparative chromatography using software that allows computer simulated modeling of non-linear effects in preparative chromatography are under way.[14]

Experimental optimization of preparative separation conditions and loading study are usually done on analytical scale. Primary evaluation and selection of the stationary and mobile phases, column efficiency, and product retention experiments under over load conditions are usually done on analytical 0.46×25 cm columns filled with the stationary phase available in bulk quantities for PHPLC. A particular set of chromatographic conditions also includes column dimensions, gradient conditions, sample diluent, and collection points. These conditions are evaluated to obtain maximum recovery of the desired material with required purity, or the maximum available purity for the required yield based on the HPLC analysis of collected fractions. Not all of the separation parameters can be improved simultaneously, and the optimization process often requires multiple experiments. In addition, separation problems, such as sample "bleeding" through the column during loading, or the product not completely eluting from the column, should be identified and corrected. Steps of a carefully designed HPLC optimization experiment include: 1) preliminary recording of the peak area/concentration plot for a pure product standard; 2) calculation of the amount of the target material in the solution prepared for separation; 3) running the designed separation and collecting all fractions by time, starting after the eluted void volume and ending after the column is washed with the strong mobile phase for regeneration (*note*: During the time in which the product and closely retained impurities elute, samples have to be taken more frequently); 4) analysis of all collected fractions to determine the purity (A) and the recovery (C) of the product in each fraction; and 5) measurement of the material balance of the product amount before and after separation.

The calculated product recovery $C_{\Sigma i}$ (%) if i fractions are combined is

$$C_{\Sigma i} = C_1 + C_2 + \cdots + C_i$$

The calculated product purity $A_{\Sigma i}$ (%) if i fractions are combined is

$$A_{\Sigma i} = (A_1 \times C_1 + A_2 \times C_2 + \cdots + A_i \times C_i)/ (C_1 + C_2 + \cdots + C_i)$$

where $C_1, C_2, \ldots, C_i$ = product recovery (%) in fractions 1, 2,..., i is calculated as a part of the total desired product presented in the injected crude material; A_1, A_2,..., A_i = product purity (%) in fractions 1, 2,..., i.

Comparison of the optimization results on recovery and purity assists in the selection of the optimized PHPLC conditions for scale-up. After optimum conditions are determined, a scale-up factor (Y) can be calculated, based

on the results obtained on an analytical column, using the following equation:

$$Y = L_1 \times (D_1)^2 / L_2 \times (D_2)^2$$

where L_1 and L_2 specify column lengths for the scale-up column and analytical column, respectively, and D_1 and D_2 are the respective internal column diameters.

PREPARATIVE CHROMATOGRAPHY IN DRUG DEVELOPMENT PROCESS

Preparative HPLC is routinely and successfully used in drug discovery for the isolation of biologically active compounds from synthetic combinatorial libraries for initial screening. In process chemistry, it is used for the preparation of pure standards and for the purification of sufficient amounts of the synthetic intermediates to help in the optimization of synthetic routes. Preparative chromatography is also used as an effective tool for the isolation of minor impurities (sometimes present at the less than 0.1% level) for consequent structural elucidation. Use of PHPLC in the preparation of the final batches of the drug substance still remains an ultimate dilemma for pharmaceutical companies because of the high, scale-dependent cost of this technique. However, with the rapid development of continuous processes, preparative chromatography is attracting considerable interest for industrial separations in the pharmaceutical industry, particularly for the resolution of enantiomers. At a drug evaluation level, PHPLC provides a definitive way to speed up synthesis and testing of prospective drug candidates, followed by elimination of the less successful compounds, and to subsequently redirect resources in search for new efficient and safe drugs.

Preparative TLC

Edward Soczewinski
Teresa Wawrzynowicz
Department of Inorganic and Analytical Chemistry, Medical University of Lublin, Lublin, Poland

INTRODUCTION

Thin-layer chromatography (TLC) is mostly used as a separation technique combined with qualitative (identification) and quantitative analytical methods; the lower limit of the sample size depends on the sensitivity of detection. For ultraviolet (UV) and chemical detection, it is usually in the microgram or nanogram range. The separated spots can also be isolated for further investigations (chemical derivatization, mass spectrometry, or as chromatographic standards). To increase the scale, the dimensions and thickness of the layer are increased so that it is no longer "thin"; Nyiredy[1] proposed denoting preparative planar chromatography with the abbreviation PLC (preparative layer chromatography) (1 mg to 1 g). The flow of mobile phase during development may be due to capillary forces, pressure [forced-flow planar chromatography (FFPLC), overpressured layer chromatography (OPLC)], or centrifugal force (rotation planar chromatography, RPC).

DISCUSSION

In analytical TLC, linear adsorption isotherms and compact spots are obtained for the loading of sample below 10^{-3} g mixture/1 g adsorbent. To increase throughput, PLC is operated under overloaded conditions, at 1 mg/1 g adsorbent or more. The overloading can be of concentration or volume type; the former is more advantageous.[2]

The main goal of PLC is not the maximal peak (spot) capacity, but the maximal yield of separation.

The increased sample size is obtained by multiple spotting along the start line; when larger volumes are spotted, a series of microcircular chromatograms is obtained as the starting band; streaking from a syringe moving along the start line (e.g., as aerosol—using a programed applicator); especially in OPLC, online zonal application across the plate is possible: The sample is injected into the continuous stream of eluent, distributed across the plate in a narrow channel parallel to the edge, and collected at the farther end of the layer so that the layer acts as a flat column.[1] Similar online injection and collection is possible in centrifugal RPC.

The online application of sample, even of large volumes, is possible with certain horizontal chambers provided with distributors (Camag linear chamber, DS-chamber[3,4]). When the mixture contains few components and the selectivity of the system is high, even large volumes of sample can be introduced from the edge of the layer so that the components are partly separated already in the application stage (frontal chromatography) and, because of mutual displacement effects, may become fully separated during development (Fig. 1), with high yield. To form a compressed starting band, the sample should be dissolved in a solvent weaker than the eluent.

Wide starting bands can also be formed by putting the edge of the plate in the sample solution. To avoid contamination of the eluent in the chamber during development, its bottom is covered by a strip of paper wetted with the eluent; more eluent is introduced when the starting band leaves the edge of the plate.

For thicker layers, the attainment of equilibrium in the gas–mobile phase–adsorbent system to avoid complicating effects (solvent demixing, preadsorption) is more difficult. The solutes migrate in a non-equilibrated layer with differentiated velocity—more rapidly in the surface layer (because of the evaporation of solvent) and less rapidly closer to the carrier plate.

Two stages of PLC determine the success of separation: application of the sample and development. In the former stage, three different situations are possible: (a) sample dissolved in the eluent; (b) sample dissolved in diluted eluent; (c) sample dissolved in a solvent of different quantitative and qualitative compositions.

In case (a), minimal disturbances can be expected at the start of development; however, a wide starting band may be obtained. To obtain a narrow starting band, it is advantageous to dissolve the sample in a weaker solvent, {i.e., of lower content of modifier [case (b)]}.The solubility of the sample is the limiting factor here; the rule is to dissolve a large sample in a small volume of solvent. A good solvent of low eluent strength is chloroform or dichloromethane (e.g., for alkaloids), toluene, or ethers. The application of sample solvent different from the eluent [case (c)] may lead to precipitation of the solutes at the beginning of development; the gradual dissolution of the precipitate in the mobile phase is reflected by comblike tailing of the starting band. It should also be taken into account that, in TLC, the ratio of volumes of the sample solvent (e.g., 0.5 ml) and eluent is greater than in analytical and

preparative column chromatography and may have a more significant effect on the variation of eluent strength of the mobile phase. Evaporation of the sample solvent before development may cause precipitation of the solutes; their delayed dissolution in the mobile phase leads to tailing, which is detrimental to separation. Therefore, online application of the sample is advantageous.

The choice of mobile phase in PLC is also determined by the subsequent recovery of the separated solutes. Less volatile components (water, acetic acid, butanol) should be avoided, as well as non-volatile components—buffer solutions and ion association reagents. Normal-phase chromatography and non-aqueous eluents should, therefore, be preferred. The rules of choice of eluents are otherwise similar to those for analytical chromatography (i.e., basing on eluotropic and isoeluotropic series) depending on the properties of the separated solutes. Usually, eluents giving R_F values in the lower range (0.1–0.5) are chosen, because the application of larger sample volumes leads to wide starting zones and increase of R_F values. For polar adsorbents, ethyl acetate belongs to the recommended modifiers, because of the good solubility of many non-polar and moderately polar solutes, rapid equilibrium, and easy evaporation of the separated fractions.

In PLC, sorbents applied in TLC are usually used: silica, alumina, Florisil, cellulose, and silanized silica. Binding agents such as gypsum and somewhat lower amounts of water are recommended (e.g., for 1 mm silica layers, the weight ratio of water and adsorbent is 1:1.5 or 1:2). Plates with thicker layers should be dried in air in a horizontal position for a longer time (e.g., for 1 mm layers, ~1 hr; for 2 mm layers, 2–4 hr) and then dried and activated in an oven in gradually increasing temperatures. Equilibration in the chamber should also be prolonged. Because chemically bonded adsorbents are relatively expensive and, moreover, reversed-phase (RP) sorbents are poorly wettable by aqueous eluents, polar adsorbents and non-aqueous eluents of low viscosity are usually applied in PLC. Special precoated plates of 0.5–2 mm layers are commercially available (e.g., silica gel 60 $F_{254+366}$). Such plates can be applied directly without activation; however, drying at 80°C for 2 hr is recommended. Although the capacities of layers increase with their thickness, the separation efficiency decreases for thickness above 1.5 mm, so that optimal for PLC are layers of 0.5–1 mm thickness.

The development distance in PLC should not exceed 20 cm, because of the decreasing flow rate for longer distances and increasing diffusion of zones. A suitable system should have a resolution $R_s \geq 1.5$ in the analytical scale.

Marked improvement of separation efficiency in the separation of complex samples may be obtained by stepwise gradient elution[5] because of enhanced mutual displacement of the components in the concentrated starting band. A simple stepwise gradient of four to five steps is frequently sufficient; the generation of stepwise gradients is possible in some types of horizontal chambers[6] by consecutive delivery of eluent fractions of increasing concentrations of modifier.

Preparative layer chromatography can also be used as a pilot technique for column preparative chromatography in the same solvent–adsorbent system.

Abstract
An efficient separation of apple procyanidins (oligomeric catechins) was performed by high-speed countercurrent chromatography (HSCCC) in a one-step operation from an apple condensed tannins fraction using a hydrophilic two-phase solvent system composed of methylacetate-water (1:1, v/v). In further matrix-assisted laser desorption initiation–time-of-flight mass spectrometry (MALDI–TOF-MS) analyses of the solute oligomers, the elution order of the procyanidins in the HSCCC was coincident with their degree of polymerization.

INTRODUCTION

Unripe apple contains polyphenols (including dihydrocalcons, phenolic acids, and others), constituting up to 50% of the total mass of solids; beside consisting of monomers, dimers, trimers, and oligomers of catechin and/or epicatechin, which are called apple procyanidins or apple condensed tannins (ACTS). Highly polymerized procyanidins have attracted attention in the fields of pharmacology and food chemistry because of their physiologic activities, such as hair growth promotion, antiallergic, antibiotic, and inhibitory activities against enzymes and receptors. These properties of procyanidins depend on the degree of polymerization of catechin and/or epicatechin.

In order to correlate these pharmaceutical activities with their degree of polymerization, it is necessary to establish an efficient, reliable separation method. However, the application of liquid chromatography (LC) to the separation of these procyanidin oligomers is difficult because the oligomers above hexamers tend to cause irreversible adsorption onto the column packing materials.

Countercurrent chromatography (CCC)[1] is a liquid–liquid partition technique that eliminates various complications arising from the use of solid supports. The high-speed CCC (HSCCC), the most advanced form in terms of partition efficiency and separation time, has been used for the separation and purification of a wide variety of natural products. The recent model of HSCCC, which facilitates the stationary phase retention for polar solvent systems, is particularly useful for the separation of hydrophilic, highly polymerized procyanidins.[2,3]

APPARATUS

The CCC separation of procyanidin oligomers from apple condensed tannin was performed using a type-J HSCCC centrifuge (Fig. 1). The apparatus holds a multilayer coiled separation column and counterweight symmetrically at a distance of 10 cm from the central axis of the centrifuge. The separation column is fabricated by winding a single piece of 2.0 mm I.D. and 21 m long polytetrafluoroethylene (PTFE) tubing directly onto the holder hub, making four coiled layers between a pair of flanges. The total capacity of the column is about 72 ml. The speed of the apparatus is regulated at 1000 rpm with a speed controller. The coil rotates around its axis as it simultaneously revolves around a central axis, producing an efficient mixing of the two phases while retaining a sufficient amount of the stationary phase in the column.

Fig. 1 Photograph of the type-J multilayer coil planet centrifuge.

PREPARATION OF ACTS FOR CCC SAMPLE

The unripe apples were homogenized in potassium pyrosulfite solution, and the mixture was allowed to stand for 1 day. The supernatant was centrifuged and filtered with a glass filter funnel. The filtrate was applied to adsorption chromatography, and the ACT fraction was evaporated and lyophilized. Purified ACTs were a mixture of monomers (catechin and/or epicatechin) and oligomers from dimers to pentadecamers, as shown in Fig. 2.

MEASUREMENT OF PARTITION COEFFICIENT OF CATECHIN AND/OR EPICATECHIN AND ACTS

CCC utilizes a pair of immiscible solvent phases that have been pre-equilibrated in a separatory funnel: One phase is used as the stationary phase and the other as the mobile phase. In order to achieve efficient separation of higher polymerized, large oligomers from ACTs, the partition coefficient values (K_D) of catechin and/or epicatechin and ACTs were determined in the following four hydrophilic solvent systems:

1. *n*-Butanol/water (1:1)
2. *n*-Butanol/acetic acid/water (4:1:5)
3. Methyl *tert*-butyl ether/acetonitrile/water (2:2:3)
4. Methyl acetate/water (1:1)

As the chromatographic process in CCC is based on the partition of a solute between the mobile and stationary phases, the K_D value is the most important parameter in CCC. A K_D value of around 1.0 is most desirable in CCC, wherein a solute with $K_D = 1.0$ elutes with its retention volume equivalent to the total column capacity. In the above two-phase solvent systems, the K_D values of monomers (catechin and/or epicatechin) were greater than 1.0, and those of the ACTs are always smaller than 1.0, suggesting that monomers are more hydrophobic than their oligomers present in ACTs. Among these four solvent systems, we selected a simple binary system of methyl acetate/water for the separation of procyanidin oligomers from ACTs by CCC.

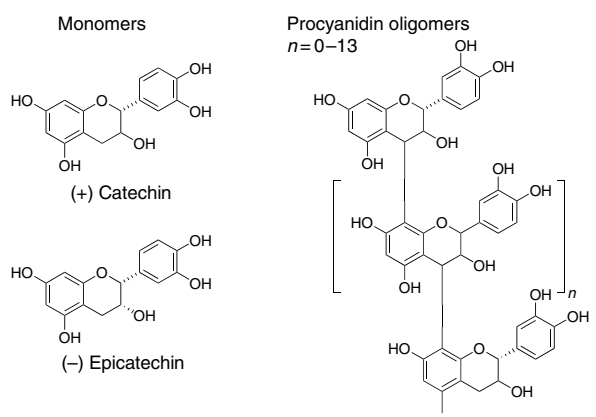

Fig. 2 Chemical structures of catechin, epicatechin, and procyanidin oligomers.

CCC SEPARATION OF ACTS BY HYDROPHILIC SOLVENT SYSTEM

Fig. 3 shows a chromatogram obtained from ACTs using the two-phase solvent system composed of methyl acetate/water (1:1). After filling the multilayer coil with the lower aqueous stationary phase, 2 ml of the sample solution, containing 100 mg of ACTs, was injected into the column. The separation was performed by pumping the upper phase into the column at a flow rate of 1.0 ml/min at 1000 rpm rotational speed. The effluent was monitored at 280 nm and fractions were collected at 3 ml per tube. The masses of the fractionated oligomers were determined by matrix-assisted laser desorption initiation/time-of-flight mass spectrometry (MALDI–TOF-MS) analysis.

After the elution of the trimers, the lower aqueous phase was eluted through the column to facilitate a rapid elution of the oligomers still remaining in the column. The tetramers and pentamers fraction, the pentamers, hexamers, and heptamers fraction, and higher polymerized oligomers over the hexamers fraction were subsequently eluted from the column in this order. Interestingly, the elution order is also coincident with the degree of polymerization of catechin and/or epicatechin. With the exception of the solutes in last large peak (highly polymerized catechins), the degrees of polymerization of solute oligomers in all CCC fractions in Fig. 3 were clearly determined by MALDI–TOF-MS analyses. The lower stationary phase retained in the column was

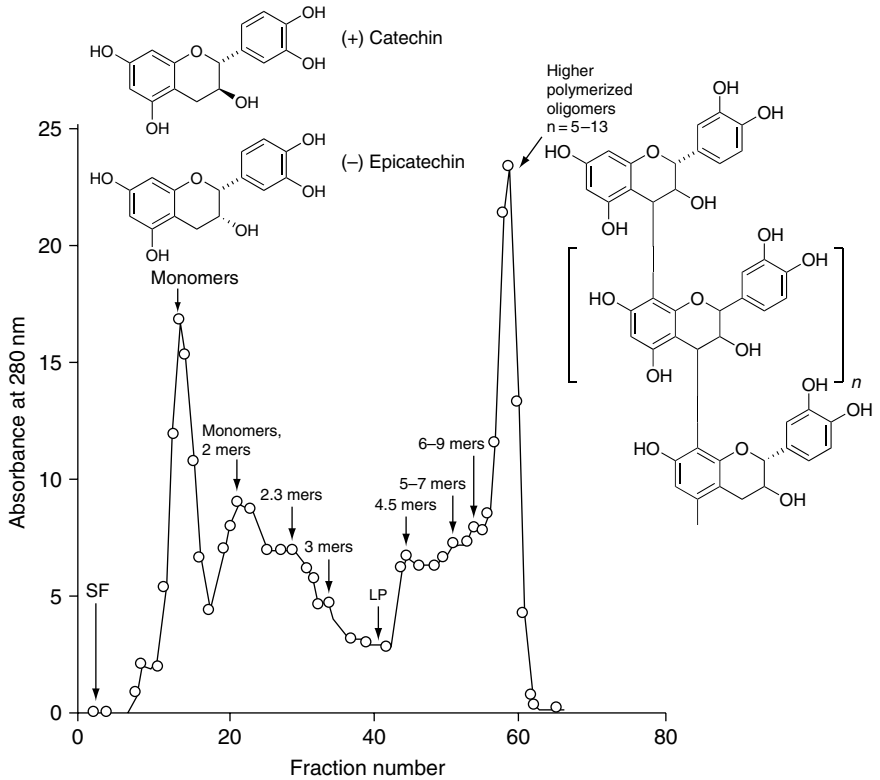

Fig. 3 Separation of procyanidins in the order of their degree of polymerization by countercurrent chromatography.

estimated as 82% of the total column capacity (72 ml) prior to the application of the elution with lower phase. The separation was completed within 3 hr.

The chromatogram shown in Fig. 3 was the first separation profile of oligomeric procyanidins by HSCCC using a two-phase solvent system. In recent times, other hydrophilic solvent systems, such as hexane/methyl acetate/acetonitrile/water three-phase system,[4,5] methyl *tert*-butyl ether/1-butanol/acetonitrile/water two-phase systems,[6,7] and ethyl acetate/1-butanol (or 2-propanol)/water two-phase systems,[8,9] were also applied to HSCCC separations of other proanthocyanidins and/or related polyphenolic oligomers.

CONCLUSIONS

The results indicate that the present method is capable of fractionating the apple procyanidin oligomers from ACTs according to the degree of polymerization. The highly polymerized, very hydrophilic oligomers, which tend to be adsorbed on the column packing materials by high-performance liquid chromatography (HPLC), were all recovered from the CCC column.

Programmed Flow GC

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

There are three methods that can be used to accelerate the elution of strongly retained peaks during chromatographic development. Flow programing, where the flow of mobile phase is continuously increased during the development of the separation, temperature programing, and gradient elution, the latter being exclusively used in liquid chromatography. We reserve our discussion here to flow programing.

DISCUSSION

Flow programing is not as effective in reducing the elution time of well-retained components and tends to cause increased band dispersion; it is, however, more gentle than temperature programing and would be chosen when separating thermally labile materials. The complexity of the theoretical treatment depends on whether the mobile phase is compressible or not. In gas chromatography, the mobile phase is compressible, and this must be taken into account in the first theoretical treatment.

We shall assume that under flow programing conditions, the mass flow rate will be increased linearly with time (i.e., $Q_{0(t)} = (Q_0' + \alpha t)$ where Q_0' is the *initial exit flow rate*, $Q_{0(t)}$ is the exit flow rate after time t and α is the program rate. These conditions are usual for modern gas flow programing devices that utilize mass flow controllers which are computer operated. Now, if ΔV_0 is an increment of exit flow, measured at atmospheric pressure, then employing the usual pressure correction factor, the corrected gas flow (ΔV_r) will be

$$\Delta V_r = \frac{3}{2}\Delta V_{r(0)}\left(\frac{\gamma^2 - 1}{\gamma^3 - 1}\right)$$

where γ is the inlet/outlet pressure ratio of the column. Then, under the above-defined programing conditions,

$$\Delta V_{r(t)} = \frac{3}{2}\left(\frac{\gamma_t{}^2 - 1}{\gamma_t{}^3 - 1}\right)(Q_0 + \alpha t)\Delta t \qquad (1)$$

where (γ_t) is the inlet/outlet pressure ratio at time t and $\Delta V_{r(t)}$ is the increment of volume flow at time t.

Now, as the flow is increased, the inlet pressure will also increase and, thus, the inlet/outlet pressure ratio (γ) will change progressively during the program; the *mean* flow rate will be reduced according to the pressure correction function and the decrease in elution rate will not be that which would be expected. Consider an open-tubular column; from Poiseuille's equation,

$$P_0 Q_{(0)t} = \frac{(P_t{}^2 - P_0{}^2)\pi a^4}{16\eta l}$$

or

$$P_0(Q_0 + \alpha t) = \frac{(P_t{}^2 - P_0{}^2)\pi a^4}{16\eta l} \qquad (2)$$

where P_t is the inlet pressure at time t, P_0 is the outlet pressure (atmospheric), η is the viscosity of the gas at the column temperature, l is the length of the open-tubular column, and a is the radius of the open-tubular column.

A similar equation would be used for a packed column, except the constant (π/16) would be replaced by the D'Arcy constant for a packed bed. Rearranging,

$$\frac{P_0(Q_0 + \alpha t)16\eta l}{\pi a^4} + P_0{}^2 = P_t{}^2$$

thus,

$$\gamma_t = \frac{P_t}{P_0} = \left(\frac{(Q_0 + \alpha t)16\eta l}{P_0 \pi a^4} + 1\right)^{0.5} \qquad (3)$$

Assuming the column dimensions are 320 μm in inner diameter (radius $a = 0.0160$ cm) and 30 m in length, and it is operated at 120°C using nitrogen as the carrier gas which, at that temperature, has a viscosity of 129×10^{-6} P, then, by using Eq. 3, the change (γ)

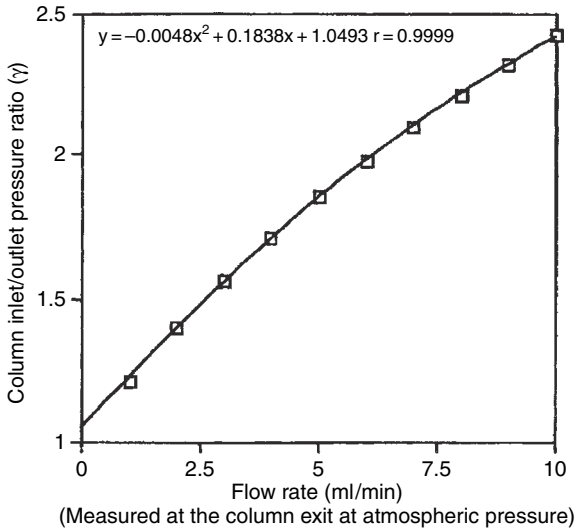

Fig. 1 The relationship between the inlet/outlet pressure ratio and exit flow rate for an open-tubular column.

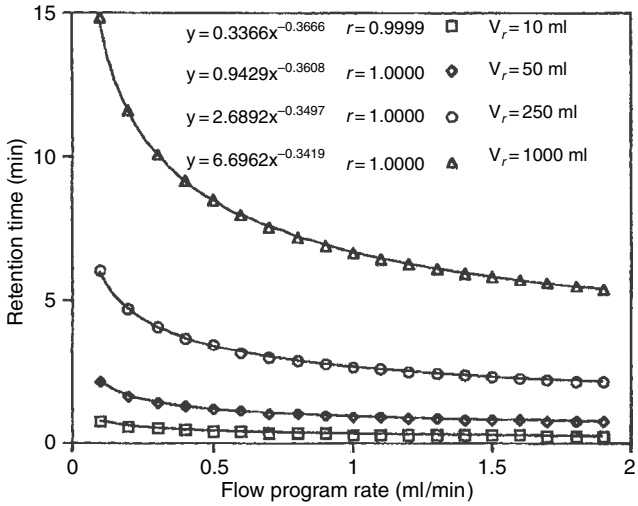

Fig. 2 Curves relating elution time to flow program rate for solutes having different retention volumes.
Source: From *Gas Chromatography 1964*.[1]

can be calculated for different flow rates. The relationship between flow rate (as measured at the column exit and at atmospheric pressure) and the column inlet/outlet pressure ratio is shown in Fig. 1. The inlet/outlet pressure ratio changes significantly during a mass flow rate program, which will attenuate the elution rate as shown by the pressure correction factor. It is seen that the curve is a close fit to a second-order polynomial function, but this relationship is fortuitous, although it might be used empirically to predict inlet/outlet pressure ratios.

It is now possible to use the values for γ_t to calculate when the solute is eluted at the retention time t_r for different flow program rates. Employing Eq. 1, when the sum of all the increments of ΔV_r is equal to the retention volume V_r, then t will be t_r, the retention time:

$$V_r = \sum_{t=0}^{t=t_r} \frac{3}{2}\left(\frac{{\gamma_t}^2 - 1}{{\gamma_t}^3 - 1}\right)(Q_0 + \alpha t)$$

With a simple computer program, the retention time t_r can be calculated for a range of different program rates (α) and for solutes having retention times of 10, 50, and 250 ml, respectively. The column was again assumed to be 320 mm in inner diameter and 30 in length and operated at 120°C using nitrogen as the carrier gas which, at that temperature, has a viscosity of 129×10^{-6} P. The results are shown in Fig. 2.

The effect of program rate on retention time is much as would be expected. For any individual solute, the retention time is related to some power of the solute retention volume, but the indices vary significantly with the retention volume of the solute. This relationship does not have a theoretical explanation at this time but

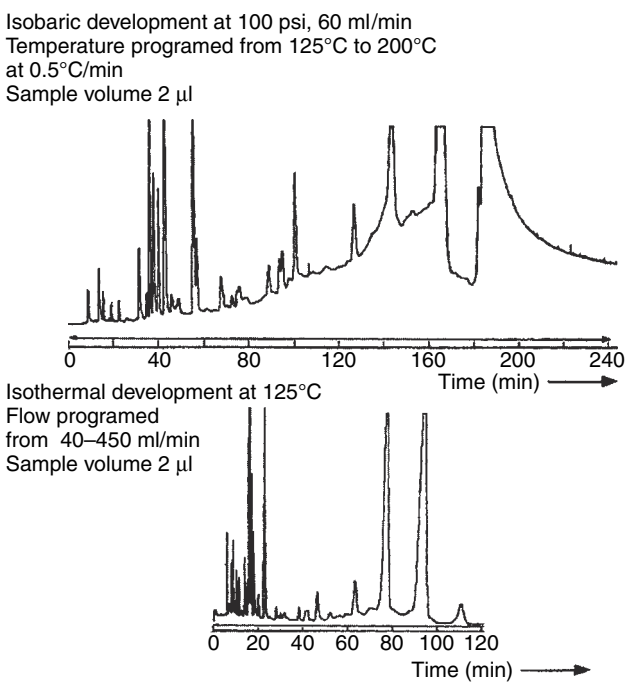

Fig. 3 The separation of lemon grass oil by temperature programing and by flow programing.

might be useful for predicting retention times from experimental data. Despite the attenuating effect of the pressure correction factor, the use of flow programing is effective in reducing the retention time of strongly retained solutes. However, unless the diffusivities of the solutes in the mobile phase are high (i.e., mobile phases such as hydrogen or helium are employed), there will be significant peak dispersion at the higher velocities, the column efficiency will be reduced, and resolution will be lost.

An excellent example of the use of flow programing was given in a very early article describing the technique.[1] Lemon grass oil contains two substances that are very thermally labile, and these are eluted very late in the chromatogram. If temperature programing is employed, the substances decompose at the higher temperatures, producing a sloping baseline as shown in the upper chromatogram in Fig. 3. The baseline does not return to its normal level until the thermally unstable compounds have been completely eluted. If the separation is carried out isothermally at a temperature where the decomposition is minimal, and the mixture is developed by flow programing, all the solutes are eluted on a relatively stable baseline. The elution times are high, due to long packed columns being employed, as opposed to capillary columns.

Programmed Temperature GC

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

Temperature programing becomes necessary when the sample contains components that have polarities and/or molecular weights that extend over a wide range. Such samples, if separated isothermally, may well result in the less retained solutes being adequately resolved and eluted in a reasonable time. However, the more polar or higher-molecular-weight solutes may be held on the column for an inordinately long period, and the solute peaks, when they are eluted, are likely to be wide and flat and difficult to evaluate quantitatively. To avoid this situation, the column temperature can be progressively increased during development so that the late eluting peaks are accelerated through the column and are still sharp and eluted in a reasonable time. This procedure is called temperature programing.

APPLICATION

The corrected retention volume of a solute (V_r') is given by (see *Rate Theory in GC*, p. 2000)

$$V_r' = KV_s$$

where K is the distribution coefficient of the solute with respect to the stationary phase and V_s is the volume of stationary phase in the column.

The value of K varies with temperature in the following manner (see *Thermodynamics of Retention in GC*, p. 2307)

$$\ln(K) = -\left(\frac{\Delta H}{RT} - \frac{\Delta S}{R}\right)$$

$$\text{or} \quad K = \exp\left[-\left(\frac{\Delta H}{RT} - \frac{\Delta S}{R}\right)\right]$$

where ΔH is the standard enthalpy of distribution, ΔS is the standard entropy of distribution, R is the gas constant, and T is the absolute temperature. Thus,

$$V_r' = \exp\left[-\left(\frac{\Delta H}{RT} - \frac{\Delta S}{R}\right)\right]V_s$$

It is seen that as T increases, K decreases. It follows that K and, consequently, the retention volume can be progressively decreased by increasing the column temperature. In practice, this is usually achieved by situating the column in an oven, the temperature of which is controlled by appropriate electronic circuitry. Theoretically, the temperature of the oven can be increased as any function of time, but almost all program profiles are linear in form.

Consequently, programing the column from temperatures T_1 for a period of t, using a linear program (i.e., $T = T_1 + \alpha t$, where t is the elapsed time), the mean value of K will be given by the following function:

$$K = t_1^{-1}\sum_{t=0}^{t=t_1}\exp\left[-\left(\frac{H}{R(T_1+\alpha t)} - \frac{S}{R}\right)\right]$$

where t_1 is the time period of the program. [Preferably t_1 for maximum accuracy, should be defined in small units (e.g., seconds and not minutes).] Similarly, the program rate α must be defined in degrees Celcius per second.

Now, when the solute is eluted, V_r' will equal the product of the mean flow rate Q_m and t_1, which will be the retention time; that is,

$$V_r' = Q_m t_1$$

The mean flow rate through a GC column is given by[1]

$$Q_m = Q_0\frac{3(\gamma^2-1)}{2(\gamma^3-1)}$$

where γ is the and/or pressure ratio and Q_0 is the exit flow rate.

Thus, when the solute elutes,

$$V_r' = V_s K\sum_{t=0}^{t=t_1}\exp\left[-\left(\frac{H}{R(T_1+\alpha t)} - \frac{S}{R}\right)t_1\right]$$
$$= Q_0\frac{3(\gamma^2-1)}{2(\gamma^3-1)}t_1$$

where V_s is the volume of stationary phase in the column.

Solving for t in the classical manner is a cumbersome mathematical procedure and it is easier to employ a numerical method to calculate t. To demonstrate the effect of temperature programing on solute elution, a computer program was used to calculate the retention time of a given solute eluted at different programing rates. The data used

were that of Liao and Martire[1] for 3-methyl hexane chromatographed on *n*-octadecane at temperatures of 30°C, 40°C, 50°C, and 60°C.

By curve-fitting the retention data to the reciprocal of the absolute temperature, the numeric form of the distribution coefficient was found to be

$$K = \exp\left(\frac{1737.777}{T} - 2.75115\right)$$

A simple computer program provided values for the retention time, calculated for different linear program rates, and the results are shown as curves relating retention time to program rate in Fig. 1. The and/or pressure ratio (γ) was assumed to be 2 and the flow rate at the column exit was 20 ml/min (0.3333 ml/s). The logic of the program was based on a search for that value of t where the value (V_r') of equaled the product of t and the mean column flow rate. It should be noted that the data were reported as the corrected retention volume per gram of stationary phase; thus, for simplicity, the curves are calculated on the assumption that the column contains 1 g of stationary phase. Retention times for columns containing more stationary phase would be appropriately longer. Due to the change in both the density and viscosity of a gas with temperature, the mean flow rate will change slightly during the program, but the error will be small, provided that a *mass flow controller* is employed and not a pressure controller. For the calculations, the inlet pressure was assumed to remain constant throughout the program.

This procedure is a general method for calculating the effect of the program rate on retention time. Basically, the corrected retention volume must be measured for each solute of interest at two different temperatures to provide the thermodynamic constants. The above equations will then allow the effect of different linear temperature programs on the corrected retention volume to be calculated for each solute. The effect of program rate on resolution can also be observed if some solutes elute close together. In fact, the equation can be used for program functions other than linear, but these are rarely employed. The relationship between retention time and program rate is approximately linear and can be assumed so for most practical purposes. For more accurate work, a second-order polynomial should be used to describe the retention time as a function of the program rate, which can give very accurate values.

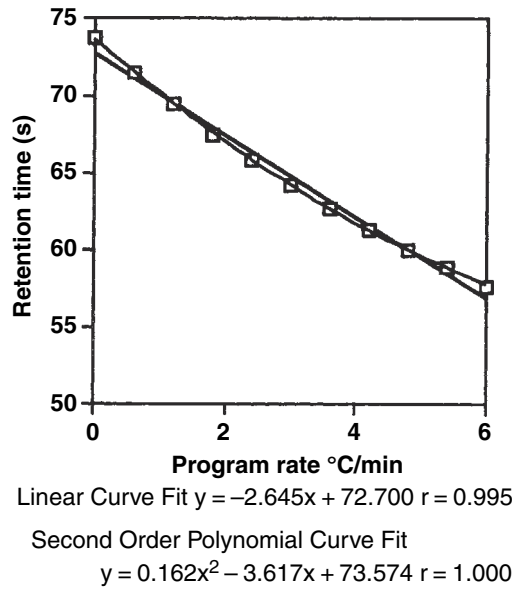

Fig. 1 Graph of retention time versus program rate.

Prostaglandins, Isoprostanes, and Synthetic Prostanoid Drugs: Analysis by HPLC

Harald John
Bundeswehr Institute of Pharmacology and Toxicology, Munich, Germany

Abstract
Prostaglandins (PGs), isoprostanes (IPs), as well as thromboxanes are unsaturated oxidized derivatives of naturally occurring ubiquitous arachidonic acid and similar fatty acid precursors exhibiting very weak UV absorptivity. Whereas PGs are produced enzymatically via the cyclooxygenase(COX)-complex, iPs are generated following a non-enzymatic free-radical mechanism. These compounds are multifunctional physiological regulators and act as chemical messengers in mammalian cellular behavior, thus affecting, e.g., platelet aggregation or contraction and dilation of muscles and vessels. Due to this widespread biological activity synthetic structural analogs (prostanoids) are administered as drugs characterized by optimized efficacy and stability for therapeutic intervention of, e.g., pulmonary arterial hypertension, glaucoma, and induction of abortion.

To elaborate physiological mechanisms of action and investigate pharmacokinetic characteristics, bioanalytical procedures that allow selective trace level quantification are required. The more or less lipophilic and acidic compounds are typically extracted from biological fluids after acidification by liquid–liquid extraction (LLE), solid-phase extraction (SPE), or by the more sophisticated novel approaches of online techniques making use of on-column hydrophilic–lipophilic interactions. To achieve sufficient lower limits of quantification, PGs are often converted into highly UV-absorbing or fluorescent derivatives. Chromatographic separations by reversed-phase (RP) high-performance liquid chromatography (HPLC) coupled to sensitive and selective mass spectrometric (MS) or fluorescence detection are well-established tools that overcome the drawbacks of the more classical and conventional gas chromatographic techniques. The use of modern LC–MS techniques by electrospray ionization (ESI) and collision-induced dissociation (CID) for analyte fragmentation realize an optimum of selectivity as well as sensitivity. In addition time-consuming sample preparation steps as well as derivatization can be avoided, making LC–MS/MS the most promising chromatographic technique for PG analysis.

INTRODUCTION: PHYSIOLOGY AND CHEMISTRY[1–3]

Prostaglandins (PGs) are a class of substances representing natural metabolites of three 20-carbon fatty acids differing in their number of double bonds: arachidonic acid (AA, 5,8,11,14-eicosatetraenoic acid); 8,11,14-eicosatrienoic acid; and 5,8,11,14,17-eicosapentaenoic acid. In the following discussion, only the bisenoic PGs (produced from AA), which dominate most biological systems, will be discussed. Free AA acts as a substrate for the cyclooxygenase (COX) enzyme complex and consecutively several specific enzymes including isomerases, reductases, and synthases produce thromboxanes (TXs) and further PGs as demonstrated in Fig. 1. Furthermore, in recent years, four groups (type III–VI) of the AA-derived isoprostanes (iPs) were investigated extensively. These iPs are isomeric to PGs that are physiologically produced as racemic mixtures by non-enzymatic reactions based on free-radical mechanisms initiated by reactive oxygen species implicated in membrane damage (Fig. 2). Their weak ultraviolet (UV) absorption maxima are found at 192 nm and at 217 nm for PGA_2, 228 nm for 15-oxo-PGE_2, and 278 nm for PGB_2, arising from delocalized electron systems of conjugated double bonds and oxo groups. Prostanoids are known for their high and widespread physiological potency in acting as chemical messengers capable of regulating cellular behavior in mammalian tissues. The influences on platelet aggregation, contractory or dilatory effects on muscles and vessels, mediating inflammatory diseases, and pain are only a few examples that make these compounds of great interest for diagnostic and therapeutic purposes. Therefore, numerous additional synthetic prostanoid drugs, which possess chemical structures similar to naturally occurring PGs but exhibit improved pharmacological properties like prolonged stability and enhanced biological potency, are approved and used in therapy.

Currently, prostanoids are administered for various therapeutic interventions: e.g., 1) treprostinil, beraprost, and iloprost (Fig. 3) are analogs of PGI_2 (prostacyclin) which are used to treat pulmonary arterial hypertension (PAH) to overcome the drawback of short circulation

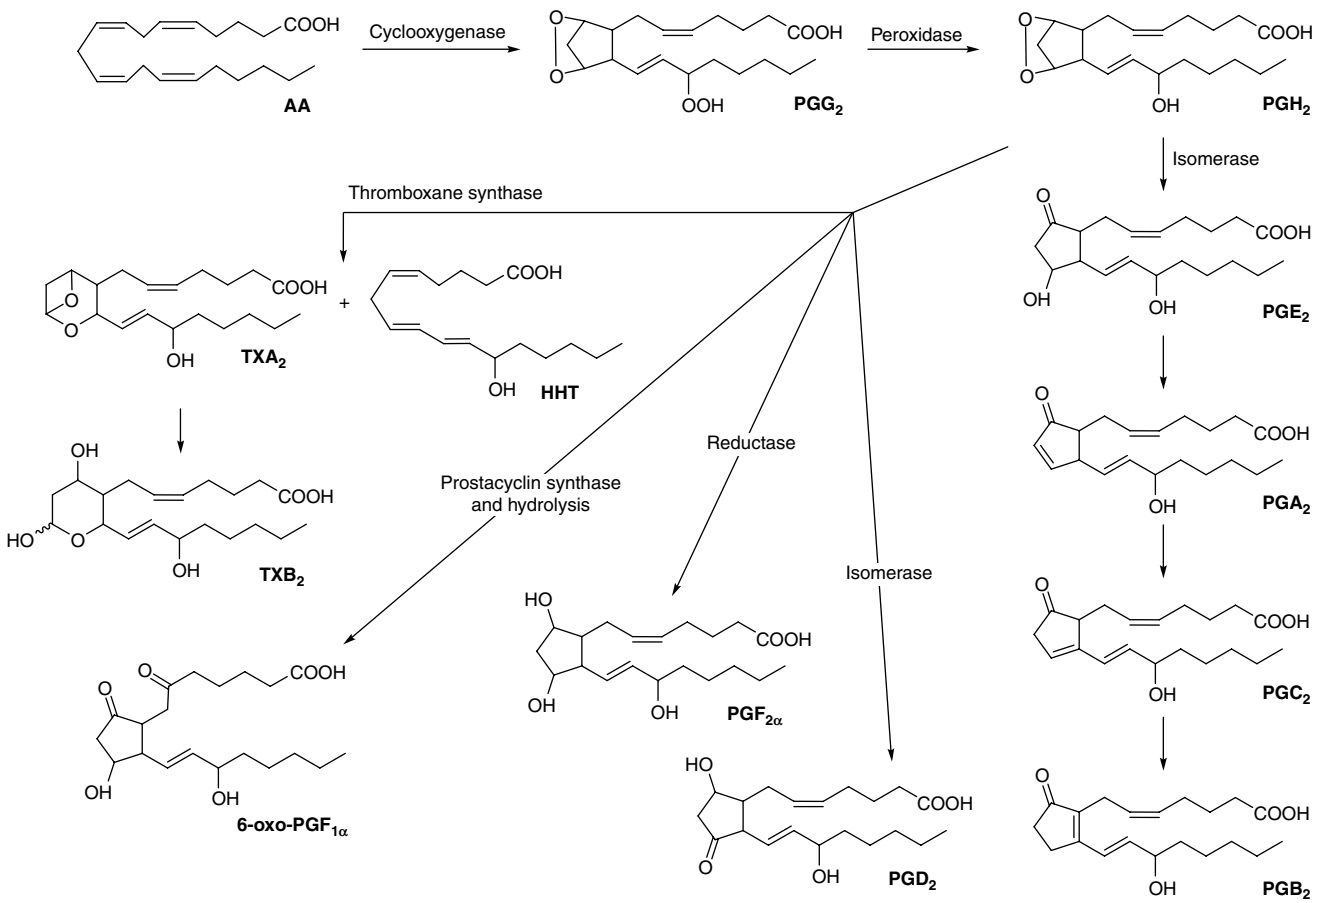

Fig. 1 Cyclooxygenase-initiated metabolization of arachidonic acid (AA) to prostaglandins (PGs) and thromboxanes (TXs).

half-life of epoprostenol (sodium salt of PGI_2) applied as a potent vasodilator and antithrombotic agent; 2) synthetic analogs of $PGF_{2\alpha}$ (Fig. 1) act as potent and selective agonists on the $PGF_{2\alpha}$ receptor and are therefore used for the treatment of glaucoma to reduce intraocular pressure (travoprost and latanoprost, Fig. 3), or to induce estrus in mares in veterinary medicine (fluprostenol, Fig. 3); cloprostenol (Fig. 3) is an additional $PGF_{2\alpha}$ analog that is 200 times more potent than $PGF_{2\alpha}$ itself to terminate pregnancy and elicits luteolysis and uterine contraction; 3) structural analogs of PGE_2 (Fig. 1) are clinically used for, e.g., postoperative cervical dilatation and induction of abortion (sulprostone, Fig. 3); 4) analogs of PGE_1 can be clinically beneficial by decreasing the frequency of gastric mucosal lesions (ulceration) occurring in patients receiving nonsteroidal anti-inflammatory drugs (misoprostol, Fig. 3) and by their strong vasodilatory and antiplatelet activities (limaprost, Fig. 3). An additional large number of prostanoid compounds are known for therapeutic intervention and physiological regulation but a more detailed introduction would go beyond the scope of this entry.

In contrast to endogenous PGs, several prostanoid drugs contain esterified or amidated carboxyl groups, thus acting as prodrugs that need to be converted into their free acids for optimum activity (e.g., bimatoprost, latanoprost, travoprost; Fig. 3). Following in vivo administration, liberated drugs exhibit improved biological activity for which reason the corresponding drug concentrations are adjusted to be much smaller than those known for endogenous PGs. Therefore, analytical methods that allow the trace-level determination of PGs, iPs, and prostanoid drugs from different complex biological sources like serum, plasma, seminal fluid, urine, or culture medium are needed.

In many cases, endogenous PGs are measured by highly specific immunoassays, although they do not enable the simultaneous determination of multiple components in a single experiment. Besides high-performance liquid chromatography (HPLC) techniques, gas chromatography (GC) methods are often used in combination with mass spectrometry (MS), flame ionization detector (FID), or electron capture detectors (ECD). However, HPLC is still a very useful, versatile, and widespread tool for analytical or preparative separation and detection under mild conditions, allowing qualitative and quantitative measurement of oxygen-sensitive prostanoids. In addition, the development of prostanoid drugs is also supported by highly efficient HPLC techniques used in preclinical and clinical trials for selective pharmacokinetic studies toward drug approval.

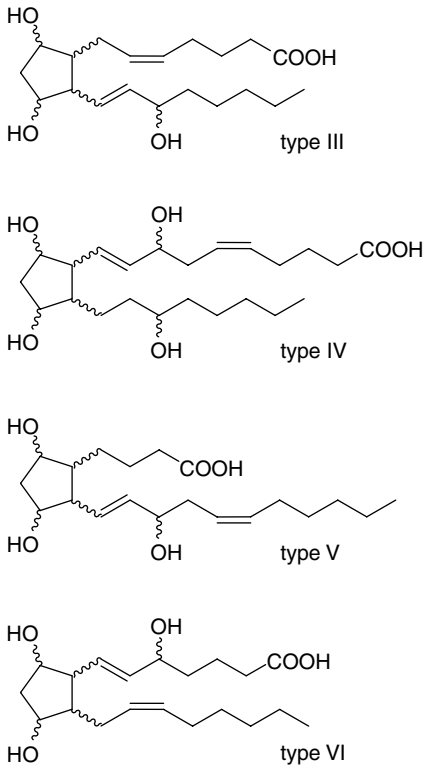

Fig. 2 Arachidonic acid derived groups of isoprostanes (types III–VI).

SAMPLE PREPARATION[4–6]

Endogenous prostanoids only occur in trace levels in complex biological samples. Therefore, the removal of substances impairing chromatographic resolution and detection, and concentration of the analytes are required. Most of the samples are extracted using liquid–liquid extraction (LLE) or solid-phase extraction (SPE) methods without longer time of storage, thus avoiding the non-enzymatic production of iPs by autoxidation of AA.[7] Owing to the free carboxylic groups of prostanoids, samples are acidified to pH 3–4 usually by acetic (HOAc), formic, citric, or hydrochloric acid. Acidification to lower pH values has to be avoided owing to the chemical instability and degradation of some PGs: PGE_2 dehydrates irreversibly to PGA_2, isomerizing to PGB_2; PGD_2 might be dehydrated to an inverted version of PGA_2. Epimerization at C15 and *cis–trans* isomerization may occur, as demonstrated for the TX synthase product 12-*S*-hydroxyheptadecatrienoic acid (HHT).[8] LLE is carried out by the addition of a onefold to fivefold volume of non-polar solvents like diethyl ether, chloroform, or ethyl acetate, followed by shaking or stirring for a few minutes. Consecutive centrifuging enables efficient phase separation and pellets the particulate matter resulting in recoveries of 80–98%. Repetition of this procedure is seldom done and does not improve the recovery significantly. The organic layers are evaporated to dryness under reduced pressure or a gentle stream of nitrogen, to concentrate the prostanoids prior to further preparations or chromatography. Extraction of biological samples using petrol ether or hexane at neutral pH values prior to extraction of acidified matrix removes non-polar fatty acids and lipids, preventing their possible negative interferences.

Using SPE methods, adsorption of prostanoids is routinely and efficiently done by a straight-phase material like silic acid or by a reversed-phase C_{18} material. Clean up and washing steps using eluents of rising polarity for silica-based columns (e.g., increasing content of methanol in an ether–hexane–toluene mixture) or decreasing polarity for octadecyl columns [e.g., increasing content of acetonitrile (ACN), ethanol, or ethyl acetate in an aqueous mixture] enable sufficient extraction. These stepwise and fractionating procedures allow consecutive elution of different substance classes like polar compounds (polar lipids), fatty acids and their monohydroxy derivatives, PGs and TXs, and hydrophilic components. Recoveries for all prostanoids are in the range 90–98%. Recent applications—especially for synthetic drugs—make use of the macroporous OASIS HLB material, which allows combined hydrophilic–lipophilic interactions with the analyte. This adsorbent is a copolymer of divinylbenzene (lipophilic) and *N*-vinylpyrrolidone (hydrophilic) applicable in cartridges or 96-well plate formats.[9] Extracts are evaporated to dryness prior to further processing.

For avoiding these manual and time-consuming extraction methods, the use of packed precolumns coupled to reversed-phase (RP)-HPLC equipped with a conventional six-port injector is a suitable alternative, especially for small sample volumes. Techniques for online sample preparation combined with two-dimensional (2-D) HPLC allow PG extraction on a strong cation exchange material directly transferable onto RP-separation columns as recently described for the analysis of cell culture supernatants with tandem MS (MS/MS) detection.[10]

DERIVATIZATION[11–14]

Owing to the low physiological concentrations in the femtomolar to picomolar range and the very weak UV absorptivity of prostanoids, derivatization is often required when analyzing by HPLC procedures. Many methods that improve detection sensitivity and selectivity have been developed allowing the quantitative and qualitative determination of these eicosanoids. Most of these techniques represent a selective and rapid precolumn derivatization of the extracted sample. Many procedures, especially for esterification of the carboxylic function, have been established. In the following discussion, the stationary phases used for the separation of derivatized PGs are indicated in parentheses. Fluorescent derivatives with exceedingly high UV absorptivities can be obtained in almost quantitative yields by *p*-(9-anthroyloxy)-phenacyl bromide, also known as panacylbromide

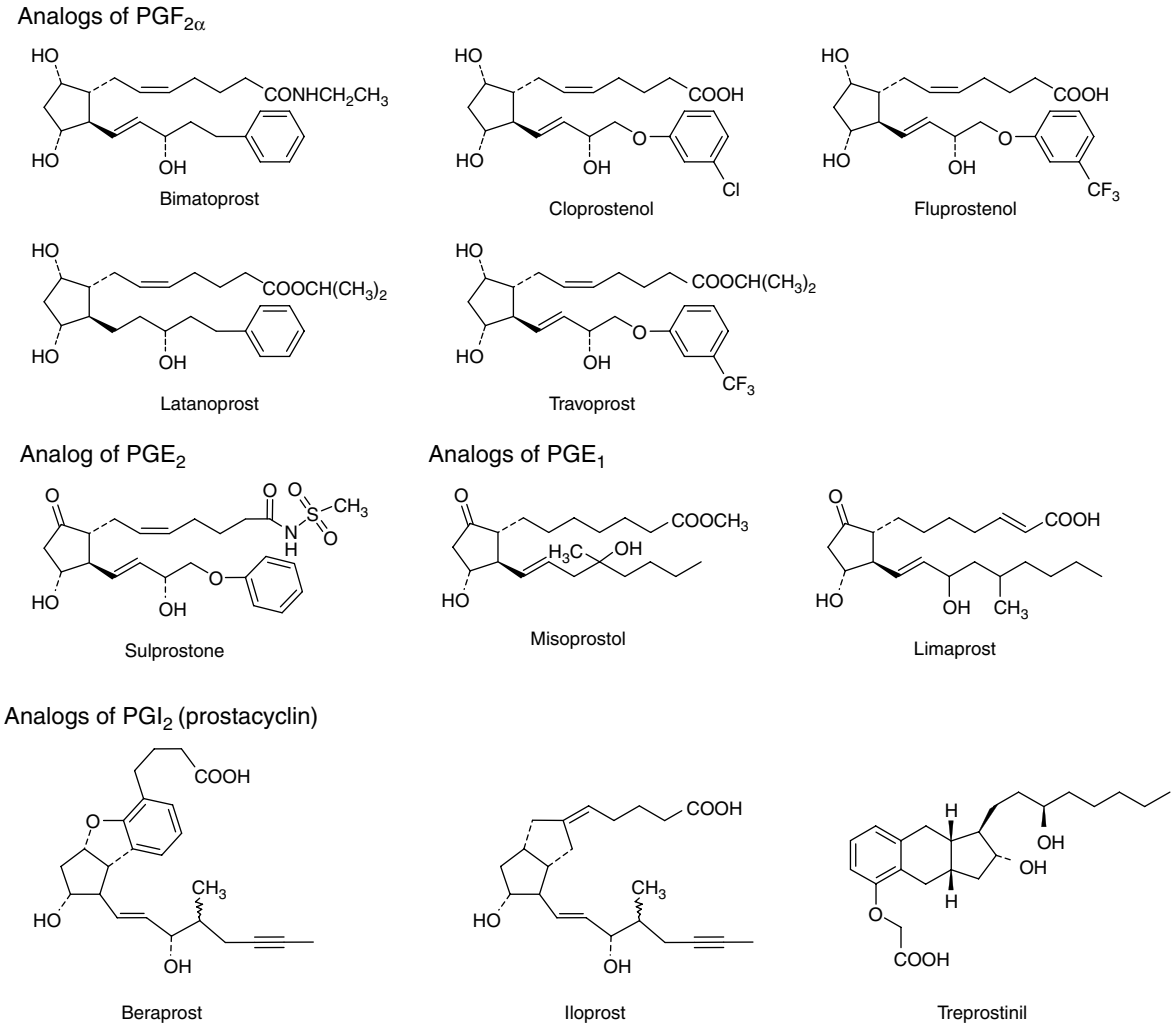

Fig. 3 Chemical structures of common synthetic prostanoid drugs.

(LiChrosorb 100 Diol, or μ-Bondapak C18, or Radial Pak B). Panacyl esters are produced within 0.5–2 hr under mild reaction temperatures between 20°C and 45°C. This reaction requires alkaline reagents like KOH or K_2CO_3 as catalysts in an organic solvent and, additionally, crown ethers as phase-transfer agents. Ultraviolet detection is possible at 254 nm combined with fluorescence detection at about 450 nm after excitation at about 360 nm. Interferences of native fluorescent compounds are weak owing to their emission wavelength range of 300–400 nm.

Comparable phenacyl esters are synthesized with *p*-bromophenacyl bromide or *p*-nitrophenacyl bromide with a similar spectroscopic behavior (both μ-Bondapak C18). Useful derivatization by tagging the COOH group can also be done with α-bromo-2′-acetonaphthone resulting in well-soluble and strongly UV-absorbing (254 nm) naphthanyl esters after a reaction time of only 10 min at ambient temperature (LiChrosorb Si-100). Furthermore, coumarin derivatives (substituted at position 7 for higher fluorescence quantum yields) are predestinated to fluorescent ester preparation (λ_{ex} ~330–390 nm and λ_{em} ~410–470 nm) using 4-bromomethyl-7-methoxycoumarin (LiChrosorb 100 Diol or Varian CN-10 Micropak) or 4-bromomethyl-7-acetoxycoumarin (BrMAC) (LiChrosorb RP18). In addition, 2-(2,3-naphthalimino)ethyl trifluoromethanesulfonate (NE-OTf) was introduced to derivatize the carboxyl groups of eicosanoids, enabling analyte fluorescence detection at 396 nm after excitation at 260 nm (Symmetry C18). These derivatives are also very well-detectable in the positive-selected ion mode by electrospray ionization (ESI)–MS (Fig. 4). Luminarin-4 (a labeling reagent with a quinolizinocoumarin structure) in combination with peroxyoxalate (Ultraspher ODS-2 or Spherisorb ODS-2) enables chemiluminescence detection. These reactions requiring catalysis and phase-transfer agents are carried out under more drastic conditions at about 70°C in aprotic solvents. When using BrMAC, postcolumn hydrolysis of separated PG esters, which results in detection limits of about 10 fmol, is neccessary for online detection of the fluorophore. Hydrazone or amide derivatives

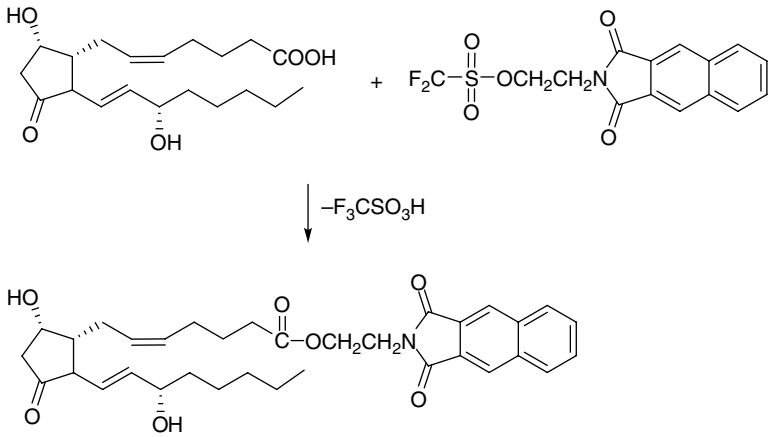

Fig. 4 Derivatization of PGD_2 with 2-(2,3--naphthalimino)ethyl trifluoromethanesulfonate (NE-OTf) for fluorescence and mass spectrometric detection.
Source: From Fast and simple online sample preparation coupled with capillary LC–MS/MS for determination of prostaglandins in cell culture supernatants, in J. Sep. Sci.[10]

are also suitable for fluorescence detection as well as 3-bromomethyl-6,7-dimethoxy-1-methyl-2(1H) quinoxalinone (YMC Pack C8) and 4-(*N,N*-dimethylaminosulfonyl)-7-(1-piperazinyl)-2,1,3-benzoxadiazole (DBD-PZ, $\lambda_{ex} = 440$ nm, $\lambda_{em} = 569$ nm), for converting the COOH group of numerous natural PGs within 30 min at room temperature, or 9-anthroyldiazomethane (ADAM) characterized by its low stability (Nucleosil ODS-silica). Electrochemical detection of readily reduced active compounds can be carried out with low applied potential owing to low background current and noise level in the oxidative mode after COOH derivatization using compounds with aromatic structures like 2,4-dimethoxyaniline (Nucleosil C18), 2-bromo-2′-nitroacetophenone, *p*-nitrobenzyloxyamine, or 2,4-dinitrophenylhydrazine. Thermospray (TSP)–MS detection has been used after esterification with diazomethane followed by oxime synthesis using trimethylanilinium hydroxide (TMAH) and separation on Zorbax ODS.

In addition to the derivatization of the COOH function, PGs can also be modified using their hydroxyl functions. Oxidation with pyridinium dichromate to 15-oxo-PGs enables UV detection at 230 nm on account of the conjugated oxo and C13=C14 double bonds (Microbore C18). Analysis using TSP–MS in the positive-ion mode is possible after overnight reaction at 5°C with acetic anhydride in pyridine to form acetyl derivatives capable of better chemical ionization. About 20 PGs have been determined in the range of 0.5–10 pmol using the selected ion monitoring (SIM) method without a gradient system (Nucleosil 100-5C18).[15] Combined derivatization to panacyl esters prior to methoximation using methoxamine hydrochloride enables good chromatographic separations, especially for the hemiacetalic TXB_2 and $PGF_{2\alpha}$ (Ultraspher ODS C18 or LiChrocart Superspher 100-RP-18). Furthermore, oxo functions present in most PGs can be modified to *p*-nitrobenzyloximes at 40°C within 2 hr, after methyl ester formation by diazomethane, allowing UV detection at 254 nm (μ-Bondapak C18).

In general, quantitative analyses are carried out as usual, using internal or external standards and calibration curves. Detection limits in the lower picogram range can be achieved depending on the selected derivatization procedure.

MOBILE AND STATIONARY PHASES[6,11,16]

In most cases, PGs or their derivatives are separated by partition chromatography on reversed-phase columns using gradients of organic solvents and water with increasing organic content during elution. ACN enables better separation than MeOH when combined with aqueous media acidified using HOAc, trifluoric acid, or phosphoric acid. Separated by rising hydrophobicity, pure PGs are eluted typically in the following order of retention times: 6-oxo-$PGF_{1\alpha}$ < TXB_2 < $PGF_{2\alpha}$ < PGE_2 < PGD_2 < 13,14- dihydro-15-oxo-$PGF_{2\alpha}$ < 13,14-dihydro-15-oxo-PGE_2 < PGA_2 < PGB_2. Monohydroxy metabolites of AA and other fatty acids often present in PG-containing samples are eluted at much higher content of organic solvents, demanding a wide-range gradient.

Early PG analysis using HPLC techniques was carried out as adsorption chromatography on normal-phase (NP) columns packed with silica or alumina. A non-polar mobile phase consisting of organic solvents (hexane, toluene, ethyl acetate, and HOAc) allows separation of PGs that are unstable in aqueous media (e.g., PGH_2 on cyano- or phenyl-bonded phases). Usually, the injection medium must be fairly polar to dissolve the PGs. This is achieved by the addition of small volumes of isopropanol resulting in much poorer resolution of monohydroxy acids simultaneously analyzed. Furthermore, NP chromatography enables excellent separation of geometrical isomers like PGE_2 and PGD_2. The lock–key type steric fitting of solute molecules with the discrete adsorption sites of the silica surface is responsible for this effect. However, adsorption chromatography requires a strict control of

temperature, as it influences retention time and, therefore, reproducibility and ruggedness.

Besides the dominating NP and RP techniques, silver-ion-loaded cation- and strong-anion-exchange chromatographies have been introduced as well. The silver-ion method, based on interactions between Ag^+ and double bonds and polar–polar attractive forces between the stationary phase and the solute, is carried out using polar solvents containing low concentrations of ACN. The separation of *cis–trans* isomers can be achieved by this chromatographic modification. Anion-exchange chromatography has been described for underivatized PGs using tromethamine acetate–ACN mixtures at neutral pH as mobile phase and a pellicular strong anion-exchange column as stationary phase.

However, NP or RP methods represent the most powerful and common chromatographic techniques allowing PG analysis with very good reproducibility, sensitivity, wide linear ranges for quantitative analysis, and a broad spectrum of detectors.

RADIO- AND UV DETECTION[3,6,11,15,17]

For investigating metabolization or stability of prostanoids, radiolabeled precursors or analytes are often used. The tritiated or ^{14}C-labeled compounds can easily be detected without any further derivatization using online or off-line liquid scintillation, which is not impaired by any interferences from matrix components. Efficient, though less sensitive, PG analysis is possible by UV detection (190–210 nm) of underivatized substances, which demands the removal of interfering contaminants or simple sample matrices like buffers or some cell supernatants.

LC–MS ANALYSIS[9,10,18–24]

During the last few years, the reliability and sensitivity of modern mass spectrometric equipment has improved, and interface technologies for online detection of HPLC eluates that have a broad applicability have been introduced. ESI and atmospheric pressure chemical ionization (APCI) sources were designed to operate with high aqueous chromatographic flow rates (>1 ml/min) allowing the selective detection of cationic analytes in the positive-ion mode or anionic analytes in the negative-ion mode. Owing to technical advancement LC–MS today represents a reliable alternative to the traditionally used GC–MS methods applied in a constantly rising number of studies. The soft ESI conditions prevent fragmentation of prostanoids during the ionization process, enabling the detection of intact molecules in the full-scan mode. Subsequent optional fragmentation by collision-induced dissociation (CID) in the mass analyzer during MS/MS generates specific fragments (product ions) which are of highest value for the identification of compounds. Furthermore, LC–MS allows the quantification of PGs and related compounds without derivatization and long chromatographic separation times, and at the same time characterized by lower limits of detection and quantification of approximately 10 pg/ml of sample fluid. Highly selective detection in the negative selected reaction monitoring (SRM) mode enables simultaneous measurement of multiple analytes even if they coelute. These outstanding features are highly important for the investigation of iPs, which naturally appear in various endogenous isoforms of identical molecular weights. Usually, LC–ESI–MS/MS measurements are performed on triple quadrupole mass spectrometers to detect the underivatized singly charged quasi-molecular ion $[M–H]^-$ resulting from the loss of a proton. Negative ionization is supported by the use of ammonium acetate buffer at a basic pH (about 7.4–9). The corresponding MS/MS fragmentation pattern often shows a typical loss of 44 amu owing to the cleavage of the carboxylate anion, as well as further signals allowing the unambiguous assignment to individual molecular structures. Characteristic transitions from parent ions to product ions increase method selectivity and the signal-to-noise ratio, which are important for low limits of quantification. Quantitative analyses of PGs and iPs from cell culture medium, urine, or organ extracts are often performed using related tetradeuterated compounds as internal standards resulting in excellent precision and accuracy. On account of these obvious advantages, LC–MS/MS procedures are highly valuable for quantitative screening approaches of eicosanoids in biological fluids including not only prostanoids but also leukotrienes as recently demonstrated in the investigation of 23 analytes in rat kidney tissue.[25]

Nowadays, especially pharmaceutical applications make use of the highly selective and sensitive LC–MS/MS methods for both qualitative and quantitative analysis. Depending on the structure of the synthetic prostanoids, product ions of highest intensity generated by CID may be derived from larger non-natural substituents, e.g., 3-trifluoromethylphenolate (from travoprost or fluprostenol, Fig. 3).[22]

Reliable hardware and software tools for coupling techniques and system control have enabled the establishment of more complex two- or multidimensional HPLC systems, which allow consecutive chromatographic steps performed online on different stationary phases also including steps of analyte trapping or sample preparation.[9,26,27]

In contrast to the commonly applied ESI negative-ion mode, a sophisticated method has been described using postcolumn addition of a $AgBF_4$ solution in isopropanol as a cationization reagent for neutral lipids. The resulting adducts of the analyte and silver cations allow the MS detection in the positive mode. This technique has been successfully applied to the discovery of PGE_2 methyl ester 15-acetate isolated from gorgonian corals.[28] Although derivatization procedures are unusual for LC–MS analyses of PGs and iPs, pentafluorobenzyl (PFB) bromide has been

used to modify the COOH group for subsequent LC–APCI–MS/MS investigations. The resulting PFB derivatives dissociate during electron capture ionization liberating a free PFB radical and an anionic analyte detectable by the negative-ion mode MS.[29] Despite the anionic properties of dissociated prostanoids, unusual detection in the positive ESI mode was also reported targeting ammoniated molecules produced during chromatographic separation in the presence of ammonium acetate.[30]

SPECIAL FEATURES OF HPLC IN PROSTAGLANDIN ANALYSIS

Besides quantitative determinations of endogenous PGs, HPLC techniques have been used for some special features in clinical, chemical, and pharmaceutical research, including investigations of stability, metabolization and enantiomeric purity, thermodynamic characterizations of chemical equilibria, validation of immunological methods by matrix separations, and preparative purifications.[5,6,8,11,16,31,32]

CONCLUSIONS

Methods based on HPLC for the quantitative or qualitative analysis of PGs, iPs, and prostanoid drugs are widely used as reliable and sensitive procedures. As UV detection of unlabeled analytes is often of insufficient selectivity and sensitivity, especially for complex biological samples, derivatization protocols have been introduced for transforming the lipid analytes into strongly fluorescent or UV-absorbing compounds. Modern MS detection overcomes the drawbacks of time-consuming derivatization steps, thus allowing direct measurement of natural compounds by LC–ESI–MS/MS technologies. Formation of the quasi-molecular ion $[M–H]^-$ enables straightforward, comfortable, and rapid analysis in the negative-ion mode. Subsequent collision-induced fragmentation in MS/MS experiments provides additional information for structure elucidation and confirmation. Thus, HPLC techniques are highly important tools of instrumental analysis in prostaglandin research used for quantification, identification, and elaboration of thermodynamic equilibria and chemical or physiological reactions.

Protein Immobilization

Jamel S. Hamada
Southern Regional Research Center, Agricultural Research Service, U.S. Department of Agriculture (USDA-ARS), New Orleans, Louisiana, U.S.A.

INTRODUCTION

Affinity chromatography is a powerful high-resolution separation technique for biomolecules. It is based on a highly specific and unique stereochemical interactions between biomolecules. Examples of these interactions are the binding of enzymes to coenzymes and inhibitors and the interactions between antigens (e.g., protein A) and antibodies. In affinity chromatography, a ligand is covalently bound to a solid matrix which is packed into a chromatography column. A mixture of components is then applied to the column. The unbound contaminants, which have no affinity for the ligand, are washed through the column, leaving the desired component (protein, peptide, etc.) bound to the matrix. Elution is accomplished by changing the pH and/or salt concentration or by applying organic solvents or a molecule which competes for the bound ligand. The purpose of this entry is to review methods for immobilization of protein ligands for affinity chromatography.

MATRIX MATERIAL (CARRIER)

Immobilized ligand is prepared by covalently attaching the biospecific ligand to a chromatographic bed support material, the matrix. A variety of insoluble support materials are used as matrices in affinity chromatography. These include agarose, cellulose, crosslinked dextran, polystyrene, polyacrylamide gels, and porous silica gels. The majority of matrices used in affinity chromatography are either agarose based or polyacrylamide based. The available reactive groups on these matrices are hydroxyl and amide nitrogen groups, respectively. By far the most popular support materials in use are beaded derivatives of agarose due to their ideal physical and chemical characteristics that are necessary for ligand immobilization. For instance, Sepharose, a bead-formed agarose gel manufactured by Amersham Pharmacia Biotech, has virtually all the features required of a successful matrix for immobilizing biologically active molecules. The hydroxyl groups on the sugar residues can easily be used to covalently attach a ligand. Sepharose 4B (Amersham Pharmacia Biotech) is the most popular and widely used matrix. Its advantages include open-pore structure, molecular exclusion limit of 20×10^6 Da, easy and good binding capacities, and low non-specific attachment. A spacer arm, which is interposed between the matrix and ligand, is sometimes needed to facilitate the binding particularly when coupling small molecules (e.g., enzyme cofactors). Spacer arms are also useful for coupling ligands containing free carboxyl or amine groups and for further chemical reactions to permit the attachment of phenolic groups and diazonium derivatives to agarose matrix.

PROTEIN LIGANDS

Protein ligands most commonly used in affinity chromatography are as follows: (a) protein with very high specific affinity for moieties on the desired protein; a wide range of plant lectins with a variety of sugar specificities are used as ligands to purify glycoproteins and enzymes having sugar moieties in their structures; (2) immobilized antibodies, which represent the ideal affinity separation because of the precise specificity of many antibodies, particularly monoclonial antibodies, to their specific antigens; (3) proteins or enzymes with unique affinity for other proteins or peptides, which are used as affinity ligands for the particular proteins or peptides.

PREPARATION OF IMMOBILIZED PROTEINS

The immobilization of proteins and enzymes through covalent bond formation between the protein or enzyme and an activated insoluble carrier entails two processes of activation and coupling. These procedures are classified on the basis of the type of reaction that facilitates the bonding between the protein and the insoluble carrier. Mostly, with matrices containing readily available hydroxyl groups such as agarose derivatives, a variety of activation procedures are used, after which the amino groups of protein ligands are readily incorporated into the matrix (coupling reaction). After coupling of the protein ligands to the matrix, unreacted activated coupling groups are usually hydrolyzed to inactive derivatives during washing of the coupling resin at lower pH. Alternatively, these groups can be blocked by adding an excess of an inert blocking reagent. The following methods are most commonly used for activation and coupling of protein ligands to agaraose and other matrices.

Cyanogen Bromide Activation Method

The aim of the reaction of cyanogine bromide with hydroxyl groups on agarose matrix is to produce reactive carrier to which proteins can be coupled through amino groups. Cyanogen bromide activation method is the most used method for the preparation of affinity gels because of its simplicity and its mild reaction conditions, particularly for immobilizing sensitive proteins such as enzymes and antibodies. Cyanogen bromide reacts with these hydroxyl groups and converts them to imidocarbonate groups, as shown in Fig. 1. Agarose activated with cyanogen bromide have been used to bind a variety of proteins and enzymes. The activated groups react with primary amino groups of a protein ligand to form isourea linkages according to the reactions in Fig. 1.

Acylation Reactions

In this type of protein immobilization, reactions involve the acylation of an NH_2 group on a protein or an enzyme by pendent groups of the carrier such as azide, acid anhydride, carbodiimide, sulfonyl chloride, and hydroxysuccinimide esters. Copolymers of acrylamide and maleic anhydride have been useful for enzyme immobilization through the acid anhydride reaction with the enzyme. This system of

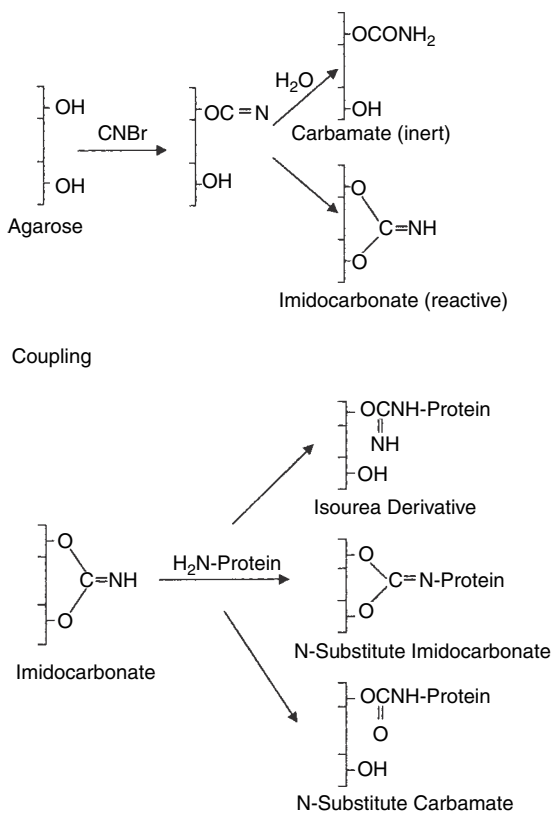

Fig. 1 Immobilization of protein ligands on agarose (activation and coupling) by cyanogen bromide.

protein immobilization involves the use of a reagent that contains an acylating or alkylating agent and a group which can form a covalent link with a carrier polymer. For instance, few protein immobilization methods are based on condensation by carbodimides (e.g., dicyclohexylcarbodimide). Mixing the carbodiimide reagent with the matrix and a protein ligand, stable amide bonds can be formed between an amino group on the ligand and a carboxyl group of matrix (or vise versa) in a one-step procedure of activation and coupling as follows:

$$R{-}COOH + R_1N{=}C{=}NR_2 \rightarrow R{-}C(NHR_1){-}O{-}C{=}NR_2$$

Soluble protein — Carbomiide — Immobilized protein

Arylation Reactions

Arylation or alkylation are used for activation of support and linking of a protein ligand. In such reactions, the functional group on the carrier combines with an NH_2 group of the protein (e.g., by 3-fluoro-4,6-dinitrophenyl group or 2–4 dichloro-*S*-triazine). In this approach, a chloro-*S*-triazine is coupled to an arylazide. The azide is converted to a nitrene, which upon activation by light reacts with a polymer carrier to form a covalent bond. The chlorotriazine then couples with the protein.

Alkylation Reactions by Bisepoxirane, Epichlorohydrin, and Divinylsulfone

Bisepoxirans activations allows the coupling of ligands containing —OH, —NH_2, and —SH groups with agarose matrix. Here, the ligands are provided automatically with a hydrophilic spacer arm.

Organic Sulfonyl Chlorides, Tosyl and Tresylchloride Methods

These methods enable the activation and the coupling of ligands containing —NH_2 and —SH groups with matrices such as agarose, cellulose, or silica derivatives.

Methods for Polyacrylamide Matrices

The glutaraldehyde and hydrazine reactions are used for matrices having amide groups such as polyacrylamide. Glutaraldehyde and hydrazine react with the polymer, and the enzyme or protein is readily bound to the treated polymer. The mechanism of the reactions involved in the activation and coupling are not well understood. In general, insoluble supports such as polyacrylamide, which tend to swell in water, form immobilized proteins or enzymes when mixed with a solution and treated with

Table 1 Activated affinity matrices marketed by two major soft-gel chromatography suppliers for coupling of protein ligands.

Matrix	Ligand specificity	Activator and functional groups	Manufacturer
CNBr-activated Sepharose 4B (or Fast Flow)	—NH_2	CNBr	Amersham Pharmacia Biotech
EAH Sepharose 4B	—COOH	Carbodiimide coupling via 6-carbon spacer arm	Amersham Pharmacia Biotech
ECH Sepharose 4B	—NH_2	Carbodiimide coupling via 6-carbon spacer arm	Amersham Pharmacia Biotech
Epoxy-activated Sepharose 6B	—NH_2, —OH, —SH	1,4-bis (2, 3-epoxypropoxy-butane)	Amersham Pharmacia Biotech
Activated Thiol Sepharose 4B	—SH, —C ═O, —CNH	Glutathione-2-pyridyl disulfide	Amersham Pharmacia Biotech
Affi-Gel 10 gel (or Affi-Prep 10, pressure stable)	—NH_2	*N*-Hydroxysuccinimide ester via 10-atom spacer arm	Bio-Rad Laboratories
Affi-Gel 15 gel	—NH_2	*N*-Hydroxysuccinimide ester via 15-atom spacer arm	Bio-Rad Laboratories
Affi-Gel 102 gel	—COOH	Carbodiimide coupling	Bio-Rad Laboratories
CM Bio Gel A	—NH_2	Carboxymethyl, carbodiimide coupling	Bio-Rad Laboratories

glutaraldehyde. Polyacrylamide support is activated by treatment with hydrazine (heated) followed by sodium nitrite in hydrochloric acid. The amino groups of protein ligands can then be coupled to the activated matrix via stable amide bonds.

AFFINITY SUPPORTS: ACTIVATED AND READY-TO-USE MEDIA

Chromatography suppliers offer affinity gels for a wide range of biomolecular applications. Availability of activated supports allows the users to make their own affinity matrix of choice by coupling a ligand such as an antibody, enzyme, antigen, or receptor. Ready-activated supports or matrices are less expensive than the ready-to-use matrices usually offered by the same manufacturer. These activated matrices are dependable and provide flexibility and convenience in affinity chromatography. With this particular option, the chromatographer has the choice of preparing affinity matrix by activating a support, then coupling or only coupling using ready-to-use activated affinity supports. Table 1 shows the activated supports marketed by two major soft-gel chromatography suppliers that are suitable for coupling of affinity protein ligands.

On the other hand, ready-to-use matrices have a specific ligand already coupled to an affinity support. Amersham Pharmacia Biotech has developed a wide range of ready-to-use affinity gels with specific protein ligands coupled to the matrix. In specified bulletins, Amersham Pharmacia Biotech details the preparation procedures of these affinity gel columns containing immobilized proteins. Applications include monoclonal and polyclonal antibodies, fusion proteins, glycoproteins, enzymes, cells, and other proteins such as fibronectin, and membrane proteins. Likewise, Bio-Rad Laboratories offer two types of supports. One type such as Affi-Gel supports, based on agarose or polyacrylamide, are available as lowpressure gels suitable for most laboratory-scale affinity purification with a peristaltic pump or gravity flow elution. Affi-Prep supports, based on a pressurestable macroporous polymer, are suitable for preparative and process scale applications. The immobilized protein ligands in these ready-prepared matrices include lectins, protein A, gelatin, avidin, and calmodulin. Affi-Gel and Affi-Prep protein A supports are used to produce highly purified immunoglobulins (IgG), to selectively remove IgG prior to analysis of other immunoglobulin classes, or to adsorb immune complexes to purify antigens. Protein A from *Staphylococcus aureus* binds to the F_c region of immunoglobulins, especially IgG from mammalian species. Affi-Prep supports offer linear flow rates up to 2000 cm/hr, pressure stability up to 1000 psi (70 bar), and high chemical stability, according to the manufacturer.

CONCLUSIONS

In affinity chromatography, a ligand is covalently bound to a solid matrix by matrix activation and ligand coupling. In protein immobilization, a covalent bond is formed between

the protein ligand and an insoluble solid matrix or carrier. Most of protein immobilization steps entail the formation of the insoluble immobilized proteins on crosslinked agarose gels. Most common reactions used in making immobilized proteins and enzymes are discussed. These processes are classified on the basis of the type of reaction which forms the covalent bond between the protein and the insoluble carrier. Also, a wide range of commercial ready-to-use supports with specific protein ligands already coupled to a base matrix are discussed.

Proteins: Affinity Ligands

Ji-Feng Zhang
Massachusetts Institute of Technology, Cambridge, Massachusetts, U.S.A.

INTRODUCTION

Affinity chromatography using proteins as ligands explores the three-dimensional complementary molecular interactions between the ligand and its target. This non-covalent and reversible binding are the results of ionic interaction, hydrophobic interaction, hydrogen-bonding, and van der Waals–London forces. The binding constant between the immobilized ligand and the target molecule ranges from $10^4/M$ to $10^8/M$. The multiplicity of the interaction forces offers the superior specificity to protein-based affinity chromatography for biomolecule separation among all the chromatographic techniques.

DISCUSSION

After the protein ligand is immobilized on a matrix support, a crude sample mixture, including the desired substance, is loaded into the affinity column under appropriate conditions. If the desired molecule forms a stable and reversible complex with the protein ligand, it will be retained and all the other contaminants are washed away. Then, the eluting buffer disrupts the binding between the desired substance and the protein ligand to recover the substance. When the interaction between the desired molecule and the ligand is too weak to form a stable complex with the ligand, it is eluted later than all the other substances in the crude sample and an eluting buffer is not required.

Protein-based affinity chromatography has found wide applications in both academic and industrial settings. The affinity chromatography using proteins as the ligand is an indispensable technique for recombinant protein purification. This review will touch the general aspects of matrix, immobilization of protein ligands, and the application of protein-based affinity chromatography. It is by no means an exhaustive review of the current technologies in protein-based affinity chromatography and only serves as an introduction to this topic. Interested readers should explore those articles listed in Bibliography for more information.

MATRIX

One of the key elements for protein-based affinity chromatography is the matrix, on which the protein ligand is immobilized. The ideal matrix material should have the following characteristics (Porath, 1974): insolubility, sufficient permeability, large surface area, strong mechanical strength, zero adsorption capacity, resistance to microbial and enzyme attack, chemical reactivity for coupling protein ligand, and stability under the operating conditions. Based on their physical strength, the matrices can be divided into two categories: low pressure and high pressure. For example, agarose, dextran, polyacrlyamide, and methacrylate are typical low-pressure matrices and silica and polystyrene–divinylbenzene are high-pressure matrices.

When a matrix is chosen in affinity chromatography applications, its advantages and disadvantages should be taken into account to assess its potentials and limitations. Agarose is hydrophilic and, therefore, its matrix surface has low non-specific binding. The presence of the hydroxyl group from agarose provides a convenient way for immobilizing the protein ligand. The drawbacks of agarose are its solubility in hot water and non-aqueous solutions and its susceptibility to microbial degradation. The lack of mechanical strength for agarose limits its application only in low-pressure operation and the separation process is slow. Silica and synthetic polymers are the alternative choices of matrix support. The major advantages for those matrix supports over agarose are their rigidity, reduced diffusion rate, and well-defined pore size (i.e., 5–20 μm in diameter). The above factors decide that those matrices can be operated in fast linear flow rate under high pressure to achieve rapid separation. Non-specific binding in silica-based matrices is a concern because of the negative-charged silanol groups and because also silica has increased solubility at alkaline pH.

IMMOBILIZATION

The unique specificity of affinity chromatography is the result of the complementary interaction between the protein ligand and the target in the separation

process. It is therefore essential to maintain the structure integrity of the protein ligand during immobilization of protein ligand. It is critical to consider the following in the immobilization step: (a) The binding site in the protein ligand should be accessible after the immobilization; (b) the amino acids located at the binding site should not be modified during the immobilization step; (c) the three-dimensional structure of the binding site should be maintained after the coupling step.

Usually, the immobilization of protein ligand is a two-step process: (1) activation and functionalization of the matrix and (2) coupling of the protein ligand to the modified matrix. To avoid the possible reactions between the rest of the activated sites and the protein components from the sample, a third step is often required to quench those activated sites after the protein ligand is coupled. The most exploited function groups for coupling from the protein ligand are the C-terminal carboxyl group, the carboxyl groups of glutamic and aspartic acids, the N-terminal α-amino group, and the ϵ-amino group of lysine. Sometimes, phenolic hydroxyl groups of tyrosine, imidazole anion of histidine, or the –SH group of cysteine residues may be the candidates for coupling. The ideal linkage between the matrix and the protein ligand from Step 1 should be fairly hydrophilic and neutral to avoid the introduction of a non-specific interaction. Carbonyldiimidazole and 2-fluoro-1-methylpyridinium toluene-4-sulfonate are two of the popular reagents for activation of the hydroxyl-containing matrix and coupling with an aminecontaining protein ligand.

Because there are many options of immobilization chemistries, different immobilization strategies should be evaluated for a particular protein ligand. After immobilization, the binding site should be affected in a minimal way so that the binding function is maintained. The protein ligand could have multiple sites for coupling with the activated matrix surface. The immobilization could be a random process if those sites are located in a similar steric environment. Another undesired scenario is immobilization by multiple-site attachment, which could destroy the native structure of the protein ligand and loss of its binding ability. If feasible, site-specific immobilization is preferred because it would give better reproducibility in both surface chemistry and column performance. Carbohydrate moieties from glycoproteins (i.e., antibodies and enzymes) are often particularly taken advantage of as the coupling sites because, generally, the complementary binding site in the protein ligand is away from the oligosaccharide chains. Immunoglobins (IgG) is often immobilized through the carbohydrates on the F_c region, and, as a result, the binding sites are readily available located on the F_{ab} region of IgG.

The leaching of the protein ligand presents a significant problem for introducing contaminants into the purified product. The solvolysis of the bonds between either the matrix–activator or activator–protein is the major source of leaching. It is the reason that an extra chromatography step is often required to remove protein ligand contaminant after affinity chromatography purification.

APPLICATIONS

Adsorption and desorption are involved in the operation of affinity chromatography utilizing proteins as affinity ligands. One of the major differences for protein-based affinity chromatography from other modes of chromatographic techniques (i.e., ion-exchange chromatography, reversed-phase (RP) chromatography, and hydrophobic interaction chromatography) is that the protein ligand could be denatured or attacked in other ways and lose its affinity consequently. Extreme pH, heat, and organic solvents are worrisome for protein-based affinity chromatography. If any one of them is employed, its effect on the column life should be evaluated.

For method development in protein-based affinity chromatography, the theme is to promote the specific interaction between the protein ligand and its counterpart and minimize the non-specific interaction between the matrix and the sample components. Because ionic and hydrophobic interactions contribute to the specific binding between the ligand and its counterparts, ionic strength and pH are probably the two simple and convenient parameters to be evaluated for separation method development. The variation of pH can affect the charge distribution on both the protein ligand and its target, leading to a different binding constant between them. Changing the ionic strength of the solution could modulate the hydrophobic interaction. Another very important parameter is the binding kinetics between the immobilized protein ligand and its target. The flow rate study could provide some clue on how fast the binding reaches the equilibrium. The strategy for minimizing the non-specific interaction depends on the surface chemistry of the matrix. For example, a running buffer of high ionic strength (0.2 *M*) can suppress the non-specific ionic interaction between the sample components and the negative-charged silanol group on the silica matrix.

Many proteins have been utilized as affinity ligands and there are literally thousands of references using this technique. The following are a few samples of proteins used as affinity ligands. Antibodies or antigens are used as immunoaffinity ligand to separate the complementary counterparts. Often, only a single purification step is needed because of the superior selectivity of

immunoaffinity column. Protein A and protein G are the perfect ligands for antibody purification because of their specificities and robustness.

In summary, affinity chromatography using proteins as affinity ligands provides a unique scheme for purification. Currently, a great number of matrices are available and the chemistries for immobilization of protein ligands are significantly improved. The specific three-dimensional interaction between the protein ligand and its counterpart distinguishes this technique from other chromatography methods. The key issue is maintaining the structure integrity of the binding site in the protein ligand throughout the immobilization and column operation.

Proteins: Cross-Axis Coil Planet Centrifuge Separation

Yoichi Shibusawa

Yoichiro Ito
National Heart, Lung, and Blood Institute (NHLBI), National Institutes of Health (NIH), Bethesda, Maryland, U.S.A.

Abstract
The different types of cross-axis coil planet centrifuges (cross-axis CPCs) were tested for the retention of the stationary phase of aqueous–aqueous polymer-phase systems such as poly(ethylene glycol) (PEG) 1000–potassium phosphate and PEG 8000–dextran T500. The XL and XLL CPC are suitable for the PEG 1000–potassium phosphate, which has a relatively large difference in density between the two phases. On the other hand, the XLLL and L CPC are required to acheive satisfactory phase retention phase retention of the PEG–dextran system. These cross-axis CPCs were utilized for the separation of several proteins.

INTRODUCTION

Countercurrent chromatography (CCC) is a form of support-free liquid–liquid partition chromatography in which the stationary phase is retained in the column with the aid of the Earth's gravity or a centrifugal force.[1] Partition of biological samples such as proteins, nucleic acids, and cells has been carried out using various aqueous polymer-phase systems.[2] Among many existing polymer-phase systems, poly(ethylene glycol)–dextran (PEG–dextran) and PEG–phosphate systems have been most commonly used for the partition of biological samples. Whereas these polymer-phase systems provide an ideal environment for biopolymers and live cells, high viscosity and low interfacial tension between the two phases tend to cause a detrimental loss of stationary phase from the column in the standard high-speed CCC centrifuge system (known as type J).

The cross-axis coil planet centrifuge (cross-axis CPC), with column holders at the off-center position on the rotary shaft, enables retention of the stationary phase of aqueous–aqueous polymer-phase systems such as PEG 1000–potassium phosphate and PEG 8000–dextran T500. Since the last decade, various types of cross-axis CPC (types XL, XLL, XLLL, and L) have been developed for performing CCC with highly viscous aqueous polymer-phase systems.[3,4] The separation and purification of protein samples, including lactic acid dehydrogenase (LDH) from bovine heart crude extract,[5] single-stranded DNA binding protein (SSB) from *Escherichia coli* cell lysate,[6] glucosyltransferase from *Streptococcus mutans* cell lysate[7] and *Streptococcus sobrinus* cell culture medium,[8] maltose-binding protein-tagged histone deacetylase from *E. coli* cell lysate,[9] and so on, were achieved using these cross-axis CPCs.[10]

APPARATUS

The cross-axis CPCs, which include types X and L and their hybrids, are mainly used for protein separations. These modified versions of the high-speed CCC centrifuge have a unique feature among the CPC systems in that the system provides reliable retention of the stationary phase for viscous polymer-phase systems. Fig. 1 presents a photograph of the latest type XL CPC unit and schematically illustrates the orientation and motion of the coil holder in the cross-axis CPC system, where R is the radius of revolution. There are five types of cross-axis CPC, in which the degree of lateral shift of the coil holder is conventionally expressed by L/R. This parameter for types X, XL, XLL, XLLL, and L CPCs is 0, 1, 2, 3.5, and ∞, respectively. Our studies have shown that the stationary-phase retention is enhanced by laterally shifting the position of the coil holder along the rotary shaft, apparently due to the enhancement of a laterally acting force field across the diameter of the tubing.

The polymer-phase system composed of PEG and potassium phosphate has a relatively large difference in density between the two phases, so that it can be retained well in both XL and XLL column positions, which provide efficient mixing of the two phases. On the other hand, the viscous PEG–dextran system, with an extremely low interfacial tension and a small density difference between the two phases, has a high tendency of emulsification under vigorous mixing. Therefore, the use of either the XLLL or L column position, which produces less

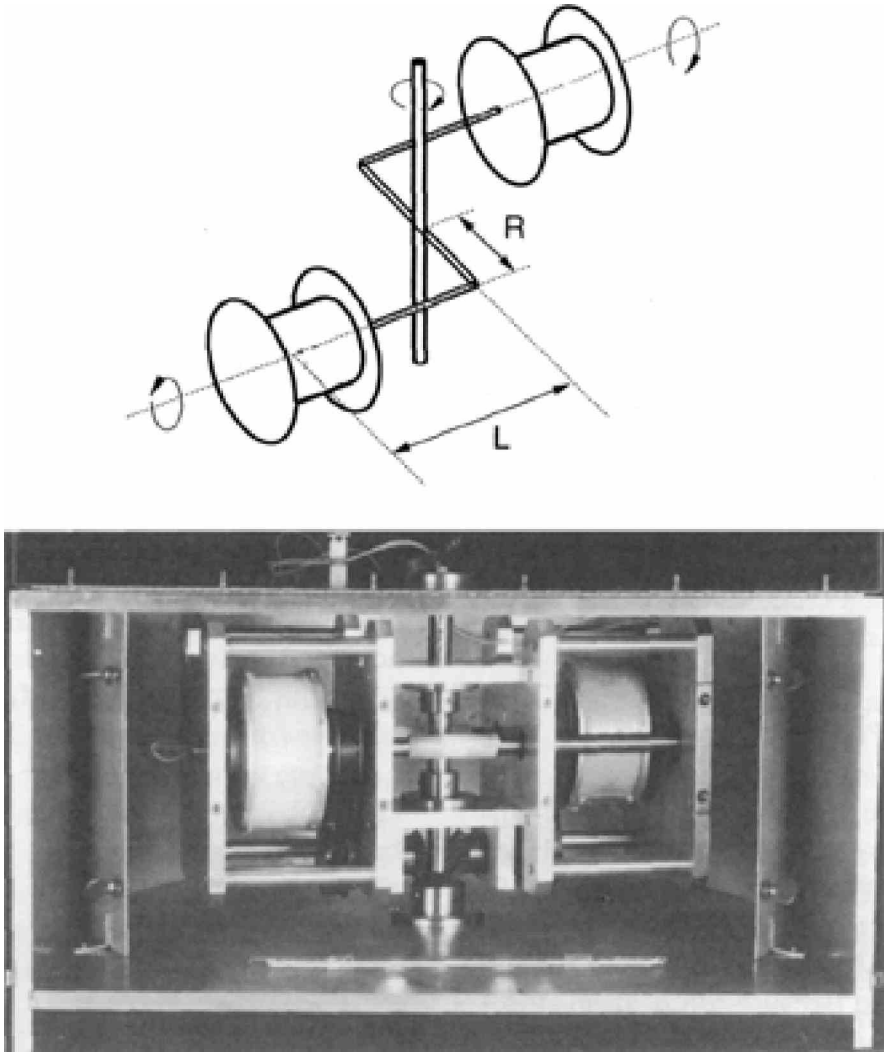

Fig. 1 Photograph of the latest type XL cross-axis coil planet centrifuge (cross-axis CPC).

violent mixing and an enhanced lateral force field, is required to achieve satisfactory phase retention of the PEG–dextran system.

The photograph of the XL cross-axis CPC ($L/R = 1.0$) equipped with a pair of multilayer coil separation columns is shown in Fig. 1. The multilayer coil separation column was prepared from a 2.6 mm inner diameter (I.D.) polytetrafluoroethylene (PTFE) tubing by winding it onto the coil holder hub, forming multiple layers.

POLYMER-PHASE SYSTEMS FOR PROTEIN SEPARATION

CCC utilizes a pair of immiscible solvent phases that have been pre-equilibrated in a separating funnel: One phase is used as the stationary phase and the other as the mobile phase. A solvent system composed of 12.5% or 16.0% (w/w)PEG 1000 and 12.5% (w/w) potassium phosphate is usually used for the type XL and XLL cross-axis CPCs. These solutions form two layers: The upper layer is rich in PEG and the other layer is rich in potassium phosphate. The ratio of monobasic to dibasic potassium phosphates determines the pH of the solvent system. This effect can be used for optimizing the partition coefficient of proteins.

A solvent system composed of 4.4% (w/w) PEG 8000, 7.0% (w/w) dextran T500, and 10 m*M* potassium phosphate is used with the type XLLL and L cross-axis CPCs for the separation of proteins that are not soluble in the PEG–phosphate system. This two-phase solvent system consists of the PEG-rich upper phase and the dextran-rich lower phase. The cross-axis CPC may be operated in four different elution modes: P_IHO, P_{II}TO, P_ITI, and P_{II}HI. The parameters P_I and P_{II} indicate the direction of planetary motion, where P_I indicates counterclockwise and P_{II} clockwise when observed from the top of the centrifuge. H and T indicate the head–tail elution mode, and I and O the inward–outward elution mode along the holder axis. In mode I (inward), the mobile phase is eluted against the laterally acting centrifugal force, and in mode O (outward), this flow direction is reversed. These three parameters

yield a total of four combinations for the left-handed coils. Among these elution modes, the inward–outward elution mode plays the most important role in the stationary-phase retention for the polymer-phase systems. To obtain a satisfactory retention of the stationary phase, the lower phase should be eluted outwardly along the direction of the lateral force field (P_IHO and P_{II}TO) or the upper phase in the opposite direction (P_ITI or P_{II}HI).

APPLICATION OF CROSS-AXIS CPC FOR PROTEINS

Type XL Cross-Axis CPC

The performance of the XL cross-axis CPC, equipped with a pair of columns with a 165 ml capacity, was evaluated for purification of LDH from a crude bovine heart filtrate. Successful separation of the LDH fraction was achieved with 16% (w/w) PEG 1000–12.5% (w/w) potassium phosphate at pH 7.3. The separation was performed at 500 rpm at a flow rate of 1.0 ml/min using the potassium phosphate-rich lower phase as the mobile phase. The sodium dodecyl sulfate–polyacrylamide gel electrophoresis (SDS–PAGE) analysis of the LDH fractions showed no detectable contamination by other proteins. The enzymatic activity was also preserved in these fractions.

The purification of SSB from an *E. coli* lysate was also performed by CCC using the XL cross-axis CPC. About 5 ml of *E. coli* lysate was separated by CCC using a polymer-phase system composed of a 16% (w/w) PEG 1000 and 17% (w/w) ammonium sulfate aqueous polymer two-phase solvent system. The precipitation of proteins in the lysate took place in the CCC column, and the SSB protein was eluted in the fractions. Many other impurities were eluted immediately after the solvent front or precipitated in the column. The identities of the proteins in the fractions and the precipitate were confirmed by SDS–PAGE.

Type XLL Cross-Axis CPC

The XLL cross-axis CPC, with a 250 ml capacity column, was used for the purification of recombinant enzymes such as purine nucleoside phosphorylase (PNP) and uridine phosphorylase (UrdPase) from a crude *E. coli* lysate. The polymer-phase system used in this separation was 16% (w/w) PEG 1000–12.5% (w/w) potassium phosphate at pH 6.8. The separation was performed at 750 rpm at a flow rate of 0.5 ml/min using the upper phase as the mobile phase. About 1.0 ml of crude lysate, containing PNP in 10 ml of the above solvent system, was loaded into the multilayer coil. Purified PNP was harvested in 45 ml fractions. The SDS–PAGE analysis clearly demonstrated that PNP was highly purified in a one-step elution with the XLL cross-axis CPC.

The capability of the XLL cross-axis CPC was further examined in the purification of a recombinant UrdPase from a crude *E. coli* lysate under the same experimental conditions as described earlier. The majority of the protein mass was eluted immediately after the solvent front (between 105 and 165 ml elution volume), whereas the enzyme activity of UrdPase coincided with the fourth protein peak (between 225 and 265 ml elution volume). The result indicates that the recombinant UrdPase can be highly purified from a crude *E. coli* lysate within 10 hr using the XLL cross-axis CPC.

Type XLLL Cross-Axis CPC

Although PEG–phosphate systems yield a high efficiency separation, some proteins show low solubility due to a high salt concentration in the solvent system. In this case, the PEG–dextran polymer-phase system with a low salt concentration can be alternatively used for the separation of such proteins. Because the dextran–PEG system has high viscosity and extremely low interfacial tension, it tends to cause emulsification and loss of the stationary phase in the XLL or XL cross-axis CPCs. This problem is minimized using the XLLL cross-axis CPC, which provides a strong lateral centrifugal force to provide a more stable retention of the stationary phase.

Type L Cross-Axis CPC

Cross-axis CPC provides for the universal application of protein samples with a dextran–PEG polymer-phase system. Using a prototype of the L cross-axis CPC with a 130 ml column capacity, a profilin–actin complex was purified directly from a crude extract of *Acanthamoeba* with the same solvent system as used for the serum protein separation earlier. The sample solution was prepared by adding the proper amounts of PEG 8000 and dextran T500 to 2.5 g of the *Acanthamoeba* crude extract to adjust the two-phase composition similar to that of the solvent system used for the separation. The experiment was performed by eluting the upper phase at 0.5 ml/min under a high revolution rate of 1000 rpm. The profilin–actin complex was eluted between 60 and 84 ml fractions and well separated from other compounds. The retention of the stationary phase was 69.0% of the total column capacity.

CONCLUSIONS

The overall results of our studies indicate that the retention of the stationary phase of polymer-phase systems in the cross-axis CPCs is increased by shifting the column holder laterally along the rotary shaft. Separation of proteins with high solubility in the PEG–phosphate system can be performed with the XL or XLL cross-axis CPC at a high

partition efficiency. Proteins with low solubility in PEG–phosphate systems may be separated with a dextran–PEG system using the XLLL or L cross-axis CPC, which provides more stable retention of the stationary phase.

Proteins: Flow FFF Separation

Galina Kassalainen
S. Kim Ratanathanawong Williams
Department of Chemistry and Geochemistry, Colorado School of Mines, Golden, Colorado, U.S.A.

INTRODUCTION

Flow field-flow fractionation (flow FFF) is a separation method that is applicable to macromolecules and particles.[1] Sample species possessing hydrodynamic diameters from several nanometers to tens of microns can be analyzed using the same FFF channel, albeit by different separation mechanisms. For macromolecules and submicron particles, the normal-mode mechanism dominates and separation occurs according to differences in diffusion coefficients. Flow FFF's wide range of applicability has made it the most extensively used technique of the FFF family.

DISCUSSION

The characteristic feature of flow FFF is the superimposition of a second stream of liquid perpendicular to the axis of separation. This cross-flow drives the injected sample plug toward a semipermeable membrane that acts as the accumulation wall. The cross-flow liquid permeates across the membrane and exits the channel, whereas the sample is retained inside the channel in the vicinity of the membrane surface. Sample displacement by the cross-flow is countered by diffusion away from the membrane wall. At equilibrium, the net flux is zero and sample clouds of various thicknesses are formed for different sample species. As with other FFF techniques, a larger diffusion coefficient D leads to a thicker equilibrium sample cloud that, on average, occupies a faster streamline of the parabolic flow profile and subsequently elutes at a shorter retention time t_r. For well-retained samples analyzed by flow FFF, t_r can be related to D and the hydrodynamic diameter d by

$$\frac{t^0}{t_r} = \frac{6D}{Uw} = \frac{2kTV^0}{\dot{V}_c w^2 \pi \eta d} \tag{1}$$

where t^0 is the void time, U is the field-induced velocity, w is the channel thickness, k is the Boltzmann constant, T is the temperature, V^0 is the channel void volume, $\dot{V}_c$ is the cross-flow rate, and η is the viscosity of the carrier liquid. Eq. 1 pertains to normal-mode separations.

It is apparent, from Eq. 1, that the primary sample property measured by flow FFF is the diffusion coefficient. Secondary information includes the hydrodynamic diameter which can be obtained via the Stokes–Einstein equation and the molecular weight if the molecule shape factor is constant. Unlike other FFF techniques, the retention time in flow FFF is determined solely by the diffusion coefficient rather than a combination of sample properties. As a consequence, flow FFF is well suited for analyses of complex sample mixtures and the transformation of the fractogram to a diffusion or size distribution is straight forward. In addition, flow FFF is applicable to a wide range of samples regardless of their charge, size, density, and so forth.

Flow FFF was first introduced as a method for protein separation and characterization by Giddings et al. in 1977.[2] This first publication discusses the advantages of flow FFF over other protein separation methods that were used at the time (e.g., polyacrylamide gel electrophoresis and size-exclusion chromatography [SEC]). Flow FFF permits the calculation of diffusion coefficients and hydrodynamic diameter of proteins in different solution environments directly from retention data using straightforward analytical relationships. No other technique provides simultaneous separation and measurement of D and d for each sample component without the need for additional information such as charge and density. Moreover, the protein molecular weights (MWs) calculated from FFF diffusion coefficient data are on a sounder theoretical basis than that derived from electrophoretic mobility in gels or chromatographic retention data. The absence of packing material in a channel makes flow FFF suitable for the analysis of fragile high-MW proteins and protein complexes in comparison with SEC where shear forces and interfacial interactions can cause changes in the structure and activity of molecules. Flow FFF can be used to separate and characterize mixtures of proteins, protein aggregates, and protein complexes with a single FFF analysis covering a 500–1000-fold size difference. A series of SEC columns with different exclusion limits would be needed to span a similar size range. The cross-flow rate is programmed (i.e., decreased with respect to time) to maintain separation times of 5–20 min. The open FFF channel structure permits the analysis of protein samples suspected of containing precipitated material without special pretreatment. This is not possible by SEC and gel electrophoresis.

The main disadvantage of flow FFF is the lack of commercially available membranes with flat non-adsorbing surfaces, uniform permeability, and batch-to-batch reproducibility. These features may affect retention time, separation efficiency, and sample recovery. Numerous studies and technical improvements have been done to ensure optimum performance.

The traditional flow-FFF method, also called symmetrical flow FFF, utilizes a channel with permeable depletion and accumulation walls. The cross-flow liquid enters the channel through a microfiltration frit that acts as the depletion wall and exits through an ultrafiltration membrane that acts as the accumulation wall.[1–3] Membranes with nominal MW cutoffs in the range of 5000–30,000 Da are used to ensure that the protein sample remains in the FFF channel. Hydrophilic ultrafiltration membranes made from regenerated cellulose, cellulose acetate, and modified polyethersulfone have been used.

The sample capacity in a flow FFF channel with standard dimensions is several hundred micrograms. Sample overloading causes band broadening and a shift in retention time. The experimental procedure involves sample injection followed by a stop-flow period when the axial or channel flow is stopped and the sample is transported to equilibrium positions at the accumulation wall under action of the cross-flow. At the end of the stop-flow period, channel flow is resumed and the sample is fractionated while being swept toward the outlet. The elution of proteins is monitored with an ultraviolet (UV) spectrophotometric detector set at 280 or 210 nm wavelength. Other online detectors that are being used or evaluated include multiangle light scattering (MALS) which yields MW and photon correlation spectroscopy (PCS), which yields D. Flow FFF provides the narrow polydispersity sample fractions required for accurate MW and D determinations by the light-scattering detectors. These detectors provide a second independent measure of MW and D for comparison with values calculated from FFF retention times. In addition, MALS can be used to distinguish the polydispersity of the sample from band broadening. The main disadvantages of MALS detection for protein flow-FFF applications are the low sensitivity and particulate-free solvent requirement.

Symmetrical flow FFF has been successfully used to analyze numerous purified proteins and their dimers, protein conjugates, sodium dodecyl sulfate (SDS)–protein complexes, including precipitate[1–3] and other biological samples, as summarized in Table 1. In these applications, sample pretreatment was not required even when the proteins of interest were present in complex matrices such as plasma, dairy products, and wheat flour (in contrast to SEC and electrophoresis). Ultracentrifugation, which is commonly used to fractionate these samples, requires over 24 hr in comparison with the 5–40 min for flow FFF. The short analysis time gives flow FFF an advantage in analyzing the large number of samples encountered in the medical diagnostics, pharmaceutical, and food industries. Separation efficiencies are usually of the order of several hundred theoretical plates for a typical channel length of 25–30 cm.

A later modification of flow FFF, called asymmetrical flow FFF, has generated up to 2600 theoretical plates in the separation of viruses.[4] In the asymmetrical channel, the permeable frit or depletion wall is replaced with an impermeable glass plate. The flow of carrier liquid entering the inlet of the channel is the source of both the cross-flow and channel flow. The sample is injected through an additional port located about 2–3 cm downstream from the channel inlet. For asymmetrical flow FFF, the retention mechanism is the same as for the traditional symmetrical mode. The observed higher efficiency may be based on the different relaxation procedures. In the asymmetrical channel, a so-called focusing procedure is used. The injected sample is focused to a narrow zone at the accumulation wall under action of two opposing flows (introduced simultaneously through the inlet and outlet of the channel). However, this focusing procedure has some potential drawbacks. It may promote chain entanglement of high-MW macromolecules and increase adsorption on the membrane. Lower sample capacity (several micrograms) and recovery have been observed in comparison with the symmetrical flow FFF.

Asymmetrical flow FFF has been successfully applied to several practical problems, such as the separation of monoclonal antibodies and their aggregates in downstream processing, ribosomes, and plasma protein studies (see Table 1). For example, flow FFF separations of ribosomes and their subunits have led to an alternative method of optimizing the fermentation process without having to measure protein yields.[12] Flow FFF is the technique uniquely suited for separating highly glycosylated proteins such as 10^6 Da acid phosphatase (Apase) in cultivation media.[13] Buffers commonly used in chromatographic methods cause changes in the enzymatic activity of APase.

A second variant to the traditional symmetrical flow FFF channel utilizes a hollow-fiber membrane. Even though its feasibility in separating proteins has been demonstrated,[14] its development has been hindered by the lack of membranes suitable for use as an FFF channel.

Several studies involving FFF channel modifications and new experimental procedures have been aimed at increasing detectability. For example, frit–outlet flow FFF utilizes a section of the frit depletion wall near the channel outlet to remove sample-free carrier and, thus, concentrate the separated sample just prior to its reaching the detector. A 10-fold increase in the detector

Table 1 Examples of flow FFF protein analyses.

Application	Flow FFF type	Summary
Ribosomes from *Escherichia coli*	Asymmetrical	Separation of ribosomes, their subunits, and t-RNA/low-MW protein mixture in samples collected at different protein production phases and in the presence of antibiotics, specific genes, and proteins; calculation of a ribosome number per cell and a ribosome fraction using peak area.[13]
Yeast acid phosphatase (APase)	Asymmetrical	Separation of APase in cultivation medium; identification of APase peak by enzymatic activity measurements.[14]
Proteins from wheat flour	Asymmetrical	Fractionation of wheat proteins in the size range from 5 to 45 nm; separation of gliadins from glutenin.[5]
Wheat protein fractions	Symmetrical	Size distribution of wheat protein fractions (albumins and globulins, gliadins, glutenins) prepared by extraction; influence of oxidation on size distribution of high-MW glutenin.[6]
Monoclonal antibodies (Mab) from hybridoma cell culture	Asymmetrical	Separation of five Mab aggregates (immunoglobulins) in half the time needed for GPC; only three partially resolved peaks were obtained by GPC; separation of samples containing precipitated material.[7]
Proteins in homogenized dairy products	Symmetrical	Separation of whey proteins from fat globules; fractionation of whey proteins and casein micelles; effect of carrier ionic strength, cross-flow rate, pH, and membrane type on retention and size distribution of micelles.[8]
Reconstituted skim milk casein	Symmetrical	Fractionation of colloidal Ca^{2+}-caseinate complexes in milk samples in size range 10–50 nm after the preliminary fractionation of 10–600-nm colloids with sedimentation FFF.[9]
Plasma protein interactions with polymer colloids	Symmetrical	Measurement of changes in particle (PS latex) size due to aggregation and adsorption of proteins; effect of Pluronic™ surfactants on aggregation and protein adsorption.[10]
Lipoproteins in human plasma	Symmetrical	Separation of low-MW proteins, HDL, LDL, and VLDL. Determination of subspecies in the lipoprotein fractions with linear programmed cross-flow rate; observation of lipoprotein profiles for different individuals.[17]
Drug/plasma protein interactions	Asymmetrical	Separation of albumin, HDL, α-macroglobulin, and LDL. Determination of drug distribution in FFF fractions using a fluorimetric detector.[11]
Viruses (purified)	Asymmetrical	Separation of five aggregates of the Satellite tobacco necrosis virus; isolation of the Cow pea mosaic virus.[12]

response of purified proteins was achieved without any effect on retention time or resolution.[15] Frit–inlet flow FFF involves a modification at the channel inlet that enables the transport of sample to the accumulation wall without using stop-flow relaxation.[15,16] As a result, the experimental operation is simpler and the detector signal is free of fluctuations caused by stopping and resuming axial flow through the channel. Enhanced detectability can also be realized by programming the cross-flow rate during the run to accelerate elution of highly retained components.[16] Another experimental approach involves using the ultrafiltration membrane that serves as the accumulation wall to remove low-MW interferences. A nominal 30,000 Da MW cutoff membrane was used to selectively remove low-MW proteins from a blood plasma sample to allow determinations of high-, low-, and very low-density lipoproteins (HDL, LDL, and VLDL, respectively).

A fundamental study was performed to demonstrate that flow FFF is a good alternative technique for the rapid measurement of protein diffusion coefficients.[17] The results obtained for 15 proteins were in good agreement (within 4%) with the literature data based on classical methods and a group of modern methods such as photon correlation spectrometry (PCS), laminar flow analysis, a chromatographic relaxation method, and analytical split-flow thin-cell (SPLITT) fractionation. The advantages of flow FFF are the high-speed separations and the calculation of D values directly from retention data.

Proteins: HPLC Analysis

Karen M. Gooding
Eli Lilly and Company, Indianapolis, Indiana, U.S.A.

INTRODUCTION

Proteins were first separated chromatographically in the 1950s when carbohydrate gels were found to be effective as matrices for liquid chromatography (LC). When high-performance liquid chromatography (HPLC) gained popularity, it was assumed that its higher flow rates and concomitantly higher pressures would destroy the biological activity of proteins by disrupting their three-dimensional (tertiary) structures. This was proven incorrect in the mid-1970s, when several groups, including those of Fred Regnier at Purdue university and Jiri Coupek of Czecho slovakia, demonstrated that high recoveries accompanied the high resolution of HPLC methods for protein analysis.

MODES OF HPLC

The importance of tertiary structure on the biological activity of proteins implies that the most successful HPLC methods are those employing mobile and stationary phases, which cause minimal disruption of these features. Size-exclusion chromatography (SEC) and ion-exchange chromatography (IEC) are the gentlest methods in this regard and are generally compatible with any additives needed to enhance stability. Hydrophobic interaction and affinity chromatography have somewhat higher risk of denaturation due to either their mobile phase [high salt for hydrophobic interaction chromatography (HIC)] or stationary phase (affinity). Reversed-phase and hydrophilic interaction chromatography cause greater disruption of tertiary structure due to the presence of organic solvents, acidic pH, and/or hydrophobic stationary phases. Nonetheless, reversed-phase chromatography has shown great utility in the separation of many proteins.

SIZE-EXCLUSION CHROMATOGRAPHY

Size-exclusion chromatography is a method in which molecules are separated by size due to differential permeation into a porous support. This technique is especially useful for the separation of proteins because they are macromolecules frequently found in the presence of smaller and larger species. The peak capacity in SEC is fairly low compared to other HPLC methods because all separation must occur in the internal volume of the support, which is generally less than half the volume of the mobile phase in the column. Despite this deficiency, SEC is very effective for separating proteins from small molecules, polymeric forms, and other molecules which differ by size.

Supports for SEC of proteins are designed to be neutral and very hydrophilic to avoid disruption of protein structure and interaction of the solutes with the support by ionic or hydrophobic mechanisms. The base matrix can be either silica or polymer; efforts are made to totally mask its properties with a carbohydrate like stationary phase. The pore structure is critical to successful SEC. Not only must the total pore volume (V_i) be adequate for separation, the pore diameter must be consistent and nearly homogeneous for attainment of maximum resolution between molecules with relatively small differences in molecular size (radius of gyration or molecular weight). A twofold difference in size is usually required for separation by SEC. Pore homogeneity can be assessed from the slope of the calibration curve of the logarithm of the molecular weight vs. the retention time or the partition coefficient (K_D): $K_D = (V_R - V_0)V_i$, where V_R is the retention volume and V_0 is the void or excluded volume. A less steep slope results in the separation of more closely related molecular weights. Fig. 1 shows both an analysis of a protein mixture on an SEC column and its calibration curve. The second calibration curve is for a column with a smaller pore diameter, showing its effectiveness for separating smaller solutes.

The mobile phase is a critical factor in SEC because it must eliminate all solute–support interactions. This is effected by adjustment of pH (usually to neutrality), ionic strength (0.05–0.2 *M*), and/or addition of 5–10% organic solvent or stabilizing agents. The ionic and hydrophobic properties of proteins and their attraction to the stationary phase must be totally removed.

ION-EXCHANGE CHROMATOGRAPHY

Ion-exchange chromatography separates proteins by ionic interaction of their surface amino acids with charges on the stationary phase. Selectivity is dependent on the number and the identity of the amino acids, as well as their spatial arrangement. A protein with charges grouped in a patch on its surface will bind differently than one whose charges are dispersed throughout the surface. IEC is so selective that it can resolve isoforms and variants differing by only one

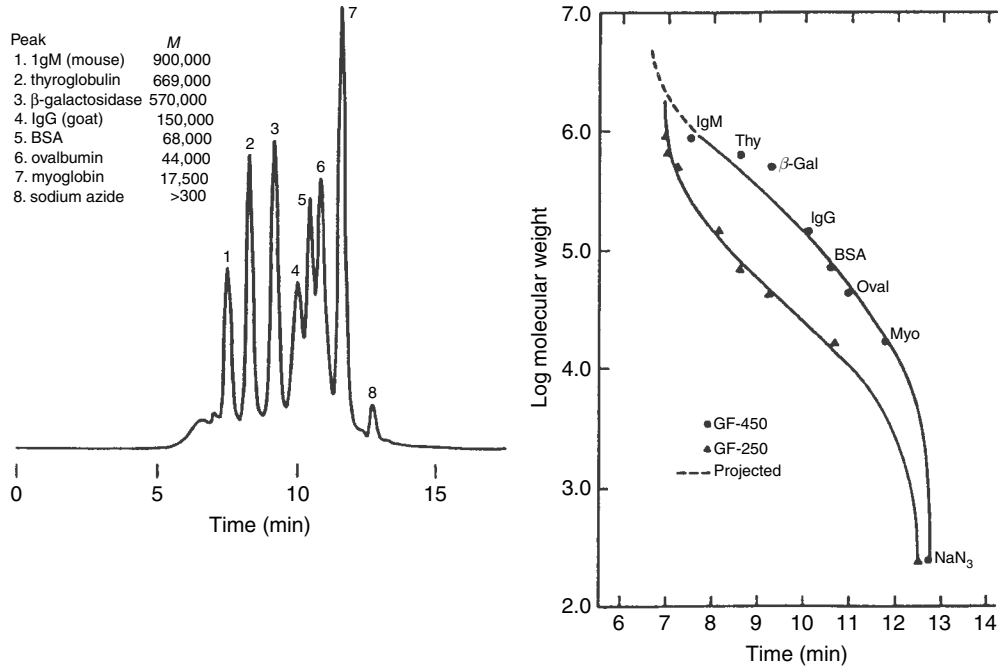

Fig. 1 Analysis of a mixture of proteins on ZORBAX® GF450. Calibration curves of proteins on ZORBAX GF250 and GF450 columns. Mobile phase: 0.2 *M* sodium phosphate, pH 7.5; UV detection at 280 nm.

amino acid. Loading on porous IEC supports is high (100 mg/g), making IEC invaluable in purification techniques.

Supports for IEC possess either anion- or cation-exchange functionalities which are positively or negatively charged, respectively. They are also classified as weak or strong to correspond to their titration curves, similar to acid and base designations. The stationary phase totally covers the silica or polymer support matrix. The pore diameter is important in that it must be large enough to allow access of the protein. This affects not only retention but also loading capacity.

In IEC, proteins are bound in a low-ionic-strength buffer (0.02–0.05 *M*) at an appropriate pH (often 1–2 pH units from the p*I*). Elution occurs when the ionic strength is increased during a concentration gradient of a salt in the same buffer. Because proteins bind via multipoint interactions, gradients are necessary for good peak shapes, resolution, and reproducibility. The pH gradients are less commonly used but can also be effective. The nature of the salt in IEC has a major effect on selectivity due to interaction of the composite ions with either the stationary phase or the solutes. Fig. 2 illustrates the differences in retention of several proteins when various salts are used as the mobile phase for anion-exchange and cation-exchange chromatography. Additives which increase protein stability or improve peak shape can usually be included in the mobile phase without deleterious effects on the separation. Lower temperatures can be used to preserve biological activity, but they also result in higher retention.

HYDROPHOBIC INTERACTION CHROMATOGRAPHY

HIC is a method in which proteins in a high salt environment interact hydrophobically with non-polar ligands. Effective salts are antichaotropic, meaning that they promote the ordering of water molecules at surfaces. Selectivity is based on the hydrophobic amino acids and patches on the surface of the proteins. Many proteins, which generally remain in their native states in this technique, retain their biological activities when separated by HIC.

Supports for HIC have short alkyl chains or phenyl functionalities, the length of which is related to retention. The matrix can be either silica or polymer, as it is totally covered by the bonded phase and, thus, not exposed to the solute. Pore diameters are at least 300 Å to allow access by proteins. Loading capacities are high and similar to those of ion-exchange supports.

In HIC, molecules are bound with a high concentration of salt, usually ammonium or sodium sulfate (1–2 *M*) in a buffer (0.02–0.05 *M*). Elution is attained by a gradient to a lower concentration of salt in the buffer. The pH is controlled and is usually in the range of 6–8, but it is not a critical factor in selectivity. Additives to enhance protein stability are generally compatible with the process. Contrary to its effect on other modes of chromatography, reducing the temperature decreases the retention in HIC due to its being an entropy-driven technique.

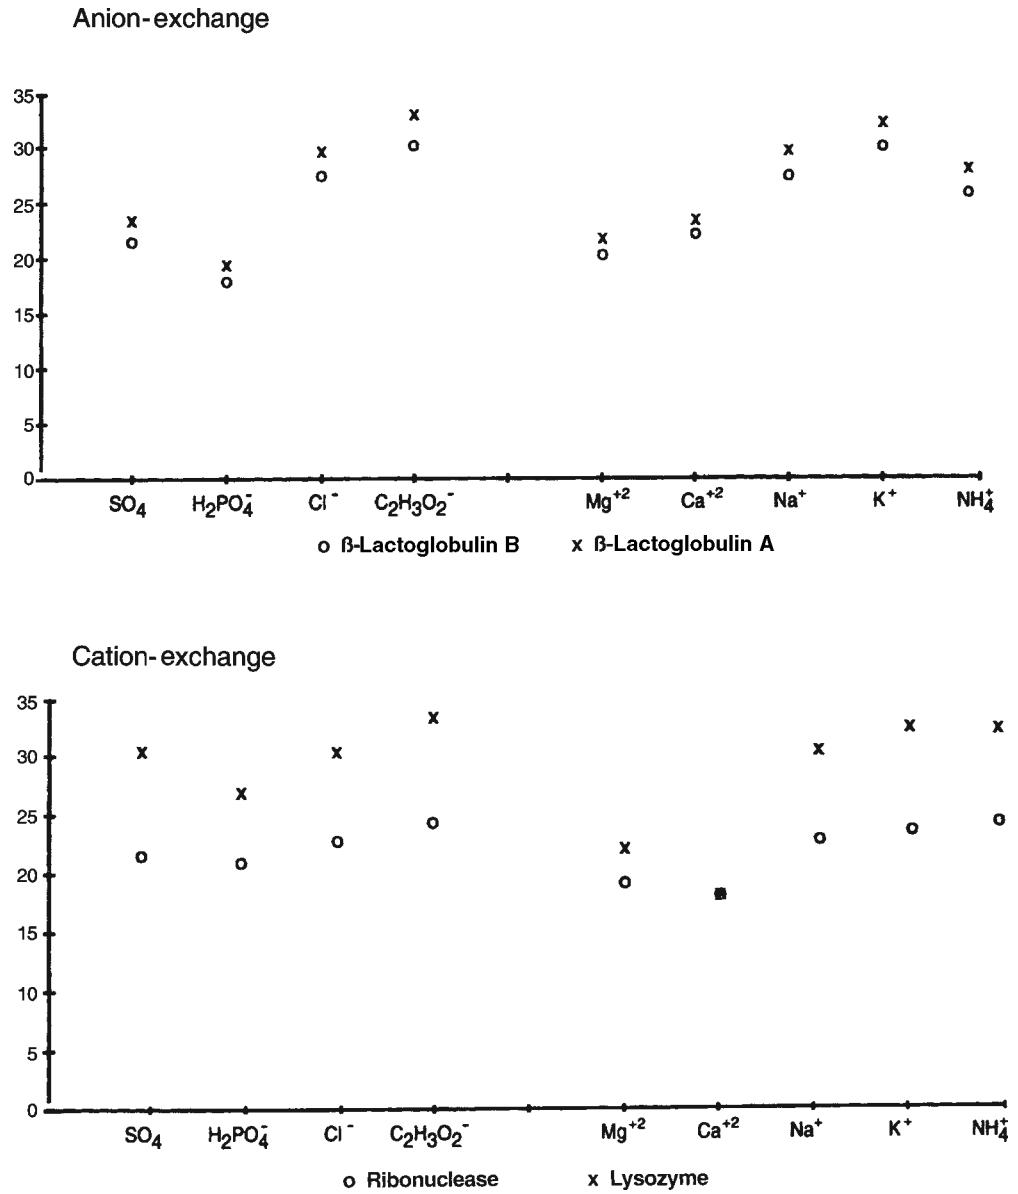

Fig. 2 Effect of salt on protein retention. Columns: SynChropak AX300 and SynChropak CM300; 30 min gradient from 0–1 *N* salt in 0.02 *M* Tris, pH 7.

AFFINITY CHROMATOGRAPHY

Affinity chromatography (AFC) is a method in which biomolecules are attracted to ligands due to biospecificity. AFC is a very specific and selective technique in the aspect that many ligands are used, being customized to the analyte of interest. It is generally unlike other HPLC processes because particle diameters are larger and retention tends to be bind-release rather than partitioning, thus separating one protein or class of proteins from everything else in a mixture. Recoveries of biological activity are often high.

The variety of ligands for AFC includes proteins, cofactors, and any other molecules for which a solute has special affinity. Some common ligands are protein A, antibodies, and concanavalin A. Elution is attained by either a change in pH or ionic strength conditions or the addition of a competitor for the binding. Conditions are as varied as the number of ligands.

REVERSED-PHASE CHROMATOGRAPHY

Reversed-phase chromatography (RPC) is a method in which molecules are bound hydrophobically to non-polar ligands in the presence of a polar solvent. Solutes are generally bound in an acidic mobile phase with elution

occurring during a gradient to an organic solvent. The combination of acidic and organic mobile phases and a hydrophobic bonded phase usually results in tertiary structure disruption, which may or may not be reversible. Binding involves internal as well as surface amino acids depending on the extent of unfolding. The utility of RPC for protein analysis is limited by its generally denaturing characteristics; however, it can be a good method for non-preparative techniques where preservation of biological activity is unimportant. Some enzymes, such as trypsin and chymotrypsin, can be renatured after RPC, regaining biological activity.

There are many ligands used for RPC, but the most popular for protein analysis are butyl (C_4) and octyl (C_8). Little difference in selectivity for proteins is observed with ligand-chain-length variation, but mass recovery is often enhanced on the shorter chains. Due to their higher efficiencies and wettability, silica-based supports are generally used for protein analysis. The silica matrix is sometimes a factor in retention because reversed-phase bonded phases often do not totally eliminate silanols on the support. Pore diameters used for proteins are at least 300 Å; non-porous supports offer a high-resolution option with lower capacities. Loading capacities of RPC are at least 50% lower than those of IEC or HIC.

Many operational factors can change selectivity in RPC. The strength of the organic solvent which causes elution increases from methanol to acetonitrile to isopropanol. Acetonitrile is the most popular solvent due to its transparency at low wavelengths (<210 nm) and its tendency to yield narrow peak widths. The transparency is not critical for proteins, which can usually be detected at 254 or 280 nm. Ion-pairing agents, such as trifluoroacetic acid, can be added to the mobile phase to change the ionic or hydrophobic properties of either or both of the bonded phase or the solute. Generally, acidic pH is utilized to minimize silanol interactions; however, distinct pH conditions yield different selectivities. Increased temperatures result in shorter retention times and are especially effective in reducing the pressure generated by small-particle-diameter supports.

HYDROPHILIC INTERACTION CHROMATOGRAPHY

Hydrophilic interaction chromatography (HILIC) is a variation of normal-phase chromatography in which solutes are retained on a polar bonded phase under high concentrations (80–90%) of organic solvent and released during a gradient to a more aqueous solvent. The organic mobile phase usually causes at least partial denaturation of proteins.

The HILIC bonded phases are hydrophilic, including amide and/or polyhydroxy functionalities. Pore diameters are at least 300 Å to allow penetration of proteins. Supports can be based on either silica or polymer because the matrix is not exposed to the solutes.

The mobile phase can offer some differences in selectivity in HILIC. A buffer is usually used to control pH. It may also serve to change the hydrophobicity of the solutes by ion-pairing; thus, it may greatly effect retention. For this reason, the pH is less important than the identity of the salt. The denaturing aspects of HILIC diminish its utility in protein analyses, particularly for preparative purification.

CONCLUSIONS

High-performance liquid chromatography provides a number of rapid and effective methods for analysis and purification of proteins and enzymes. In modes such as SEC and IEC, quantitative yields are often obtained with full preservation of biological activity. The ability to change selectivity using the mobile phase has resulted in versatile techniques which can be rapidly optimized and implemented.

Pump/Solvent Delivery System Design for HPLC

Andrei Medvedovici
Victor David
Department of Analytical Chemistry, University of Bucharest, Bucharest, Romania

Abstract
Constructive and functional principles of solvent delivery systems used in high-pressure liquid chromatography (HPLC) as well as in ultra-high-pressure liquid chromatography (UHPLC) are discussed. The main building parts such as solvent degassers, HPLC and UHPLC pumps, proportioning valves, inlet and outlet valves, mass flow sensors, pressure sensors, mixers, and dampers are described. The different technical setups for solvent gradient formation are highlighted together with micro/nano flow creating principles. Some aspects related to maintenance and troubleshooting of solvent delivery systems are also discussed. Basic operational qualifications principles are reviewed.

INTRODUCTION

The solvent delivery system (SDS) is an integral part of the structure of a liquid chromatograph that has the following functions:

1. Conditioning the components of the mobile phase (filtering and degassing).
2. Mixing the components to obtain the required composition of the mobile phase.
3. Pumping the mobile phase through the chromatographic system at a controlled flow rate, without any variations (pulses), if possible. Accurately measuring the flow rate and regulating it through feedback of the column flow against the primary pump flow (optional characteristic of pumping systems at micro- or nano-level flow rates).
4. Measuring the pressure within the chromatographic system.
5. Preserving the chromatographic column from any possible damage brought about by the mobile phase (optional).

GENERAL CONSIDERATIONS

The SDS belonging to a liquid chromatograph represents a multimodular system. It incorporates a solvent container (having storage and conditioning roles), a high-pressure pump (includes the functions of proportioning and mixing of components and pressure measurement), a damper (to attenuate flow pulses), and a precolumn to act on the mobile phase so as to preserve the integrity of the stationary phase (e.g., elimination of residual water from mobile phases designated for normal-phase separation mechanism or saturation of $[Si(OH)_6]^{2-}$ ions in the case of alkaline mobile phases in contact with silica gel-based stationary phases). Integration of the SDS in a liquid chromatograph is schematically represented in Fig. 1.

Development of liquid chromatography over the last decade refers to the following evolution directions: 1) increase in the pressure regime sustained by the pumps at very high or ultrahigh levels; 2) capability of delivering micro or nano flow rates. The very high-pressure chromatography, or ultra-pressure liquid chromatography (UPLC), deals with a relatively moderate extension of the pressure regime sustained by the SDS up to 600–1400 bar. This can normally be achieved using commercially available instrumentation with improvements in terms of materials and production technologies of the different active constructive elements. Ultra-high-pressure liquid chromatography (UHPLC) deals with pressure regimes between 1400 and 9000 bar and requires special constructive modifications of the pumping systems. Very high and ultra-high-pressure LC applications involve separations carried out on columns packed with sub-two-micrometers particle size stationary phases, low internal diameters (below 1 mm), and increased lengths (up to 60 cm). The major achievements of such separations are increased resolution, very high separation speed, and improved sensitivity.

The ongoing tendency to reduce particle size and column internal diameter leads also to a reduction of the required optimal flow rates. Micro-LC applications consist of columns with internal diameters less than 1 mm and require flow rates between 1 and 100 μl/min. Nano-LC applications require flow rates in the 100–1000 nl/min range. For a micro- or nano-LC setup, the flow is controlled by means of a flow sensor (FS) situated after the purge valve. The FS works in a feedback loop with the electronically controlled

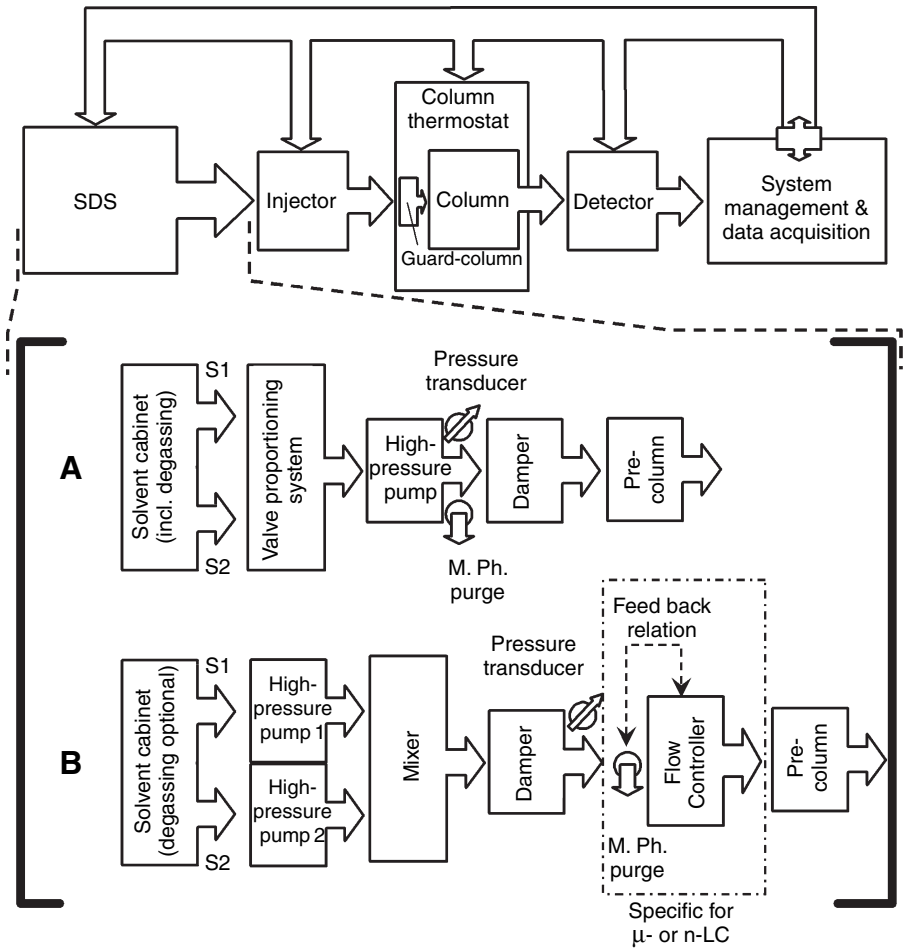

Fig. 1 General diagram of an SDS within the structure of a liquid chromatograph. A, Low-pressure solvent mixing design; B, High-pressure solvent mixing design.

purge valve, allowing the maintenance of precise and accurate flow rate values in the micro- or nanoliters per minute range.

The use of ultra-high-pressure regimes and/or flow rates in the micro- or nanoliters per minute range imposes unique requirements on LC system hardware, such as pumps, valves, injectors, connecting tubing, column construction, stationary phases, column heating systems, detection flow cells, and the detector's data collecting speed.

CLASSIFICATION

Isocratic SDS is used when the mobile phase contains a unique component or the components are premixed. It is obvious that such an SDS is designated only for isocratic elution. The structure of the SDS depicted in Fig. 1A is known as the low-pressure mixing setup. It uses a single high-pressure pump, and the components of the mobile phase (generally not more than four) are proportioned before entering the pump, at low pressure. Such a setup strongly requires a solvent degassing module. More often, air solubility in individual solvents is higher, compared to the case of mixed solvents. Mixing components under a low-pressure regime, before entering the pump, will produce degassing within the pump body, thereby resulting in a cavitation phenomenon and significant variations of the flow rate and pressure. Precision and accuracy in the formation of the mobile-phase composition are poorer, compared to those in the setup presented in Fig. 1B. This model uses a high-pressure pump for each solvent component (usually two components). Components are mixed under a high-pressure regime, after their controlled delivery. Because a high-pressure regime increases gas solubility in liquids, degassing of the individual components should be considered as optional. Both low-pressure and high-pressure solvent mixing configurations are used for the gradient elution mode in LC. However, isocratic elution is also possible, by automated mixing of the components of the mobile phase in definite volumetric proportion by the SDS itself.

CONSTRUCTIONAL ASPECTS

Solvent Containers

Solvent containers are generally used for storage, online filtering, and, eventually, degassing of the constituents of

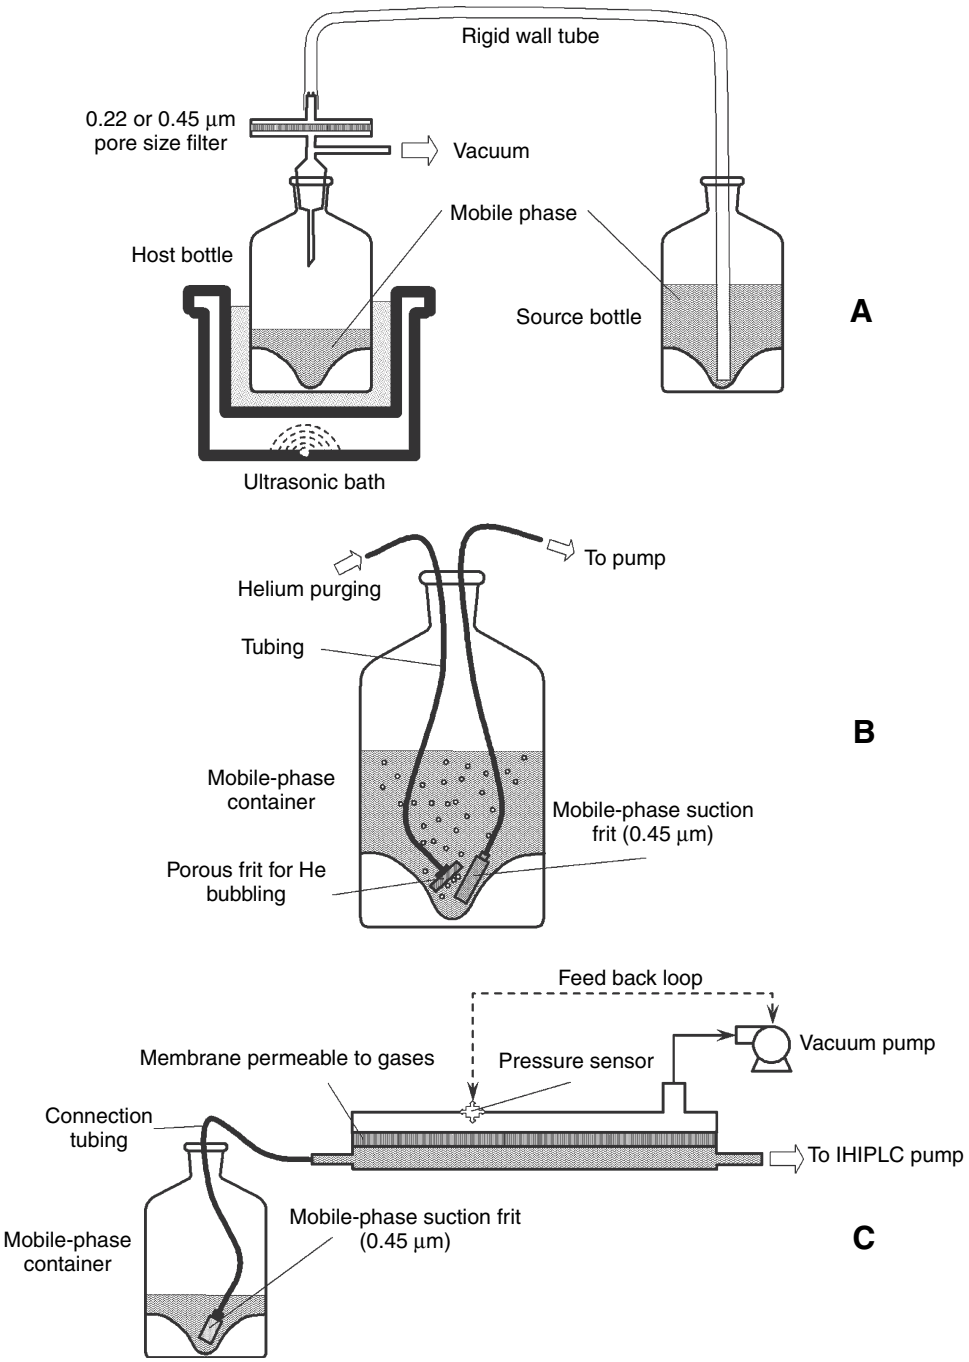

Fig. 2 Different modes for degassing solvents: A, off-line vacuum filtration and ultrasound; B, online helium purging; and C, online vacuum degassing system.

the mobile phase. Liquids are stored in glass bottles of appropriate volume and geometry. If solvent or solvent mixtures stored in containers are subject to photo- or biodegradation under the effect of sunlight, the use of amber glass bottles is strongly recommended. Addition of preservatives to the constituents of the mobile phase may be possible if such compounds are tolerated by the chromatographic separation and/or the detection system (e.g., sodium azide is usually added to mobile phases containing sodium acetate buffers and for size exclusion separation mechanism on saccharidic stationary phases to preserve the integrity of both mobile and stationary phases). Solvents are suctioned from reservoirs by means of 0.45 μm pore size frits (metal- or ceramic-based materials are used). Appropriate geometry of the reservoir bottom may facilitate the use of the solvent until the last droplet (Fig. 2).

When metal frits are used, the possible corrosive effects of solvents and/or additives on the material should be duly considered (e.g., hydrochloric acid produced in chloroform during storage reacts with stainless-steel frits). Bacterial growth within the constituents of the mobile phase may also block the pores. Technical solutions for solvent degassing are extremely variable. The first attempts were oriented toward heating the solvent in its reservoir just below the boiling point (dissolved air is eliminated on account of its decreased solubility in the liquid phase). Despite its efficacy, such an approach became obsolete, owing to some major drawbacks: 1) necessity of cooling the solvents back to the ambient temperature before pumping and 2) safety concerns related to the inflammability of the solvents. An off-line solution for solvent degassing is given in Fig. 2A. The mobile-phase component is transferred from one bottle to another under vacuum and filtration over 0.22 μm pore size membrane with simultaneous application of ultrasound. Degassing may be effective over a period of time depending on the nature of the mobile-phase constituents. Another approach (Fig. 2B) relies on a continuous helium purge through the solvent. As helium has the lowest solubility in liquids, it readily removes dissolved gases. The process is continuous, online, simple, and effective, but expensive (because of the use of large volumes of highly purified helium). The technical solution illustrated in Fig. 2C is based on the component transfer through a bicompartmental evacuated chamber having an inner separation membrane that is permeable to gases. The low-pressure regime is kept under control by means of a sensor working in a feedback loop with the vacuum pump. Good degassing yield is obtained, and the process runs online, but it requires more expensive equipment. Moreover, salt deposition (from buffers) strongly affects membrane efficiency, while malfunctioning of the vacuum system and/or excessive flows may result in membrane breakout and serious leakages.

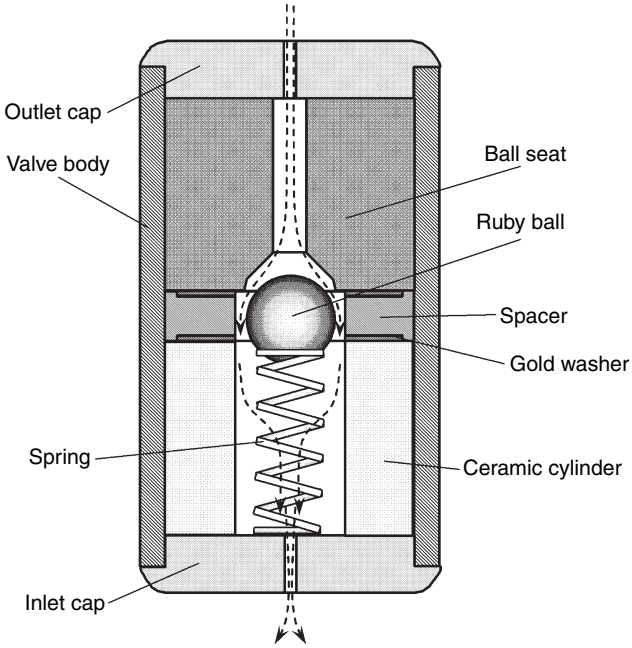

Fig. 4 Construction of a ball valve (inlet or outlet) for high-pressure pumps.

High-Pressure Pumps

The high-pressure pump design is most often based on the operational principle of the piston pump (Fig. 3).

The reciprocating movement of the piston within the pump body (cylinder) causes solvent delivery. Owing to the direct contact of piston and inner pump body surfaces with the carried liquids, high chemical inertness is required. Pistons are usually made of ceramics, synthetic sapphire, or zirconia, while the pump body may be produced from titanium, stainless steel, or even polymeric materials (e.g., PEEK^{TM}). Prevention of back flush of liquid from the pump body to the solvent reservoir when the piston moves forward is achieved by means of an inlet

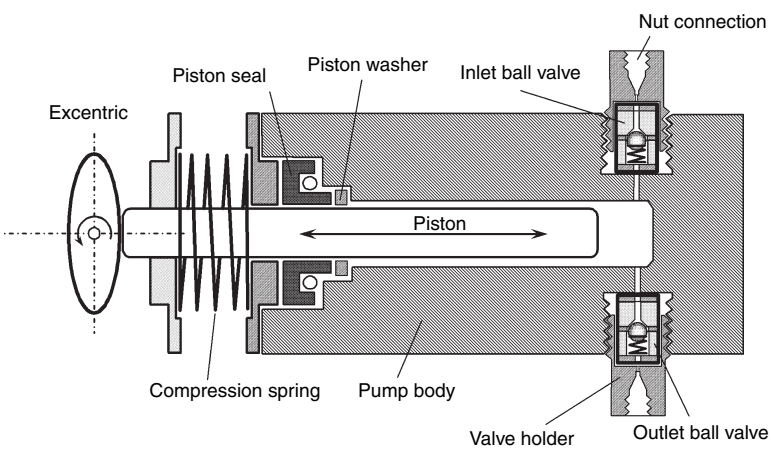

Fig. 3 Scheme of a single-piston high-pressure pump.

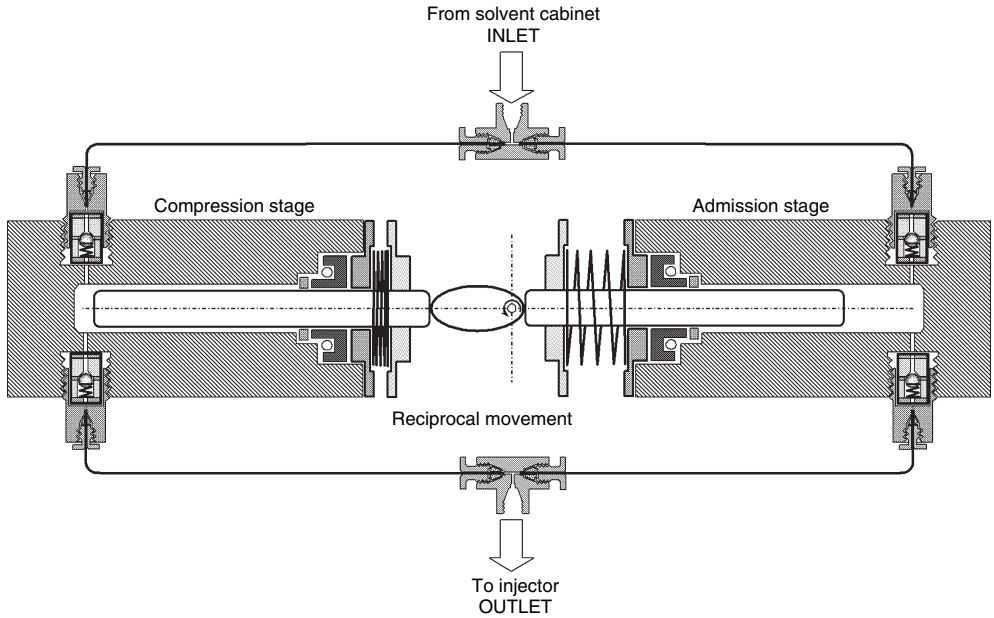

Fig. 5 Construction of a reciprocal high-pressure pump for HPLC.

ball check valve. The back flush from the connection tubing to the pump body when the piston moves backward is prevented by the outlet ball check valve. Ball check valves allow unidirectional passage of the liquid by means of a ruby ball moving out or into a specially designed seat according to the liquid flow direction (Fig. 4). Perfect fitting of the ruby ball against the seat could optionally be enhanced by means of a spring.

The single-piston pump delivers a pulsed flow (flow occurs when the piston is moving forward and flow stops when the piston is moving backward). To reduce flow pulses, the solvent admission into the pump body can be realized by means of a fast backward movement of the piston. Under such conditions, liquid compressibility and viscosity should be taken into consideration.

One of the easiest solutions to generate constant flows uses two piston pumps operating at 180° out of phase (meaning that one of the pumps is in admission, while the other is in the compression stage). This design is called the reciprocal mode and is illustrated in Fig. 5.

Increased flow control can be achieved by replacing the piston with an elastic membrane. The membrane is periodically flexed by means of a viscous liquid (e.g., mineral oil) contained in a closed cavity in which a piston moves forth and back at a high frequency (~10 Hz). Oil is recirculated in the cavity through a unidirectional valve. A second cavity, containing the mobile phase, fits to the elastic membrane. The flow through this cavity is determined by the inlet and outlet ball check valves. Such a design represents the membrane (or diaphragm) pump, a basic scheme of which is given in Fig. 6. The membrane pump has two major drawbacks: 1) if the membrane fails, the mineral oil gets mixed with the mobile phase, which may irreversibly damage the column and 2) liquid admission through the inlet valve must be achieved at a positive pressure regime (meaning that a low-pressure pump is required).

The only possibility to deliver a pulse-free mobile-phase flow through the chromatographic system is the syringe pump design (Fig. 7). Frequently used in the past for micro-LC applications (flow rates below 10 μl/min), the syringe pump suffers from limitation of the delivered

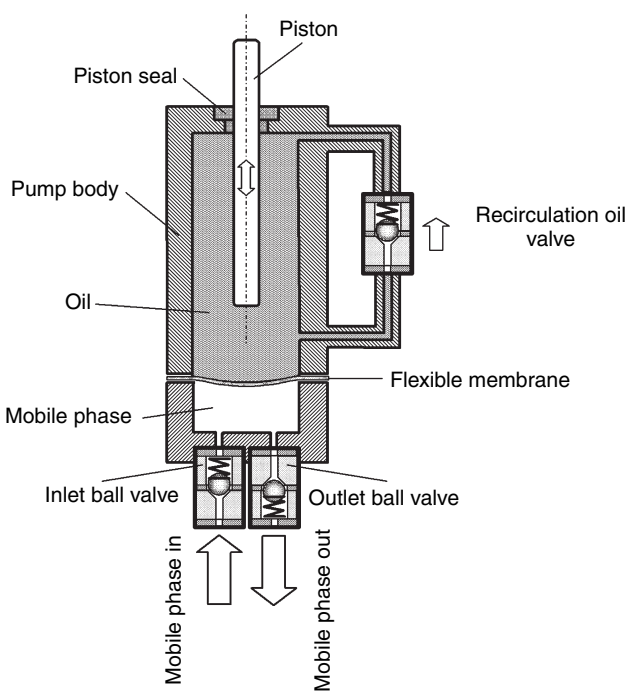

Fig. 6 Construction of a membrane (diaphragm) pump.

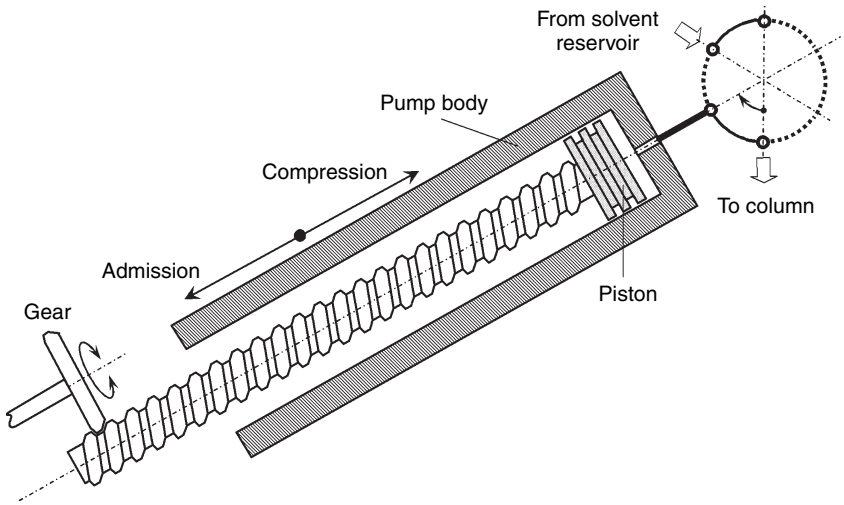

Fig. 7 Syringe pump.

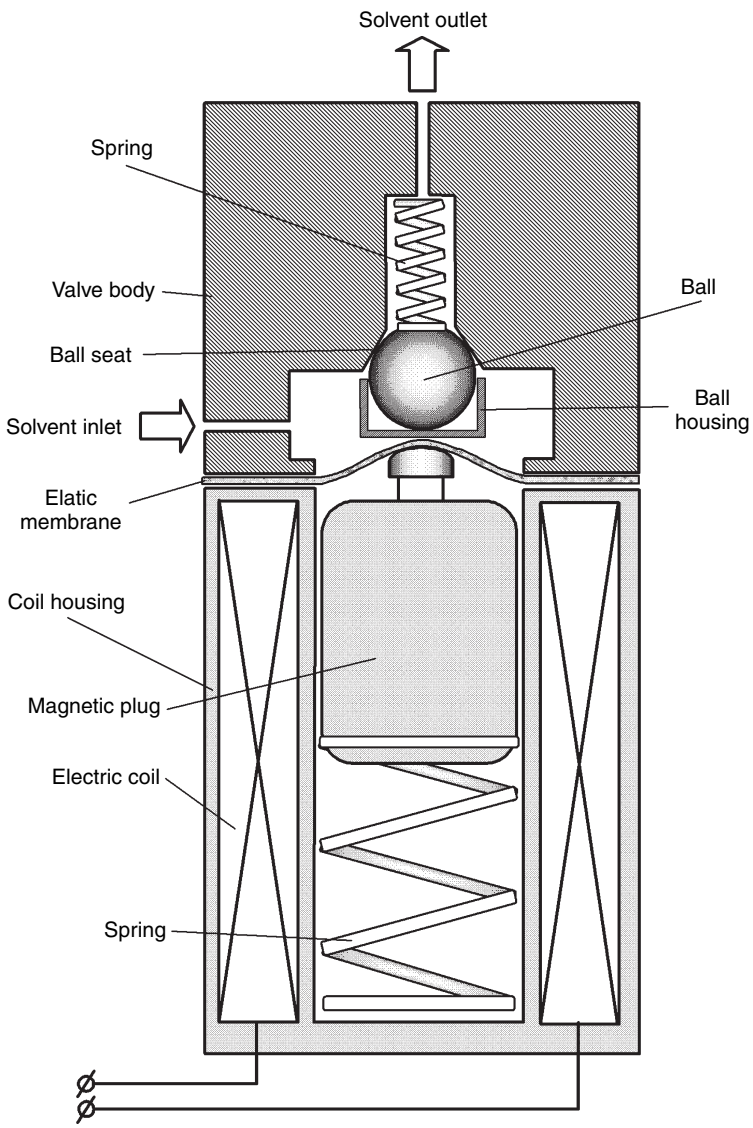

Fig. 8 Electrically driven proportioning valve for low-pressure mixing in HPLC configurations.

volume of the mobile phase (resulting in the limitation of the chromatographic run time) and from some major technical difficulties in creating composition gradients.

Generally, high-pressure pumps may work in two different modes: constant flow and constant pressure. Usually, the constant-flow mode characterizes LC, while the constant-pressure mode is often used in capillary supercritical fluid chromatography (SFC).

Mobile-phase composition control is achievable in the low-pressure solvent mixing setup by means of electrically driven proportioning valves placed between the solvent containers and the high-pressure pump. Proportioning valves' working principle is similar to that of the ball valves fitted to the high-pressure pump (Fig. 8). Pushing the ball into and out of the seat is controlled by means of a magnet plunger operated within a coil (activated when electric current passes through it and deactivated when the flow is cut). Proportioning valves work on time-based cycles. For instance, if the time cycle is 1 sec and it is necessary to create a mobile phase by mixing solvents A, B, and C in the volumetric ratio of 1:1:2, the proportioning valves corresponding to A and B remain open for 0.25 sec, while that corresponding to C is kept open for 0.5 sec.

Ultra-High Pressure Pumps

The earliest and still the most commonly used pumps for UHPLC are air-driven liquid pumps, or pneumatic amplifier pumps. The piston area on the air-driven side is much larger than that on the liquid side, so that very high liquid pressures are obtained via relatively low air pressures. The major advantages of pneumatic amplifier pumps refer to high pressure levels (9000 bars) obtained, commercial availability, and relatively low costs. Disadvantages are mainly related to the fact that pneumatic amplifier pumps are controlled by pressure instead of volume, which makes difficult the generation of elution gradients, and their large sizes.

Another approach to generate ultra-high pressures is to use a conventional HPLC pump with a hydraulic amplifier (see Fig. 9). The differential area provided by the difference in the diameters of the pistons creates a pressure amplification that is proportional to the ratio of the areas. Specifically, the pressure amplification can be calculated as follows:

$$P_2 = P_1 \times \frac{D^2}{d^2}$$

where P_2 and P_1 are the pressures acting on the secondary and the primary pistons, and D and d are the diameters of the primary and the secondary pistons, respectively. As an example, if the diameter of the primary piston is 3 cm and the diameter of the secondary one is 0.5 cm then the pressure will be amplified 36 times; if the HPLC pump delivers the hydraulic fluid at 300 bar, then the pressure in the UHPLC part will be 10,800 bar. In addition to pressure amplification, the hydraulic amplifier also creates a flow reduction. As the primary and the secondary pistons have substantially identical linear velocities, the difference in cross-sectional areas results in a reduction in flow rate, computed according to the following relationship:

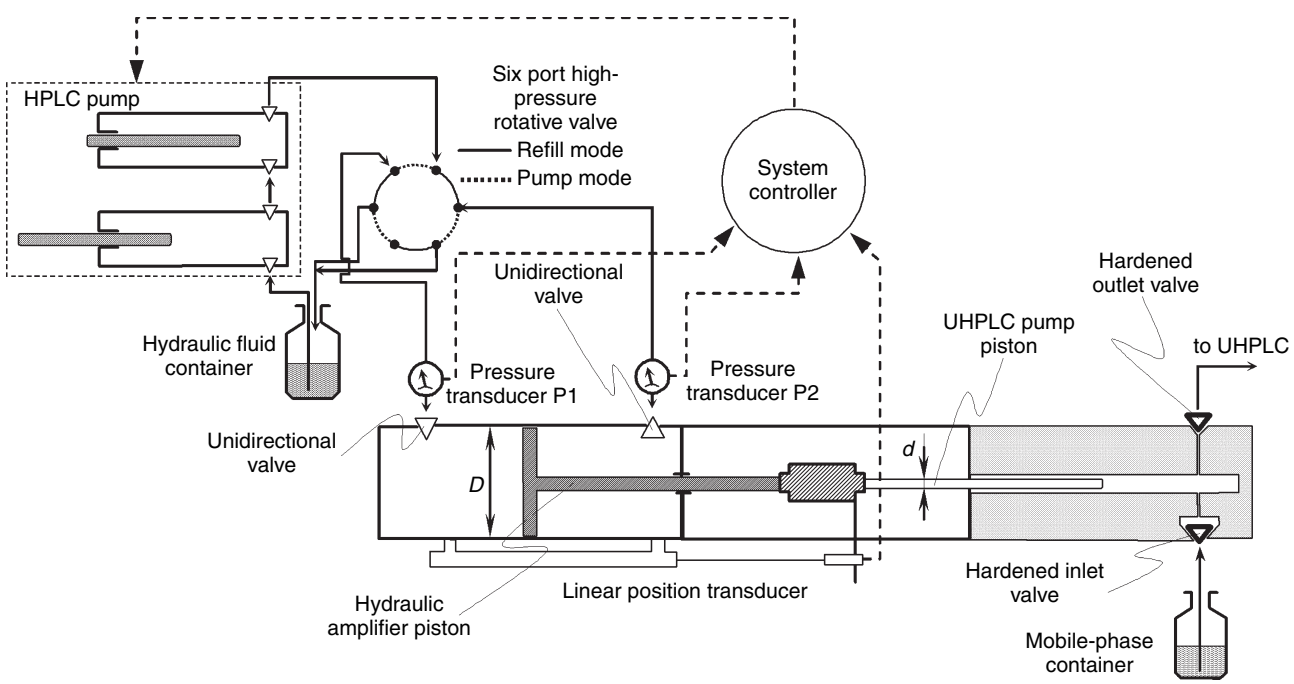

Fig. 9 Hydraulic amplification principle for ultra-high-pressure liquid chromatography applications.

$$F_2 = F_1 \times \frac{d^2}{D^2}$$

where F_1 and F_2 are the flow rates in the primary and secondary stages, and d and D are the diameters of the secondary and the primary pistons, respectively. Considering the piston diameters from the previous example and a flow rate of the HPLC pump of 2 ml/min, the UHPLC flow will drop to 0.056 ml/min.

In UHPLC conditions, solvents become compressible. Consequently, a significant portion of the piston stroke is used for compressing the solvent. Owing to this fact, it is advantageous to run the primary HPLC pump at high flow rates until the desired secondary operating pressure is achieved. As well, both compression and decompression

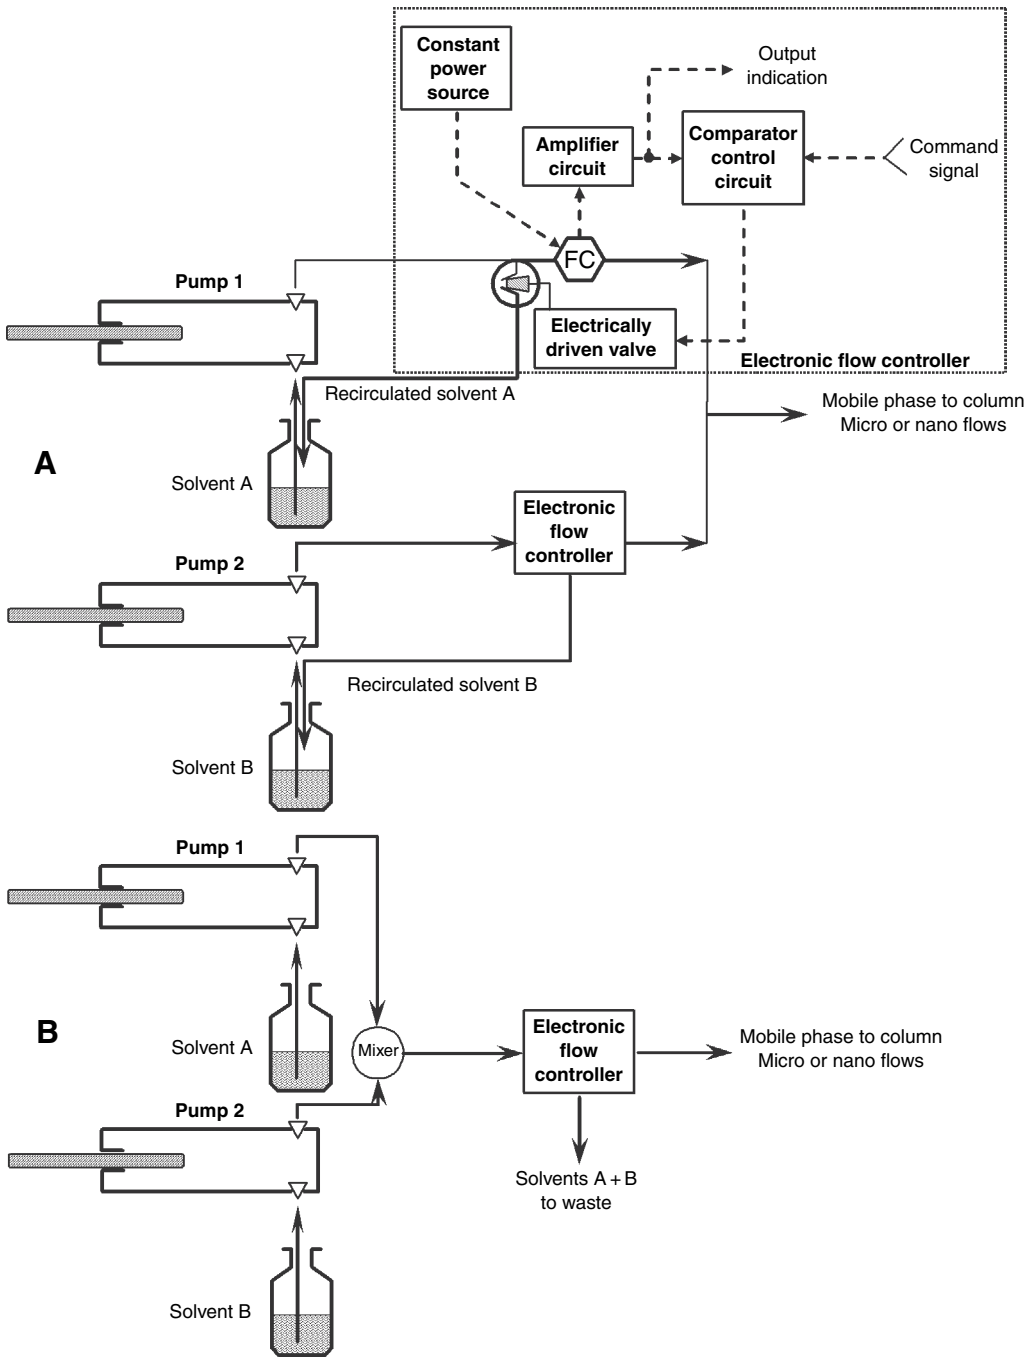

Fig. 10 Micro/nano pump functioning principle: A, flow control and solvent recirculation for each pump and B, flow control and purging of mobile-phase excess after mixing.

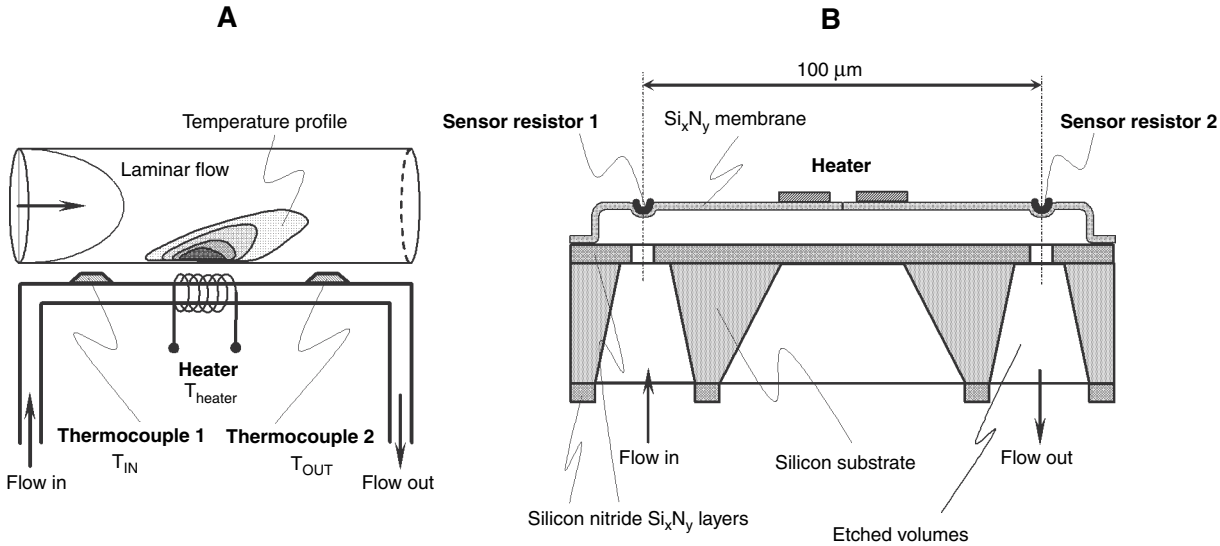

Fig. 11 Thermal mass flow sensing principle (A) for normal flows and (B) for micro and nano flows (MEMS).

stages of the eluent must be considered in terms of heating and changes in the solvent's structure.

Micro- and Nano-HPLC Pumps

Operation of HPLC pumps for delivering micro- to nanoliters per minute flow rates is based on the capability to make precise flow measurements and the feedback control through an electronically driven purge valve situated before the flow sensing area. Such an electronic flow control system may be placed after formation of the required mobile-phase composition (from two or more high-pressure pumps) or may be used for each specific pump. In the first case, the mobile-phase flow exceeding the threshold is purged as a waste, while in the second case the solvent may be recirculated back to the reservoir. The two setups are depicted in Fig. 10A and B.

The measuring principle of a thermal mass FS is as follows: the flow is led through a U-shaped tube where two temperature sensor elements (or a configuration of constantan–copper thermopiles) are placed with a heater in the middle. When there is no flow through the pipe, the temperature profile is symmetric around the heater (see Fig. 11A). When the fluid is flowing through the pipe, from left to right, the temperature profile will shift to the right side. The temperature shift is obtained as the difference ΔT between the upstream and downstream sensor measurements. The signal output of the sensor is proportional to the mass flow according to the relationship

$$\text{Output} \propto \Phi_m = \frac{P}{\Delta T \times c_p \times K}$$

where Φ_m is the mass flow, P is the power feed to the heater, ΔT is the temperature shift, c_p is the heat capacity of the fluid, and K is the sensor's constant.

The construction of a FS having nanoliters per minute measuring capability is based upon micromachining technology (see Fig. 11B). The flow sensing process takes place in a silicon nitride microchannel created by etching of a poly-Si sacrificial layer. Inlet and outlet of the channel are obtained by KOH etching of the backside of the substrate. The platinum resistors deposited on the top of the microchannel perform liquid flow sensing by monitoring the temperature profiles of the heater placed in the middle position. Such devices are called "micro-electrical-mechanical systems" (MEMS), which are micromachined systems containing both electrical and mechanical components with characteristic sizes ranging from nanometers to millimeters. MEMS based on resonant Coriolis mass flow sensing are also commercially available.

Damper

The main role of the damping unit is to reduce flow fluctuations. The functioning principle is based upon the attenuation of the mobile-phase flow fluctuations by means of an elastic membrane separating two cavities. In the first cavity, a liquid with a low compressibility coefficient is introduced. The mobile phase runs through the other cavity. Usually, the damper also incorporates the pressure transducer. The liquid filling the first cavity pushes back the plunger placed on the opposite side of the elastic membrane. Outside the cavity, the plunger is placed in direct contact with a sensor monitoring the pressure within the chromatographic system (Fig. 12).

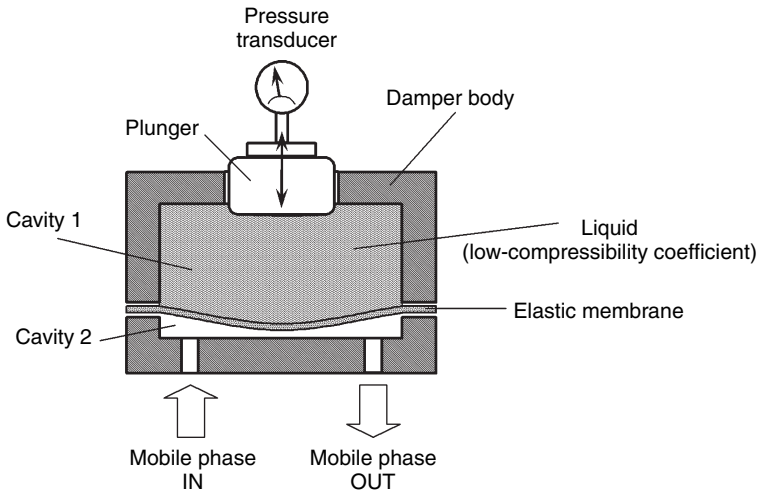

Fig. 12 Scheme of a damper incorporating the pressure transducer.

Mixer

Mixers are designed to ensure homogeneity of the mobile phase, whose composition is determined by means of the pumping system from two or more solvents. Mixing of the mobile-phase constituents is achieved in dynamic or static mode. The dynamic mixer is based on the principle of a magnetic stirrer, as shown in Fig. 13A. The static mixer may be a simple column packed with stainless-steel spheres; tortuosity of the flow through the packing induces mixing of the components (Fig. 13B). It is essential that the internal volume of the mixing unit be as small as possible. This feature will reduce the delay between gradient formation in the pumping system and in the chromatographic column (same observation is valid also for dampers).

Precolumn

The precolumn acts on the mobile phase. Its role is to reduce unwanted interactions between mobile and stationary phases within the chromatographic column. It is well-known that traces of water contained in organic solvents accumulate on the silica gel surface. Water bound to silanol sites is strongly retained by means of hydrogen bonds and will shift the phase retention mechanism from adsorption to partition, resulting in serious disturbances in the chromatographic behavior. A precolumn packed with a desiccant material will solve this problem related to the normal-phase retention mechanism. An alkaline-buffered mobile phase strongly influences the characteristics of silica gel-based stationary phases, owing to its dissolution as complex anions. If such a problem is expected, a precolumn packed with silica gel will saturate the mobile phase and will consequently preserve the stationary phase from deterioration.

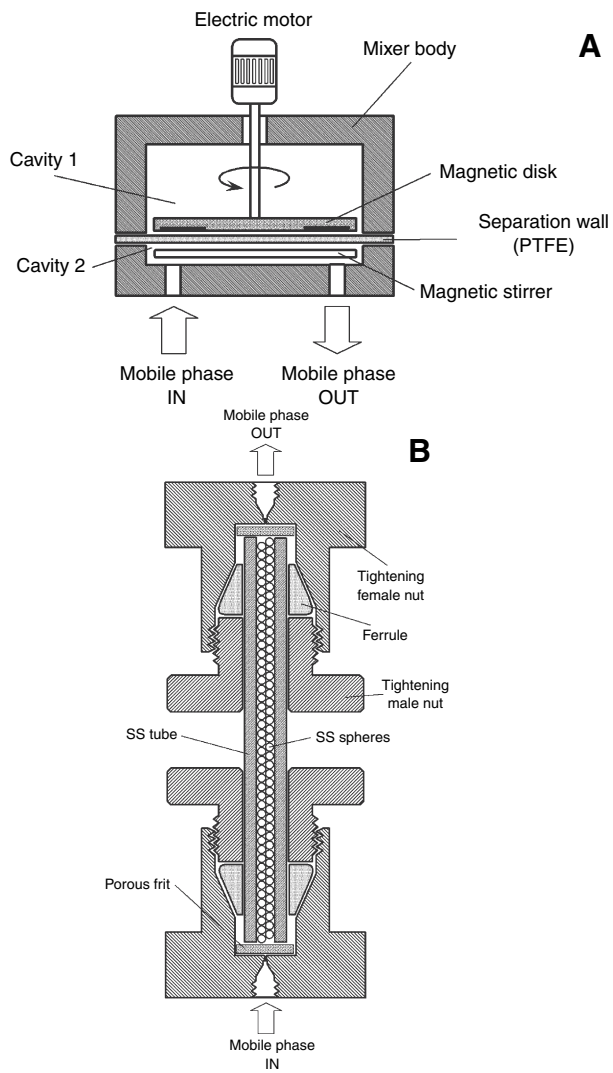

Fig. 13 Mixers: A, dynamic mixer and B, static mixer.

Table 1 Some problems related to the functioning of HPLC pumps.

Problems	Observable symptoms	Solution
	Solvent cabinet	
Blocked frit	No accurate mixing proportioning; serious shifts in retention pressure remains constant, but at a level different from the usual	Change frit or clean the blocked one with 60% nitric acid and ultrasounds
Air bubbles within solvent connecting tubes	Pressure and flow fluctuations	Degas the solvents off-line; purge the pumping system
Membrane permeable to gases broken in the vacuum-based degasser	Large flow and pressure variations; significant leaks in the online degasser	Replace degassing chamber
Defective vacuum pump in the degasser	Pressure and flow fluctuation; unstable baseline in chromatogram	Replace vacuum pump
	Pump	
Defective seal	Leak behind pump head; pressure and flow variations	Replace seal
Scratched piston surface	Leak behind pump head; pressure and flow variations	Replace piston
Defective inlet or outlet ball valve	Pulsed flow; very low flow; large "shark tooth" pressure variation; sinusoidal baseline	Clean ball valve in methanol–water mixture and ultrasound; change ball valve
Defective proportioning valve	Inaccurate composition of the mobile phase; irreproducible retention; large shifts in retention time within the chromatogram	Replace proportioning valve
Broken piston	No flow; visual observation	Replace piston and piston seal
Air entrapment within the pump body	Large flow and pressure variations	Purge pump
Seal incompatibility with one or more of the solvents	Excessive baseline noise, short column life time	Replace the seal with another seal compatible with the solvents used
	Mixers and damper	
Blocked frits (static mixers)	High-pressure regime within the system	Replace or clean frits
Burned electrical motor (dynamic mixer)	Erratic retention in chromatogram; small and random pressure variations	Replace electric motor
Broken membrane in the damper	Fluctuations in flow; large variations in pressure readouts (if pressure transducer is incorporated in the damper); mobile-phase contamination	Replace membrane

Troubleshooting SDS

Problems related to the functioning of SDS are highly varied, and they induce serious disturbances in a chromatographic system. A summary of commonly arising malfunctions is illustrated in Table 1.

Maintenance of SDS

To keep the SDS properly functioning, some actions are mandatory to be carried out during daily activity. Maintenance operations should be carried out with rigorous frequency, and interventions should be noted in a log.

The following actions are advisable:

1. When using mobile phases containing inorganic buffers, flush the system with water at the end of the working sessions, starting with the solvent container.
2. When the mobile phase contains concentrated inorganic buffer solutions, use an online piston/seal-washing accessory.
3. Replace piston seals at least once a year and pistons every two years.
4. Do not use hydrochloric acid solution as an aqueous component of the mobile phase.
5. Periodically inspect and wash the suction frits within the solvent container.
6. When inorganic buffers are used, filter the solvent through a 0.45 μm membrane before use.
7. Repeat SDS operational qualification after each mechanical intervention in the pump.
8. When changing from reversed-phase to normal-phase separation mechanism, flush the SDS intermediately with *i*-propanol.
9. If the pump is opened, replace the piston seal.

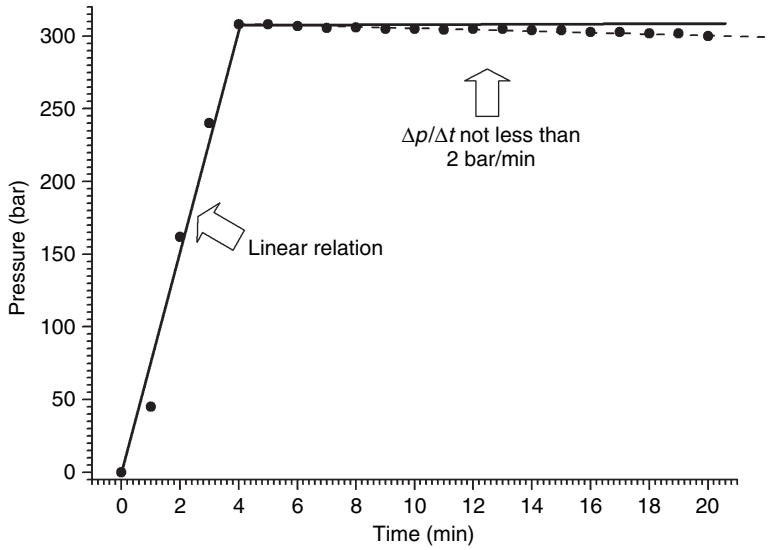

Fig. 14 Plot illustrating the tightness test for HPLC pumps.

OPERATIONAL QUALIFICATION OF AN SDS

Operational qualification of the SDS refers to the following aspects:

1. Pressure readout accuracy test
2. Tightness or leak test
3. Accuracy of the delivered flow rate
4. Gradient formation test
5. Dwell time test

Pressure Readout Accuracy Test

This test should be considered optional, as long as pressure indications are precise and accurate. Verification of the pressure accuracy relates to a null indication when the sensor is isolated from the system (usually the damper incorporating the pressure transducer is removed from the LC configuration) and the indication of a true value when a restriction is placed within the system instead of the column, generating a known pressure drop for a specified flow rate and a given density of the mobile phase.

Leak Test

The leak test formally checks for loss of tightness within the SDS. More specifically, it focuses on possible leaks at the piston seal level. To carry out the test, the SDS is isolated from the chromatographic system and is fed and flushed with degassed i-propanol. After an appropriate equilibration period, the flow rate is set to a low value (i.e., 0.1 ml/min) and the outlet of the SDS is blocked. Pressure readouts are monitored. On reaching a pressure regime of above 300 bar, the flow rate is set to zero and monitoring of pressure indications is continued for at least 5 min. Plotting the pressure readouts against time should generate a result analogous to the dependence in Fig. 14. There are two mandatory criteria to be fulfilled. The first relates to a linear pressure ramp observed during the first stage of the test (corresponding to the low flow rate). The second imposes a pressure variation on the plateau corresponding to the null flow rate with a slope ranging from –2 to 0 bar/min.

Accuracy of the Delivered Flow

This test requires additional equipment, such as certified analytical balance, certified thermometer, certified chronograph, and certified class A volumetric flask and a piece of stainless-steel tubing having 0.12 mm I.D. and 2 m length. The SDS is fed and flushed with degassed HPLC-grade water until full equilibration is achieved. The chromatographic column is replaced with a piece of stainless-steel tubing, acting as a restrictor, and the detector is taken out of the configuration. A flow rate value is set on the SDS controller, and the mobile phase is collected over a period of time at the other end of the restrictor, into a previously weighed volumetric flask. Collected effluent is checked for volume by weighing with an analytical balance. Density correction for water should be made if the measured temperature is outside the $25 \pm 1^{\circ}C$ interval. Alternatively, it is possible to check the time period needed to fill up the volumetric flask up to a specified mark, measured with a chronograph. Deviations higher than $\pm 1\%$ with respect to the set flow rate values should be considered as out of the acceptable limits. An ideal flow rate accuracy test should be run three times consecutively for at least three values covering the assumed operational interval of flow rates.

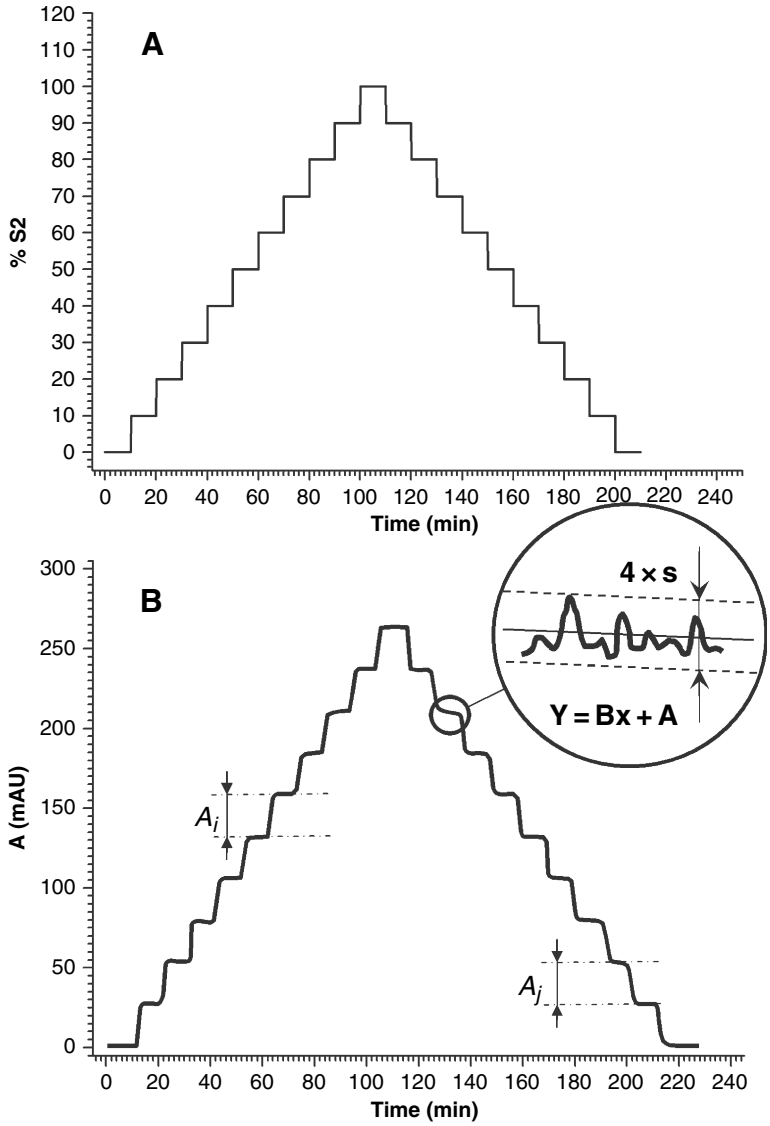

Fig. 15 The gradient test for operational qualification of high-pressure pumps in LC: A, typical gradient profile for checking the accuracy of gradient formation and B, result of the gradient formation test to be evaluated for documenting pump status.

Gradient Formation Test

The test uses two channels of the SDS. The first channel (S1) is fed with HPLC-grade water, while the second one (S2) carries aqueous 5% acetone solution (acetone acts as a UV-active tracer). Configuration of the chromatographic system is complete, including a UV-qualified detector monitoring at 254 nm wavelength. The chromatographic column is replaced by a restrictor. A gradient program is built up on the SDS controller, as illustrated in Fig. 15A. The gradient program consists of successive 10% stepwise increases of S2 volumetric proportion in the mobile phase, followed by at least 10 min of isocratic plateaus. After changing the mobile-phase composition from 100% S1 to 100% S2, the same procedure is used to go back to 100% S1. Baseline shift has to be recorded. The result is depicted in Fig. 15B.

In the data sheet, we need to measure A_i and A_j jumps. Relative standard deviations for A_i and A_j values should be lower than 0.5%. Accuracy of gradient formation is evaluated by calculating the mean optical absorbance value corresponding to each plateau. Conversion of the mean absorbance values into %S2 is carried out by applying the following relationship:

$$\%S2_{(Plateau)} = (\overline{A}_{(Plateau)} - \overline{A}_{(\%S2=0)}) \times \frac{100}{(\overline{A}_{(\%S2=100)} - \overline{A}_{(\%S2=0)})}$$

Biases against set values obtained for each plateau should not be higher than 0.5% for binary pumps (solvents

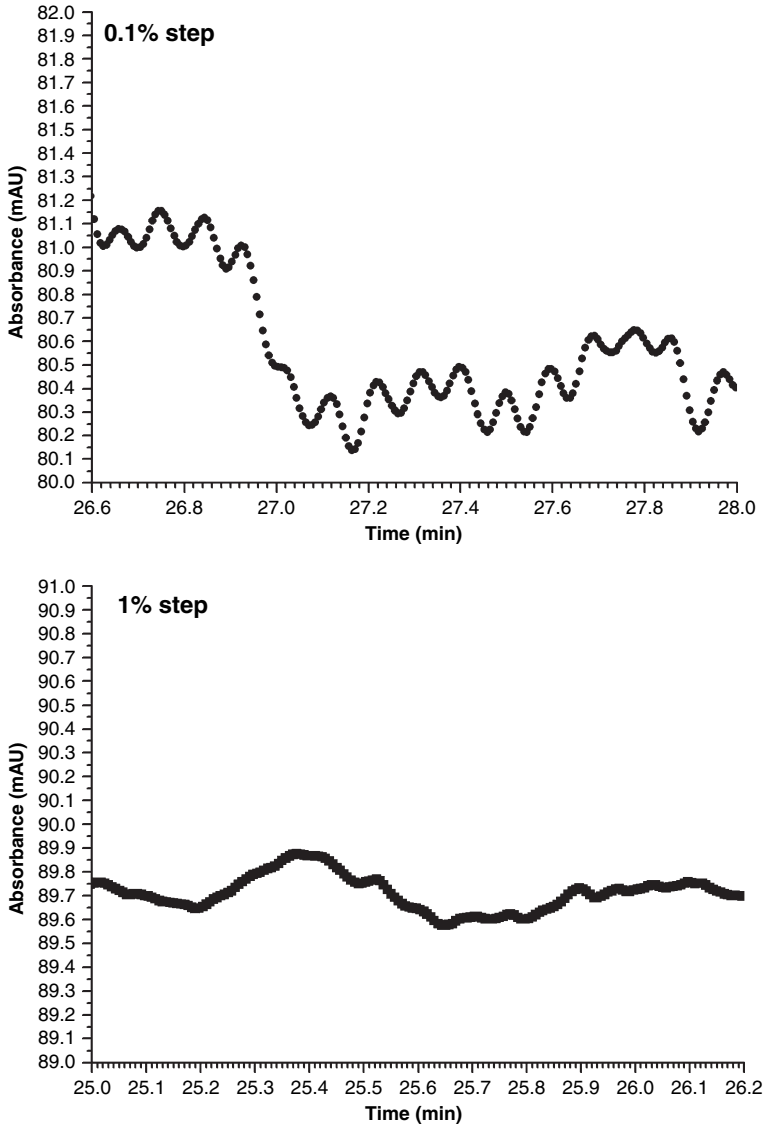

Fig. 16 Ripple of the HPLC pump on a constant-composition plateau during gradient formation test for 0.1% and 1% modification steps.

mixed at a high-pressure regime) and 0.7% for quaternary pumps (solvents mixed via proportioning valves at a low-pressure regime).

The linear regression applied to the data sets obtained over each plateau should be characterized by a slope as close as possible to 0. The normal dispersion (four times the standard deviation) of experimental data acquired over each plateau should correspond to a maximum 0.5% variation of the %S2 (such acceptance criteria is known as ripple). For SDS especially featured for sensitive applications (including micro or nano ones), the same algorithm may be applied for 1% or even 0.1% modification steps for the S2 channel. Reducing the amplitude of the step gradient should be compensated by a proportional increase of the UV tracer in the S2 channel. Some differences in ripple for 0.1% and 1% gradient steps are illustrated in Fig. 16 (note that the extension of the ordinate is the same and corresponds to 2 mAU).

Dwell Time Test

The dwell time test calculates the delay in gradient formation between the pump and the detection area (transit duration of a modification in mobile-phase composition over the chromatographic system). Chromatographic system characteristics are identical to those used during the gradient formation test. The only difference is in the application of the gradient profile. The stepwise gradient profile is replaced by a linear gradient of the S2 solvent (i.e., 5%/min). The time corresponding to the median of the height jump of the monitored baseline is determined (Fig. 17). The

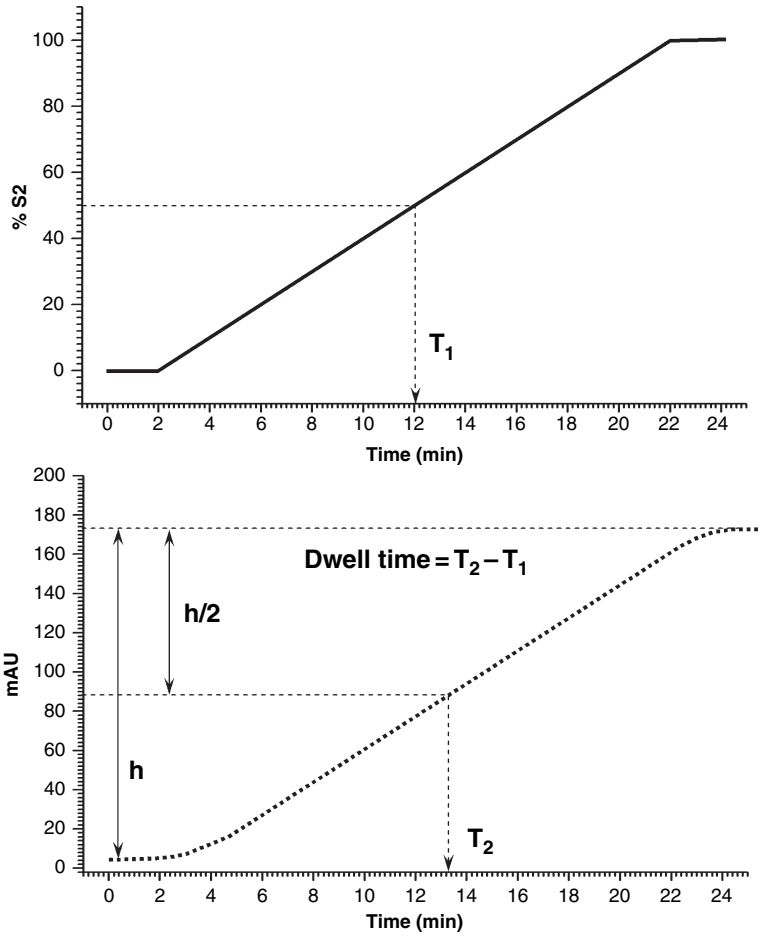

Fig. 17 Determination of the dwell time for HPLC systems: A, applied gradient and B, resulting data plot.

difference between the experimentally determined value and the theoretical time moment corresponding to the middle of the set gradient profile is called the dwell time. Dwell time should be as low as possible.

Operational qualification of an SDS should be repeated yearly. Each maintenance operation carried out during this period comprises the requalification of the SDS. Acceptance limits presented above should be considered as recommendations only. Other specific intervals may be imposed depending on the intrinsic quality of the tested systems and the characteristics of the applications running on these systems.

System suitability tests should be considered to certify that an SDS system operates accurately during each specific application. The system suitability test(s) are more often analyzed before the standard/sample sequences. Adequate acceptance criteria should be imposed. SDS functionality may be expressed in terms of absolute retention, chromatographic resolution between a critical pair, and noise amplitude. Generally, such criteria also include the column quality characteristics.

CONCLUSIONS

The desirable characteristics of an SDS for chromatographic applications have been presented. Design features of isocratic, low-pressure gradient, and high-pressure gradient SDSs as well as ultra-high-pressure hydraulic amplifiers are described, together with test protocols for ensuring their proper operation. An annual maintenance/validation program is recommended.

Purge-Backflushing Techniques in GC

Silvia Lacorte
Department of Environmental Chemistry, Chemical and Environmental Research Institute of Barcelona (IIQAB), Barcelona, Spain

Anna Rigol
Department of Analytical Chemistry, University of Barcelona, Barcelona, Spain

INTRODUCTION

Monitoring of volatile organic compounds (VOCs) in the environment has become a subject of concern because many of these compounds are toxic and persistent[1] and, in addition, are responsible for odor and taste problems in various types of water.[2] Their presence in water is mainly associated with industrial and urban discharges, chlorination of municipal wastewater, or on-land application of pesticides.[3] Analysis of VOCs has been performed using various techniques involving purge and trap (P&T), headspace, liquid–liquid extraction, solid-phase microextraction (SPME), or closed loop stripping analysis (CLSA).[4] However, P&T is the most commonly used technique because it permits the extraction of a wide range of analytes of different chemistries.

The present work is an overview of purge–trap, coupled to GC (P&T–GC) for the analysis of a wide range of VOCs. This technique has been applied to the determination, in water and solid matrices, of compounds that have sufficiently high volatility and low water solubility to be removed from water, e.g., aromatic hydrocarbons, alcohols, aldehydes, ketones, chloroaliphatic compounds, halogenated compounds, etc. In this technique, VOCs are sparged (purged) from the sample by bubbling inert gas for a fixed period of time. Purged sample components are trapped in a solid sorbent trap, generally containing Tenax®. Afterwards, the trap is rapidly heated and backflushed with helium to desorb the trapped sample components and introduce them directly into the GC. Desorption can be performed with cryofocusing, which lead to better peak shapes. Chromatographic techniques are then used to identify and quantify target compounds. This entry reports the optimization parameters of P&T–GC, such as sample volume, type of trap and analytical column, most widely used detectors for VOCs, and precautions that have to be taken with the sample handling and analysis of VOCs, in order to have a reliable result. Finally, the last section will be devoted to the monitoring of VOCs in environmental waters, comprising surface, groundwater, and industrial effluents.

OPTIMIZATION OF THE PURGING CONDITIONS

VOCs represent a group of contaminants of low reactivity, characterized for having low water solubility (from 0.05 to 19 g/L at 25°C), vapor pressures of 0.13–25 kPa (184 kPa for bromomethane), boiling points (bp) ranging from −13.9 to 180°C, and Henry's law constants varying, in general, from 0.1 to 3 kPa m^3/mol. The Henry's law constant is used to predict the movement of VOCs in the environment, but it is also a key factor to determine the stripping process during P&T analysis. Purgable compounds must have a sufficiently high Henry's law constant to enable extraction from water or solid matrix.

P&T is a standardized method dictated by the U.S. Environmental Protection Agency (US EPA), Series 500 and 600, and is extensively used due to its wide application range, good precision, absence of solvents, ease of coupling with GC, and the possibility of automation. When a MS detector is used, as described in US EPA Method 524.2,[5] more than 60 compounds can be analyzed in a single run. In this method, 5–25 ml of water is purged with He at a flow rate of 30–40 ml/min for 11 min at ambient temperature. Compounds are retained in a trap which is, thereafter, heated to 180–230°C to desorb the compounds either with or without cryofocusing. Fig. 1 shows a general scheme of a P&T device. The stripping efficiency depends on the partition coefficients of the compounds, while the efficiency in trapping the stripped VOCs depends on the type of compounds and on the retention characteristics of the trap. Several purge parameters can be optimized to afford higher sensitivity and selectivity. The most relevant are:

(i) Type of trap column.
(ii) Purged sample volume.
(iii) Gas flow rate and purging time.
(iv) Desorption conditions.

Typical values are indicated in Table 1.

The type of trap should be selected so that target analytes can be easily trapped and efficiently removed. It should provide good recoveries and good chromatograhic resolution so that VOCs can be precisely

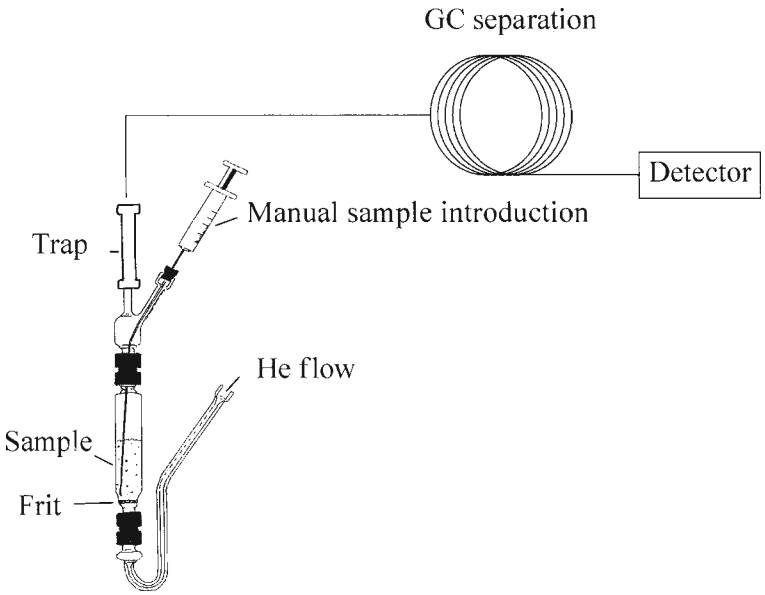

Fig. 1 Schematic of manual purge and trap GC for the analysis of volatile organic compounds in water.

quantified. Different types of trap sorbents are generally available in the market. Tenax® was widely adopted in 1970; it provided reliable results with high precision and detection limits at the μg/L levels.[5] It is stable at temperatures of 180°C, and, if properly cleaned, no background contamination is observed. The main drawback is that it may lead to losses of the more volatile compounds such as vinyl chloride. This problem can be overcome by the use of mixed sorbents with Tenax®-SilicaGel-Charcoal or Tenax®-activated charcoal (Spherocarb/Carvosieve). These sorbents permit trapping of compounds with higher molecular weights and support higher desorption temperatures, thereby enabling faster transfer of the analytes and better chromatographic separations. These combined phases also provide more reliable recoveries and allow the retention of a broader range of chemicals. The use of activated carbon and Tenax® is especially suitable to trap the lightest VOCs. Because the analytes are desorbed by backflushing the trap, compounds with high molecular weights are never in contact with the strong sorbent; thus, they are easily eluted. Baking of the trap is necessary to avoid memory effects between different samples. The baking temperature and time depends on the type of trap used. In general, the system is set at 230°C for 10 min, and, with these conditions, no carryover is generally observed.

Table 1 Parameters that can be optimized during P&T–GC/MS and common values used for the determination of a wide range of VOCs in waters.

P&T conditions		GC/MS conditions	
Type of trap	Tenax	Interface temperature	250°C
	Combined phases	Injector	Split/splitless ratio, 20:1
Sample volume	5–20 ml	Column	DB-624
Purge temperature	35°C	Temperature program	35°C (5 min) to 160°C at 7°C/min (1 min) and to 210°C at 5°C/min
Purge flow rate	20–50 ml/min		
Desorption temperature	180–250°C	Carrier	He, 1 ml/min (max. 1.2)
Desorption flow rate	3–4 ml/min	MS source temperature	200°C
Desorption time	1–5 min	Emmission current	100 μ;A
Bake time	10–15 min	Detector voltage	380 V
Bake temperature	230–280°C	Scan range	35–300 amu

The sample volume that can be purged depends on the system configuration and the type of sample to be analyzed. Foaming is one of the problems that arises when purging samples with high organic content. In such cases, the sample should be diluted, or a small sample volume should be sparged. In order to have a reproducible result, a 25 ml vessel should be filled with at least 5 ml and up to 15 ml. Lower volumes may lead to high intraday variations. Higher volumes often produce problems of clogging and contamination of the trap, and, often, this may lead to long cleaning requirements for achieving stable baselines. The sample volume is also strongly related to the type of matrix involved. For "clean" water samples, such as ground or drinking water, the established purged volume is 11–13 ml, according to the EPA methods. This permits the achievement of detection limits below 0.1 μg/L for most compounds. For industrial

effluents and charged waters, it is advisable to dilute the samples, e.g., to ~5–10%. This still permits detection of the analytes of interest and, at the same time, avoids interference. For soil and sediment samples, Kester[6] has described a protocol in which 4 g of sample is dispersed in methanol. After sonication for 1 min, followed by centrifugation, an aliquot of, generally, 100 μl is added to HPLC water which is purged as indicated above. This protocol is easy to perform, but suffers from low sensitivity, because only a small aliquot of the sample is analyzed. Increasing the volume of the extract results in a methanol peak that may overlap with some of the analytes of interest. More suitable are the specific configurations especially designed to purge solid samples, such as soils and sediments, which are provided with large bore tubes and orifices to prevent clogging and can be adapted for homogenizing the samples to provide precise extraction and delivery of analytes.

The gas flow rate and purging time must be optimized to achieve maximum sensitivity. According to EPA Method 524.2, a pre-fixed value is purged with He at 40 ml/min for 11 min. Higher purging time or flow may lead occasionally to lower limits of detection. However, precaution has to be exercised so as not to exceed the breakthrough volume, which would lead to poor recoveries.

Desorption of the analytes is accomplished by heating the trap to 180–200°C and simultaneously backflushing with an inert gas at 3–4 ml/min for around 4–5 min. If P&T is coupled to an MS system, the desorption time must be optimized to a minimum value so that it ensures the total desorption of the analytes from the trap without affecting the vacuum requirements of MS. The use of a cryogenic interface or cryofocusing is recommended to improve peak shapes. In this case, desorbed analytes are transferred to a cool trap set at −150°C. Desorption from the cool trap is performed by heating at 250–300°C; analytes are transferred into a capillary column. At this time, the temperature program of the GC starts. The injector is then programmed in a split ratio of 20:1.

Instrumentation is available from various suppliers, and sample loading can be performed either manually or by using automated systems. Automation implies no sample manipulation and the sources of errors are minimized. Being, therefore, a highly robust technique. The automated system permits a high sample throughput and is especially indicated in routine monitoring programs.[3] Recent work related to the use of P&T for survey of VOCs in surface waters indicates the suitability and robustness of the technique for long-term monitoring studies.[7]

SEPARATION USING VARIOUS COLUMNS

Typical columns for the analysis of VOCs are 60–75 m, 1–3 μm film thickness and high internal diameter (0.32, 0.53, or even 0.75 mm), which copes with the high flow rates often necessary to transfer the analytes from the purging device to the GC. When a wide bore column is used, chromatography can start with the onset of thermal desorption. For narrow bore columns, cryofocusing is advisable for better peak separation. GC/MS conditions are shown in Table 1. The injector is programmed in splitless mode for 2 min, and the column flow rate is maintained constant throughout acquisition. If MS is used, the flow rate should be adjusted to 1 ml/min.

For the analysis of VOCs, the most common column is a 75 m × 0.53 mm I.D. DB-624 fused silica capillary with 3 μm film thickness. A typical DB-624 permits detection from vinyl chloride (bp = −13.9°C and solubility = 2700 g/L) up to 2-chloronaphthalene (bp = 256°C), being therefore suitable to determine a wide range of compounds of different volatilities and polarities. For specific applications, e.g., control of trihalomethanes in drinking water, a short column of 30 m can be used, and the analysis time is, of course, reduced.

DETECTION TECHNIQUES

Depending on target analytes to be determined, different detectors can be used, e.g., electron capture detector which offers high sensitivity and selectivity for halogenated compounds,[8] MS which permits the analysis of a large number of compounds,[9] and atomic emission detector[10] which has been used for the analysis of environmental samples. Increasingly, however, P&T is coupled to GC with MS detection. This technique, described and validated in the EPA method 524.2,[5] permits the analysis of a large number of analytes within a single run, gives confirmatory data according to the acquisition technique (scan mode or selected ion monitoring, registering three ions per compound for confirmatory purposes), and, finally, gives limits of detection at the 0.1 or 0.01 μg/L level, ideal for the analysis of VOCs in environmental matrices. For these reasons, it is the sole technique that avoids false positives/negatives by unequivocally assuring the presence of analytes using a single column.

Irrespective of the detection method used, the analysis of VOCs often involves the presence of interferences in the chromatogram. This is normally due to VOCs present in the atmosphere, such as normal laboratory solvents (acetone, dichloromethane, chloroform, acetonitrile, or methanol) which can be detected, especially when using a universal detector such as a mass spectrometer which operates under vacuum. This problem is eliminated when the laboratory of analysis is free of solvents and is isolated, especially from urban areas.

QUALITY CONTROL OF THE PROCESS

Due to their high volatility, the analysis of VOCs is complex and needs extreme precautions, both with the samples

and with the preparation of standard solutions. The growing need to provide reliable results leads to quality control charts for a long-term guarantee of the data generated in each laboratory. Test samples and standard solutions should be kept at 4°C, but not for more than 15 days, in order to avoid sample degradation. In addition, samples should be gathered and kept without any headspace volume in order to avoid losses of the more volatile compounds. The analytical control charts involve both the analysis of reagent blanks and spiked blanks and demonstration of laboratory accuracy and precision. The analysis of reference and certified materials is highly recommended for method validation as indicated in a recent publication.[11]

On a routine basis, the use of internal standard and surrogate is necessary to ensure an accurate measurement of all VOCs throughout an analytical experiment. In optimizing the analytical method, it is essential to use one or more surrogates that will cover the whole range of compounds studied. Depending on the equipment used, the surrogate can be automatically pumped into the purging vessel. Otherwise, the surrogate mixture can be added directly to the sample with the minimum amount of solvent possible. If an internal standard is used, a split/splitless injector is needed for direct injection. However, this option is not advisable for quantification purposes as response factors of different test compounds may vary considerably. The most common compounds used as surrogates (or internal standard, depending on the application) are fluorbenzene, 1,2-dichlorobenzene d_4, bromochloromethane, difluorobenzene, chlorobenzene d_6, 4-bromofluorobenzene, and 1,4-dichlorobutane, among others, which elute at different intervals throughout the chromatogram. The surrogate will serve not only for method control but for analyte quantification, if properly selected.

Calibration curves should be prepared by spiking HPLC or groundwater samples with the test mixture at concentrations that permit a wide linear range. Normally, VOCs are found in environmental waters at 0.1–10 μg/L. Therefore, typical linear ranges are from 0.01 to 2–3 μg/L, with higher concentrations leading to poor linearity. "Charged" samples may have levels up to 200 μg/L and should be diluted prior to purging. In addition, a sample sequence should always include a blank sample, calibration standards or quality control standards, and samples. Blank analysis with HPLC water should be performed often (every four to five samples, depending on the matrix) to avoid carryover effects. It is crucial to have blanks which are void of interferences. Therefore, precautions must be taken in cleaning the glass material, which must be performed in an ultrasonic bath, followed by rinsing with acetone and, afterward, with distilled water. All sample preparation has to be done in a laboratory atmosphere that is free of solvents.

Quantification should be done using response factors or calibration curves. Using internal standards, variability with automated systems should not exceed 5–10%. In contrast, manual purging equipment connected to an MS can have up to 10–20% variation, depending on the compounds studied. External calibration is not recommended because a response variation of up to 50% can be detected. Limits of detection and recoveries of test compounds should be calculated in order to verify the suitability of the method for specific applications. Quality parameters of selected VOCs are indicated in Table 2. According to the US EPA, recoveries higher than 70% are acceptable. If using an internal standard for quantification, results should not be corrected by recovery. However, if external calibration is used, the percentage recovery should be indicated and used for quantification.

ENVIRONMENTAL APPLICATION

Large amounts of VOCs are generated in industrialized areas and eventually are discharged into surface waters or transported by the atmosphere. Once in the environment, VOCs can be absorbed into biota and soil, and, depending on soil characteristics, they can eventually migrate to groundwater by leaching.[1,7] Compounds detected depend on the type of waters analyzed. Several directives indicate the need to regulate the use and discharge of VOCs into the environment. Some widely used and toxic VOCs are included in priority pollutant lists, and stringent regulatory requirements have resulted in routine monitoring of these compounds in different types of waters. Solvents, such as chloroform, toluene, benzene, dichloromethane, and chlorethenes, are widely used in industrial manufacturing and organic synthesis. Others, chlorobenzenes or chloropropenes, are used as solvents in the formulation of fats and in dye manufacturing. The final fate and ecotoxicological impact that they may cause depends on the type of water and their concentrations.

Surface Waters

Extensive monitoring, carried out to determine halogenated VOCs in surface water from Portugal, revealed the presence of chloroform, tetrachloroethylene, trichloroethylene, and carbon tetrachloride in 13–50% of the samples analyzed, with a median of 0.1–0.3 μg/L, except for punctual contaminated areas close to big cities where these compounds were detected up to 18 μg/L. Also, high concentrations were found in agricultural areas, where solvents are used in many pesticide formulations.[8]

Table 2 Compounds studied, retention time (min), molecular weight (MW) and other two most abundant ions monitored (in bold, ion used for quantification), and calibration data obtained for spiked groundwater samples at 1 μg/L using automated P&T coupled to GC/MS.

—: No formation of additional fragment ions at 70 eV.
RT = retention time; %R = percentage of recovery; STD = standard deviation; LD = limit of detection.

In another study,[3] in which 41 compounds of different families were studied, 37 were detected at least once at levels between 0.01 and 28 μg/L, same with that which was found in a monitoring survey carried out in surface waters from Greece.[12]

Drinking Water

Other applications of P&T are related to the control of trihalomethanes in finished drinking water. Fig. 2 shows a typical profile where chloroform, bromodichloromethane, dibromochloromethane, and bromoform were detected at 80–100 μg/L. The technique, when coupled to MS, can also be applied to identify compounds responsible for taste and odor problems in water.[13]

Groundwater Samples

Groundwater is a stable reservoir of organic pollutants. An extensive monitoring study carried out in the United States revealed that 7% of the ambient

groundwater resources of the United States contain at least one VOC at levels of 0.2 μg/L and, in urban areas, 47% of the sampled wells were positive.[7] A compound now of interest is methyl *tert*-butyl ether (MTBE), which is the most widely used ether oxygenate added to gasoline as an octane booster.[14] MTBE enters the environment during all phases of the petroleum fuel cycle. Due to its high solubility (25–50 g/L), low K_{ow} (0.94–1.43), and Henry's law constant (55.3 Pa m^3/mol), MTBE remains dissolved in surface water, where it can volatilize into the atmosphere. A small fraction can partition into soil and eventually reach groundwater where it can persist for more than 200 days, causing odor problems at low concentrations.

Industrial Effluents

A recent study indicated that more than 50 VOCs were found in effluents from high-tech industries, leading to pollution of surrounding river waters and inducing bad atmospheric odor. Benzene, toluene, chloroform, and dichloromethane were the major contributors of industrial discharges and were detected in 30% or more of the analyzed samples.[15]

CONCLUSIONS

The analysiss of VOCs in water and solid samples is complex due to the large number of compounds to be analyzed and because precaution has to be taken to provide accurate and reliable results. The use of P&T–GC/MS is the most adequate for trace analysis of VOCs because limits of detection at the ng/L levels can be achieved and confirmatory analysis can be performed. Although P&T is a well-established technique, several analytical parameters can be optimized to obtain high sensitivity and selectivity. For the specific target analytes, method optimization and quality assurance are necessary. The main drawbacks of this technique result from the fact that high purity gases are required and that the system can be easily polluted when charged samples are analyzed, producing carry over effects. These problems can be eliminated if precautions are taken in optimizing the analytical conditions prior to analysis.

Quantitation by External Standard

Tao Wang
Merck Research Laboratories, Rahway, New Jersey, U.S.A.

INTRODUCTION

An important feature of modern high-performance liquid chromatography (HPLC) is its excellent quantitation capability. HPLC can be used to quantify the major components in a purified sample, the components of a reaction mixture, and trace impurities in a complex sample matrix. The quantitation is based on the detector response with respect to the concentration or mass of the analyte. In order to perform the quantitation, a standard is usually needed to calibrate the instrument. The calibration techniques include an *external standard method*, an internal standard method, and a standard addition method. For cases in which a standard is not available, a method using normalized peak area can be used to estimate the relative amounts of small impurities in a purified sample.

In this entry, only the external standard method is discussed. Detailed discussions of other quantitation methods can be found in other entries of this encyclopedia or in Ref.[1]

DISCUSSION

The external standard method is the most general method for determination of the concentration of an analyte in an unknown sample. It involves the construction of a calibration plot using external standards of the analyte, as shown in Fig. 1. A fixed volume of each standard solution of known concentration is injected into the HPLC and the peak response of each injection is plotted versus the concentration of the standard solution. The standards used are called "external standards" because they are prepared and analyzed separately from the unknown sample(s). After constructing the calibration plot, the unknown sample is prepared, injected, and analyzed in exactly the same manner. The concentration of the analyte in the unknown sample is then determined from the calibration plot or from the response factor of the unknown sample versus that of the standard.

If the calibration plot is linear, the concentration of the analyte in the unknown sample can be determined based on the linear equation of the calibration plot:

$$Y = a + bX \tag{1}$$

where Y is the peak response of the analyte, X is the concentration of the analyte, a is the intercept, and b is the slope. The concentration X is

$$X = \frac{Y - a}{b} \tag{2}$$

In the example shown in Fig. 1, where $a = 0$ and $b = 2 \times 10^6$ the concentration (X) of the unknown sample (U), which shows a peak response of $Y = 500{,}000$, is determined to be 0.25 mg/ml using Eq. 2.

Alternatively, after the linear calibration range has been established, the concentration of an unknown sample can be determined using the *response factor*. A response factor (RF), sometimes called a *sensitivity factor*, is determined from a standard within the linear calibration range as:

$$RF = \frac{\text{Standard peak response}}{\text{Standard concentration}} \tag{3}$$

If two or more standards of different concentrations within the linear range are measured, the RF value can be taken as the average value of the response factors for all these standards to minimize the uncertainty in determining the RF. In the example shown in Fig. 1, the RF is the slope of the calibration plot and equals 2×10^6 for all three standards because the plot is linear with a zero intercept.The concentration (X) of the analyte in the unknown sample (U) can be calculated as

$$X = \frac{\text{Sample peak response}}{RF} \tag{4}$$

which is $500{,}000/(2 \times 10^6)$ 0.25 mg/ml. When RF is used for quantitation, the concentration(s) of the standard(s) selected should be similar to the expected concentration of the unknown sample.

In the aforementioned techniques, it is important that the calibration plot be linear over certain concentration range and the concentration of the sample fall within this linear range (as shown in Fig. 1) so that an interpolation can provide accurate measurement of the sample concentration. If the concentration of the sample falls outside the established linear range, extrapolation of the calibration plot should be used with caution. To ensure accuracy, it is recommended that dilution be carried out to bring the concentration of the sample into the linear range prior to the analysis.

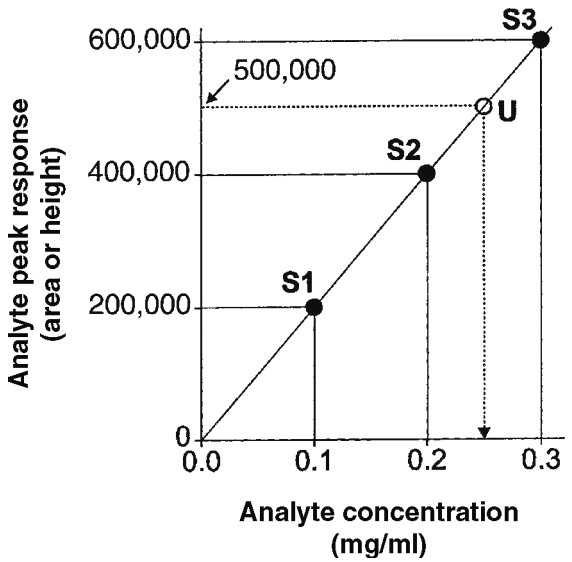

Fig. 1 Linear calibration plot for external standard method. S1, S2, and S3: external standards for calibration; U: unknown sample.

In unusual cases, where the calibration plot is not linear, the concentration of an unknown sample can be determined by interpolation of results between standards or by fitting the results of the standards into a non-linear equation and using the non-linear equation to calculate the concentration of the unknown sample. When interpolation is used, the concentrations of the two standards used to bracket the sample should be as close to the concentration of the sample as possible to enhance the accuracy of the result. When a non-linear equation is used, a large enough number of standards is needed in order to more accurately determine the non-linear equation. Obviously, quantitation in a non-linear range involves more labor and presents a higher potential of error. Therefore, this approach is used only when there are no other alternatives.

In the external standard method,it is critical that the injections are precise. With modern instruments which employ autosamplers, adequate precision (typically $\leq$0.5%) can be achieved using full-loop injection. Poorer injection precision is normally associated with manual injections or with partial-loop injections by autosamplers.

It is also critical to keep the chromatographic conditions (such as flow rate and column temperature) constant during the analysis of all standards and samples. Fluctuations of the chromatographic conditions during the analysis can cause inconsistent peak responses, which, in turn, will cause quantitation error. It is common that the HPLC system is tested using standards to ensure that the system is performing properly and reliably prior to the analysis of samples. This procedure of validating system performance is referred to as "system suitability test."

Detailed discussions on sources of error related to the external standard method, including sampling and sample preparation, chromatographic effects, and data system effects, can be found in Ref.[1] Ref.[2] presented detailed discussions on the precision in HPLC.

The peak response used for quantitation can be either peak height or peak area. Peak height is usually used when incomplete resolution of the analyte peak is encountered, because the peak height measurement is subject to less interference from the adjacent overlapping peaks. On the other hand, peak area is less influenced by changes in instrumental or chromatographic parameters. The choice of peak height or peak area for quantitation requires the understanding of the effects of chromatographic parameters on the precision of each approach. The influence of certain chromatographic parameters on the precision of peak height and peak area methods, as well as the preferred method among the two when various chromatographic parameters are subject to change, are discussed in detail in Refs.[1,3]

More thorough discussions on external standard method can be found in Refs.[1,3,4]

Quantitation by Internal Standard

J. Vial
A. Jardy
Analytical Chemistry Department, City of Paris Industrial Physics and Chemistry Higher Educational Institution (ESPCI), Paris, France

INTRODUCTION

The principle involved is the addition of a known quantity of a foreign substance (internal standard) to the analyzed sample, the response coefficient of which is known or arbitrarily fixed. Quantitation by the internal standard method enables one to compensate for errors in the injected volume.[1]

The same quantity of constituent I (internal standard) is added both to the reference solution and to the solution to be analyzed. I is supposed to interfere with none of the constituents present in the sample. This methodology is based on the constancy of the ratios between the proportionality coefficient observed on both chromatograms (determination and calibration).

ASSAY CHROMATOGRAM

The assay solution includes precisely and accurately known weights of the product to be determined and of the internal standard. An injection of an approximately known volume of this solution is made. From the resulting chromatogram, areas of peaks corresponding to the internal standard and to the product(s) to be analyzed are measured. Let M_E be the weight of the sample including solute D, the assay of which τ_D is to be determined, M_I be the weight of the internal standard I, A_D be the peak area of solute D, A_I be the peak area of the internal standard, K_D be the response coefficient of the product D, and K_I be the response coefficient of the internal standard. It is possible to establish the following relationships:

$$M_E\tau_D = K_D A_D \tag{1}$$

$$M_I = K_I A_I \tag{2}$$

and

$$\tau_D = \frac{K_D}{K_I}\frac{A_D}{A_I}\frac{M_I}{M_E} \tag{3}$$

CALIBRATION CHROMATOGRAM

The protocol is similar to the calibration solution, including accurately and precisely known weights of reference and internal standard (dilutions must be analogous to those of the assay chromatogram). An injection of an approximately known volume of this calibration solution is made. From the resulting chromatogram, areas of peaks corresponding to the internal standard and to the reference material are measured. Let M_R be the weight of the reference material, the assay of which τ_R is known, M_I' be the weight of the internal standard I, A_R be the peak area of the reference material, and A_I' be the peak area of the internal standard. Thus, it is possible to establish the following relations:
