A methanizer for reducing carbon dioxide to methane with a catalyst obtained from $Ni(NO_3)_2 \cdot 6H_2O$ and SiO_2 is described.[10] The carrier gas containing hydrogen flows through the six-port valve to a microreactor containing a nickel catalyst (Fig. 12). In position A, a sample of gas containing carbon dioxide is injected into a methanizer, reduced on a nickel catalyst and injected into a chromatographic column. The switching of the six-port valve to position B makes a stream of pure hydrogen pass through the catalyst in the microreactor for its reduction.

GC/MS Systems

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

Despite the speed and accuracy of contemporary analytical techniques, the use of more than one, separately and in sequence, is still very time-consuming. To reduce the analysis time, many techniques are operated concurrently, so that two or more analytical procedures can be carried out simultaneously. The tandem use of two different instruments can increase the analytical efficiency, but due to unpredictable interactions between one technique and the other, the combination can be quite difficult in practice. These difficulties become exacerbated if optimum performance is required from both instruments. The mass spectrometer was a natural choice for the early tandem systems to be developed with the gas chromatograph, as it could easily accept samples present as a vapor in a permanent gas.

BACKGROUND INFORMATION

The first GC/MS system was reported by Holmes and Morrell in 1957, only 4 years after the first description of GC by James and Martin in 1953. The column eluent was split and passed directly to the mass spectrometer. Initially, only packed GC columns were available and thus the major problem encountered was the disposal of the relatively high flow of carrier gas from the chromatograph (~25 ml/min or more). These high flow rates were in direct conflict with the relatively low pumping rate of the MS vacuum system. This problem was solved either by the use of an eluent split system or by employing a vapor concentrator. A number of concentrating devices were developed (e.g., the jet concentrator invented by Ryhage and the helium diffuser developed by Biemann).

The jet concentrator consisted of a succession of jets that were aligned in series but separated from each other by carefully adjusted gaps. The helium diffused away in the gap between the jets and was removed by appropriate vacuum pumps. In contrast, the solute vapor, having greater momentum, continued into the next jet and, finally, into the mass spectrometer. The concentration factor was about an order of magnitude and the sample recovery could be in excess of 25%.

The Biemann concentrator consisted of a heated glass jacket surrounding a sintered glass tube. The eluent from the chromatograph passed directly through the sintered glass tube and the helium diffused radially through the porous walls and was continuously pumped away. The helium stream enriched with solute vapor passed into the mass spectrometer. Solute concentration and sample recovery were similar to the Ryhage device, but the apparatus was bulkier although somewhat easier to operate. An alternative system employed a length of porous polytetrafluorethylene (PTFE) tube, as opposed to one of sintered glass, but otherwise functioned in the same manner.

The introduction of the open-tubular columns eliminated the need for concentrating devices as the mass spectrometer pumping system could cope with the entire column eluent. Consequently, the column eluent could be passed directly into the mass spectrometer and the total sample can enter the ionization source. The first mass spectrometer used in a gas chromatography GC/MS mass Spectrometry tandem system was a rapid-scanning magnetic sector instrument that easily provided a resolution of one mass unit. Contemporary mass spectrometers have vastly improved resolution and the most advanced system (involving the triple quadrupole mass spectrometer) gives high in-line sensitivity, selectivity, and resolution.

IONIZATION TECHNIQUES FOR GC/MS

There are a number of ionization processes that are used, probably the most important being electron-impact ionization. Electron-impact ionization is a harsh method of ionization and produces a range of molecular fragments that can help to elucidate the structure of the molecule. Nevertheless, although molecular ions are usually produced that are important for structure elucidation, sometimes only small fragments of the molecule are observed, with no molecular ion invoking the use of alternative ionizing procedures. A diagram showing the configuration of an electron-impact ion source is shown in Fig. 1. Electrons, generated by a heated filament, pass across the ion source to an anode trap. The sample vapor is introduced in the center of the source and the solute molecules drift, by diffusion, into the path of the electron beam. Collision with the electrons produce molecular ions and ionized molecular fragments, the size of which is determined by the energy of the electrons. The electrons are generated by thermal emission from a heated tungsten or rhenium filament and accelerated by an appropriate potential to the anode trap. The magnitude of the collection potential may range from 5 to 100 V, depending on the electrode geometry and the

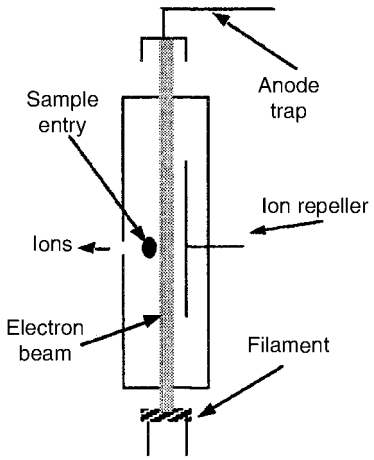

Fig. 1 An electron-impact ionization source.

ionization potential of the substances being ionized. The ions that are produced are driven by a potential applied to the ion-repeller electrode into the accelerating region of the mass spectrometer.

Unfortunately, with electron-impact ionization, there is a frequent absence of a molecular ion in the mass spectrum, which makes identification uncertain and complicates structure elucidation. One solution is to employ chemical ionization. If an excess of an appropriate reagent gas is fed into an electron-impact source, an entirely different type of ionization takes place. As the reagent gas is in excess, the reagent molecules are preferentially ionized and the reagent ions then collide with the sample molecules and produce sample + reagent ions or, in some cases, protonated ions. In this type of ionization, very little fragmentation takes place and parent ions + a proton or + a molecule of the reagent gas are produced. Little modification to the normal electron impact source is required and an additional conduit to supply the reagent gas is all that is necessary.

Chemical ionization was first observed by Munson and Field, who introduced it as an ionization procedure in 1966. A common reagent gas is methane and the partial pressure of the reagent gas is arranged to be about two orders of magnitude greater than that of the sample. The process is gentle and the energy of the most reactive reagent ions never exceeds 5 eV. Consequently, there is little fragmentation, and the most abundant ion usually has a *m*/*z* value close to that of the singly-charged molecular ion. The spectrum produced depends strongly on the nature of the reagent ion; thus, different structural information can be obtained by choosing different reagent gases. This adds another degree of freedom in the operation of the mass spectrometer. Using methane as the reagent ion, the following reagent ions can be produced:

$$CH_4 \rightarrow CH_4^+, CH_3, CH_2^+$$
$$CH_4^+ + CH_4 \rightarrow CH_5^+ + CH_3$$
$$CH_3^+ + CH_4 \rightarrow C_2H_4^+ + H_2$$

Other reactions can occur that are not useful for ionization but, in general, these are in the minority. The interaction of positively charged ions with the uncharged sample molecules can also occur in a number of ways, and the four most common are as follows:

1. Proton transfer between the sample molecule and the reagent ion

   $$M + BH^+ \rightarrow MH^+ + B$$

2. Exchange of charge between the sample molecule and the reagent ion

   $$M + X^+ \rightarrow M^+ + X$$

3. Simple addition of the sample molecule to the reagent ion

   $$M + X^+ \rightarrow MX^+$$

4. Anion extraction

   $$AB + X^+ \rightarrow B^+ + AX$$

As an example, ions, which are formed when methane is used as the reagent gas, will react with a sample molecule largely by proton transfer; that is,

$$M + CH_5^+ \rightarrow MX^+ + CH_4$$

Some reagent gases produce more reactive ions than others and will produce more fragmentation. For example, methane produces more aggressive reagent ions than isobutane. Consequently, whereas methane ions produce a number of fragments by protonation, isobutane, by a similar protonation process, will produce almost exclusively the protonated molecular ion. This is shown in the mass spectra of methyl stearate in Fig. 2. Spectrum (a) was produced using methane as the reagent gas and exhibits fragments other than the protonated parent ion. In contrast, spectrum b obtained with butane as the reagent gas, exhibits the protonated molecular ion only. Continuous use of a chemical ionization source causes significant source contamination, which impairs the performance of the spectrometer and thus the source requires cleaning by baking-out fairly frequently. Retention data on two-phase systems coupled with matching electron-impact mass spectra or confirmation of the molecular weight from chemical ionization spectra are usually sufficient to establish the identity of a solute.

The inductively coupled plasma (ICP) source is used largely for specific element identification and evolved from the ICP atomic emission spectrometer; it is probably more commonly employed in LC/MS than GC/MS. In GC/MS, the ICP ion source is used in the assay of

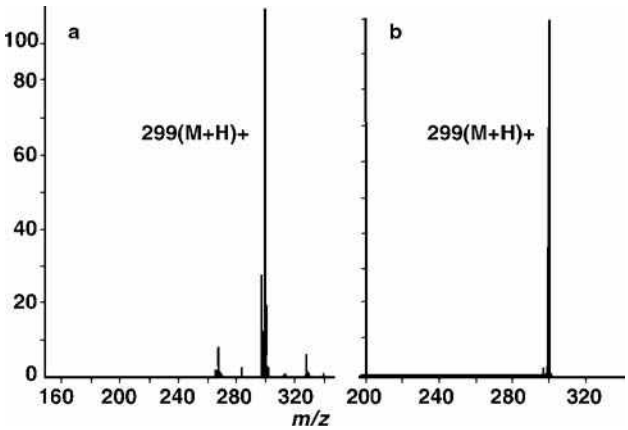

Fig. 2 Mass spectrum of methyl stearate produced by chemical ionization.

organometallic materials and in metal speciation analyses. The ICP ion source is very similar to the volatilizing unit of the ICP atomic emission spectrometer, and a diagram of the device is shown in Fig. 3. The argon plasma is an electrodeless discharge, often initiated by a Tesla coil spark, and maintained by radio-frequency (rf) energy, inductively coupled to the inside of the torch by an external coil, wrapped around the torch stem.The plasma is maintained at atmospheric pressure and at an average temperature of about 8000 K. The ICP torch consists of three concentric tubes made from fused silica. The center tube carries the nebulizing gas, or the column eluent, from the gas chromatograph. Argon is used as the carrier gas, and the next tube carries an auxiliary supply of argon to help maintain the plasma and also to prevent the hot plasma from reaching the tip of the sample inlet tube. The outer tube also carries another supply of argon at a very high flow rate that cools the two inner tubes and prevents them from melting at the plasma temperature. The coupling coil

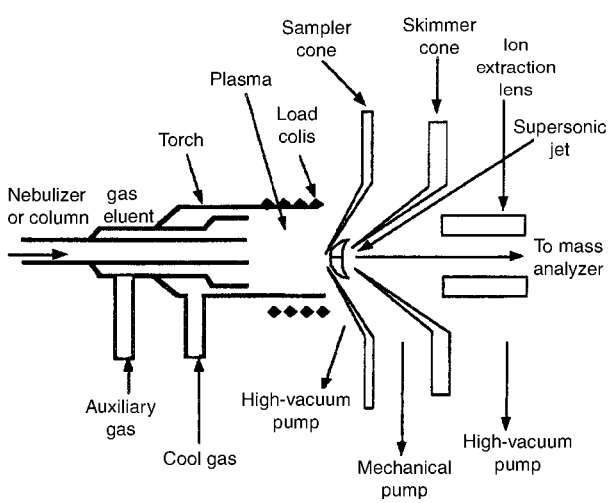

Fig. 3 ICP mass spectrometer ion source.

consists of two to four turns of water cooled copper tubing, situated a few millimeters behind the mouth of the torch. The rf generator produces about 1300 W of rf at 27 or 40 MHz, which induces a fluctuating magnetic field along the axis of the torch. Temperature in the induction region of the torch can reach 10,000 K, but in the ionizing region, close to the mouth of the sample tube, the temperature is 7000–9000 K.

The sample atoms account for less than of the total number of atoms present in the plasma region; thus, there is little or no self-quenching. At the plasma temperature, over 50% of most elements are ionized. The ions, once formed, pass through the apertures in the apex of two cones. The first has an aperture about 1 mm inner diameter (I.D.) and ions pass through it to the second skimmer cone. The space in front of the first cone is evacuated by a high-vacuum pump. The region between the first cone and the second skimmer cone is evacuated by a mechanical pump to about 2 mbar and, as the sample expands into this region, a supersonic jet is formed. This jet of gas and ions flows through a slightly smaller orifice into the apex of the second cone. The emerging ions are extracted by negatively charged electrodes (−100 to −600 V) into the focusing region of the spectrometer, and then into the mass analyzer.

The ICP ion source has the advantages that the sample is introduced at atmospheric pressure, the degree of ionization is relatively uniform for all elements, and singly-charged ions are the principal ion product. Furthermore, sample dissociation is extremely efficient and few, if any, molecular fragments of the original sample remain to pass into the mass spectrometer. High ion populations of trace components in the sample are produced, making the system extremely sensitive. Nevertheless, there are some disadvantages: the high gas temperature and pressure evoke an interface design that is not very efficient and only about 1% of the ions that pass the sample orifice pass through the skimmer orifice. Furthermore, some molecular ion formation does occur in the plasma, the most troublesome being molecular ions formed with oxygen. These can only be reduced by adjusting the position of the cones, so that only those portions of the plasma where the oxygen population is low are sampled.

Although the detection limit of an ICP/MS is about 1 part in a trillion, as already stated, the device is rather inefficient in the transport of the ions from the plasma to the analyzer. Only about 1% pass through the sample and skimming cones and only about 10^{-6} ions will eventually reach the detector. One reason for ion loss is the diverging nature of the beam, but a second is due to space-charge effects, which, in simple terms, is the mutual repulsion of the positive ions away from each other. Mutual ion repulsion could also be responsible for some non-spectroscopic interelement interference (i.e., matrix effects). The heavier ions having greater momentum suffer less dispersion than

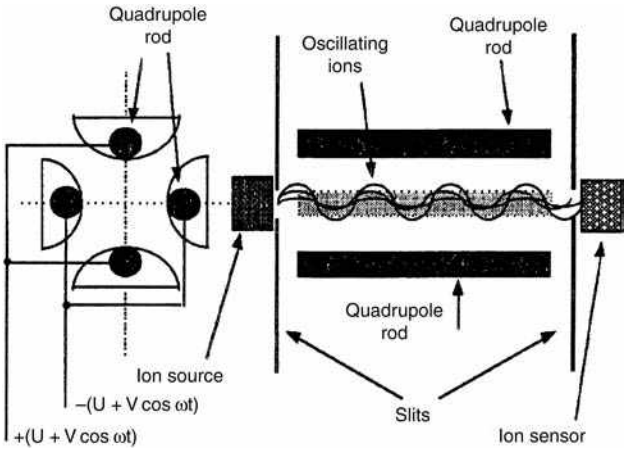

Fig. 4 Quadrupole mass spectrometer.

the lighter elements, thus causing a preferential loss of the lighter elements.

MASS SPECTROMETERS FOR MS/GC TANDEM OPERATION

The most common mass spectrometer used in GC/MS systems is the quadrupole mass spectrometer, either as a single quadrupole or as a triple quadrupole, which can also provide MS/MS spectra. A diagram of a quadrupole mass spectrometer is shown in Fig. 4. The operation of the quadrupole mass spectrometer is quite different from that of the sector instrument. The instrument consists of four rods which must be precisely straight and parallel and so arranged that the beam of ions is directed axially between them. Theoretically, the rods should have a hyperbolic cross section, but in practice, less expensive cylindrical rods are nearly as satisfactory. A voltage comprising a DC component (U) and a rf component (V_0 cos wt) is applied between adjacent rods, opposite rods being electrically connected. Ions are accelerated into the center, between the rods, by a potential ranging from 10 to 20 V. Once inside the quadrupole, the ions oscillate in the x and y dimensions induced by the high-frequency electric field. The mass range is scanned by changing U and V_0 while keeping the ratio U/V_0 constant. The quadrupole mass spectrometer is compact, rugged, and easy to operate, but its mass range does not extend to very high values. However, under certain circumstances, multiply-charged ions can be generated and identified by the mass spectrometer. This, in effect, increases the mass range of the device proportionally to the number of charges on the ion.

The quadrupole mass spectrometer can also be constructed to provide MS/MS spectra by combining three quadrupole units in series. A diagram of a triple quadrupole mass spectrometer is shown in Fig. 5. The sample enters

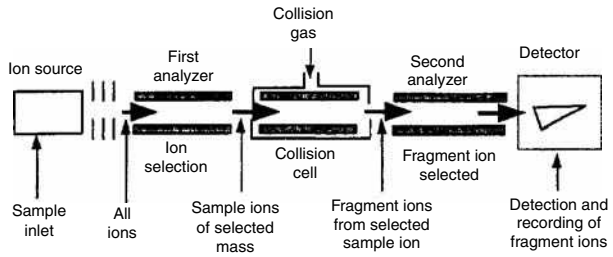

Fig. 5 Triple quadrupole mass spectrometer.

the ion source and is usually fragmented by either an electron-impact or chemical ionization process. In the first analyzer, the various charged fragments are separated in the usual way, which then pass into the second quadrupole section, sometimes called the collision cell. The first quadrupole behaves as a straightforward mass spectrometer. Instead of the ions passing to a sensor, the ions pass into a second mass spectrometer and a specific ion can be selected for further study. In the center quadrupole section, the selected ion is further fragmented by collision ionization and the new fragments pass into the third quadrupole, which functions as a second analyzer. The second analyzer resolves the new fragments into their individual masses producing the mass spectrum. Thus, the exclusive mass spectrum of a particular molecular or fragment ion can be obtained from the myriad of ions that may be produced from the sample in the first analyzer. This is an extremely powerful analytical system that can handle exceedingly complex mixtures and very involved molecular structures.

Another form of the quadrupole mass spectrometer is the ion trap detector, which has been designed more specifically as a chromatography detector than for use as a tandem instrument. The electrode orientation of the quadrupole ion trap mass spectrometer is shown in Fig. 6. The ion trap mass spectrometer has an electrode arrangement that consists of three cylindrically symmetrical electrodes comprised of two end caps and a ring. The device is small, the opposite internal electrode faces being only 2 cm apart. Each electrode has accurately machined hyperbolic internal faces. An rf voltage together with an additional DC voltage is applied to the ring, and the end caps are grounded. The rf voltage causes rapid reversals of field direction, so any ions are alternately accelerated and decelerated in the axial direction and vice versa in the radial direction. At a given voltage, ions of a specific mass range are held oscillating in the trap. Initially, the electron beam is used to produce ions, and after a given time, the beam is turned off. All the ions, except those selected by the magnitude of the applied rf voltage, are lost to the walls of the trap, and the remainder continue oscillating in the trap. The potential of the applied rf voltage is then increased, and the ions sequentially assume unstable trajectories and

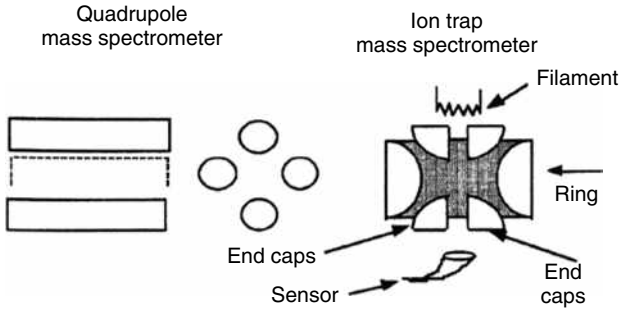

Fig. 6 Pole arrangement for the quadrupole and ion trap mass spectrometers.

leave the trap via the aperture to the sensor. The ions exit the trap in order of their increasing m/z values. The first ion trap mass spectrometers were not very efficient, but it was found that the introduction of traces of helium to the ion trap significantly improved the quality of the spectra. The improvement appeared to result from ion-helium collisions that reduced the energy of the ions and allow them to concentrate in the center of the trap. The spectra produced are quite satisfactory for solute identification by comparison with reference spectra. However, the spectrum produced for a given substance will probably differ considerably from that produced by the normal quadrupole mass spectrometer.

The time-of-flight mass spectrometer was invented many years ago, but the performance of the modern version is greatly improved. A diagram of the time-of-flight mass spectrometer is shown in Fig. 7. In a time-of-flight mass spectrometer, the following relationship holds:

$$t = \left(\frac{m}{2zeV}\right)^{1/2} L$$

where t is the time taken for the ion to travel a distance L, V is the accelerating voltage applied to the ion, and L is the distance traveled by the ion to the ion sensor.

The mass of the ion is directly proportional to the square of the transit time to the sensor. The sample is volatilized into the space between the first and second electrodes and a microsecond burst of electrons is allowed to produce ions. An extraction voltage is then applied for another short time period, which, as those further from the second electrode will experience a greater force than those closer to the second electrode, will focus the ions. After focusing, the accelerating potential (V) is applied for about 100 ns so that all the ions in the source are accelerated almost simultaneously. The ions then pass through the third electrode into the drift zone and are then collected by the sensor electrode. The particular advantage of the time-of-flight mass spectrometer is that it is directly compatible with surface desorption procedures. Consequently, it can be employed with laser-desorption and plasmadesorption techniques.

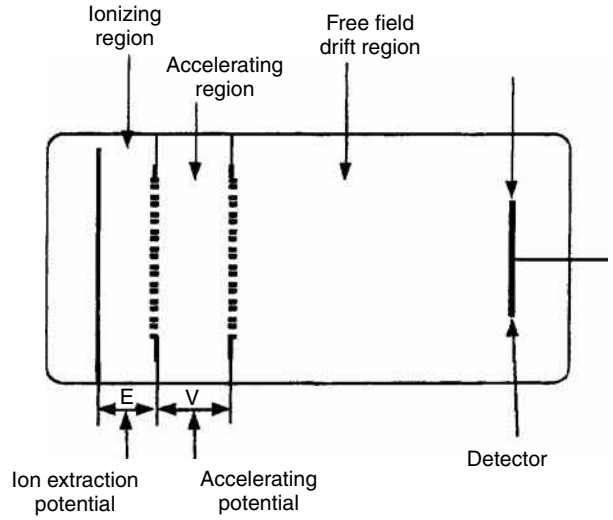

Fig. 7 The time-of-flight mass spectrometer.

An excellent discussion on general organic mass spectrometry is given in *Practical Organic Mass Spectrometry* edited by Chapman.[1]

The combination of the gas chromatograph with the single quadrupole mass spectrometer or with the triple quadrupole mass spectrometer are the most commonly used tandem systems. They are used extensively in forensic chemistry, in pollution monitoring and control, and in metabolism studies. The quadrupole mass spectrometers provide both high sensitivity and good mass spectrometric resolution. They can be readily used with open-tubular columns, and an example of the use of the single quadrupole monitoring a separation from an open-tubular column is shown in Fig. 8. The column was 30 m long with a 0.25 mm I.D. and carried a 0.5 mm film of stationary

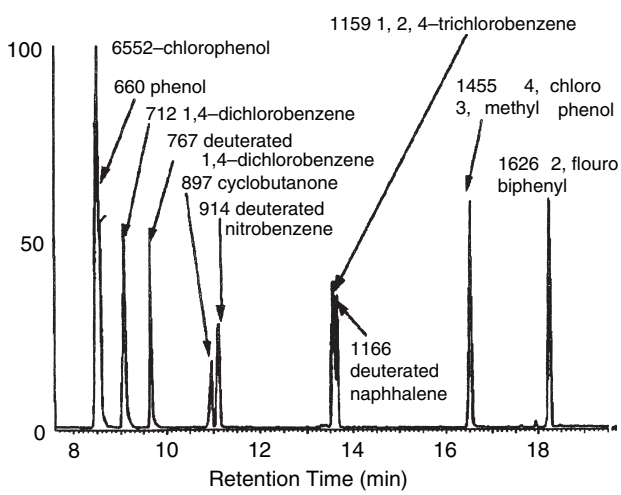

Fig. 8 A separation from an open-tubular column monitored by a single quadrupole mass spectrometer.

Source: From On-line preconcentration of aqueous samples for gas chromatographic – mass spectrometric analysis, in Analyst.[2]

phase.A 1 ml sample was used and the column was programmed from 50°C to 300°C at 10°C/min.

An elegant example of the use of GC/MS in the analysis of pesticides in river water is given by Vreuls et al.[2] A 1-ml sample was collected in an LC sample loop and the internal standard added. The sample was then displaced through a short column 1 cm long with a 2 mm I.D. packed with 10 mm particles of a proprietary PLRP-S adsorbent (styrene–divinylbenzene copolymer) by a stream of pure water.The extraction column was then dried with nitrogen and the adsorbed materials displaced into a gas chromatograph with 180 ml of ethyl acetate. The sample was passed through a short retention gap column and then to a retaining column. The GC oven was maintained at 70°C so that the ethyl acetate passed through the retaining column and was vented to waste.The solutes of interest were held in the retaining column at this temperature during the removal of the ethyl acetate. The temperature was then increased and the residual material separated on an analytical column using an appropriate temperature program. The eluents from the analytical column passed to a quadrupole mass spectrometer. An example of the chromatograms and spectra obtained are shown in Fig. 9. Fig. 9a shows the total ion current chromatogram from a sample of Rhine River water containing 200 ppt of the herbicides atrazine and simazine. The pertinent peaks are shown enlarged in the inset. Fig. 9b shows a section of the same chromatogram presented in the selected ion mode. It is seen that the herbicide peaks are clearly and unambiguously revealed. In Fig. 9c and d, the individual mass spectra of atrazine (eluted at 16.30 min) and simazine (eluted at 16.36 min) are shown. The spectra are clear and more than adequate to confirm the identity of the two herbicides.

GC: Fourier Transform Infrared Spectroscopy

Hui-Ru Dong
Peng-Yu Bi
College of Science, Beijing University of Chemical Technology, Beijing, China

INTRODUCTION

The combination of gas chromatography (GC) with Fourier transform infrared spectroscopy (FTIR) has gradually become the important analytical tool for qualitative and quantitative analysis of complex mixtures. Numerous applications have been reported in previous reviews.[1–3] Separation and identification of components in complex mixtures can be a daunting task. GC is the most common technique for separation of volatile and semivolatile mixtures. It is well accepted that when GC is coupled with spectral detection methods, such as MS, NMR, or FTIR spectrometry, the resulting combination is a powerful tool for the analysis of complex mixtures.

FTIR spectroscopy, used as a detector in GC, has many advantages. First, FTIR is the most universal of all detectors currently used in GC, because all organic compounds exhibit IR-active vibrations and, thus, absorb IR radiation. Moreover, these absorptions obey Beer's law so that the data can be used directly for quantification. Furthermore, FTIR can be used both as a selective and as a specific detector. Finally, the non-destructive character of GC/FTIR is an important advantage when compared with other detectors; it offers the opportunity to investigate GC eluates after FTIR analysis. However, despite these advantages, FTIR detection is not widely applied in GC analysis at present. This is, particularly, due to its lack of sensitivity; a second reason is the complexity of IR spectra. Yet, the power of GC/FTIR is the unique structural information that can be extracted from the spectral data and that cannot be obtained from any other method. It is, therefore, very likely that, in the next few years, this technique will attract much closer attention from analytical chemists.

Although GC/IR was first introduced in the 1960s, its use did not become widespread until the 1980s. Several factors were responsible for its application in GC analysis. That is, particularly, due to its lack of sensitivity and the interfaces.

INTERFACES

In GC/FTIR systems, three types of FTIR interfaces are currently in use: light pipe, matrix isolation (MI), and direct deposition (DD, also called cryotrapping or cryofocusing).

The light-pipe interface is the simplest design; it comprises a thin glass tube with IR-transparent windows at both ends. The entrance of the light pipe is connected to the end of the GC column by a heated transfer line. Cell and transfer line are operated at, typically, 300°C to prevent condensation. The cell is internally gold-coated to accomplish maximum light throughput. The dimensions are of the order of 0.3–1 mm in internal diameter (I.D.) and 5–10 cm in length to achieve a cell volume that matches the average peak volume of capillary-GC columns. Spectra obtained with a light-pipe interface are very similar to vapor-phase spectra. Therefore, spectra can be easily searched against commercially available collections of vapor-phase reference spectra.

DD-FTIR and MI-FTIR are very similar in that the sample is cryogenically frozen on a surface for FTIR analysis. The major difference between the two is that in the DD-FTIR interface, the surface is an IR-transparent window, usually ZnSe. GC effluent is deposited onto this window and absorption spectra are subsequently acquired. The DD technique is based on crystallization of the separated species on a moving IR-transparent window at liquid-nitrogen temperature (80 K). In a DD interface, the transfer line from the GC column is connected to an orifice (75–100 μm I.D.) that acts as a restrictor. The tip of the restrictor is located about 30 μm above the surface of the window, and eluates that leave the tip are immediately crystallized as a trace of about 100 μm wide. The window slowly moves in such a way that the immobilized spots pass through the external beam of an IR spectrometer a few seconds after deposition, thus providing chromatograms and spectra recorded on the fly. A major advantage of this interface is that the spectra are very much like conventionally recorded (KBr) spectra of solids and, herefore, can be compared with those in standard computer-readable KBr spectra, which are much larger than those available for both light–pipe- and MI-FTIR.

The MI technique is also based on cold-trapping of the GC eluates, but differs from DD in the addition of 1–2% of an inert matrix gas (typically argon) to the carrier gas. The effluent stream is sprayed onto the surface of a slowly rotating, gold-coated drum at a temperature of about

Table 1 Characteristics of various GC/FTIR interfaces.

Feature	Light-pipe	Direct deposition	Matrix isolation

10 K, and, in this way, the analytes are frozen into a cage of argon molecules, i.e., "matrix-isolated." The diameter of the spots is a little larger than that obtained with the DD technique, i.e., 200–300 μm. Matrix-isolated spectra maydiffer from spectra that have been recorded with conventional methods. In particular, relatively small molecules (MW $<$ 200) may exhibit considerable band-narrowing effects. As a consequence, identification of GC/MI-FTIR spectra demands special reference collections.

To prevent interfering crystallization of carbon dioxide and water vapor from the atmosphere, both DD and MI cold-trapping techniques require a high vacuum and a leak-tight interface housing.

Comparison studies of the different interfaces have been reported,[1,4] and the most important characteristics of different types of GC/FTIR interfaces are summarized in Table 1.

SENSITIVITY

The sensitivity of a GC/FTIR system depends on the type of interface and the molar absorbance index of the analyte. Comparative studies of the three interfaces have shown that the highest sensitivity is achieved with the DD interface. In general, the limit of detection (LOD) of the light-pipe GC/FTIR is about 10 ng on-column, while, the LODs of the DD/FTIR and MI/FTIR are 35 and 100 pg, respectively. In practice, the LODs of analytes in real samples are of the order of 0.5–25 ng on-column. To enhance the sensitivity of detection, additional clean-up and preconcentration methods are applied, such as headspace sampling, purge and trap, solid-phase extraction, and solid-phase micro-extraction. It would also be possible to achieve improved sensitivity by modifications of other parts of the analytical procedure, such as the use of large-volume sampling methods.

Heaps and Griffiths[5] have shown how the smallest quantity of molecules injected into a GC for which an identifiable infrared spectrum can be measured online has been reduced by a factor of 10 below the detection limit of the most sensitive current technique. In this entry, a commercial direct deposition interface between a GC and an FTIR spectrometer was modified by vapor-depositing an island film of silver on the surface of the ZnSe substrate; it can reduce the detection limit of the GC/FTIR interface to the point that it becomes comparable to those of GC/MS. Coating the ZnSe substrate that is used for GC/DD-FTIR measurements leads to a reduction in the limit at which molecules eluting from a GC can be identified in comparison with any other GC/FTIR technique.

Norton and Griffiths[4] studied the comparison of flow-cell and DD interfaces between GC and FTIR spectrometers. Seven barbiturates were separated on fused-silica GC capillary columns. Infrared spectra of the separated barbiturates were measured in real time by either a Hewlett-Packard infrared detector (flow-cell) interface or a Digilab Division of Bio-Rad Tracer (DD) interface. Without losing chromatographic resolution, the GC/DD-FTIR interface gave both detection limits and minimum identifiable quantities nearly two orders of magnitude lower than the flow-cell GC/FTIR interface.

Hankemeier et al.,[6] studied large-volume injection combined with GC/DD-FTIR. A loop-type injection interface was chosen because of its rather simple optimization. Large-volume injection by means of a loop-type interface can be carried out successfully in conjunction with GC/DD-FTIR. The hyphenation permits enhanced detectability of analytes by about two orders of magnitude when compared with conventional split/splitless ones. As demonstrated, the determination and identification of PAHs in river water is possible down to a level of 0.5 μg/L, even when using simple "micro" liquid–liquid extraction as a sample preparation technique. The present system may, therefore, be considered a viable approach to trace-level environmental analysis.

Auger et al.,[7] reported that GC/DD-FTIR permits coupling of GC to FTIR at a level of sensitivity of routine GC/MS coupling, but the presence of ice resulting from living organisms limits the usefulness of the system. Headspace solid-phase micro-extraction (SPME) coupled to GC/DD-FTIR leads to a rigorous absence of water and can be applied to unknown volatiles trapped in situ in combination with SPME–GC/MS. Coupling of SPME to

GC-IR can permit the development of a GC/DD-FTIR interface to-date limited by its water sensitivity. As SPME is a rapid sampling device and permits a significant reduction of the duration of GC analysis (solvent-free), SPME–GC is especially interesting for living organisms. For instance, the sensitivity of SPME–GC/DD-FTIR allows one to follow the kinetics of pheromonal emission of an individual insect "on-line."

APPLICATIONS

Analysis of Environmental Samples

The separation and characterization of environmental pollutants in aqueous samples is a demanding task. The concentration of contaminants is usually very low (typical < 10 μg/L) and the matrices may be complex. GC is necessary for analyte separation while, in most cases, IR is very suitable for this purpose because of its unique molecular fingerprinting properties. Applications of GC/FTIR are found in a wide variety of analytical fields. Most applications have been reported on the analysis of environmental samples. A representative example of what can be achieved nowadays is the identification of pesticides in water samples at the European alert and alarm levels of 0.1–1 ng/ml, as described by Hankemeier et al.,[8]

Visser et al.,[9] have developed an on-column interface to introduce large sample volume for GC/FTIR analysis and utilized it for trace analysis of environmental contaminants.

The feasibility of the technique is demonstrated by the identification of pesticides in water at a level of 0.5 μg/L using online desorption of presampled solid-phase extracted cartridges. The applicability of GC/FTIR to environmental trace analysis is largely enhanced by modification and optimization of chromatography and interfacing. Improvement of the detectability of analytes in terms of concentration by two to three orders of magnitude to the low μg/L level can be achieved by incorporation of trace-enrichment techniques. On-column interfacing LVI-GC with cryotrapping IR detection offers a selective method for monitoring and identifying contaminants in drinking water, particularly when used in conjunction with online desorption of presampled SPE cartridges.

Rodríguez et al.,[10] described a procedure for the identification and determination of structural isomers of polychlorinated phenols in drinking water. First, their acetylation and concentration on graphitized carbon cartridges were carried out. Detection is accomplished by GC/FTIR using a DD interface. In this way, it is possible to accurately identify and differentiate variably substituted isomers of chlorophenols, which is very difficult or even impossible to do by means of the widely used GC/MS instrumentation. The GC/DD-FTIR technique permits the differentiation of structural isomers of chlorophenols present in drinking water samples in quantities below the levels permitted by legislation (0.5 ng/ml). The most serious problem of the GC/DD-FTIR coupling is the presence of water as an interfering agent in the spectra; any trace of water reaching the interface is deposited as ice onto the ZnSe plate, thus interfering with the IR spectra of the analytes. This problem can be easily overcome by assuring leak-tight connections using metal ferrules.

Identification of Pharmaceutical Samples

Unequivocal identification is also very important in the analysis of forensic and pharmaceutical samples. The utility of GC/FTIR for this purpose has been widely demonstrated. Examples are the identification of drugs of abuse, such as amphetamines. Amphetamine (β-phenylisopropylamine) is the basic molecule of the amphetamines, a group of structurally related compounds with stimulating and mood-modifying properties. Despite overwhelming evidence of their dangerous effects, amphetamines remain significant drugs of abuse and addiction. So-called designer drugs are widespread drugs of abuse among recreational drug users. Therefore, many of these phenethylamines have become controlled substances. Unambiguous identification of these amphetamines is essential for the successful prosecution of these designer drug cases in a court of law. Although GC/MS spectra often yield complementary information for structure elucidation, identification of underivatized amphetamines with GC/MS alone can be difficult, owing to the very similar mass spectral fragmentation patterns of the analogues. GC/FTIR, however, is the most powerful hyphenated technique in the fingerprinting of isomeric structures and the identification of functional groups.

Dirinck et al.,[11] successfully applied GC/FTIR to the analysis of amphetamine-like compounds in judiciary exhibits. With light-pipe GC/FTIR, unique vapor-phase infrared spectra were generated, allowing the unambiguous differentiation between closely related amphetamines. The obtained vapor-phase spectra were submitted to a spectral search on a laboratory-made vapor-phase FTIR library. Several amphetamine analogues have been identified in confiscated powders and tablets using this approach.

Analysis of Food Samples

Important benefits of GC/FTIR are also found in the food industry. Compounds from natural origin, such as terpenes, isomeric sugars, and conjugated unsaturated oils, are difficult to identify by GC/MS alone, and additional GC/FTIR data appear to be very helpful in these cases. The unraveling of the molecular structures of flavors and fragrances present in, for instance, cherimoya fruit and strawberries, are largely based on the results obtained by light-pipe GC/FTIR.

The determination of the *cis*/*trans* geometry of the double bonds in natural oils is another example from the food

industry, although it is also important from the medical point of view. Knowledge of the *cis*/*trans* configuration is relevant, since the *trans*-conjugated, unsaturated fatty acids are believed to contribute to the prevention of heart attacks and cancer. Mossoba[12] studies of the determination of *cis*/*trans* double bonds were carried out by GC/DD-FTIR, and anticancer activity has been correlated with structural properties.

GC/FTIR data have also contributed to the structure elucidation of other compounds of biological origin, such as mycotoxins, which are formed by fungal activity in food products under specific environmental conditions of moisture, temperature, and host. Trichothecene mycotoxins, secondary fungal metabolites produced by species of mold, are a natural contaminant of feedstuffs and food. Because they can be toxic to humans and animals, their detection is important. Sehat et al.,[13] utilized GC/MI-FTIR and GC/MS to analyze grains for these contaminants.

The analysis of carbohydrates continues to be of considerable importance in the biological sciences. The diversity of structure and function of carbohydrates in organisms contributes to the difficulty of analysis of these materials. There exist a number of techniques for the analysis of carbohydrates, but no single technique has universal applicability. For the identification of carbohydrates, trimethylsilyl ethers are widely used in GC/MS. Veness and Evans[14] showed that GC/FTIR can also be used, with some advantages, for this purpose. A selection of 42 monosaccharides and related compounds were examined and, in each case, unique spectra were obtained for the differing compounds and their isomeric forms, allowing unambiguous identification. These results indicate that GC/FTIR of trimethylsilyl ethers of monosaccharides is a useful analytical technique for their identification. The resultant spectra are unique, easy to interpret, and stereoisomeric forms are readily differentiated.

Structural Analysis of Samples

As mentioned above, GC/FTIR is very useful for structural analysis; it may provide essential structural information for analytes, but the technique lacks the sensitivity needed to become competitive with GC/MS. In terms of data interpretation, however, IR spectra are more discriminative and provide greater confidence in identification than mass spectra. These properties make GC/FTIR a powerful tool for the discrimination of isomers and the identification of compounds with closely related structures, particularly in combination with GC/MS.

Wachholz et al.,[15] analyzed a mixture of linear and cyclic methylsiloxanes to characterize the different types of siloxane structures using GC/DD-FTIR. The main structural units are $(CH_3)_3SiO_{1/2}$, $(CH_3)_2SiO$, and $(CH_3)SiO_{3/2}$; GC–MS may provide molecular mass information, but it is not able to identify isomeric structures. Coupling GC with FTIR enables the determination of group frequencies to assign specific structures. Thus, combination of GC with MS and FTIR may be used in elucidating complex cyclosiloxane compounds.

Many natural products, particularly terpenes, bear vinyl groups conjugated to carbon–carbon double bonds. A number of these vinyl compounds are either disubstituted 1,3-butadienes with a methyl group (designated as α-type, 1, 2) or mono-substituted 1,3-butadienes (β-type, 3) with a large substituent group attached to the C-3 atom. Although ^{1}H NMR spectroscopy can be used to characterize these carbon skeletons, relatively large sample amounts (10–100 μg) in nearly pure form are required. Frequently, natural product chemists are frustrated by the unavailability of large samples. But, they can be characterized by GC/FTIR. Svatoš and Attygalle[16] have demonstrated that GC/FTIR data allow definitive deductions to be made about the stereochemistry of carbon–carbon double bonds conjugated to a vinyl group.

Yashitake and Furukawa[17] investigated the thermal degradation mechanism of α,γ-diphenyl alkyl allophanates and carbanilates as model compounds for crosslinking sites in polyurethane networks by pyrolysis-high-resolution GC/FTIR (Py-HR GC/FTIR). Pyrolysis was performed at 250°C, 350°C, 450°C, and 500°C.

Py-HRGC using a 25 ml capillary column coated with silicone OV-1 followed by FTIR was carried out. The products were identified by use of a reference system attached to the FTIR apparatus.

The primary degradation reaction was dissociation of allophanate into phenyl isocyanate and alkyl carbanilate, followed by dissociation of the alkyl carbanilate into phenyl isocyanate and alcohol. Decarboxylation of the ethyl carbanilate fragment also took place slowly. A small amount of diphenyl carbodimide was observed at the pyrolysis temperature of 450°C. In addition, decarboxylation of the isopropyl carbanilate fragment took place at 550°C. A small amount of diphenyl carbodimide was observed from 350°C to 550°C.

Sigrist, Manzardo, and Amado[18] investigated the behavior of 3-methyl-2,4-non-anedione under photooxidative conditions. The structure of main oxidation product, 3-hydroxy-3-methyl-2,4-non-anedione, was tentatively assigned based on mass (GC/MS) and vapor-phase infrared (GC/FTIR). The infrared spectrum showed the status of the OH group, and the structure was easily assigned to α-hydroxy-β-diketones.

CONCLUSION

GC/FTIR is very useful for identification analysis of volatile compounds. This technique produces excellent spectroscopic information and is best suited for discrimination of isomers and the identification of compounds with closely related structures. The GC/FTIR identification

obtained is complementary to the identification obtained from GC/MS. With the IR subtractive spectrum technique, the GC overlap peaks can be resolved without a separate step in the experiment.

It has been over 40 years since infrared spectroscopy was first applied to GC by identifying trapped effluents taken directly from the column. With the advances of FTIR spectrometers and computer techniques, these modern FTIR spectrometers and data systems provide rapid scanning, increased sensitivity, and endless disk space for data storage. All of these characteristics are necessary to merge FTIR with today's sensitive high-resolution capillary gas chromatography. Therefore, the reliability of qualitative analysis of GC/FTIR is greatly enhanced.

GC: System Instrumentation

Gunawan Indrayanto
Mochammad Yuwono
Faculty of Pharmacy, Airlangga University, Surabaya, Indonesia

INTRODUCTION

Gas chromatography (GC) was first described by Martin and James in 1952. It has become one of the most frequently used separation techniques for the analysis of gases and volatile liquids and solids. An important breakthrough in GC was the introduction of the open tubular column by Golay in 1958 and the adoption of fused silica capillary columns by Dandeneau and Zerenner in 1979.

Today, using of the capillary columns can solve many kinds of analytical problems, such as isomer separation and analysis of complex mixtures of natural products and biologicals.

The gas chromatograph involves volatilization of the sample in a heated inlet port (injector), separation of the component mixtures in a column, and detection of each component by a detector.

GC SYSTEM INSTRUMENTATION

GC, first described by James and Martin[1] in 1952, has become one of the most frequently used separation technique for the analysis of gases, volatile liquids, and solids. The major breakthrough of GC was the introduction of the open tubular column by Golay and Desty[2] in 1958 and the adoption of fused silica capillary columns by Dandeneau and Zerenner[3] in 1979. Today, using of the capillary columns can solve many analytical problems, such as isomeric separation and analysis of complex mixtures of natural products and biological samples.

The basic principle of a gas chromatograph involves volatilization of the sample in a heated inlet port (injector), separation of the component mixtures in a column, and detection of each component by a detector. Although the basic components remain the same, some improvements in gas chromatograph appeared in the commercial marketplace. GC with electronic integrators and computer-based data processing systems became common in 1970s, whereas in the 1980s, a computer was introduced to control all GC parameters automatically, such as column temperature, flow rates, inlet pressure, and sample injection, and to evaluate the data obtained. The automated equipment can be operated unattended overnight.[4,5]

Combinations of highly efficient separation columns, with specific or selective detectors, such as electron capture detector (ECD), GC/mass spectrometry (MS), and GC-Fourier transform infrared (FTIR) detector, make GC a more favorable technique. Multidimensional GC systems, which contain at least two columns operated in series, have also proved to be a powerful tool in the analytical chemistry of complex mixtures.

The dramatic advance in GC instrumentation is the introduction of portable gas chromatographs, which have been developed during 1990s to provide a field-based analysis. Recently, the micro high-speed GC portable has also appeared to carry out the analysis up to 10 times faster than conventional laboratory GCs.[6–8]

The GC system (Fig. 1) consists of a carrier gas supply system, an inlet to deliver sample to a column, the column where the separations occur, an oven as a thermostat for the column, a detector to register the presence of a chemical in the column effluent, and a data system to record, display, and evaluate the chromatogram.

CARRIER GAS

The carrier gas that is used as the mobile phase transfers the sample from the injector, through the column, and into the detector. For a laboratory gas chromatograph, the carrier gas is usually obtained from a commercial pressurized gas cylinder equipped with a two-stage regulator for coarse and fine flow control. In most instruments, provision is made for secondary fine-tuning of pressure and gas flow. In 1990, electronic pressure control was developed, which allows operation at constant pressure, constant flow, and pressure-programing modes. The gas flow can be read electronically on the instrument panel or measured using a soap-bubble flow meter at the outlet of the column. The carrier gas flow is directed through a sieve trap, or a series of traps to remove the moisture, organic matter, and oxygen, and then through frits to filter off any particulate matter.[9] It is also suggested to use copper tubing for the connection of the gas cylinder to the gas chromatographs. Polymer tubing should be avoided because the oxygen from the atmosphere can often permeate the tubing walls. The oxygen in the gas stream may cause degradation of some column stationary phases at elevated operating temperatures, thereby producing unstable baselines with the ECD and shortening filament lifetime for the thermal conductivity detector. To

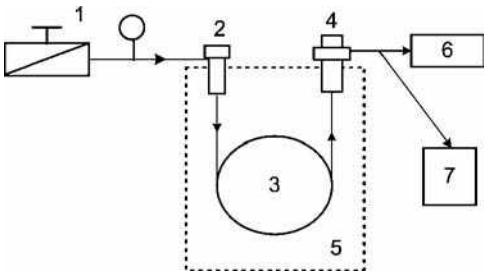

Fig. 1 Gas chromatography system schematic.

minimize contamination, high purity carrier gases are used, combined with additional chemical and or catalytic gas purifying devices. The gas chromatograph may have thermostatically controlled pneumatics to prevent drift, in which pressure regulators, flow controllers, and additional gas purifying traps and filters are housed. The carrier gas must be inert so that it reacts neither with the sample nor with the stationary phase at the operating temperature.[9] The choice of carrier gas requires consideration of the detector used, the separation problem to be solved, and the purity of the gases available. A further consideration in the selection of carrier gas is its availability and its cost. In practice, the choice of carrier gas will determine the efficiency of the GC system because the height equivalent to a theoretical plate depends on solute diffusivity in the carrier. The influence of the mobile-phase velocity on column efficiency and practical consequences of the carrier gas selection in capillary GC have been described in previous publications.[9,10] Normally, a compromise between inertness, efficiency, and operating cost make nitrogen or helium the most common GC carrier gases. The carrier gas flow can be determined by either linear velocity, expressed in cm/sec, or volumetric flow rate, expressed in ml/min. The linear velocity is independent of the column diameter, whereas the flow rate is dependent on the column diameter. For capillary columns, makeup gas is added at the column exit to obtain a total gas flow of 30–40 ml/min into the detector; it can be the same gas as the carrier gas or a different gas, depending on the type of detector being used.

SAMPLE INLET SYSTEMS

Sample introduction into the gas chromatograph is the first stage in the chromatographic process. It is of primary importance, especially in capillary GC, because its efficiency is reflected in the overall efficiency of the separation procedure and the quantitative results. The basic prerequisite of the sample injection system is that the sample should be introduced into the column as a narrow band, ideally with maintenance of constant pressure and flow. The specially designed inlet should be hot enough to flash-evaporate the sample and large enough in volume to allow the sample vapor to expand without blowing back through the septum. Care must be taken not to overheat the injector because the injection cell or the sample may decompose. The sample must be gaseous or an easily vaporized liquid or solid. Most organic compounds may be introduced onto the column in the form of a liquid sample, either as the neat compound or, in the case of a solid, as a solution. When the dilution of the solid sample would be undesirable, the solid may be encapsulated in glass capillaries and mechanically pushed into the heated injection block and crushed.[10,11]

For injecting gases and vapors, gas-tight syringes with Teflon-tipped plungers and syringe barrels are available. Many analysts favor using gas syringes for gas samples; however, the introduction of accurately measured volumes of gases remains a problem. In the alternative method, gas samples can be introduced onto a column using rotary gas switching valves, which generally consist of a rotating polymeric core, encased in a stainless-steel body. For repetitive or periodic injection of a large number of the same or different samples, auto samplers may be used.[10,12] The sample volume for analytical work depends on the dimensions of the column and on the sensitivity of the detector. For a packed column, sample size ranges from tenths of 1 μl up to 20 μl. Capillary columns need much less sample (0.01–1 μl). The most commonly used silicone-rubber septa may contain impurities that may bleed into the column above a certain temperature, resulting in unsteady baseline and ghost peaks. Recently, various kinds of septa have become available which can be used at very high temperatures.[13]

Packed and Open Tubular Column Inlet

Because of the variety of columns and samples that can be analyzed by GC, several injection techniques have been developed. The packed inlet system is designed mainly for packed and wide-bore columns. However, an adapter can be used to enable capillary columns to be used. When injection is carried out in the on-column mode, glass wool can be used for packing the injector. For capillary GC, split technique is most common, which is used for high concentration samples. This technique allows injection of samples virtually independent of the selection of solvent, at any column temperature, with little risk of band broadening or disturbing solvent effects. The splitless technique, on the other hand, is used for trace level analysis. The so-called cold injection techniques (on-column, temperature programed vaporization, cooled needle split) have also been recently developed.[4,14,15]

Pyrolysis GC

Pyrolysis involves the thermal decomposition, degradation, or cracking of a large molecule into smaller fragments. Pyrolysis GC is an excellent technique for identifying

certain types of compounds which cannot be analyzed by derivatization, e.g., polymers. The pyrolysis temperature is typically between 400°C and 1000°C. A number of analytical pyrolyzers have been introduced and are commercially available. The devices consist of platinum resistively heated and Curie point pyrolyzers. The carrier gas is directed through the system, and the platinum wire is heated to a certain temperature. The material decomposes, and the fragmentation products are analyzed.[16,17]

Headspace Analysis

Headspace analysis is an excellent technique for gas chromatography to analyze volatile samples in which the matrix is of no interest. It is readily applied to many analytical problems, such as monitoring of volatiles in soil and water, determination of monomers in polymers, aromas in food and beverages, etc. A variety of headspace auto samplers are commercially available, based on the principle of static or dynamic headspace. In static headspace, the sample is transferred to a headspace vial that is sealed and placed in a thermostat to drive the desirable component into the headspace sampling. An aliquot of the vapor phase is introduced into the GC system via a gas-tight syringe or a sample loop of a gas-sampling valve. Static headspace implies that the sample is taken from a single-phase equilibrium. To increase the detectability, dynamic headspace analysis has been developed. Driving the headspace out of the vial via an inert gas continuously displaces the phase equilibrium. A detailed discussion of headspace GC is reported in the previous work.[18]

Solid-Phase Microextraction

Solid-phase microextraction, first reported by Belardi and Pawliszyn in 1989, is an alternative sampling technique. The method has the advantages of convenience and simplicity, and it does not release environmentally polluting organic solvents into the atmosphere. The method is based on the extraction of analytes directly from liquid samples or from headspace of the samples onto a polymer- or adsorbent-coated fused silica fiber. After equilibration, the fiber is then removed and injected onto the gas chromatograph.[19–22]

Purge-and-Trap Methods

Purge and trap samplers have been developed for analysis of non-polar and medium-polarity pollutants in water samples. The commercially available systems are all based on the same principle. Helium is purged through the sample that is contained in a sealed system, and the volatiles are swept continuously through an adsorbent trap where they are concentrated. After a selected time, purging is stopped, the carrier gas is directed through the trap via a six-way valve, and the trap is heated rapidly to desorb the solutes.[4,9]

OVEN

The column is ordinarily housed in a thermostatically controlled oven, which is equipped with fans to ensure a uniform temperature. The column temperature should not be affected by changes in the detector, injector, and ambient temperatures. Temperature fluctuations in column ovens can decrease the accuracy of the measured retention times and may also cause the peak splitting effect. For conventional ovens, the oven wall is well insulated using a wire coil of high thermal capacity, which is able to radiate heat into the inner volume of the oven. The characteristics of a more efficient method can accurately control the temperature of a column and allow the operator to change the temperature conveniently and rapidly for temperature programing. It is designed by suspending the column in an insulated air oven through which the air circulated at high velocity by means of fans or pumps. Most commercial instruments employ this design and allow for the adjustment and control of temperature between 50°C and 450°C. Subambient temperature operation would normally require a cryogenic cooling system using liquid nitrogen or carbon dioxide.[4,9,10]

DETECTOR

The detector in a gas chromatograph senses the differences in the composition of the effluent gases from the column and converts the column's separation process into an electrical signal, which is recorded. There are many detectors that can be used in GC, and each detector gives a different type of selectivity. An excellent discussion and review on developments of GC detectors has been published.[23]

Detectors may be classified on the basis of selectivity. A universal detector responds to all compounds in the mobile phase except carrier gas. A selective detector responds only to a related group of substances, and a specific detector responds to a single chemical compound. Most common GC detectors fall into the selective designation. Examples include flame ionization detector (FID), ECD, flame photometric detector (FPD), and thermoionic ionization detector. The common GC detector that has a truly universal response is the thermal conductivity detector (TCD). Mass spectrometer is another commercial detector with either universal or quasi-universal response capabilities.

Detectors can also be grouped into concentration-dependent detectors and mass-flow-dependent detectors. Detectors whose responses are related to the concentration of solute in the detector cell, and do not destroy the sample, are called concentration-dependent detectors, whereas detectors whose response is related to the rate at which solute molecules enter the detector are called mass-flow-dependent detectors. Typical concentration-dependent detectors are TCD and GC/FTIR. Important

mass-flow-dependent detectors are the FID, thermoionic detector for N and P (N-, P-FID), FPD for S and P (FPD), ECD, and selected ion monitoring MS detector.

The FID is one of the most widely used GC detectors. The detection principle is based on the change in the electric conductivity of a hydrogen flame in an electric field when fed by organic compound(s). The resulting current is then directed into a high impedance operational amplifier for measurement. The FID is sensitive to all compounds which contain C–C or C–H linkages and considerably less sensitive up to insensitive to certain functional groups of organic compounds, such as alcohol, amine, carbonyl, and halogen. In addition, the detector is also insensitive toward non-combustible gases such as H_2O, CO_2, SO_2, and NO. A TCD, which was one of the earliest detectors for GC, is based on changes in the thermal conductivity of the gas stream caused by the presence of analyte molecules. This device is sometimes called a katharometer. Because the TCD reacts non-specifically, it can be used universally for the detection of either organic or inorganic substances. In the ECD, the column effluent passes over a beta-emitter, such as nickel-63 or tritium. The electrons from emitter bombard the carrier gas (nitrogen), giving rise to ions and a burst of electrons. In the absence of an analyte, the ionization process yields a constant standing current. However, this background current decreases in the presence of organic compounds that can capture electrons. The applications of the ECD illustrate the advantages of a highly sensitive special detector toward molecules that contain electronegative functional groups such as halogens, peroxide, quinines, or nitro groups.[22–24]

GC DATA SYSTEM

The GC data system performs the tasks of recording, handling, evaluation, and documentation of the chromatogram. In a modern gas chromatographic system, these can be performed by means of a computer with specialized software. Nowadays, software for calculating the quantitative results and for the method validation is available.[4]

CONCLUSIONS

Since the introduction of GC, the basic parts of a gas chromatograph have been unchanged in function and purpose, even though the improvement has been occurring in design and materials. One area of dramatic advance in GC instrumentation was the introduction of the open tubular columns. Consequently, most GC analyses in practice are performed in capillary columns that show the separation with high efficiencies and high resolution. The developments of GC instrumentation are occurring with sample handling techniques and refinements of detectors. The dramatic advance in GC instrumentation is the development of a small, high-speed, and portable gas chromatograph to provide a field-based analysis.

GPC/SEC

Vaishali Soneji Lafita
Abbott Laboratories, Inc., Abbott Park, Illinois, U.S.A.

INTRODUCTION

The basic principle of chromatography involves the introduction of the sample into a stream of mobile phase that flows through a bed of a stationary phase. The sample molecules will distribute so that each spends some time in each phase. Size-exclusion chromatography (SEC) is a liquid column chromatographic technique which separates molecules on the basis of their sizes or hydrodynamic volumes with respect to the average pore size of the packing. The stationary phase consists of small polymeric or silica-based particles that are porous and semirigid to rigid. Sample molecules that are smaller than the pore size can enter the stationary-phase particles and, therefore, have a longer path and longer retention time than larger molecules that cannot enter the pore structure. Very small molecules can enter virtually every pore they encounter and, therefore, elute last. The sizes, and sometimes the shapes, of the mid-size molecules regulate the extent to which they can enter the pores. Larger molecules are excluded and, therefore, are rapidly carried through the system. The porosity of the packing material can be adjusted to exclude all molecules above a certain size. SEC is generally used to separate biological macromolecules and to determine molecular-weight distributions of polymers.

HISTORY

It is not obvious who was the first to use SEC. However, the first effective separation of polymers based on *gel filtration chromatography* (GFC) appears to be that reported by Porath and Flodin.[1] Porath and Flodin employed insoluble cross-linked polydextran gels, swollen in aqueous medium, to separate various water-soluble macromolecules. GFC generally employs aqueous solvents and hydrophilic column packings, which swell heavily in water. Moreover, at high flow rates and pressures, these lightly cross-linked soft gels have low mechanical stability and collapse. Therefore, GFC stationary phases are generally used with low flow rates to minimize high-back pressures. GFC is mainly used for biomolecule separations at low pressure.[2]

Moore described an improved separation technique relative to GFC and introduced the term gel permeation chromatography (GPC) in 1964.[3] GPC performs the same separation as GFC, but it utilizes organic solvents and hydrophobic packings. Moore developed rigid polystyrene gels, cross-linked with divinylbenzene, for separating synthetic polymers soluble in organic media. These extensively cross-linked gels are mechanically stable enough to withstand high pressures and flow rates. The more rugged GPC quickly flourished in industrial laboratories where polymer characterization and quality control are of primary concern. Since its introduction in the 1960s, the understanding and utility of GPC has substantially evolved. GPC has been widely used for the determination of molecular weight (MW) and molecular-weight distribution (MWD) for numerous synthetic polymers.[4]

Other names such as gel chromatography, exclusion chromatography, molecular sieve chromatography, gel exclusion chromatography, size separation chromatography, steric exclusion chromatography, and restricted diffusion chromatography have been utilized to reflect the principal mechanism for the separation. The fundamental mechanism of this chromatographic method is complex and certainly will not be readily incorporated into one term. Strong arguments have been made for many of the above-listed titles.[5] In an attempt to minimize the dispute over the proper name, the term SEC will be used in this entry, as it appears to be the most widely used.

MECHANISM

SEC is a liquid chromatography (LC) technique in which a polymer sample, dissolved in a solvent, is injected into a packed column (or a series of packed columns) and flows through the column(s) and its concentration as a function of time is determined by a suitable detector. The column packing material differentiates SEC from other LC techniques where sample components primarily separate by differential adsorption and desorption. The SEC packing consists of a polymer, generally polystyrene, which is chemically cross-linked so that varying size pores are created. Several models are discussed by Barth et al.[6] to illustrate SEC separation theory. A rather simplified separation mechanism is described here. A polymer sample dissolved in the SEC mobile phase is injected in the chromatographic system. The column eluent is monitored by a mass-sensitive detector, which responds to the weight concentration of polymer in the mobile phase. The most common detector for SEC is a differential refractometer. The raw data in SEC consists of a trace of detector response proportional to the amount of polymer in solution and the

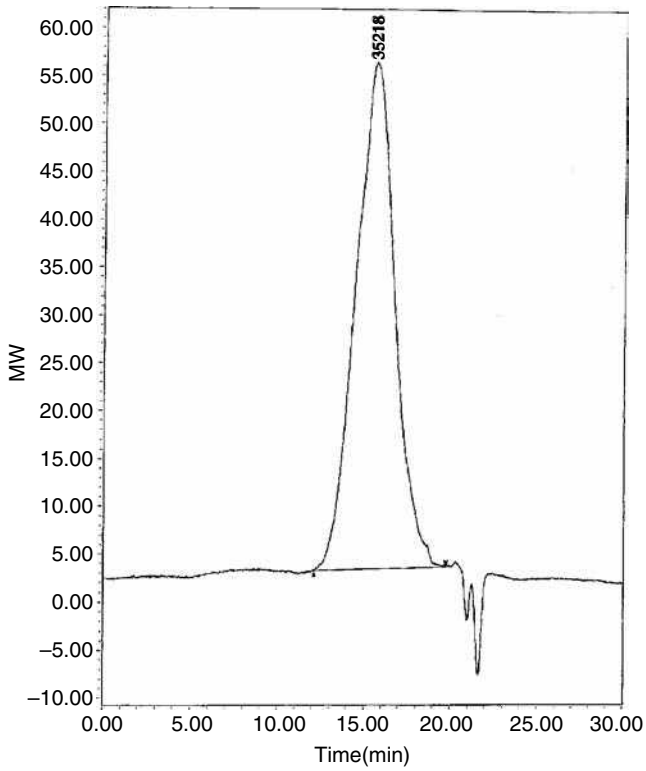

Fig. 1 Typical SEC of a polymer sample. SampleName: 6B Vial: 15 Inj: 1 Ch: 410 Type: Broad Unknown.

corresponding retention volume. A typical SEC sample chromatogram is depicted in Fig. 1. An SEC chromatogram generally is a broad peak representing the entire range of molecular weights in the sample. For synthetic polymers, this can extend from a few hundred mass units up to a million or more. The average molecular weight can be calculated in a number of ways. Both natural and synthetic polymers are molecules containing a distribution of molecular weights. The most commonly calculated molecular-weight averages using SEC are the weight-average molecular weight (M_w) and number-average molecular weight (M_n). These terms have been well defined by Cazes.[7]

The weight-average molecular weight is defined as

$$\bar{M}_w = \frac{\sum_{i=1}^{\infty} W_i M_i}{\sum_{i=1}^{\infty} W_i} \quad (1)$$

and the number-average molecular weight is defined as

$$\bar{M}_n = \frac{W}{\sum_{i=1}^{\infty} N_i} = \frac{\sum_{i=1}^{\infty} M_i N_i}{\sum_{i=1}^{\infty} N_i} \quad (2)$$

where W is the total weight of the polymer, W_i is the weight fraction of a given molecule i, N_i is the number of moles of each species i, and M_i is the molecular weight of each species i.

M_w is generally greater than or equal to M_n. The samples in which all of the molecules have a single molecular weight ($M_w = M_n$) are called monodisperse polymers. The degree of polydispersity (i.e., the ratio of M_w to M_n) describes the spread of the molecular-weight-distribution curve. The broader the SEC curve, the larger the polydispersity.

The detector response on the SEC chromatogram is proportional to the weight fraction of total polymer, and suitable calibration permits the translation of the retention volume axis into a logarithmic molecular-weight scale. Calibration of SEC is perhaps the most difficult aspect of the technique because polymer molecules are separated by size rather than by molecular weight. Size, in turn, is most directly proportional to the lengths of the polymer molecules in solution. A length, however, is proportional to molecular weight only within a single polymer type. An absolute SEC calibration would require the use of narrow molecular-weight range standards of the same polymer that is being analyzed. This is not always practical because a wide range of polymer types needs to be evaluated. SEC calibration is often achieved using the "universal calibration" technique, which assumes hydrodynamic volume is the sole determinate of retention time or volume.[8] A series of commercially available monodisperse molecular-weight polystyrenes are the most commonly used SEC calibration standards. If polystyrene standards are used to calibrate the analyses of any other type of polymer, the molecular weights obtained for a polymer sample are actually "polystyrene-equivalent" molecular weights. Numeric conversion factors are available for correlating "molecular weight per polystyrene length" to that of other polymers, but this approach only produces marginally better estimates of the absolute molecular weights. In addition, approaches such as these are usually invalid because the calibration curve for the polymer being analyzed does not often have the same shape as the curve generated with the polystyrene standards.

Size-exclusion chromatograms of narrow-distribution polystyrene standards along with a typical polystyrene calibration curve are shown in Fig. 2a and 2b. The peak retention volume and corresponding molecular weights produce a calibration curve. With a calibration curve, it is possible to determine M_w and M_n for a polymer. The SEC curve of a polymer sample is divided into vertical segments of equal retention volume. The height or area of each segment and the corresponding average molecular weight, calculated from the calibration curve, are then used for M_w and M_n calculations. There are several commercially available software packages that simplify the calculation process for molecular-weight determinations.

APPLICATION

Until the mid-1960s, molecular-weight averages were determined only by techniques such as dilute solution viscosity, osmometry, and light scattering. Most of these

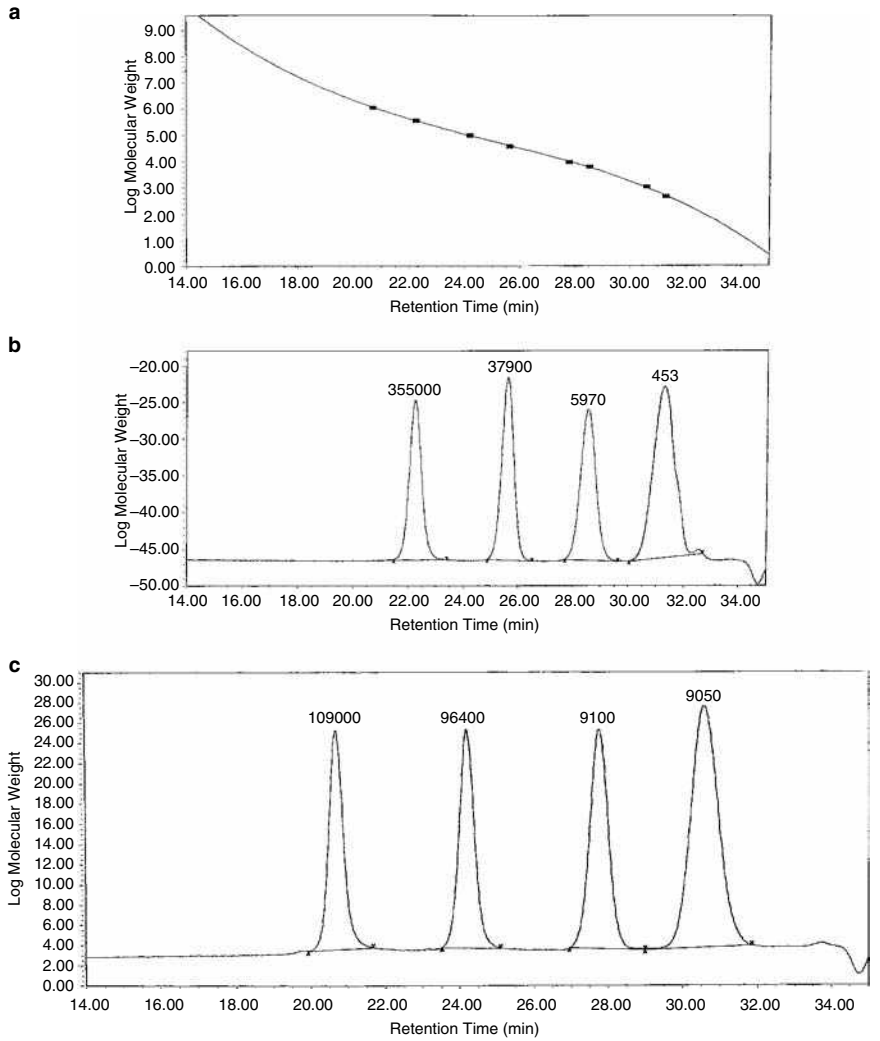

Fig. 2 Typical polystyrene narrow molecular-weight range standard chromatograms and calibration curve.

techniques work best for polymers with a narrow MWD. None of these techniques, either alone or in combination, could readily identify the range of molecular weights in a given sample. SEC was introduced in the mid-1960s to determine MWDs and other properties of polymers. During the first two decades of SEC acceptance, the emphasis was on improving the fundamental aspects of chromatography, such as column technology, optimizing solvents, and the precision of analysis. Over the past 10 years, there has been an increasing demand for deriving more information from SEC, driven by the need to characterize, more fully, an increasingly complex array of new polymers. Significant developments in SEC detection systems include light scattering, viscometry, and matrix-assisted laser desorption ionization time-of-flight (MALDI–TOF) mass spectrometry and, most recently, nuclear magnetic resonance (NMR) detection in conjunction with SEC for determining MW and chemical composition of polymers. The use of SEC for measuring physiological properties of polymers, especially biopolymers, has become an important area of research.

Finally, SEC is merely a separation technique based on differences in hydrodynamic volumes of molecules. No direct measurement of molecular weight is made. SEC itself does not render absolute information on molecular weights and their distribution or on the structure of the polymers studied without the use of more specialized detectors (e.g., viscometry and light scattering). With these detectors, a "self-calibration" may be achieved for each polymer sample while it is being analyzed by SEC. However, it is possible to calibrate the elution time in relation to molecular weight of known standards. With proper column calibration, or by the use of molecular-weight-sensitive detectors such as light scattering, viscometry, or mass spectrometry, MWD and average molecular weights can be obtained readily.[6] The combined use of concentration sensitive and molecular-weight-sensitive detectors has greatly improved the accuracy and precision of SEC measurements. Thus, SEC has become an essential technique that provides valuable molecular-weight information, which can be related to polymer physical properties, chemical resistance, and processability.

GPC/SEC Viscometry from Multi-Angle Light Scattering

Philip J. Wyatt
Ron Myers
Wyatt Technology Corp., Santa Barbara, California, U.S.A.

INTRODUCTION

Viscometric techniques have long been used in combination with gel permeation chromatography/size-exclusion chromatography (GPC/SEC) separations since the early discovery[1] that the elution of many classes of divers polymers follows a so-called "universal calibration" curve. A plot of the logarithm of the hydrodynamic volume, $M[\eta]$, where M is the molar mass and $[\eta]$ the intrinsic (or "limiting") viscosity, against the elution volume V yields a common curve (differing for each mobile phase, operating temperature, and column set) along which polymers of greatly differing conformation appear to lie. Neglecting the fact that the errors of such fits can be quite large (the results are usually presented on a logarithmic scale), the concept of universal calibration (UC) allows one to estimate (from the UC curve) the molar mass of an eluting fraction by measuring only the intrinsic viscosity, $[\eta]$, and the corresponding elution volume (time). Key to the measurement of $[\eta]$ is the determination of the specific, η_{sp}, or relative, η_{rel}, viscosity and the concentration c, both in the limit as $c \to 0$. These viscosities are defined by

$$\eta_{sp} = \frac{\eta \pm \eta_0}{\eta_0} \tag{1}$$

and

$$\eta_{rel} = \frac{\eta}{\eta_0} \tag{2}$$

where η is the solution viscosity and η_0 is the viscosity of the pure solvent. Because $\eta_{rel} = \eta_{sp} + 1$, it is easily shown for η_{sp} small compared to unity that

$$\lim_{c\to 0} = \frac{\ln(\eta_{rel})}{c} = \lim_{c\to 0}\frac{\eta_{sp}}{c} = [\eta] \tag{3}$$

For the case of GPC/SEC elutions, the concentration c following separation is generally so small that Eq. 3 is assumed to be valid.

THE MARK–HOUWINK–SAKURADA EQUATION

Even without the use of a UC curve (one must be generated for each series of measurements), measurement of $[\eta_0]$ is believed by some to yield an intrinsic viscosity-weighted molar mass.[2] Most importantly, there is a historic interest in the relation of $[\eta]$ to molar mass and/or size. Indeed, the study and explanation of UC has occupied the theorists for some time and, accordingly, there are various formulations describing such relationships.[2] For linear polymers, the most popular empirical relationship between $[\eta]$ and molar 1mass is the Mark–Houwink–Sakurada (MHS) equation

$$[\eta] = KM^a \tag{4}$$

where K and a are the MHS coefficients. For many polymer–solvent combinations, a plot of $\log([\eta])$ vs. $\log(M)$ is linear over a wide range of molar masses. In other words, both K and a are constant throughout the range. Thus, the equation may be used for such polymer–solvent combinations to determine molar mass by measuring $[\eta]$.

Unfortunately, for some solvent–polymer combinations, even for nearly ideal random coils such as polystyrene, the coefficients are not constant but vary with molar mass.

THE FLORY–FOX EQUATION

In the various theoretical attempts to explain the relation between $[\eta]$ and the molar mass M, a relation derived by Flory and Fox for random coil molecules is often applied to interpret viscometric measurements for even more general polymer structures. Although applicable to a broader range of polymers than the MHS equation, the Flory–Fox relation has its own shortcomings. Nevertheless, its frequent use and good correlation with experimental data over a wide range of polymer types confirms its potential for combination with light-scattering measurements to eliminate the need for separate viscometric determinations. In its most general form, the Flory–Fox equation is given by

$$M[\eta] = \Phi\left(\sqrt{6r_g}\right)^3 \tag{5}$$

where r_g is the root mean square radius (or "radius of gyration"). The excluded volume effect is taken into account by representing the Flory–Fox coefficient as $\Phi = \Phi_0(1 \pm 2.63\varepsilon + 2.86\varepsilon^2)$. The constant $\Phi_0 = 2.87 \times 10^{23}$ and ε is related to the MHS coefficient a by the relation $2a = 1 + 3\varepsilon$. Thus, ε ranges from 0 at the theta point to 0.2 for a good solvent. Eq. 5 is of particular interest because multiangle light-scattering (MALS) measurements [3] determine M and r_g directly. Thus, if a polymer–solvent combination is well characterized by Eq. 5, then this equation may be used directly to calculate the intrinsic viscosity without need for a viscometer.

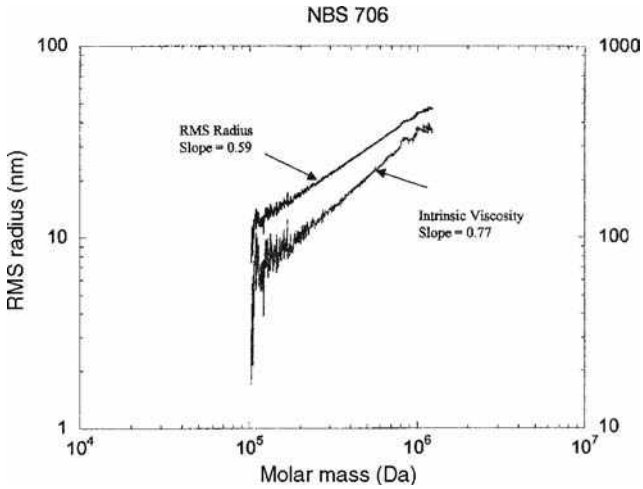

Fig. 1 Conformation plot for $\log(r_g)$ vs. $\log(M)$.

VISCOMETRY WITHOUT A VISCOMETER

As we have seen earlier, $[\eta]$ may be calculated directly from the (absolute) MALS measurements of M and r_g using Eq. 5. For linear polymers spanning a relatively broad molecular range (an order of magnitude or more), the measurement of M and r_g permits the determination of the molecular conformation defined by

$$r_g = kM^{\alpha} \tag{6}$$

where k and α are constants generally calculated from the intercept and slope of the least-squares fitted plot of $\log(M)$ against $\log(r_g)$. Combining Eqs. 4 and 5, we obtain

$$KM^{\alpha-1} = \left(\Phi\sqrt{6r_g}\right)^3 \tag{7}$$

Solving for r_g and substituting into Eq. 6 yields

$$\frac{K^{1/3}M^{(a-1)/3}}{\Phi\sqrt{6}} = kM^{\alpha} \tag{8}$$

Therefore, we have the following relations between the coefficients:

$$a = 3\alpha - 1 \quad \text{and} \quad K = \Phi\left(\sqrt{6k}\right)^3 \tag{9}$$

Eq. 9 show that we can obtain the MHS coefficients a and K directly from a MALS measurement and a determination from such measurements of the molecular conformation parameters α and k. Note that when long-chain branching becomes significant and the molecular conformation becomes more compact such that $\alpha \to {}^1/_3$, the MHS equation, Eq. 4, shows that the intrinsic viscosity no longer varies with molar mass, but becomes constant. This condition also represents a failure of the Flory–Fox equation and the concepts associated with the use of intrinsic viscosity as a means (through UC, for example) to determine molar mass. For linear polymers for which MALS measurements yield values for r_g and M at each eluting slice, all of the important viscometric parameters may be derived directly from the Flory–Fox relation and the MHS equation, as has been shown. For more complex molecular structures or solvent–solute interactions, the MHS coefficients are no longer constants and the empirical theory itself begins to fail.

It is well known,[3] however, that the MALS measurements begin to fail in the determination of r_g once r_g falls below about 8–10 nm, even though the M values generated still remain precise. This lack of precision is due to the limitations of the laser "ruler" to resolve a size much below about one-twentieth of the incident wavelength. The trouble with empirical relations, such as the relation between intrinsic viscosity and molar mass, is that they too are often limited to regions where such concepts are applicable. For very small molar masses, the conformation of a polymer molecule may be poorly described by the same theory applied for the larger constituents of a sample. Although MALS conformation measurements may be extrapolated in r_g for the case of linear polymers, such extrapolations must be used with great caution. Similar remarks apply, of course, to the use of viscometric measurements for characterizing complex molecules whose conformations (and, therefore, MHS coefficients) are changing with M.

Fig. 1 presents the conformation plot for $\log(r_g)$ vs. $\log(M)$ as obtained from a MALS measurement for the

polystyrene broad linear standard NIST706 in toluene. Superimposed thereon is a plot of the calculated $\log[\eta]$ as a function of $\log(M)$ for the same sample. From the latter plot, the MHS coefficients may be deduced by inspection of the slope and intercept to yield $a = 0.77$ and $K \approx 0.008$.

GPC/SEC/HPLC without Calibration: Multi-Angle Light Scattering

Philip J. Wyatt
Wyatt Technology Corp., Santa Barbara, California, U.S.A.

INTRODUCTION

Traditional size-exclusion chromatography (SEC) or gel permeation chromatography (GPC) as used to obtain molar masses and their distributions has been described elsewhere in this volume. The method suffers from three shortcomings:

1. The calibration standards generally differ from the unknown sample;
2. The results are sensitive to fluctuations in chromatography conditions (e.g., temperature, pump speed fluctuations, etc.); and
3. Calibration must be repeated frequently.

DISCUSSION

By adding a multiangle light-scattering[1] detector directly into the separation line, as shown schematically in Fig. 1, the eluting molar masses are determined *absolutely*, thus obviating the need for calibration and elimination of all of the three shortcomings listed. Fig. 1 illustrates also two most important elements associated with making quality light-scattering measurements: an inline degasser and an inline filter. The inline degasser is essential to minimize dissolved gases and, thereby, prevent the production of bubbles during the measurement process. Scattering from such bubbles can overwhelm the signals from the solute molecules or particles. Perhaps even more importantly, the system requires that the mobile phase be dust-free. The filter illustrated is placed between the pump and the injector. Usually, this filter station is comprised of two holders, holding, respectively, a 0.20 μm filter followed by a 0.02 or 0.01 μm filter. Although providing for such pristine operating conditions may seem bothersome, it has been shown that so-called "dirty" solvents, although rarely affecting the refractive index detector (RID) signal, do actually contribute significantly to the degradation of HPLC and SEC columns as well as resulting in the more frequent need to rebuild pumps. The additional solvent cleanup effort is well worth it!

An "absolute" light-scattering (LS) measurement is one that is independent of calibration standards which have "known" molar masses to which the unknown is compared. A LS measurement requires the chromatographer to determine the fundamental properties of the solution (refractive index, *dn/dc* value) and the detector response (field of view, sensitivity, solid angle subtended at the scattering volume). In addition, other factors must be determined, such as the light wavelength and polarization, geometry of the scattering cell, refractive index of all regions through which the scattered and incident light will pass, and the ratio of the scattered light to the incident light. Generally, these determinations are made in conjunction with appropriate multiangle light-scattering (MALS) software. The importance of light scattering's independence of a set of reference molar masses to determine the molar mass of an unknown cannot be overemphasized.

THEORY

As described in detail in Refs.,[1–3] the fundamental equation relating the quantities measured during a MALS detection and the quantities derived is, in the limit of "... vanishingly low concentrations...,"[2] given by

$$\frac{K^{*}c}{R(\theta)} \approx \frac{1}{MP(\theta)} + 2A_2c \tag{1}$$

where $K^{*} = 4\pi^2(dn/dc)^2 n_0{}^2(N_A\lambda_0{}^4)^{-1}$, M is the weight-average molar mass, N_A is Avogadro's number, dn/dc is the refractive index increment, λ_0 is the vacuum wavelength, θ is the angle between the incident beam and the scattered light, and n_0 is the refractive index of the solvent. The refractive index increment, dn/dc, is measured off-line (or looked up in the literature) by means of a differential refractive index (DRI) operating at the same wavelength as the one used for the MALS measurements. It represents the incremental refractive index change dn of the solution (solvent plus solute) for an incremental change dc of the concentration in the limit of vanishingly small concentration. Most importantly, the excess Rayleigh ratio, $R(\theta)$, and form factor $P(\theta)$ are defined respectively by

$$R(\theta) = \frac{f(\theta)_{\text{geom}}[I(\theta) - I_S(\theta)]}{I_0} \tag{2}$$

$$P(\theta) = 1 - \alpha_1 \sin^2(\theta/2) + \alpha_2 \sin^2(\theta/2) - \cdots \tag{3}$$

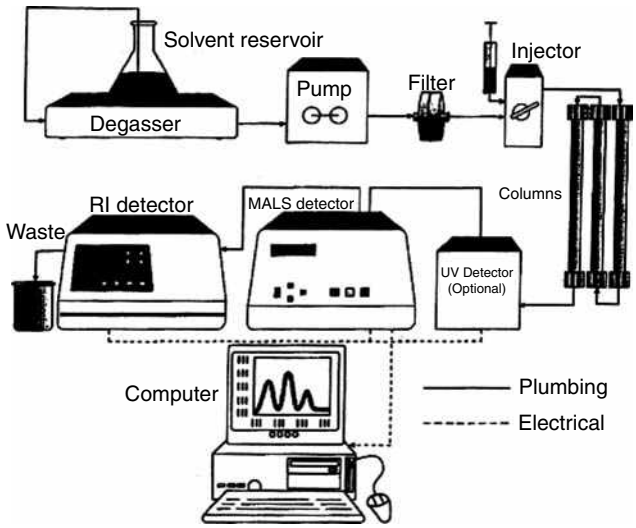

Fig. 1 Schematic diagram showing elements of traditional chromatograph with added MALS detector and dust- and bubble-reducing elements.

where

$$\alpha_1 = \frac{1}{3}\left(\frac{4\pi n_0}{\lambda_0}\right)\langle r_g{}^2\rangle \tag{4}$$

I_0 is the incident light intensity (ergs/cm^2/sec), $f(\theta)_{\text{geom}}$ is a geometrical calibration constant that is a function of the solvent and scattering cell's refractive index and geometry, and $I(\theta)$ and $I_S(\theta)$ are the normalized intensities respectively of light scattered by the solution and by the solvent per solid angle. The mean square radius is given by Eq. 5, where the distances r_i are measured from the molecule's center of mass to the mass element m_i:

$$\langle r_g{}^2\rangle = \frac{\sum_i r^2 m_i}{\sum_i m_i} = \frac{1}{M}\int r^2 dm \tag{5}$$

For MALS measurement following GPC separation, the sample concentration at the LS detector is usually diluted sufficiently that the term $2A_2c$ often may be safely dropped from Eq. 1. In some applications involving very high molar masses, it is often worthwhile to perform an off-line determination of the second virial coefficient from a Zimm plot[1–2] to confirm its negligible effect on the derived molar mass of Eq. 1.

BASIC PRINCIPLES

In the limit of vanishingly small concentrations, and the extrapolation of Eq. 3 to very small angles, the two basic principles of light scattering are evident:

1. The amount of light scattered (in excess of that scattered by the mobile phase) at $\theta \approx 0$ is directly proportional to the product of the weight-average molar mass and the concentration (ergo, measure the concentration and derive the mass!).
2. The angular variation of the scattered light at $\theta \approx 0$ is directly proportional to the molecule's mean square radius (i.e., size).

The successful application of absolute MALS measurements requires a sufficient number of resolved scattering angles to permit an accurate extrapolation to $\theta \approx 0$. Again, all required calculations are performed by the software. Whenever the mobile phase is changed, its corresponding refractive index must be entered into the software program, which should correct automatically for the resultant change of scattering geometry. Fig. 2 shows the normalized light-scattering signals at each scattering angle (detector) as a function of elution volume for a relatively broad sample. Also indicated is the corresponding concentration detector signal.

In conventional SEC measurements, it is necessary to calibrate the mass detector [DRI or ultraviolet (UV)] so that its response yields concentration directly. For example, a DRI detector, following calibration, should produce a response proportional to the refractive index change (Δn) detected. This is related to the concentration change Δc by the simple result $\Delta c = \Delta n/(dn/dc)$. Implicit in the use of a DRI detector, therefore, is that measurement of the concentration of the unknown requires that its differential refractive index, *dn/dc*, be measured, or otherwise determined.

Combining SEC with MALS to produce absolute molar mass data without molecular calibration standards also requires prior calibration of the concentration detector as well as calibration of the MALS detector itself. The latter calibration involves the determination of all geometrical contributions such that the MALS detector measures the Rayleigh excess ratio at each scattering angle. This is most

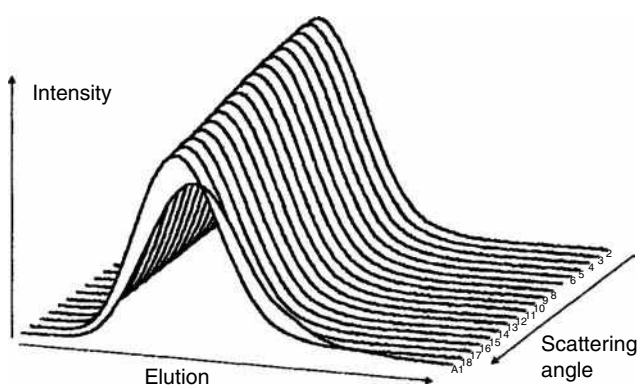

Fig. 2 Light-scattering and DRI signals from MALS setup shown in Fig. 1.

easily achieved by using a turbidity standard such as toluene. Details are found in Ref.[2] Once the refractive index of the mobile phase is entered, the software[4] performs the required calibration.

DERIVED MASS, SIZE, AND CONFORMATION

The MALS detector produces the absolute molar mass and mean square $\langle r_g^2 \rangle$ radius at each eluting slice. The *root mean square* (RMS) *radius* $r_g = \langle r_g^2 \rangle^{1/2}$ is often referred to by the misnomer "radius of gyration." There is a lower limit to its determination, which is generally about 8–10 nm. Below this value, MALS cannot generally produce a reliable value. Nevertheless, whenever both r_g and molar mass M are determined by MALS over a range of fractions present in an unknown sample, the sample's so-called conformation may be determined by plotting the logarithm of the RMS radius vs. the logarithm of the corresponding molar mass. A resultant slope of unity indicates a rodlike structure, a slope of 0.5–0.6 corresponds to a random coil, and a slope of 1/3 would indicate a sphere. Values below 1/3 generally suggest a highly branched molecular conformation.

Fig. 3 shows the MALS-derived molar mass and RMS radius as a function of elution volume for a broad polystyrene sample. Measurements were made in toluene at 690 nm.The value of *dn/dc* chosen was 0.11. From Fig. 3, it should be noted that the radius data begins to deteriorate around 10 nm, whereas the mass data extends to its detection limits. From the mass and radius data of Fig. 3, a conformation plot is easily generated with a slope of about 0.57 (i.e., corresponding to a random coil). These same data can also be used immediately to calculate the mass and size moments of the sample as well as its polydispersity as shown in the next section.

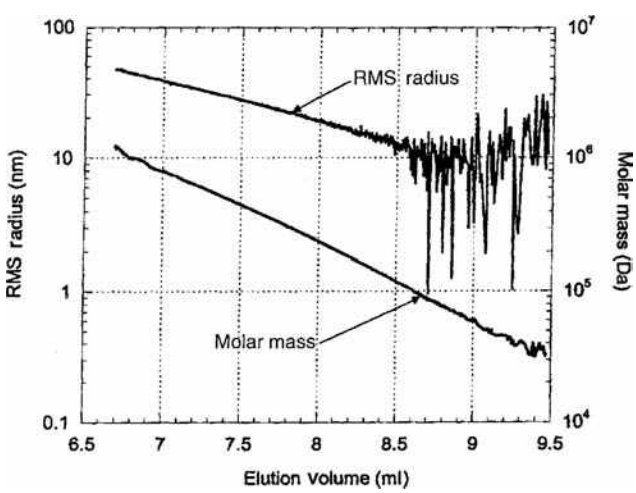

Fig. 3 Molar mass and RMS radius generated from data of Fig. 2 as a function of elution volume.

MASS AND SIZE MOMENTS

If we assume that the molecules in each slice, i, following separation by SEC, are monodisperse, the mass moments of each sample peak selected are calculated from the conventional definitions[3,5] by

$$M_n = \frac{\sum_i n_i M_i}{\sum_i n_i} = \frac{\sum_i c_i}{\sum_i c_i / M_i} \tag{6}$$

for the *number*-average molar mass, where n_i is the number of molecules of mass M_i in slice i and the summations are over all the slices present in the peak; the concentration c_i of the ith species, therefore, is proportional to $M_i n_i$;

$$M_w = \frac{\sum_i c_i M_i}{\sum_i c_i} = \frac{\sum_i n_i M_i^2}{\sum_i n_i M_i} \tag{7}$$

for the *weight*-average molar mass; and

$$M_z = \frac{\sum_i n_i M_i^3}{\sum_i n_i M_i^2} = \frac{\sum_i c_i M_i^2}{\sum_i c_i M_i} \tag{8}$$

for the z-average ("centrifuge") molar mass. Note how these "moments" are defined. In particular, the zaverage moment corresponds to "the next higher weighting" of both numerator and denominator by the factor Eqs. 6 and 7, of course, have a simple physical interpretation in terms of molecular numbers and concentration. From Eq. 8, it is a simple matter to write down expressions for the z + 1, z + 2, ... moments.

A similar set of expressions may be written down for the so-called size number and weight moments by replacing the mass terms M_i by the mean square radius values at each slice $\langle r_g^2 \rangle_i$ in Eqs. 6 and 7. A z-average term, on the other hand, takes on a more convoluted form.[5] For a random coil conformation under socalled theta conditions, the molar mass is directly proportional to $\langle r_g^2 \rangle$, and an expression that looks identical to Eq. 8 with one of the M_i of the numerator sum replaced by $\langle r_g^2 \rangle_i$ is obtained. However, in general, this "equivalence" is not the case and the "light-scattering" value LS is a better description, namely

$$\langle r_g^2 \rangle_{LS} = \frac{\sum_i c_i M_i \langle r_g^2 \rangle_i}{\sum_i M_i c_i} \tag{9}$$

Despite the non-random-coil-at-theta conditions, Eq. 9 is commonly referred to as the z-average mean square radius. The cross-term $M_i \langle r_g^2 \rangle_i c_i$ of Eq. 9 is a quantity measured directly by light scattering, at small $\sin^2(\theta/2)$, as clearly may be seen by expanding the term $1/P(\theta)$ in Eq. 1 using the expansion of $P(\theta)$ of Eq. 3.

POLYDISPERSITY

Within the peak selected, the sample polydispersity is simply the ratio of the weight to number average (viz. M_w/M_n) obtained from Eqs. 7 and 6, respectively.

DIFFERENTIAL MASS WEIGHT FRACTION DISTRIBUTION

The MALS measurements illustrated by Fig. 2 also may be used directly to calculate the differential mass weight fraction distribution, $x(M) = dW(M)/d(\log_{10}M)$ by using the measured $\log_{10}M$ as a function of the elution volume V. Thus, if the concentration detector's baseline subtracted response is $h(V)$, then $dW/dV = \pm h(V)/\int h(V)\,dV$, the integral representing the sum over all contributing concentrations to the peak. It is then easily shown[6] that

$$x(M) = -\frac{h(V)/\int h(V)dV}{d(\log_{10}M)/dV} \tag{10}$$

Note that for so-called "linear" column separations, the denominator $d(\log_{10}M)/dV$ is just a constant and, therefore, the differential weight fraction distribution will appear as a reflection (small mass first, from left to right) of the DRI signal. In general, column separations are not linear, so the DRI signal is not a good representation of the mass-elution distribution.

BRANCHING

The MALS measurements which eliminate the need for column calibration and all of its subsequent aberrations also permit the direct evaluation of branching phenomena in macromolecules because the basic quantitation of branching may only be achieved from such measurements as shown in the article by Zimm and Stockmayer.[7] Empirical approaches to quantitate branching, using such techniques as viscometry, have been shown to yield consistently erroneous results especially when long-chain branching becomes dominant.

REVERSED-PHASE AND OTHER SEPARATION TECHNIQUES

Because MALS determinations are independent of the separation mechanism, they may be applied to many types of HPLC. Reversed-phase separations are of particular significance because they cannot be calibrated, as sequential elutions do not occur in a monotonic or otherwise predictable manner. Again, as with all MALS chromatography measurements, all that is required is that the concentration and MALS's signals be available at each elution volume (slice).

Another separation technique of particular application for proteins, high-molar-mass molecules, and particles is the general class known as field-flow fractionation (FFF) in its various forms (cross-flow, sedimentation, thermal, and electrical). Once again, MALS detection permits mass and size determinations in an absolute sense without calibration. For homogeneous particles of relatively simple structure, a concentration detector is not required to calculate size and differential size and mass fraction distributions. Capillary hydrodynamic fractionation (CHDF) is another particle separation technique that may be used successfully with MALS detection.

GPC/SEC: Calibration with Narrow Molecular-Weight Distribution Standards

Oscar Chiantore
Department of Inorganic, Physical, and Material Chemistry, University of Torino, Torino, Italy

INTRODUCTION

In size-exclusion chromatography (SEC), polymer solutions are injected into one or more columns in series, packed with microparticulate porous packings. The packing pores have sizes in the range between ~ 5 and 10^5 nm, and during elution, the polymer molecules may or may not, depending on their size in the chromatographic eluent, penetrate into the pores. Therefore, smaller molecules have access to a larger fraction of pores compared to the larger ones, and the macromolecules elute in a decreasing order of molecular weights. For each type of polymer dissolved in the chromatographic eluent, and eluting through the given set of columns with a pure exclusion mechanism, a precise empirical correlation exists between molecular weights and elution volumes. This relationship constitutes the calibration of the SEC system, which allows the evaluation of average molecular weights (MWs) and molecular-weight distributions (MWDs) of the polymer under examination.

Direct column calibration for a given polymer requires the use of narrow MWD samples of that polymer, with molecular weights covering the whole range of interest. The polydispersity of the calibration standards must be less than 1.05, except for the very low and very high MWs ($<10^3$ and $>10^6$), for which polydispersity can reach 1.20. The chromatograms of such standards give narrow peaks and to each standard is associated the retention volume of the peak maximum.

There is a limited number of polymers for which narrow MWD standards are commercially available: polystyrene, poly(methyl methacrylate), poly (α-amethyl styrene), polyisoprene, polybutadiene, polyethylene, poly(dimethyl siloxane), polyethyleneoxide, pullulan, dextran, polystyrene sulfonate sodium salt, and globular proteins. In some cases, the standards available cover a limited molecular weight range, so it may be impossible to construct the calibration curve over the complete column pore volume.

Standard methods for calibration of SEC columns with narrow MWD samples have been published by the American Society for Testing and Materials (ASTM D2596-97) and the Deutsches Institut for Normung (DIN 55672-1).

PROCEDURE

Fresh solutions of the standards are prepared in the solvent used as chromatographic eluent. Calibration solutions should be as dilute as possible, in order to avoid any concentration dependence of sample retention volumes. The concentration effect causes an increase of retention volumes with increased sample concentration. As a rule of thumb, when high efficiency microparticulate packings are used, the concentration of narrow standards should be $\leq 0.025\%$ (w/v) for MW over 10^6, $\leq 0.05\%$ for MW between 10^6 and 2×10^5, and $\leq 0.1\%$ for MW down to 10^4. With a lower MW and in the oligomer range, the sample concentration can be higher than the previously suggested values.

Two or more standards may be dissolved and injected together to determine several retention volumes with a single injection. In such a case, the MW difference between the samples in the mixture should be sufficient to give peaks with baseline resolution. A sufficient number of narrow MWD standards, with different MWs, are required for establishing the calibration of a SEC column system. At least two standards per MW decade should be injected, and a minimum of five calibration points should be obtained in the curve.

MW FRACTIONATION RANGE OF THE COLUMN SET

The maximum injection volume depends from column size and packing pore volumes, and for high-efficiency 300×8 mm columns, it is generally recommended not to exceed 100 μl per column.

The flow rate of the chromatographic apparatus must be extremely stable and reproducible: Flow rate fluctuations about the specified value should be lower than 3%, and long-term drift lower than 1%. Repeatability of flow rate setting is extremely important, as a 1% constant deviation of the actual flow rate from the required value may give 20% differences in calculated MW averages.

The systematic errors introduced by flow rate differences may be avoided by adding to the solutions a

minimum amount of a low-molecular-weight internal standard (*O*-dichloro benzene, toluene, acetone, sulfur) which must not interfere with the polymer peaks. Flow rate is monitored in each chromatogram by measuring the retention time of the internal standard, and eventual variations may be corrected accordingly.

The peak retention times for the narrow polymer standards are measured from the chromatograms and transformed into retention volumes according to the real flow rate. For each standard, the logarithm of nominal molecular weight is plotted against its peak elution volume. Often, retention times are directly employed and plotted as the measured variable, and in this case, the condition of equal flow rate elutions for all the standards and for any subsequent sample analysis is achieved by means of the internal standard elution.

The molecular weight of the standards is supplied by the producers, either with a single value which should correspond to that of peak maximum, or with a complete characterization data sheet containing the values of M_n and M_w determined by osmometry and light scattering. In the latter case, the peak molecular weight to be inserted in the calibration plot is the mean value $(M_n M_w)^{1/2}$. A typical calibration curve for a threecolumn set, 300×7.5 mm, packed with a mixture of individual pore sizes is shown in Fig. 1. The calibration curve has a central part which is essentially linear and becomes curved at the two extremes: on the high-MW side when it approaches the retention value of totally excluded samples; on the low-MW side with a downward curvature until it reaches the retention time of total pore permeation.

The calibration curve, therefore, defines the extremes of retention times (or volumes) for the specific column system, the useful retention interval for sample analysis, and the related MW range. Columns packed with a balanced mixture of different pore sizes are capable of giving linear calibrations over the whole MW range of practical interest, from the oligomer region to more than 10^6.

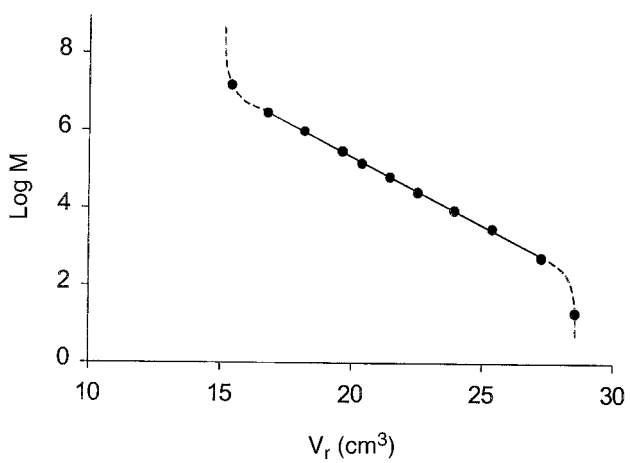

Fig. 1 Example of calibration curve with narrow MWD standards.

The plot of log M vs. peak retention volumes of narrow standards is represented in the more general form by a nth-order polynomial of the type

$$\log M = A + BV_r + CV_r^2 + DV_r^3 + \cdots$$

the coefficients of which are determined by regression on the experimental data. Most usually, when the linear plot is not sufficient to fit the points, a third-order polynomial will be adequate to represent the curve. Higher-order equations, although improving the fit, should be used with great care, as they can lead to unrealistic oscillations of the function.

The goodness of different equations fitted to the experimental data points is assessed by the results of statistical analysis or by simply considering the standard error of the estimate. It should be also considered that the adequacy of the calibration function for the determination of correct MW values is also dependent on the quality of the narrow MWD standards. Their nominal MWs are determined with independent absolute methods and are affected by experimental errors which may be different between samples with different MWs, or coming from different producers. A check of the quality of the narrow standards may be obtained by calculating the percent MW deviation of each standard from the calibration curve:

$$\Delta M(V_i)\% = \frac{M_{\text{pcak}}(V_i) - M_{\text{calc}}(V_i)}{M_{\text{pcak}}(V_i)} \times 100$$

A plot of $\Delta M(V_i)\%$ vs. log M results in positive and negative values scattered around the MW axis, which allows one to visualize the limits of percent error into which the MW of standards are estimated by the calibration curve. If the MW error of some standard is found to be significantly larger than all the others, it is likely that its nominal MW is incorrect. The point of such sample should be removed from the calibration and the regression recalculated.

The calibration curve should always cover the MW of the samples that must be analyzed. Extrapolation of the calibration outside the range of injected polymer standards should be avoided in MW determinations.

From the calibration curve, the resolution power of the column set may also be evaluated. Resolution between two adjacent peaks, 1 and 2, is defined in terms of their retention volumes, V_r, and peak widths, w:

$$R_S = \frac{2(V_{r2} - V_{r1})}{w_1 + w_2}$$

The calibration is often expressed in the form of ln M vs. V_r, and assuming a linear function, it may be written as

$$\ln M = \ln D_1 - D_2 V_r$$

By solving for V_r and substituting into the relationship for R_S, we obtain

$$R_S = \frac{\ln(M_1/M_2)}{wD_2} = \frac{\ln(M_1/M_2)}{4\sigma D_2}$$

valid for peaks of similar width or standard deviation σ, where $w_1 \approx w_2 = w = 4\sigma$. The above equation shows that the MW fractionation of SEC columns is linked to both their useful pore volume (slope D_2 of the calibration curve) and to packing quality (column efficiency or number of plate heights, determining peak widths). Working with columns having linear calibration in their whole fractionation range guarantees equal resolution power over several MW decades.

GPC/SEC: Calibration with Universal Calibration Techniques

Oscar Chiantore
Department of Inorganic, Physical, and Material Chemistry, University of Torino, Torino, Italy

INTRODUCTION

Direct calibration of (gel permeation chromatography/size exclusion chromatography) GPC/SEC columns requires well characterized polymer standards of the same type of polymer one has to analyze. However, narrow molecular-weight distribution (MWD) standards are available for a limited number of polymers only, and well-characterized broad MWD standards are not always accessible. The parameter controlling separation in GPC/SEC is the size of solute in the chromatographic eluent. Therefore, if different polymer solutes are eluted in the same chromatographic system with a pure exclusion mechanism, at the same retention volume, molecules with the same size will be found.

DISCUSSION

By plotting the logarithm of solute size vs. retention volume, the points of all different polymers will be represented by a unique curve—a universal calibration curve. Thus, by application of the universal calibration, average molecular weights (MWs) and MWDs of any type of polymer may be evaluated from the SEC, provided that the relationship between molecular size and polymer molecular weight is known.

Several size parameters can be used to describe the dimensions of polymer molecules: radius of gyration, end-to-end distance, mean external length, and so forth. In the case of SEC analysis, it must be considered that the polymer molecular size is influenced by the interactions of chain segments with the solvent. As a consequence, polymer molecules in solution can be represented as equivalent hydrodynamic spheres,[1] to which the Einstein equation for viscosity may be applied:

$$\eta = \eta_0(1 + 2.5\phi_s) \tag{1}$$

η and η_0 are the viscosities of solution and solvent, respectively, and ϕ_s is the volume fraction of solute particles in the solution.

By expressing the solute concentration c in grams per cubic centimeter, the relationship holds:

$$\phi_s = \frac{cN_AV_h}{M} \tag{2}$$

where N_A is Avogadro's number and V_h and M are the hydrodynamic volume and the molecular weight of the solute, respectively. Substituting in Eq. 1 and taking into account that

$$[\eta] = \lim_{c\to 0}\left(\frac{(\eta - \eta_0)/\eta_0}{c}\right) \tag{3}$$

we obtain

$$[\eta]M = 2.5N_AV_h \tag{4}$$

Eq. 4 states that the hydrodynamic volume of a polymer molecule is proportional to the product of its intrinsic viscosity times the molecular weight.

The use of $[\eta]M$ as size parameter for GPC/SEC universal calibration was first proposed by Benoit and coworkers[2] and shown to be valid for homopolymers and copolymers with various chemical and geometrical structures. Their data are reported in the semilogarithmic plot of Fig. 1.

The hydrodynamic volume parameter $[\eta]M$ has been proven to be applicable also to the cases of rodlike polymers[3] and to separations in aqueous solvents[4] where, however, secondary non-exclusion mechanisms often superimpose and affect the sample elution behavior. In the latter situation, careful choice of eluent composition must be made in order to avoid any possible polymer-packing interaction.

The application of universal calibration requires a primary column calibration with elution of narrow MWD standards. For SEC in tetrahydrofuran, polystyrene (PS) standards are generally used. Intrinsic viscosities of the standards are either known or calculated from the proper Mark–Houwink equation, so that the plot of $\log[\eta]_{PS}M_{PS}$ values vs. retention volumes V_r may be created. The universal calibration equation is obtained by polynomial regression, in the same way described for the calibration with narrow MWD standards.

Average-molecular weights and MWDs of any polymer sample eluted on the same columns with pure exclusion mechanism may be calculated by considering that, at any retention volume, the following relationship holds:

$$[\eta]_iM_i = [\eta]_{PS,i}M_{PS,i} \tag{5}$$

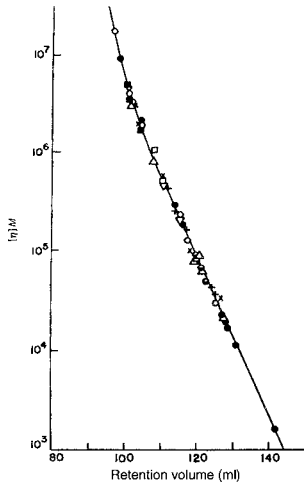

Fig. 1 Retention volume vs. $[\eta]M$.
Source: From A universal calibration for gel permeation chromatography, in J. Polym. Sci. B.[2]

from which

$$M_i = \frac{[\eta]_{\mathrm{PS},i} M_{\mathrm{PS},i}}{[\eta]_i} \tag{6}$$

To solve Eq. 6, the denominator must be known. Substituting into the denominator the Mark–Houwink expression $[\eta] = KM^a$ for the investigated polymer and rearranging, we obtain

$$M_i = \left(\frac{[\eta]_{\mathrm{PS},i} M_{\mathrm{PS},i}}{K} \right)^{1/1+a} \tag{7}$$

where K and a are the constants of the viscosimetric equation for that polymer, dissolved in the chromatographic eluent and at the temperature of analysis.

From Eq. 7, the molecular weight of each fraction in the chromatogram is obtained and average molecular weights may be calculated by application of the appropriate summations. The numerator in Eq. 7 is the value of the universal calibration at each retention volume.

The necessary conditions for application of the universal calibration method and for calculation of molecular weights through Eq. 6 is the knowledge of the $[\eta]_i$ values, which are obtained from the Mark–Houwink equations when the pertinent values of K and a constants are known. An alternative way is to make a continuous measurement of $[\eta]_i$ at the different elution volumes with an online viscometer detector coupled to the usual concentration detector system.

Methods for application of the universal calibration have been developed also for cases where K and a of the polymer of interest are not known and neither $[\eta]_i$ values are measured. Such methods are based on the availability of two broad MWD standards, having different molecular weights, of the polymer under examination.[5]

One important property of the universal calibration concept is that, in the SEC separation of complex polymers (i.e., polymers with different architectures or copolymers with non-constant chemical composition), at each retention volume, $V_{r,i}$, molecules with same hydrodynamic volume but possibly different molecular weights will elute. It has been demonstrated that, in such a case, the application of the hydrodynamic volume parameter, $[\eta]M$ gives the number-average molecular weight, M_n, of the polymer.[6] In fact, at each retention volume, the intrinsic viscosity of the eluted fraction is given by the weight average over the n different molecular species present:

$$[\eta]_i = w_1[\eta]_1 + w_2[\eta]_2 + \cdots + w_n[\eta]_n \tag{8}$$

Eq. 8 may be written as

$$[\eta]_i = \frac{[\eta]_1 M_1 w_1}{M_1} + \frac{[\eta]_2 M_2 w_2}{M_2} + \cdots + \frac{[\eta]_n M_n w_n}{M_n} \tag{9}$$

As the condition holds, at each retention volume

$$[\eta]_1 M_1 = [\eta]_2 M_2 = \cdots = [\eta]_{\mathrm{PS}} M_{\mathrm{PS}} \tag{10}$$

Eq. 9 becomes

$$[\eta]_i = [\eta]_{\mathrm{PS}} M_{\mathrm{PS}} \sum \left(\frac{w_i}{M_i} \right) = \frac{[\eta]_{\mathrm{PS}} M_{\mathrm{PS}}}{M_{n,i}} \tag{11}$$

$$[\eta]_i M_{n,i} = [\eta]_{\mathrm{PS}} M_{\mathrm{PS}} \tag{12}$$

By considering all the fractions of the chromatogram, the M_n value of the whole sample may be then calculated.

Experimental aspects for the determination of molecular weight averages and MWD distributions by GPC/SEC using universal calibration are described in a standard ASTM method.[7] Detailed discussion on the validity and limitations of the method may be also found in Ref.[8]

GPC/SEC: Experimental Conditions

Sadao Mori
PAC Research Institute, Mie University, Nagoya, Japan

INTRODUCTION

In order to calculate the molecular-weight averages of a polymer from the size-exclusion chromatography (SEC) chromatogram, the relationship between the molecular weight and the retention volume (called the "calibration curve") needs to be known, unless a molecular-weight-sensitive detector is used. The retention volume of a polymer changes with changing experimental conditions; therefore, when molecular-weight averages of the polymer are calculated using the calibration curve, care must be taken with the effect of experimental conditions.[1]

DISCUSSION

Sample concentration is one of the most important operating variables in SEC, because the retention volumes of polymers increase with increased concentration of the sample solution. The concentration dependence of the retention volume is a well-known phenomenon and the magnitude of the peak shift to higher retention volume is more pronounced for polymers with a higher molecular weights than for those with lower molecular weights. This phenomenon is almost improbable for polymers with a molecular weight lower than 10^4 and is observed ever at a low concentration, such as 0.01%, although the peak shift is smaller than that at a higher concentration.

In this sense, this concentration dependence of the retention volume should be called the "concentration effect," not "overload effect" or "viscosity effect." If a large volume of a sample solution is injected, an appreciable shift in retention volume is observed, even for low-molecular-weight polymers; this is called the "overload effect."

The retention volume increases with increasing concentration of the sample solution and the magnitude of the increase is related to the increasing molecular weight of the sample polymers.[2] The reason for the increase in retention volume with increasing polymer concentration is considered to result from the decrease in the hydrodynamic volume of the polymer molecules in the solution.

Molecular-weight averages calculated with calibration curves of varying concentrations may differ in value. As the influence of the sample concentration on the retention volume is based on the essential nature of the hydrodynamic volume of the polymer in solution, it is necessary to select experimental conditions that will reduce the errors produced by the concentration effect.

By rule of thumb, the preferred sample concentrations, if two SEC columns of 8 mm inner diameter (I.D.) $\times$ 25 cm in length are used, are as follows. The sample concentrations should be as low as possible and no more than 0.2%. For high-molecular-weight polymers, concentrations less than 0.1% are often required, and for low-molecular-weight polymers, concentrations of more than 0.2% are possible. The concentrations of polystyrene standards for calibration should be one-half of the unknown sample concentration. For polystyrene standards with a molecular weight over 10^6, it is preferable that they are one-eighth to one-tenth and for those with a molecular weights between 5×10^5 and 10^6, a quarter to one-fifth of the sample concentration.

The retention volume of a polymer sample increases as the injection volume increases.[3] In some cases, the increase in the retention volume from an injection volume increase from 0.1 to 0.25 ml was 0.65 ml, whereas that from 0.25 to 0.5 ml was only 0.05 ml, suggesting that a precise or constant injection is required even if the injection volume is as small as 0.1 or 0.05 ml. In view of the significant effect of the injection volume on the retention volume, it is important to use the same injection volume for the sample under examination as that used when constructing the calibration curve. The use of a loop injector is essential, and the same injection volume must be employed for all sample solutions including calibration standards, regardless of their molecular-weight values. The increase in the injection volume results in a decrease in the number of theoretical plates, due to band broadening, which means that the calculated values of the molecular-weight averages and distribution deviate from the true values (Fig. 1).

The retention volume in SEC increases with increasing flow rate.[3] This is attributed to non-equilibrium effects, because polymer diffusion between the intrapores and extrapores of gels is sufficiently slow that equilibrium cannot be attained at each point in the column. With a decreasing flow rate, the efficiency and the resolution are increased. Bimodal distribution of a PS standard (NBS706) with a narrow molecular weight distribution was clearly observed at the lower flow rate.

Separation of molecules in SEC is governed, mainly, by the entropy change of the molecules between the mobile phase and the stationary phase, and the temperature independence of peak retention can be predicted. However, an

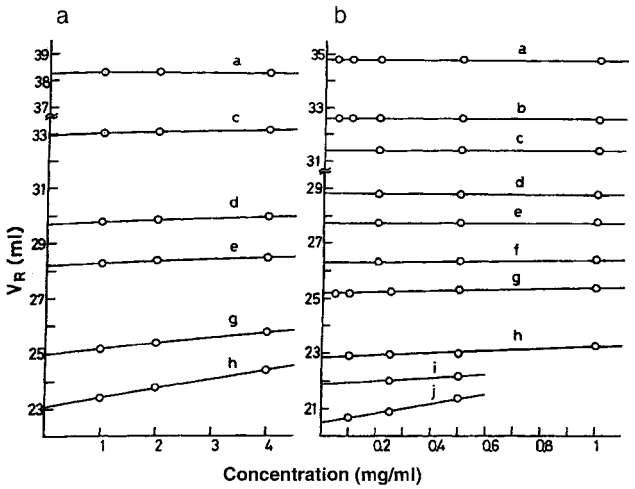

Fig. 1 Concentration dependence of retention volume for polystyrene in good solvents on polystyrene gel columns: (a) in toluene on microstyragel columns (3/8 in. × 1 ft × 4) (10^6, 10^5, 10^4, and 10^3 nominal porosity) at a flow rate 2 ml/min and injected volume 0.25 ml; (b) in Tetrahydrofuran on Shodex A 80 *M* columns (8 mm × 50 cm × 2) (mixed polystyrene gels of several nominal porosities) at a flow rate 1.5 ml/min and injected volume 0.25 ml. Molecular weight of polystyrene standards: (a) 2100; (b) 10,000; (c) 20,400; (d) 97,200; (e) 180,000; (f) 411,000; (g) 670,000; (h) 1,800,000; (i) 3,800,000; (j) 8,500,000.

increase in retention volume with increasing column temperature is often observed. A temperature difference of 10°C results in a 1% increase in the retention volume, which corresponds to a 10–15% change in molecular weight.[4]

Two main factors that cause retention-volume variations with column temperature are assumed: an expansion or a contraction of the mobile phase in the column and the secondary effects of the solute to the stationary phase. When the column temperature is 10°C higher than room temperature, the mobile phase (temperature of the mobile phase is supposed to be the same as room temperature in this case) will expand about 1% from when it entered the columns, resulting in an increase in the real flow rate in the column due to the expansion of the mobile phase and the decrease in the retention volume. The magnitude of the retention-volume dependence on the solvent expansion is evaluated to be about one-half of the total change in the retention volume. The residual contribution to the change in retention volume is assumed to be that due to gel–solute interactions such as adsorption.

In order to obtain accurate and precise molecular-weight averages, the column temperature, as well as the difference of both temperatures, the solvent reservoir and the column oven, must be maintained.

Other factors affecting retention volume are the viscosity of the mobile phase, the sizes of gel pores, and the effective size of the solute molecules. Of these, the former two can be ignored, because they exhibit either no effect or only a small effect. The effective size of a solute molecule may also change with changing column temperature. The dependence of intrinsic viscosity on column temperature for PS in chloroform, tetrahydrofuran, and cyclohexane were tested.[5] The temperature dependence of intrinsic viscosity of PS solutions was observed over a range of temperatures. The intrinsic viscosity of PS in tetrahydrofuran is almost unchanged from 20°C up to 55°C, whereas the intrinsic viscosity in chloroform decreased from 30°C to 40°C. Cyclohexane is a theta solvent for PS at around 35°C and intrinsic viscosity in cyclohexane increased with increasing column temperature.

Because the hydrodynamic volume is proportional to the molecular size, the intrinsic viscosity can be used as a measure of the molecular size and optimum column temperatures and solvents must be those where no changes in intrinsic viscosity are observed.

Gradient Development in TLC

Wojciech Markowski
Department of Inorganic and Analytical Chemistry, Medical University of Lublin, Lublin, Poland

INTRODUCTION

The main task of analytical TLC is separation of sample from matrix, separation of sample components, their identification, and the measurement of peak heights or areas for quantitative purposes. Finally, the peaks should be narrow and symmetrical. Two problems are related to the analysis: choice of suitable conditions of development, such that all components of the sample are eluted in optimal range of retention factor; and their separation, allowing for identification and quantitation.

GENERAL ELUTION PROBLEM

In practice, a problem that appears very often is components of widely differing retention properties being present in the sample.[1–3] For example, consider a model mixture composed of 15 components with capacity factors $k_0(j)$ forming a geometrical progression and exponentially dependent on the modifier concentration (molar or volume fraction φ), in accordance with the Snyder–Soczewiński model of adsorption (Fig. 1A–D).[4]

$$k_0(j) = \frac{25.6}{2^j}, \quad k(j,i) = \frac{k_0(j)}{c(i)^{m(j)}} \tag{1}$$

$$R_F(j,i) = \frac{1}{1 + k(j,i)} \tag{2}$$

where j is the code of the solute (1–15), i the number of elution step (elution fraction), $k(j, i)$ the capacity factor of solute j in the ith step, $R_F(j, i)$ the retardation factor of solute j in the fraction of eluent of concentration $\varphi(i)$, $\varphi(i)$ the concentration of modifier (mole/volume fraction) in the ith step, $v(i)$ the volume of eluent delivered in the ith step, and $m(j)$ the slopes of linear plots of $R_M(j,i) = R_M^0(j) - m(j)\log\varphi(i)$.

In Fig. 1 are presented chromatograms (simulated) to illustrate the "general elution problem" addressed to TLC. Consider a representative mixture for components of a wide range of polarity. If the elution conditions are suitable for weakly polar compounds, the strongly polar ones will remain at or near the start line. On the other hand, if the system is set up so that strongly polar components are separated, the weakly polar ones will accumulate at the mobile-phase front. It can be seen from the picture that no isocratic eluent can separate all components. A pure modifier of $\varphi = 1.0$ (100%) well separates solutes S3–S6, and the less polar solutes accumulate near the solvent front (Fig. 2A); for $\varphi = 0.5$ (50%), solutes S5–S8 are well separated, the remaining ones accumulating near either the start line or the front line (Fig. 2B); for $\varphi = 0.05$ (5.0%), solutes 1–11 accumulate near the start line; only solutes S12–S15 are separated in the optimal R_F window (Fig. 2C). Thus, only about one-third of the components can be satisfactorily separated by isocratic elution. This problem is named "the general elution problem" and is attacked in different ways in different modes of chromatography (Fig. 2D). Usually, some kind of change of parameters is done. This involves a stepwise or continuous change of chosen parameter. Both in column chromatography and in TLC, the isocratic mode is preferred unless the "general elution problem" is encountered. Its solution may consist of gradient elution (stepwise or continuous), gradation of stationary phase, development with a mixed eluent composed of solvents of different polarity (polyzonal TLC), or temperature programming.[3,5,6] When the strength of mobile phase delivered to the layer is programmed, this is called gradient development. One of advantages of gradient TLC is the feasibility of application of both simple and reversed gradients (decreasing modifier concentration) and a complex gradient—a combination of both types of gradient. The gradient of the mobile phase is both simple and practical in application. In a simple gradient, the eluent strength is increased from the beginning to the end of the development process. The reversed gradient can be applied in the case of multiple development (MD), and the eluent strength decreases with increase in number of developments.

DESCRIPTION OF THE MOBILE-PHASE GRADIENT

The gradient is defined by the variation of elution strength of a series of single solvents or a mixture of solvents, or by the variation of composition of the mobile phase, by the percentage content of the weaker component A and the stronger component B, called the modifier. The gradient is also characterized by its steepness, shape, and complexity. The steepness is defined by the concentration of the modifier of the first and last fractions of the eluent delivered to the adsorbent layer. When the differences in modifier concentrations between all steps are constant, the gradient is

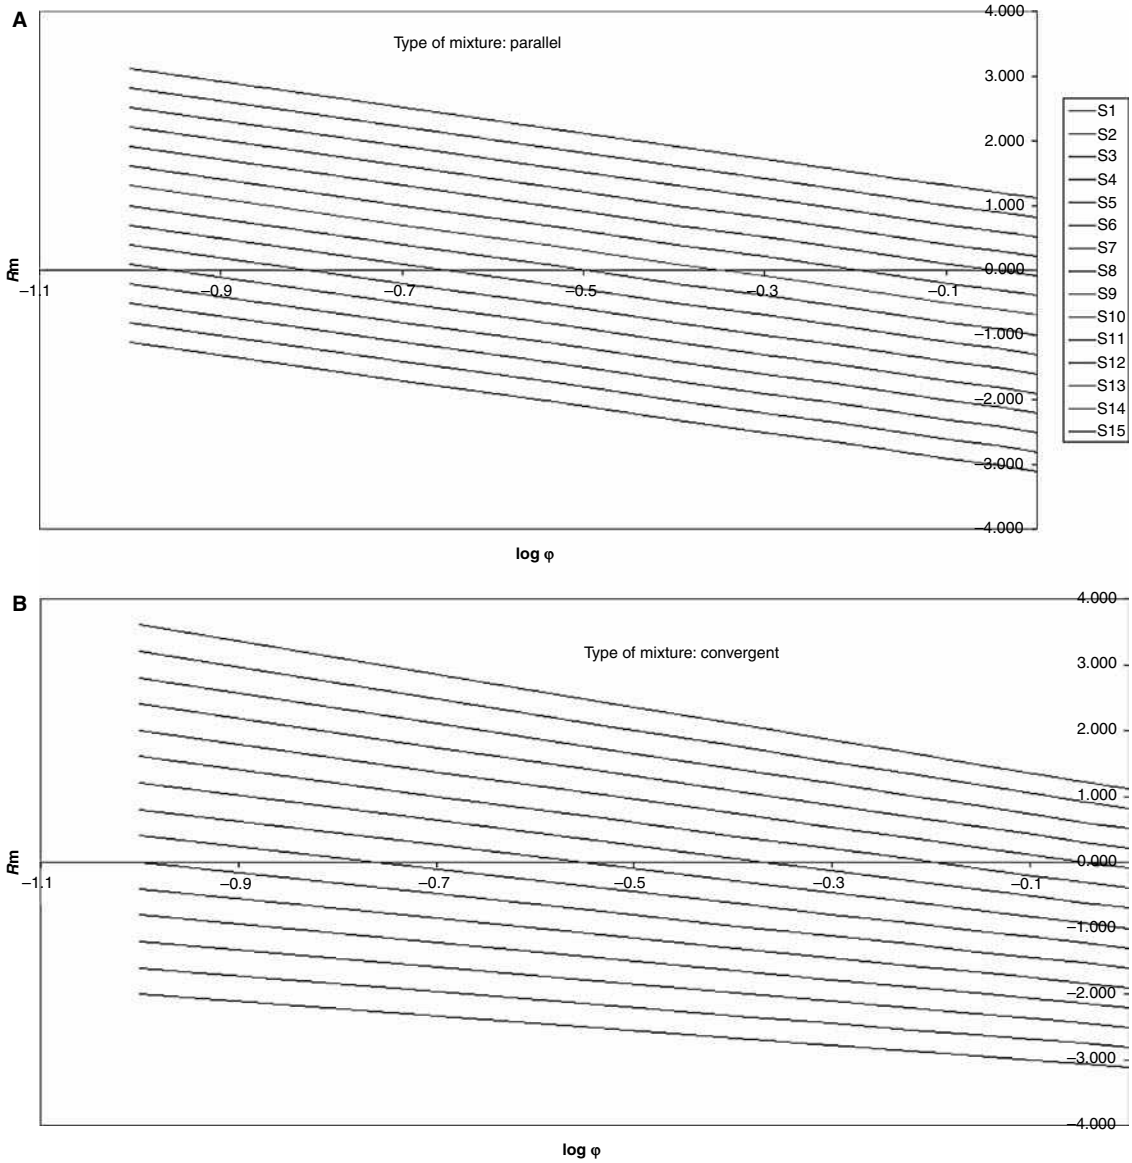

Fig. 1 Family of 15 $R_M(j,i) = R_M{}^0(j) - m(j)\ \log\ c(i)$ plots for model mixture of solutes S1–S15 according to adsorption model of Snyder–Soczewiński. A, Family of parallel lines; B, family of convergent lines; C, family of divergent lines; and D, family of crossing lines.

called linear. When these differences are large in the beginning and then decrease in the consecutive steps, it is known as a convex gradient program, and in the opposite case, as a concave gradient. The complexity of the gradient is related to the number of fractions of mobile phase delivered to the layer and combination of three basic profiles and dimensions of the volume of fractions. Fig. 3 illustrates different profiles of stepwise simple gradient use in TLC.

MIGRATION OF SOLUTES UNDER MOBILE-PHASE GRADIENT CONDITIONS

The use of a stepwise gradient of the mobile phase is well described by the theoretical models.[4–8] In the ideal situation, the spots of solutes are overtaken by consecutive fronts of increased modifier concentration, accelerating their migration so that even strongly retained solutes start to migrate. Depending on the polarities of the solutes, some migrate all the time in the first concentration zones [when the retardation factor of the solutes follow the condition $R_F(j,1) \geq 1 - v(1)$], or they are overtaken by the consecutive zones of higher concentration. It can be seen (Fig. 4) that both weakly polar (15–13) and strongly polar (1–5) compounds are well separated in the final chromatogram. The migration of the components under conditions of stepwise gradient with one void volume of mobile phase is describing by the following equations: In the case when solutes migrate only in the first zone, the final position $R_P(j)$ is specified by

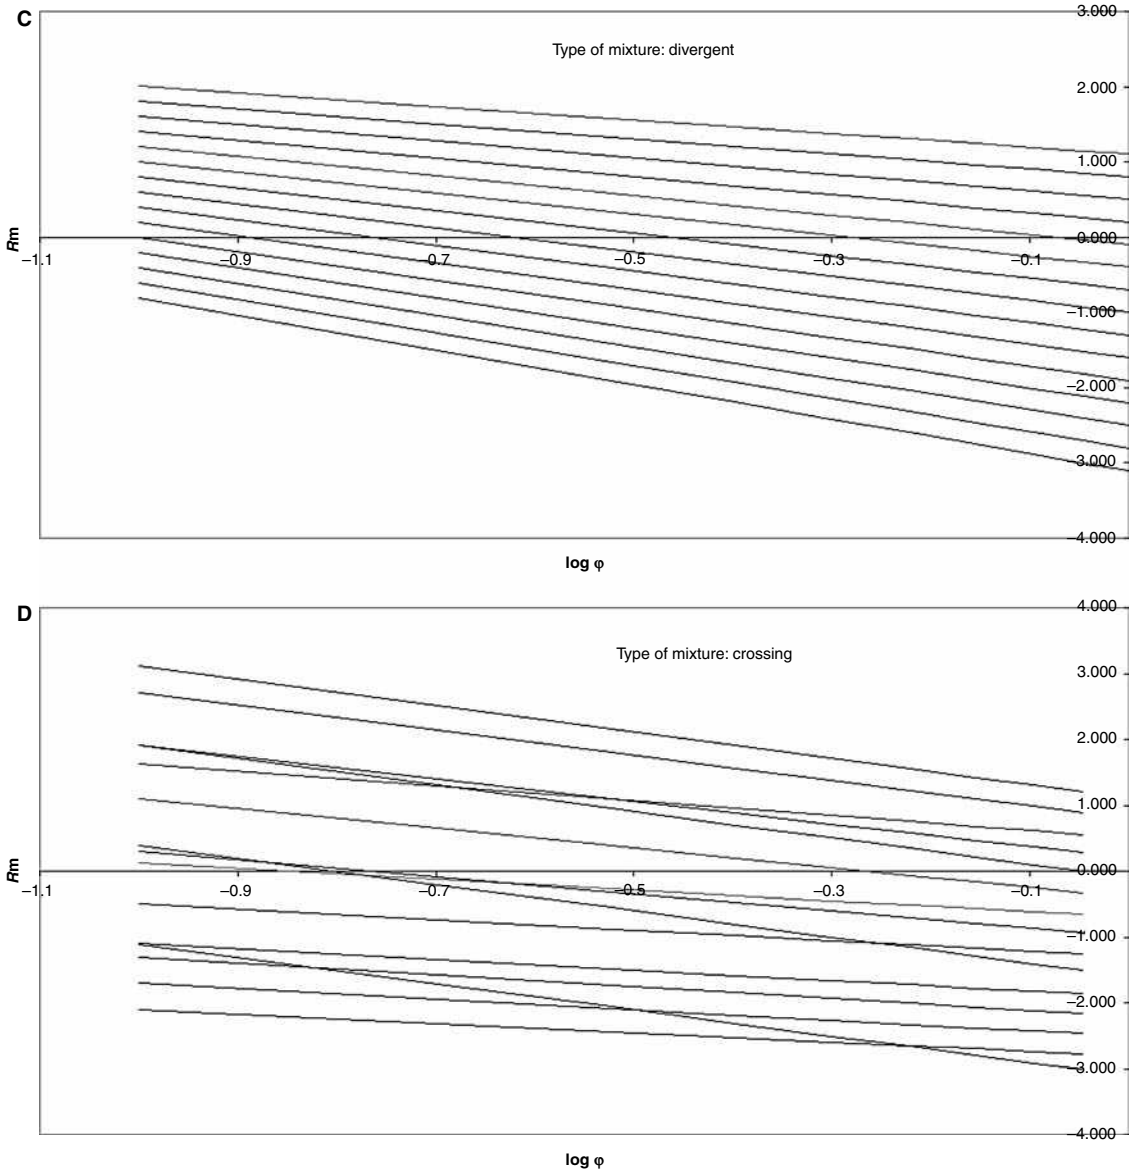

Fig. 1 (*Continued*).

$$R_{\mathrm{P}}(j) = R_{\mathrm{F}}(j,1) = \frac{1}{1 + k(j,1)} \tag{3}$$

and for other solutes migrating through different zones of concentration, the final position is specified by

$$R_{\mathrm{P}}(j) = \sum_{i=1}^{h-1} v(i) \frac{R_{\mathrm{F}(j,i)}}{1 - R_{\mathrm{F}(j,i)}} + R_{\mathrm{F}(j,h)} \left(1 - \sum_{i=1}^{h-1} v(i) \frac{1}{1 - R_{\mathrm{F}(j,i)}} \right) \tag{4}$$

(For detailed derivation and discussion, see Ref.[7]) Both equations could be applied to formulate computer programs (in any programming language or using a spreadsheet) that calculate the final spot position for a given gradient program and retention–eluent composition relationships. The retention–eluent composition relationships are obtained from preliminary isocratic runs. The experimental results obtained in Refs.[9,10] are in good agreement with the theoretical values calculated from Eqs. 1 and 2 (average error 1.5% and 0.17%). The simulation of gradient development can help considerably in the selection of an optimal program for a given system of adsorbent/mobile phase.[11] In the model, it is assumed that the stagnant mobile phase in the pores of the adsorbent is rapidly displaced and demixing does not occur. In reality, demixing takes place (especially in the first fractions of low concentrations of modifier) and the exchange of the stagnant solvent in the pores with the mobile phase is slow;

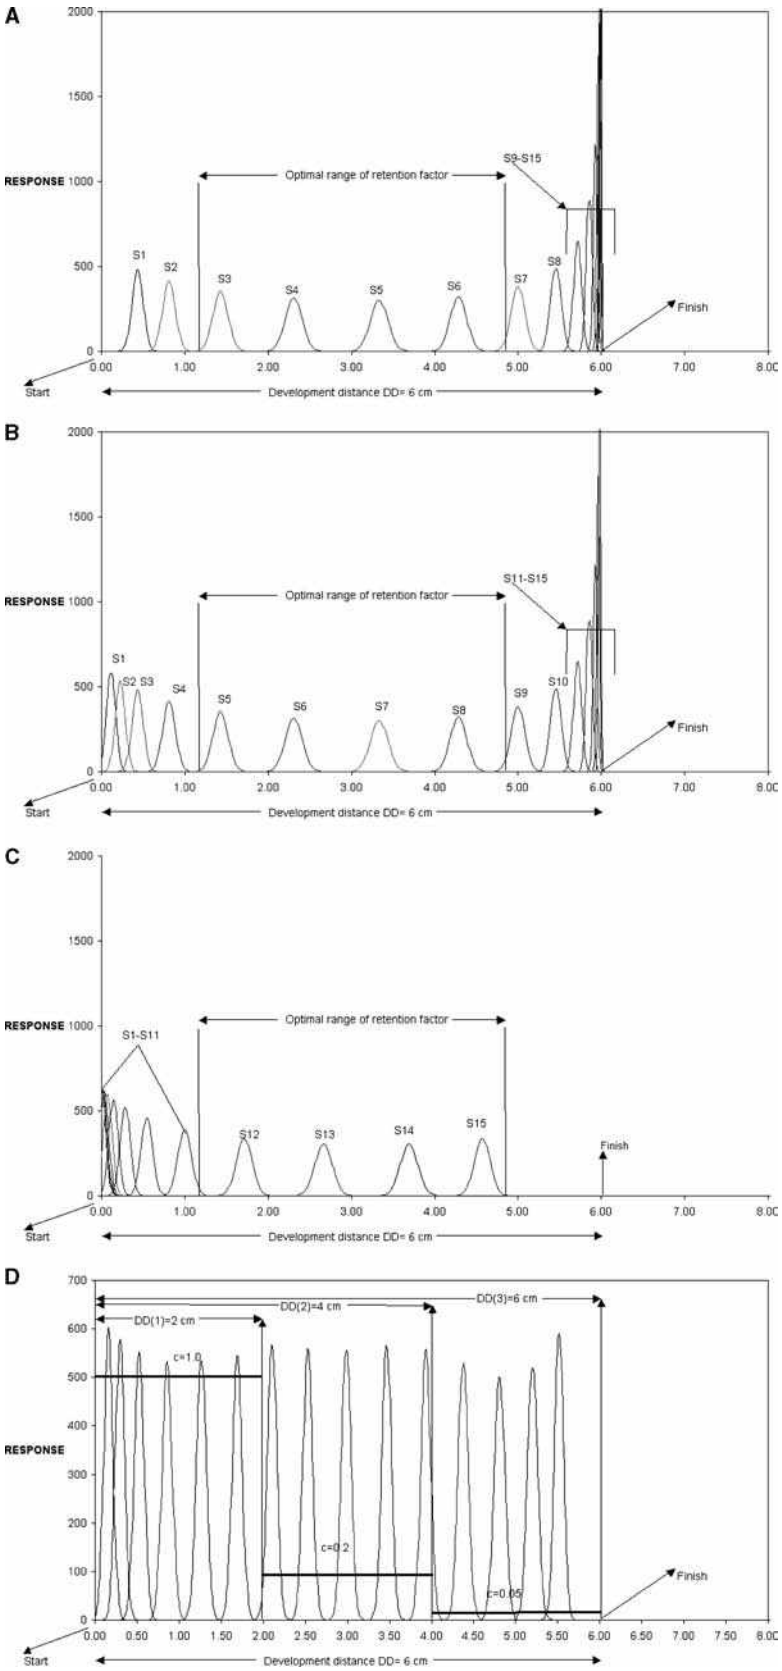

Fig. 2 Simulated chromatograms of hypothetical solutes S1–S15 (Fig. 1) for isocratic conditions of development. Concentration of modifier in volume fraction: A, $\varphi = 1.0$; B, $\varphi = 0.5$; C, $\varphi = 0.05$. Other conditions of simulation: development distance $DD = 6$ cm; spreading of zone (according to Eqs. 8–10 and Belenkii model of spot broadening.[5] D, Simulated chromatogram of hypothetical solutes S1–S15 for G IMD. Number of developments $n = 3$; increment of development distance $IDD = 2$ cm; total distance of development $DD = 6$ cm. Reverse gradient of mobile phase: $\varphi(1) = 1.0$; $\varphi(2) = 0.2$; $\varphi(3) = 0.05$.

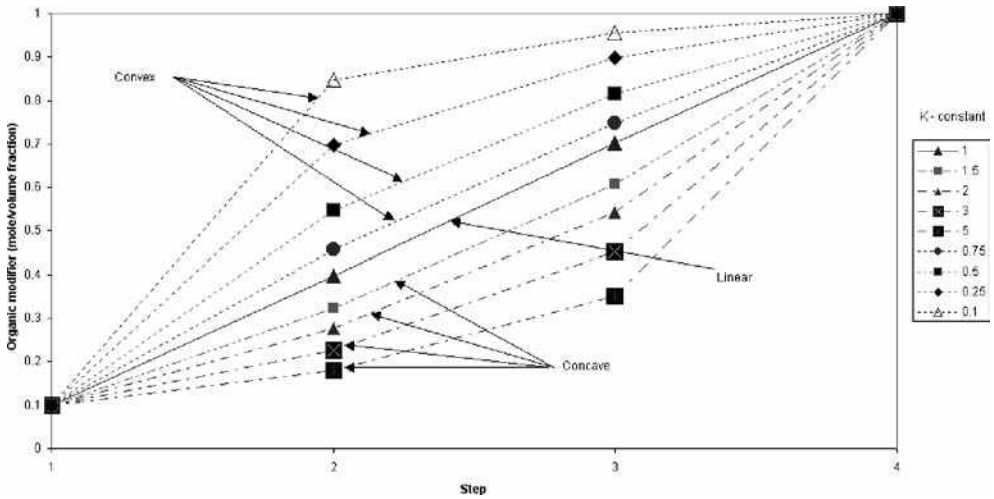

Fig. 3 Various stepwise gradient profiles used in simple gradient. Constant K is a measure of deviation from linearity by convex and concave profiles of gradient.

therefore, the boundaries of the concentration zones are not sharp but somewhat diffuse, and the solutes migrate in zones of intermediate properties. The demixing effect may cause deviation of the gradient profile from the planned one, especially for low concentration of modifier, and in consequence, the concentration fronts are delayed. For this reason, the distances of migration of solutes in lower concentration zones are smaller. The final relative position is lower in comparison to the position expected for ideal conditions. Because of the complexity of gradient development, only some rules of thumb can be given. In planning the gradient program, it is necessary to choose conditions under which the weakly retained components do not migrate with the front of the mobile phase and the strongly retained ones do not remain on the start line. After the choice of adsorbent (the first choice is silica gel), the next step is selection of the eluent. After Ref.,[8] the following series of solvents with increasing elution strength can be applied to TLC on silica gel: heptane, trichloroethylene, dichloromethane, diisopropyl ether, ethyl acetate, and isopropanol. They can be used as one-component mobile phases or as components of multiple-component mobile phases. These solvents can be replaced by other solvents with similar strength but different selectivity belonging to the eight groups exploited in the Prisma model of optimization.[12] The conditions of development depend on the type of mixture of components. Inspection of many experiments carried out on the relationships between retention parameter (R_M) and log φ or φ permits one to distinguish the following groups of solutes (Fig. 1): parallel, crossing, convergent, divergent.[13] The parameters that influence the separation are number of steps, volumes of steps, and profile of gradient including difference in concentration between the first and last step. Additionally, with the same number of steps of gradient, the volumes of eluent fractions can be equal or different. In Fig. 4, there are examples showing the influence of profile (linear, concave) and different volumes of the steps on the separation of an illustrative mixture of 15 solutes (parallel). In Table 1 are presented the minimal resolution (R_{Smin}—elementary criteria) and the multipeak criterion (MPC—product of the elementary criteria) values obtained for basic type of mixture and three programs of gradient (concave, linear, convex). These criteria were selected for estimation of the quality of chromatograms.[14] The R_{Smin} is given for the least resolved solute pair. The MPC is expressed as a percentage. When all compounds are equally spaced from each other and from the chosen boundaries, the function has a maximal value of 100%. It follows from the data presented in Table 1 that profiles can be ordered as follows: concave, linear, and convex. The application of the stepwise mobile-phase gradient greatly improves the separation of complex mixtures (e.g., plant extracts). In such cases, a gradient program with more steps of different concentrations is recommended; in many cases, the number of recognized spots is considerably increased in comparison to isocratic elution.[15] An example of practical application of a simple stepwise gradient is presented in Fig. 5, where separation of a quaternary alkaloid mixture is reported.[16] The application of a stepwise gradient using organic eluents allows one to avoid more time consuming systems, like cellulose powder and aqueous eluents.[17]

GRADIENT MULTIPLE DEVELOPMENT (MD)

In all techniques of MD, the plate is repeatedly developed in the same direction, with intermittent removal of the

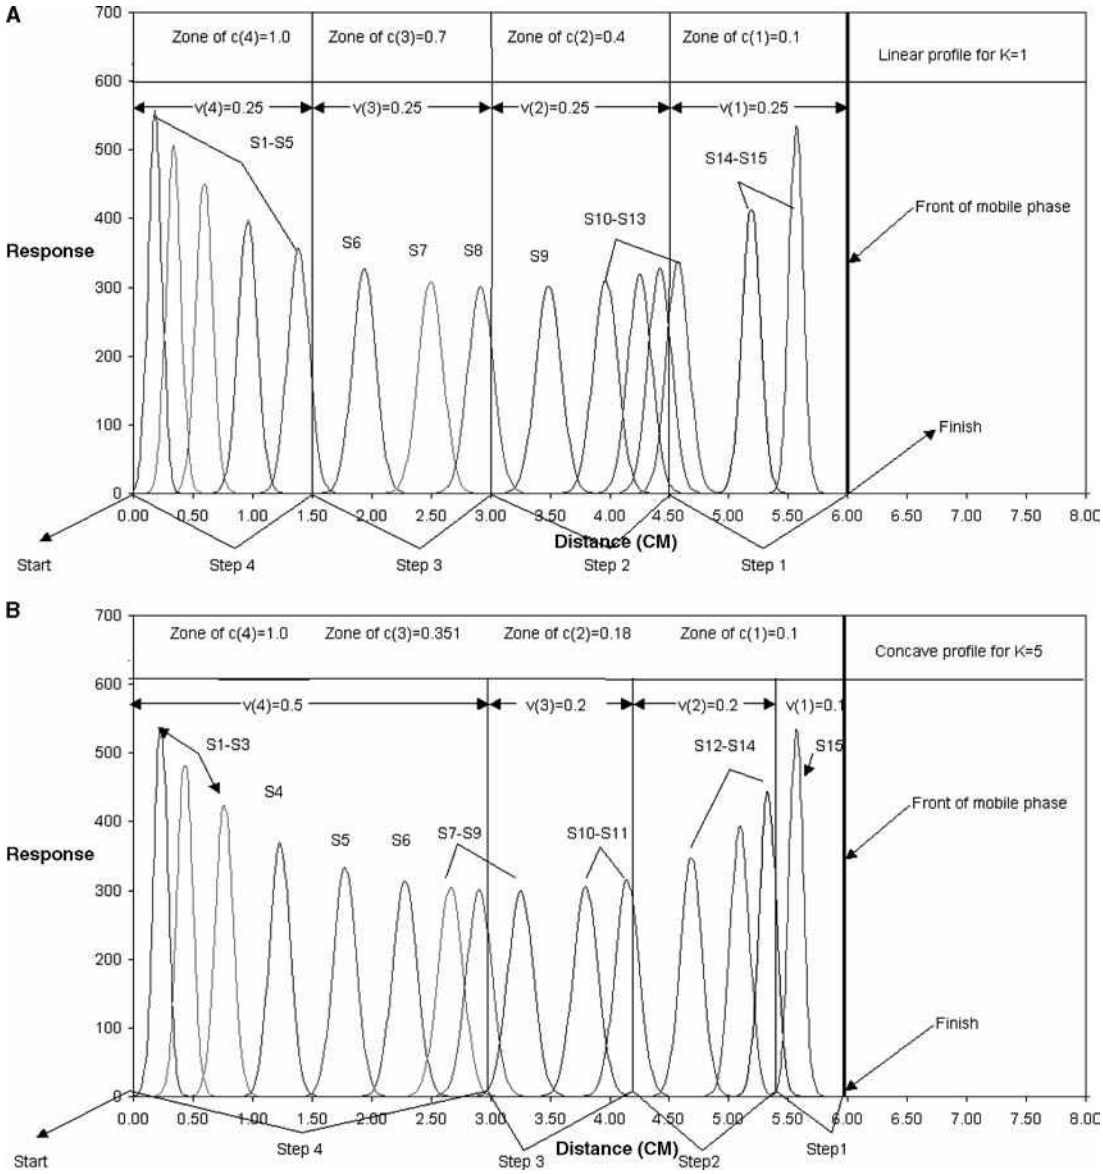

Fig. 4 Simulated chromatograms of hypothetical solutes S1–S15 for simple gradient development. A, Linear profile for $K = 1$; and B, concave profile for $K = 5$.

mobile phase between consecutive developments. Three basic criteria can be used to classify the methods of MD.[18–20] They are distance of development, properties of the mobile phase used in the process of development, and automation of the development and drying processes—automatic multiple development (AMD). The simplest version of MD is when the distances of development are identical in each step (unidimensional multiple development—UMD) and the mobile phase in each step is identical as well. A variation of this technique, called incremental multiple development (IMD), consists of stepwise change of the development distance, which is shortest in the first step and is then increased, usually by a constant increment (equal distance or time); the last development step corresponds to the maximum development distance. If, in the process of MD, the solvent strength of the mobile phase is varied, the technique is called gradient multiple development (G UMD or G IMD). The change in the mobile phase may concern several or all steps. The MD technique gives the possibility to use, in sequence, systems of mobile phase with very different selectivity and of increasing or, in most cases, decreasing elution strength. The process of MD with any variation of distance and mobile-phase composition can be described by the model and equations reported, modified to take into account the intermittent evaporation of solvents:[19]

Table 1 Influence of gradient profile on selected criteria for estimation of quality of separation of different types of mixtures in stepwise gradient development.

	Parallel		Convergent		Divergent		Crossing	
Profile of gradient	R_S[a]	MPC[b]	R_S	MPC	R_S	MPC	R_S	MPC
Linear	0.392	19.15	0.513	4.098	0.140	7.128	0.170	0.204
Convex	0.044	0.07	0.192	0.660	0.047	0.340	0.494	0.867
Concave	0.472	12.99	0.641	5.5	0.600	27.079	0.537	0.900

[a]Minimal values.
[b]Multipeak criterion in %.

$$SMD(j) = SMD(j, n-1) + [DD(n) - SMD(j, n-1)] \cdot R_F(j, n) \quad (5)$$

$$R_P(j) = \frac{SMD(j)}{DD(n)} \quad (6)$$

where $SMD(j)$ is the total migration distance of solute j after n steps, frequently expressed in millimeters, $SMD(j, n-1)$ the sum of the migration distances of solute j after $n-1$ steps, and $DD(n)$ the development distance in the last, nth step. $R_P(j)$ is the final position of the spot after n steps of gradient and is equal to the sum of distances traveled by a solute, divided by development distance corresponding to the distance between start and finish. Eqs. 5 and 6 are of typical recurrent type, in which the $(k-1)$th value for the sum of migration distances traveled by a solute is needed to calculate the kth value. In the simplest case, e.g., two groups of solutes with strong differences in polarity, the version of a decreasing stepwise gradient with two steps can be applied. The layer is developed 2/3 of the distance with a polar eluent that separates the most polar components in the lower part of the chromatogram; the less polar components are accumulated in the front area. Their separation occurs in the second stage, when the layer is developed to the full distance with a less polar eluent (Fig. 6).[21,22] The polar components are not significantly affected by the mobile phase used in the second step and keep their positions from the first step. The incremental, multistep version of this technique, with programmed, automated development and evaporation steps, is called automated multiple development (AMD) and the method is considered to be the most effective and versatile TLC technique.[23]

Eqs. 5 and 6 could be applied to formulate computer programs that calculate the final values of $R_P(j)$ for a given gradient program and the retention–eluent composition relationships for selected systems. The systems very often applied in MD contain thin layers of adsorbents with definite groups like diol, cyano, or amine.[24] The basic equation describing the retention of solutes in such systems has the form of Eq. 2 or the following formula:[25]

$$R_F(j, i) = \frac{1}{1 + k_0(j)/10^{m(j)\cdot c(i)}} \quad (7)$$

G IMD permits application of gradient profiles similar to those presented in Fig. 3. The gradient profiles begin with a high concentration of modifier and end with

a low concentration. In MD, it is also possible to create segmented gradients. In the majority of practical applications, the number of systems used in the program of development can be more than two. The chromatograms obtained in MD (G IMD) show mostly evenly distributed peaks between the start and finish line. Fig. 7 shows a densitogram of chamomile extract obtained in MD with improved separation compared to the isocratic mode. The marked fractions on the densitogram were recovered from the plate and further analyzed by GC/MS. Chromatograms obtained in this way are much simpler (compared to that of the extract), which simplifies their identification by GC/MS.[26]

The application of G IMD to the analysis of complex mixtures is based on the selection of mobile phases suitable to each group of solutes present in the mixture, e.g., polar, weakly polar, and/or non-polar. In the next step, it is possible to design a gradient program. The profile of the gradient can be adjusted to specific properties of the components of particular groups. The number of steps may be varied depending on the number of components—more components require more steps.

Considering the distance of development, it is possible to develop chromatogram on the total distance with a mobile phase of rather low elution strength and, after removal of the mobile phase, to develop on a shortened distance with a very strong mobile phase. Fig. 8 illustrates the separation of two groups of alkaloids by this method.[27] The condition for the second step of development was that solutes to be separated in the second step still be on or near the start line after the first step. In this mode of MD, the compression effect related to multiple passing of the mobile phase is absent. In UMD, the application of a simple gradient is possible as well. It is used to fractionate complex mixtures by separating just a few solutes in each step. In this case, the plate has to be scanned after some steps and the results recorded. This mode cannot be applied when the picture of the final separation is required as a single chromatogram.

The AMD technique finds application in various fields, such as, for example, the determination of pesticides in water,[28,29] herbicides in plants,[30] and biogenic amines in fish meal,[31] the separation of gangliosides,[32] and the analysis of plant material by coupling with other

chromatographic (reverse-phase HPLC, HPLC/MS) and spectroscopic methods (UV, FTIR).[33–35]

MECHANISM OF COMPRESSION OF CHROMATOGRAPHIC ZONES

One of the advantages of gradient elution is the compression of zones. Each passage of the front of the mobile phase or of the concentration of the multiple-component mobile phase through a spot leads to compression of the spot in the direction of development. This is due to the fact that the front of the increased eluent concentration first reaches the lower edge of the spot, so that the solute molecules in this region start to move (MD) or accelerate their migration (gradient) earlier than the molecules in the farther parts of the spot. When the front of the mobile phase or of the concentration zone overtakes the whole spot, the compressed spot continues to migrate and gradually becomes more diffuse, as in isocratic elution. If the two mechanisms, compression and diffusion, become counterbalanced, the spot may migrate through considerable distances without any marked broadening (Fig. 9). The final width of the spot can be calculated from the equation

$$\sigma_x{}^2 = \sigma_{\text{spotting}}{}^2 + \sigma_{\text{chrom}}{}^2 + \sigma_{\text{inst}}{}^2 + (-\Delta)_{\text{compression}} \qquad (8)$$

The last term of the equation is responsible for the compression effect. The contributions of particular terms of the equation can be estimated from the following equations. For spreading of the zone caused by the process of chromatography,

$$\sigma_{\text{chrom}}{}^2 = \overline{H \cdot MD(j,i)} \qquad (9)$$

where $\overline{H}$ is the average height equivalent to a theoretical plate and $MD(j, i)$ is migration distance for solute j in the ith step. The values of this term depend on the efficiency of chromatographic layer and on the velocity of the mobile phase associated with migration distance $MD(j, i)$.

The compression effect can be calculated from the formula

$$\Delta = [0.25 \cdot w(j, i-1) \cdot R_{\text{F}}(j,i)]^2 \qquad (10)$$

where $w(j, i–1)$ is the width of the zone at the end of the preceding step. The compression effect is most effective for zones with high R_{F} value. The contribution to zone broadening associated with the properties of the detection and recording devices are negligible. During the MD process, the migration distances of particular solutes are rather short; the contribution is not very high and decreases with the progress of development. Additionally, the effect of compression keeps the spots narrow. The formation of more compact spots causes an increase in sensitivity of detection, in comparison to the spots after single development, and an increase of peak capacity.[36]

Incremental multiple development provides superior separation in comparison to multiple chromatography, in this case, by minimizing zone broadening and enhancing the zone center separation by migrations of the sample components over a longer distance while maintaining a mobile-phase flow rate range close to the best value for the separation. This variant can also be achieved by change of the point of delivery of the eluent to the layer.[37] Not all compounds are suitable for separation by MD. Compounds with significant vapor pressure may be lost during the repeated solvent evaporation steps. Certain solvents of low volatility and/or high polarity, such as acetic acid, triethylamine, dimethyl sulfoxide, and so forth are unsuitable as mobile phases because of the difficulty of removing them from the layer by vacuum evaporation between development steps. Water can be used, but the drying steps are then lengthy. The solvent residues remaining after the drying step can modify the selectivity of mobile phases used in later

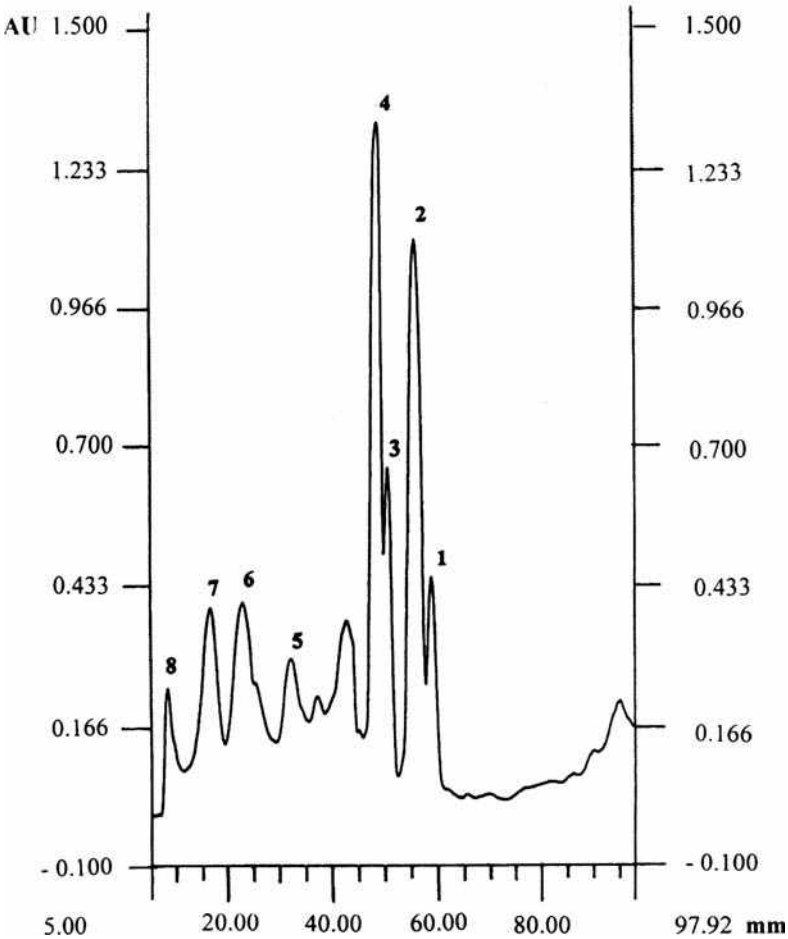

Fig. 8 Two-step gradient elution of the fraction of quaternary alkaloids of *Chelidonium majus* L. Stationary phase: Kieselgel Si 60. steps, resulting in irreproducible separations. Although precautions can be taken to minimize the production of artifact peaks in MD, the separation of light- and/or air-sensitive compounds is probably better handled by other techniques such as simple gradient development.

POLYZONAL TLC

Polyzonal TLC is the simplest method for formation of gradients in TLC. The main effect utilized is solvent demixing, which occurs in the case of the application of binary and polycomponent solvents, especially those of differentiated polarity. For an *n*-component mixed eluent, *n*–1 solvent fronts are formed, ordered in the sequence of polarity of the components. A gradient of eluent strength is thus formed along the layer; the solutes migrate in various zones, and the passage of fronts leads to compression of the TLC spots.[3,6]

EQUIPMENT FOR GRADIENT TLC

Depending on the type of gradient, various apparatuses are applied for its generation. Numerous gradient generators have been described.[3,5] The gradient of the mobile phase can be formed in some types of horizontal chambers (Fig. 10) (e.g., Camag, Muttenz, Switzerland; Chromdes, Lublin, Poland; Desaga, Wiesbaden, Germany). The generation of stepwise gradients is simple for sandwich chambers with distributors, which allow for complete absorption of the eluent fractions from the reservoir. For sandwich chambers, eluent fractions of increasing eluent strength (increasing concentrations of the polar modifier) are introduced under the distributor. After absorption of the preceding eluent fraction by the adsorbent layer, the next fraction of eluent of changed strength is delivered; the total volume of the eluent fractions corresponds to the development distance. Any gradient program, including continuous and multiple-component gradients, can be

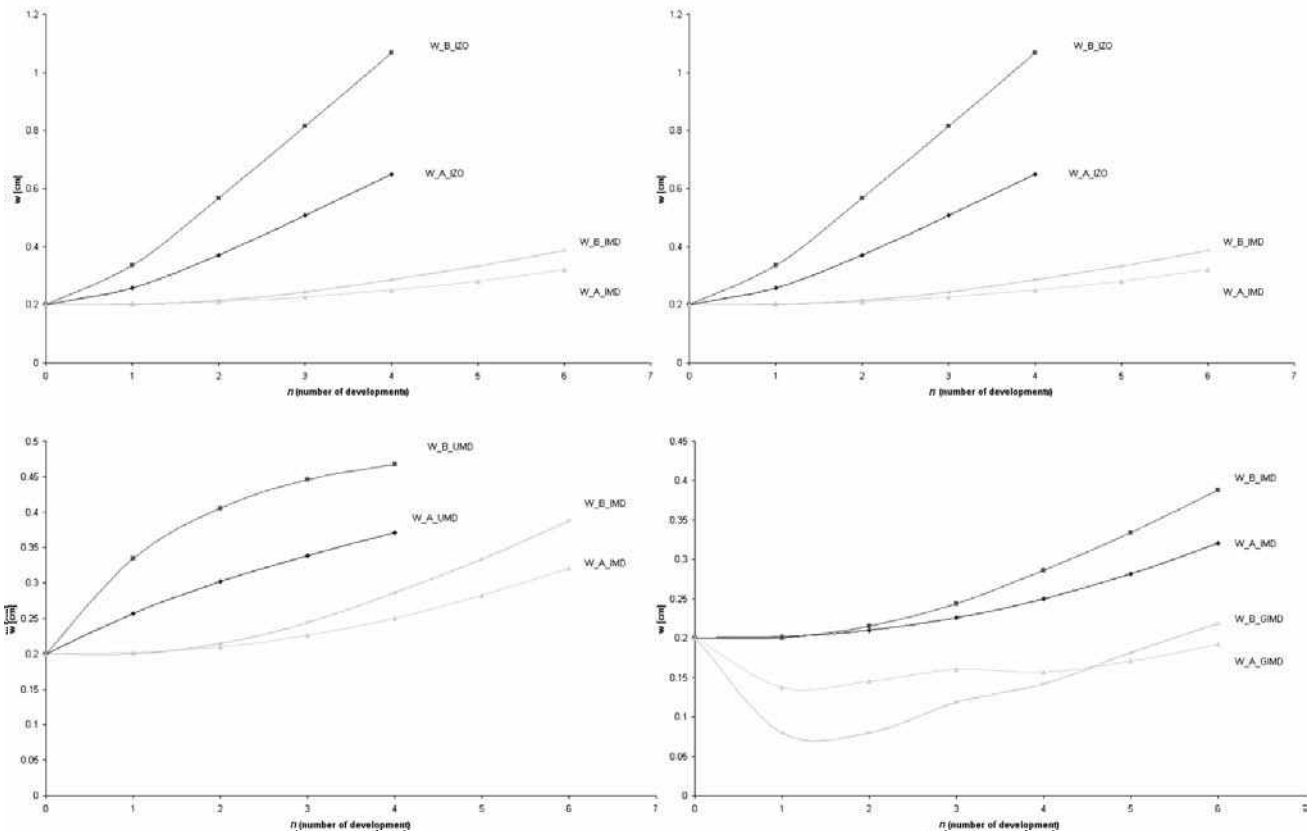

Fig. 9 Comparison of zone width in different modes of MD. (A) Zone width in a single isocratic development and unidimensional development. $R_F(A) = 0.091$, $R_F(B) = 0.288$, $\varphi = 0.05$. (B) Zone width in a single isocratic development and IMD. Increment of development distance $IDD = 1$ cm; number of developments $n = 6$; $\varphi = 0.5$. (C) Zone width in UMD and IMD. (D) Zone width in IMD and GIMD. Gradient: number of steps $n = 6$; concentration program: $\varphi(1) = 0.3$, $\varphi(2) = 0.2$, $\varphi(3) = 0.1$, $\varphi(4) = 0.05$, $\varphi(5) = 0.05$, $\varphi(6) = 0.05$; increment of development distance $IDD = 1$ cm.

generated in this way. The process of MD can be fully automated (Fig. 11) (AMD2 chamber, Camag Scientific; TLC–MAT, Desaga). An apparatus comprises an N-type chamber with connections for adding and removing solvents and gas phases. AMD2 involves the use of a stepwise gradient of different mobile phases with decreasing strength in 10–30 successive developments increasing in length by about 1–5 mm. The initial solvent, which is the strongest, focuses the zones during the first short run, and the solvent is changed for each, or most, of the following cycles. The mobile phase is removed from the chamber, the plate dried and activated by vacuum evaporation, and the layer conditioned with a controlled atmosphere of vapors prior to the next development. High resolution and improved detection limits are achieved because zones are focused during each development stage. The widths of the separated zones are approximately constant at 1–3 mm, and the separation capacity for baseline-resolved peaks is 25–40. Zones migrate different distances according to their polarity. The reproducibility of values is 1–2% (CV) for multiple spots on the same plate or different plates from

the same batch. A typical universal gradient for a silica gel layer involves 25 steps, with methanol, dichloromethane, or *tert*-butyl ether, and hexane as the component solvents.

A discontinuous gradient of the stationary phase can be obtained easily using an ordinary spreader. The trough is divided into separate chambers filled with suspensions of mixtures of adsorbents. The carrier plates are covered in the usual way.[3,5] Another method of formation of gradients of stationary-phase activity is the use of a Vario-KS chamber, which permits adsorption of various vapors on the adsorbent surface or control of the activity of the adsorbent.[6]

CONCLUSIONS

To sum up, the development process, applied as a simple gradient or combined with MD, can improve the separation power of planar chromatography in cases when transport of the mobile phase is controlled by capillary forces. The advantages of gradient development are as follows:

- More compact zones.
- Greater separation capacity.
- Greater sensitivity.

Other benefits of gradient follow:

- Possibility of separation of complex samples containing components with a wide spectrum of polarity or samples containing groups of solutes with different properties.
- More optimal use of solvents of different strength and selectivity.
- Possibility of coupling with HPLC and spectroscopic techniques

In the case gradient development is carried out, the following conditions need to be fulfilled:

- Application of sample by an automatic device.
- Development with use of an automatic developing chamber.
- Densitometric evaluation and documentation with image processing.

Then the technique can be recognized as a very powerful modern instrumental system that offers reproducible and accurate quantitation for a wide variety of applications.

Gradient Elution Fundamentals

J.E. Haky
D.A. Teifer

INTRODUCTION

The term *gradient elution* refers to a systematic, programmed increase in the elution strength of the mobile phase during the chromatographic run. Of all the techniques used to provide quality separations among complex mixtures, gradient elution offers the greatest potential.[1] Basically, the composition of the mobile phase is varied throughout the separation so as to provide a continual increase in solvent strength and, thereby, a more convenient elution time and sharper peaks for all sample components.[2] What makes this method so useful is the ability to choose from a variety of different eluents. Although most instruments permit gradients to be automatically prepared from various concentrations of only a two-eluent mixture, sample mixtures of a wide range of polarities can be separated efficiently.

DISCUSSION

The process of mixing eluents is a sensitive one. When two solvents with a large difference in their elution strengths are used, even a small increase in the polar component produces a sharp rise in elution strength. Such an effect is undesirable because the components are almost always eluted at the beginning of the analysis and displacement effects may result from demixing of eluent mixtures.[1] According to Poole et al.,[3] the most frequently used gradients are binary solvent systems with a linear, convex, or concave increase in the percent volume fraction of the stronger solvent, as depicted in the following equations:

Linear gradient

$$\theta_B = \frac{t}{t_G} \tag{1}$$

Convex gradient

$$\theta_B = 1 - \left(1 - \frac{t}{t_G}\right)^n \tag{2}$$

Concave gradient

$$\theta_b = \left(\frac{t}{t_B}\right)^n \tag{3}$$

In these equations, θ_B is the volume fraction of the stronger eluting solvent, t is the time after the gradient begins, t_G is the total gradient time, and n is an integer controlling gradient steepness.

Complex gradients can be constructed by combining several gradient segments (i.e., rates of increase of strong solvent composition) to form the complete gradient program.[3] Linear gradients are most commonly used, with convex and concave gradients employed only when necessary to optimize more complex separations. In a linear-solvent-strength gradient, the logarithm of the capacity factor for each sample component, k', decreases linearly with time, according to Eq. 4:

$$\log k = \log k_0 - b\frac{[t]}{[t_m]} \tag{4}$$

In this equation, k_0 is the value of k determined isocratically in the starting solvent, b is the gradient steepness parameter, t is the time after the start of gradient and sample injection, and t_m is the column dead time. Ideally, this equation shows that a linear-solventstrength gradient should result in equal resolution and bandwidths of all components. Unfortunately, this is not always possible. There are certain cases where linear- solvent-strength gradient is not the ideal method. In some cases, for example, b actually increases regularly with solute retention, which reduces the separation of late-eluting components. Such an effect is observed in the separation of polycyclic aromatic hydrocarbons.[3]

There are three things to consider when finding a suitable gradient for a separation: (a) the initial and final mobile-phase compositions, (b) the gradient shape, and (c) the gradient steepness.[3] A convex gradient leads to the elution of bands with a lower average capacity factor and a shorter total analysis time. In other words, the later-eluting bands appear wider and better resolved than the early eluting bands. A concave gradient resolves the early bands to a greater degree than the later bands.

Solvent selection is one of the most important facets of gradient elution. The choice of the first solvent influences the separation of the initial bands, whereas the strength of the final solvent influences the selectivity of the separation and the retention times and peak shapes of later-eluting

bands. If solvent B is too weak, the analysis time may become very long and the latereluting bands might broaden excessively; thus, a stronger solvent B may be required.[3]

Abbott et al.,[4] devised a method designed to predict the retention times in gradient elution under the assumption that the retention factor as determined under isocratic conditions is a log-linear function of solvent composition according to Eq. 5, where k_w is the retention factor obtained in water, φ_0 refers to the volume fraction of the organic component, and S refers to the solvent strength for which the values can be obtained as the negative slope of plots of log k vs. volume fraction:

$$\log k = \log k_w - S\varphi_0 \tag{5}$$

Engelhardt and Elgass[5] found that if the gradient volume is held constant and the initial and final compositions of the eluent are fixed, each component of a sample is eluted at a given solvent composition. Snyder et al.[6] derived a simple relationship between the elution time of a solute and the rate of change of solvent composition in gradient elution. Utilizing Eq. 6, they found that the elution time t_e is related to column dead time, t_0, and an experimental parameter b whereby k_0 is the retention factor that would be obtained in isocratic elution with mobile-phase composition used at the beginning of the gradient:[1]

$$t_e\left(\frac{t_0}{b}\right)\log(2.31k_0b + 1) + t_0 \tag{6}$$

The parameter b is defined as

$$b = \frac{\phi S t_0}{100} \tag{7}$$

where Φ is the rate of increase in the concentration of the solvent component having eluent strength S and given as volume percent of organic solvent component per minute.[1]

Many technical problems can occur with gradient elution, some of which can be avoided through various methods. To begin, gradient elution relies upon the purity of the solvents used. The high-performance liquid chromatography (HPLC) column can collect impurities, in the mobile phase, which may or may not elute as sharp peaks at a certain eluent composition. These can be mistaken for sample components. Such peaks are called "ghost peaks" and can result in inaccurate data. Water presents its own set of problems. Contaminated water can also result in ghost peaks. Even deionization of water by ion exchangers can leach out organics from the resin.[1] For this reason, it is advisable to run a gradient first without injecting the sample and use commercially available, purified solvents, including the water, to determine if they result in the elution of ghost peaks.

Another thing to consider with gradient elution is changes in the eluent viscosity. When gradient elution with a hydro-organic mobile phase is used (e.g., methanol-water), systematic variations in the flow rate are expected under conditions of constant-pressure operation, and systematic variations in the operating pressure will be found when a constant flow rate is used.[1] The compressibility of the solvent is species-specific.

In summary, gradient elution is a powerful method for the separation and analysis of complex mixtures containing components with a wide variety of polarities and hydrophobicities. It can also be used to help establish an isocratic mobile phase for the analysis of simpler mixtures. In either case, utmost care must be taken in the selection and use of solvents of high purity and selectivity.

Gradient Elution in CE

Haleem J. Issaq
National Cancer Institute at Frederick (NCI-Frederick), National Institutes of Health (NIH), Frederick, Maryland, U.S.A.

INTRODUCTION

Gradient elution is routinely used in high-performance liquid chromatography (HPLC) to achieve the complete resolution of a mixture which could not be resolved using isocratic elution. Unlike isocratic elution, where the mobile-phase composition remains constant throughout the experiment, in gradient elution the mobile-phase composition changes with time. The change could be continuous or stepwise, known as the *step-gradient*. In the continuous gradient, the analyst can pick one of three general shapes: linear, concave, or convex.

DISCUSSION

Gradient elution in HPLC is achieved using two pumps, two different solvent reservoirs, and a solvent mixer. In capillary electrophoresis (CE), electro-osmotic flow controls the flow of the mobile phase, which is, in most cases, an aqueous buffer and is used in place of a mechanical pump.

A manual step-gradient was used by Balchunas and Sepaniak[1] to separate a mixture of amines by micellar electrokinetic chromatography (MEKC). Stepwise gradients were produced by pipetting aliquots of a gradient solvent to the inlet reservoir which was filled with 2.5 ml of running buffer. A small magnetic stirring bar was used to ensure thorough mixing of the added gradient solvent with the starting mobile phase. The gradient elution solvent was manually added, in four 0.5 ml increments, spaced 5 min apart, 5 min after start of the experiment.

Bocek and his group[2] developed a method for controlling the composition of the operational electrolyte directly in the separation capillary in isotachophoresis (ITP) and capillary zone electrophoresis (CZE). The method is based on feeding the capillary with two different ionic species from two separate electrode chambers by simultaneous electromigration. The composition and pH of the electrolyte in the separation capillary is thus controlled by setting the ratio of two electric currents.This procedure can be used, in addition to generating the mobile-phase gradient, for generating pH gradients.[3,4] Sepaniak et al.[5–7] produced continuous gradients of different shapes (linear, concave, or convex) by using a negative-polarity configuration in which the inlet reservoir is at ground potential and the outlet reservoir at a very high negative potential. This configuration allows two syringe pumps to pump solutions into and out of the inlet reservoir. Tsuda[8] used a solvent-program delivery system, similar to that used in HPLC, to generate pH gradients in CZE. A pH gradient derived from temperature changes has also been reported.[9] Chang and Yeung[10] used two different techniques (i.e., the dynamic pH gradient and electro-osmotic flow gradient) to control selectivity in CZE. A dynamic pH gradient from pH 3.0 to 5.2 was generated by a HPLC gradient pump. An electro-osmotic flow gradient was produced by changing the reservoirs containing different concentrations of cetylammonium bromide for injection and running.

Capillary electrochromatography (CEC) is a separation technique which combines the advantages of micro-HPLC and CE. In CEC, the HPLC pump is replaced by electro-osmotic flow. Behnke and Bayer[11] developed a micro-bore system for gradient elution using 50 and 100 μm fused-silica capillaries, packed with 5 μm octadecyl reversed phase silica gel and voltage gradients, up to 30,000 V, across the length of the capillary. A modular CE system was combined with a gradient HPLC system to generate gradient CEC. Enhanced column efficiency and resolution were realized. Zare and his coworkers[12] used two high-voltage power supplies and a packed fused-silica capillary to generate an electro-osmotically driven gradient flow in an automated manner. The separation of 16 polycyclic aromatic hydrocarbons was resolved in the gradient mode; these compounds were not separated when the isocratic mode was employed. Others[13–16] used gradient elution in combination with CEC to resolve various mixtures.

Multiple, intersecting narrow channels can be formed on a glass chip to form a manifold of flow channels in which CE can be used to resolve a mixture of solutes in seconds. Harrison and coworkers[17] showed that judicious application of voltages to multiple channels within a manifold can be used to control the mixing of solutions and to direct the flow at the intersection of channels. The authors concluded that such a system, in which the applied voltages can be used to control the flow, can be used for sample dilution, pH adjustment, derivatization, complexation, or masking of interferences. Ramsey and coworkers[18] used a microchip device with electrokinetically controlled solvent mixing for isocratic and gradient elution in MEKC. Isocratic and gradient conditions are controlled by proper setting of voltages applied to the buffer reservoirs of the microchip. The precision of such control was successfully tested for gradients of various shapes (linear, concave, or

convex) by mixing pure buffer and buffer doped with a fluorescent dye. By making use of the electro-osmotic flow and employing computer control, very precise manipulation of the solvent was possible and allowed fast and efficient optimization of separation problems.

Gradient Elution Program: Selection and Important Instrumental Considerations

Adriana Segall
Pharmacy and Biochemistry Faculty, University of Buenos Aires, Buenos Aires, Argentina

Abstract
A review of gradient elution chromatography application and instrumental considerations is presented. Gradient elution refers to any kind of intentional variation of mobile-phase composition with time during the course of an analysis. Solvent programing should take place in such a way that the solvent strength increases with time; in other words, the migration velocity of analytes increases as a result of the gradient. This entry describes the advantages and disadvantages of gradient elution. An initial gradient elution run is often the best starting point for liquid chromatography (LC) method development, even where a final isocratic method may be possible. Two kinds of equipment are used for gradient elution: high-pressure mixing systems and low-pressure mixing systems. With either of these devices, changes in the composition of the mobile phase during gradient elution can be stepwise or continuous, depending on the mode of control. One limitation is that many detectors cannot be used.

INTRODUCTION

Isocratic liquid chromatography (LC) is able to separate a limited number of peaks, typically 10 or 12. The general elution problem, which arises when a complex mixture of solutes having widely varying k' (capacity factor) values are required to be separated, is most conveniently solved by the use of gradient elution (Figs. 1 and 2). Gradient elution in LC is analogous to temperature programing in gas chromatography. While the advantages and disadvantages of gradient elution must be weighed for each application, many separations are only possible using gradient elution program.

The use of gradient elution for routine application is recommended for the following kinds of samples:

- Samples with a wide k' range (i.e., where no isocratic conditions result in $0.5 < k' < 20$ for all bands of interest).
- Samples composed of large molecules (e.g., with molecular weights above 1000 and especially samples of biological origin).
- Samples containing late-eluting interferences that can either foul the column or overlap subsequent chromatograms.
- Dilute solutions of the sample dissolved in a weak solvent (e.g., aqueous sample solutions for injection onto a reversed-phase column).

In addition, an initial gradient elution run is often the best starting point for LC method development, even where a final isocratic method may be possible.

INSTRUMENTAL CONSIDERATIONS

The disadvantages of gradient elution are the following:

- Gradient equipment is not available in some laboratories.
- Gradient elution cannot be used with some LC detectors (e.g., refractive index detectors).
- Gradient elution is more complicated, and it appears to make both method development and routine application more difficult.
- Gradient runs take longer, because it is necessary for column equilibration after each run.
- Gradient methods do not always transfer well, because differences in equipment can affect separation.
- Baseline problems are more common with gradient elution, and solvents must be of higher purity.
- Certain column–mobile-phase combinations are not recommended for gradient elution.

DISCUSSION

In LC, "gradient" is short for gradient elution and both terms are commonly used as synonyms for solvent programing. Solvent programing refers to any kind of intentional variation of mobile-phase composition with time during the course of an analysis. Solvent programing should take place in such a way that the solvent strength increases with time; in other words, the migration velocity of analytes increases as a result of the gradient.

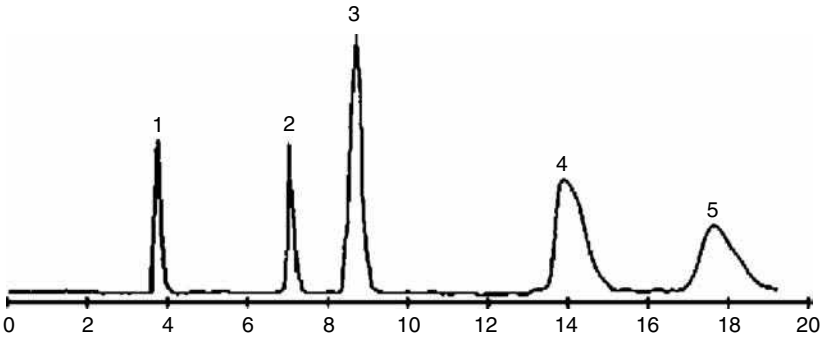

Fig. 1 Chromatogram obtained using isocratic LC: 1, Theophylline; 2, acetylsalicylic acid; 3, propanolol; 4, nortriptyline; 5, trimipramine. Column: C_{18}, 3 μm; mobile phase: 0.1% trifluoroacetic acid (TFA) in water; flow rate: 2.5 ml/min; detector: evaporative light-scattering detector (ELSD).

The initial conditions at the start of the run are chosen such that the retention factor of the first (relevant) component is within the optimal window (typically $1 < k' < 10$) or higher. Under these conditions, no relevant components are eluted too early in the chromatogram. However, some components may have very high k' values under initial conditions. When the solvent strength increases, the retention factors of these components start to become smaller. In gradient elution, mobile-phase strength (%B) increases during separation, which means that sample retention, measured as k', decreases for each band as it migrates through the column. It is assumed that band X is the first sample band that elutes, and band Z is the last band. At the beginning of the separation process, %B is low and k' for band X is large. After some time, however, the increase in %B results in a k' value for band X that is small enough ($k' < 10$) to allow it to start moving in the column. With time, k' for band X continues to decrease and X migrates faster and faster. Eventually, at the band retention time t_x, X reaches the outlet of the column and appears in the detector to be recorded as a peak in the chromatogram.

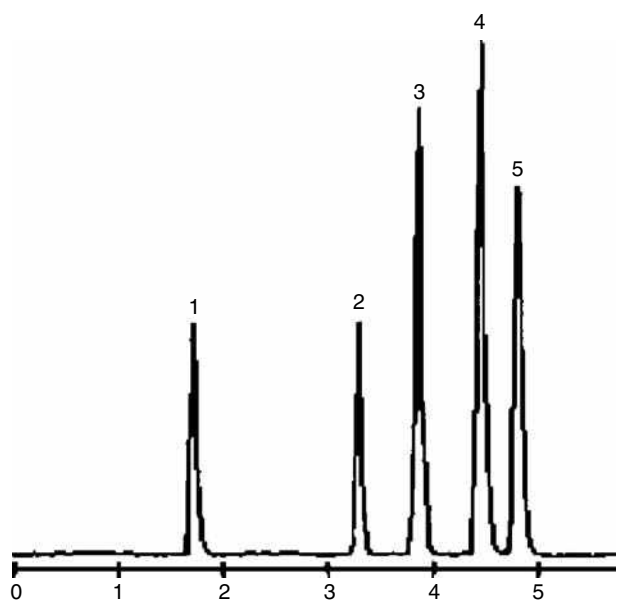

Fig. 2 Chromatogram obtained using gradient elution LC: 1, Theophylline; 2, acetylsalicylic acid; 3, propanolol; 4, nortriptyline; 5, trimipramine. Column: C_{18}, 3 μm; mobile phase: A, 0.1% TFA in water; B, 0.1% TFA in acetonitrile; gradient: time 6 min; %B 10–90; flow rate: 2.5 ml/min; detector: ELSD.

The value of k' for each band in isocratic elution is quite important in understanding and controlling LC separation. In gradient elution k' is equally important. The effective value of k' in gradient elution is equal to k' for the band when it has migrated halfway through the column. This average value of k' in gradient elution, defined as k^*, determines sample resolution and bandwidth, just as in isocratic separation.

The last band, Z, remains at the column inlet for a longer time, but eventually the mobile phase becomes strong enough for $k' < 10$. Band Z then migrates through the column in similar fashion as the first band, elutes at a retention time t_z, and its effective k' value, k^*, is also equal to 2. As a result, every band in a linear-gradient chromatogram will have similar widths, and sample resolution will not necessarily be poorer at the beginning of the chromatogram, as is so often the case in isocratic separation.

Gradients result from the mixing of two or more different solvents. The following restrictions apply to isocratic solvents: selectivity, safety, sample compatibility, column compatibility, detector compatibility, viscosity, corrosivity, purity, cost. The same restrictions apply to gradient solvents, as well as, miscibility, mutual compatibility, and insensitivity of detector for variations in composition.

In addition, certain considerations apply specifically when selecting gradient solvents. Miscibility of the different solvents is an obvious requirement. Even when solvents are considered to be well miscible, as in the case of methanol and water, there may be a significant heat effect on mixing. In this particular example, there is also a significant contraction (i.e., a mixture of methanol and water has a smaller volume than the sum of the individually measured components).

When buffers or salts are added to (one of) the solvents, miscibility considerations become more urgent. Buffer solubility is typically much higher in water than in organic solvents, methanol being better than acetonitrile. In organic solvents, organic buffers tend to be more soluble

than typical inorganic buffers. When using gradient elution, online mixing of solvents must take place and, during this process, local conditions may cause solubility problems. For example, when mixing an aqueous buffer with a pure organic solvent, buffer precipitation may occur more quickly than mixing. Some useful practical tips are listed below:

1. Always verify the miscibility of the individual solvents in an off-line (test tube) experiment, especially when using buffers, salts, or other solid additives.
2. Keep a safety margin relative to the verified solubility. For example, keep the buffer concentration in online mixing well below that tried in the off-line experiment.
3. Use partially mixed solvents in the reservoirs when possible. Mixing a solution of 10% A in B with one of 10% B in A is much safer than mixing pure A with pure B.

The column must be equilibrated, re-equilibrated to the initial high aqueous solvent composition before another analysis can be performed. Normally this re-equilibration is included at the end of the gradient. How much equilibration time is enough? In reality, it depends on the column length, flow rate, and the hydrophobicity of the sample peptides. Some chromatographers use 10 min as the standard equilibration time. Equilibration is all about fitness of purpose. One should determine the equilibration time experimentally; the criteria should be, does the analyte really stick to the column and chromatograph appropriately and reproducibly for subsequent analyses. If this part of the method development is taken care of, it will undoubtedly be rewarded with improved chromatography and better cycle time.

INSTRUMENTAL ASPECTS

Equipments for carrying out gradient elution in LC can be divided into two distinct types: low-pressure mixing systems and high-pressure mixing systems. With either of these systems, changes in the composition of the mobile phase during gradient elution can be stepwise or continuous, depending on the mode of control. Changes in solvent composition can be programed on a linear basis but, often, some type of exponential change (convex or concave) is preferred for optimum separation.

HIGH-PRESSURE MIXING SYSTEMS

This type of gradient device involves the high-pressure mixing of two solvents to generate a mobile-phase gradient by programing the delivery from the high-pressure system. In this type of LC system, the output from two or more high-pressure pumps is programed into a mixing chamber before it flows into the column. Both reciprocating- and displacement-type pumps have been used. Since the output of each pump can be separately controlled (electronically), it is possible to conveniently generate almost any kind of gradient; systems of this type are widely used in commercial instruments. However, this arrangement is expensive, as two or more high-pressure pumps plus a gradient controller are required. An important limitation is that reciprocating pumps operate with poor precision at low flow rates (e.g., less than 0.1 ml/min). This poses a problem at both extremes of the solvent program, where a small amount of one solvent is mixed with the other. As a result of this imprecision of solvent delivery at low flow rates by reciprocating pumps, the gradients that are formed at the initial and final stages of the program can be imprecise and the solute elution erratic. For example, to add 2% methanol to an otherwise aqueous eluent at a combined flow rate of 1 ml/min, the methanol pump is required to perform reliably at a level of 20 μl/min. Such a value is low for most common LC pumps. If a specifically designed micro-LC pump were to be used, problems might arise when methanol concentration would be increased to much higher values.

Another complication is that the delivered flow rate varies with the eluent. Different solvents have different compressibilities and viscosities. These properties may have a fundamental and an empirical effect (respectively) on the resulting flow rate. Often, pumps can be calibrated to compensate for such effects.

LOW-PRESSURE MIXING SYSTEMS

In this approach, solvent gradients are first formed by mixing two or more solvents at atmospheric pressure, then pumped via a single pump. The simplest arrangement of the low-pressure gradient systems involves adding the modifying stronger solvent to a stirred reservoir filled with the lower-strength initial solvent, which feeds the pump.

A more versatile and precise approach is used by several suppliers. In this approach, a series of reservoirs containing mobile phases of increasing solvent strength is used. Separation starts with the weakest solvent A. The gradient is produced by sequentially opening and closing valves leading to reservoirs containing solvents of increasing strength, B and C. The concentrations of these solvents can be selected by proportioning the time that the valves to the various reservoirs are opened and closed, using a microprocessor control system. After the desired solvent mixture is generated, it is mixed and fed to a single reciprocating pump for pressurization. Useful gradients can be generated with two reservoirs containing solvents of different strengths. However, by using additional solvents (e.g., up to 20) more sophisticated gradients can be generated that are capable of resolving mixtures containing compounds of widely differing chemical properties.

Low-pressure mixing systems require advanced software control for the opening and closing of the valves. This is mainly because LC pumps are designed to deliver a flow that is as constant as possible. The suction (input) flow, however, is extremely variable. For the delivery stroke to be smooth, the suction (refill) stroke has to be rapid. Yet, it is in this inlet flow stream that mixtures and gradients are being generated.

A typical pump head of an LC pump may have a volume of 100 μl. To generate mixtures with an accuracy of 0.1%, the composition of the solvent entering the pump has to be controlled to within 100 nl.

Degassing of solvents is the final subject that deserves attention. The heat effect of mixing solvents, especially water and organics, can be quite considerable. This may easily cause the emergence of dissolved gases in the form of bubbles, which in turn can affect the performance of the pump to a great extent. Extensive degassing of the individual solvents by helium purging has long been the method of choice, except for premixed mobile phases (mixtures of two or more solvents), salt or buffer solutions, etc. A quick burst of helium followed by leaving a helium cap (low flow of helium) in the bottle is then recommended. In recent years, in-line degassers have emerged, in which the mixed eluent passes alongside a membrane, the other side of which is pumped to a vacuum. In-line degassers allow effective degassing without affecting the composition of mixed eluents.

CONCLUSIONS

Some samples are well separated by isocratic elution, but they contain late-eluting interferences that either contaminate the column or interfere with subsequent separations. As gradient elution LC is an invaluable separation technique for complex mixtures of non-volatile solutes, it would solve this problem. Two kinds of equipment are used for gradient elution: high-pressure mixing systems and low-pressure mixing systems. One limitation is that many detectors cannot be used. In scouting separations of unknown samples, the flexibility and power of gradient elution will continue to make it a popular technique for solving the general elution problem.

Gradient Elution Techniques

Ioannis N. Papadoyannis
Kalliopi A. Georga
Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece

INTRODUCTION

Gradient elution is the elution method in which the mobile-phase composition changes during time. It may be considered as an analogy to the temperature programming in gas chromatography (GC).

DISCUSSION

The main purpose of gradient elution is to move strongly retained components of a mixture faster, while having the least retained components well resolved. At the beginning of the analysis, the solvent used is appropriate to elute some of the components, but is "weak" in terms of its ability to remove other compounds from the column and separate them from one another.

Gradient elution operates on the principle that, under the initial mobile-phase conditions, many of the components have a k' (capacity factor) value of essentially infinity, in that these components are stopped in a narrow band near the head of the column. As the solvent composition is changed and its solvent strength is increased, sample components dissolve at a characteristic solvent strength and then migrate down the column, leaving the remaining components behind. Changes in the mobile-phase composition may be "continuous" with a predetermined set of conditions or may be done in "steps" of substantial solvent composition changes.

The typical gradients used in reversed-phase chromatography are linear or binary (i.e., involving two mobile phases). Convex and concave gradients are used occasionally for analytical purposes, particularly when dealing with multicomponent samples requiring extra resolution either at the beginning or at the end of the gradient (Fig. 1).

The concentration of the organic solvent is lower in the initial mobile phase (mobile phase A) than it is in the final mobile phase (mobile phase B). The gradient then, regardless of the absolute change in percent organic modifier, always proceeds from a condition of high polarity (high aqueous content, low concentration of organic modifier) to low polarity (higher concentration of organic modifier, lower aqueous content). Reversed-phase separations can be achieved using either a stepwise or a continuous gradient to elute sample components. Step gradients (i.e., a series of isocratic elutions at different percentages of B) are useful for applications such as desalting, but for separations requiring high resolution, a linear continuous gradient is required.

Step gradients are also ideal when performing process scale applications providing the desired resolution can be obtained; less complex instrumentation is required to generate step gradients. Additionally, step gradients can be generated more reproducibly than linear gradients.

Gradient shape (combination of linear gradient and isocratic conditions), gradient slope, and gradient volume are all important considerations in reversed-phase chromatography. Typically, when first performing a reversed-phase separation of a complex sample, a broad gradient is used for initial screening in order to determine the optimum gradient shape.

The ideal gradient shape and volume are empirically determined for a particular separation. Generally, the sample is chromatographed using a broad-range linear gradient to determine where the molecules of interest will elute. The initial conditions usually consist of mobile phase A containing 10% or less organic modifier and mobile phase B containing 90% or more organic modifier. The initial gradient runs from 0% B to 100% B over 10–30 column volumes. A blank gradient is usually run prior to injecting the sample, in order to detect any baseline disturbances resulting from the column or impurities originating in the mobile phase.

After the initial screening is completed, the gradient shape may be adjusted to optimize the separation of the desired components. This is usually accomplished by decreasing the gradient slope, where the desired components elute, and increasing it before and after. The choice of gradient slope will depend on how closely the contaminants elute to the target molecule. Generally, decreasing the gradient slope increases the resolution. However, the peak volume and retention time increase with decreasing gradient slope. Shallow gradients with short columns are generally optimal for high-molecular-weight biomolecules.

Gradient slopes are generally reported as change in percent B per unit time (% B/min) or per unit volume (% B/ml). When programming a chromatography system

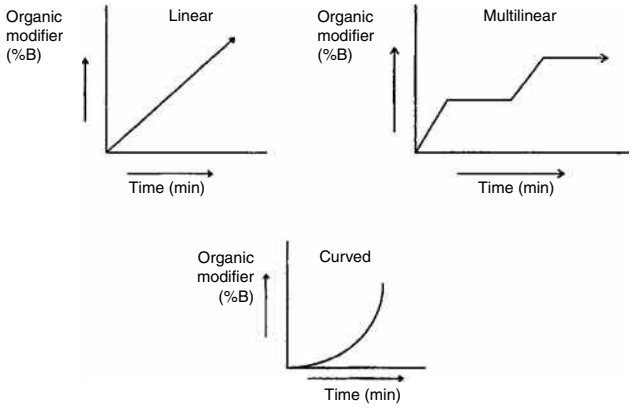

Fig. 1 Various gradient shapes.

in the time mode, it is important to remember that changes in flow rate will affect gradient slope and, therefore, resolution.

Resolution is also affected by the total gradient volume (gradient volume × flow rate). Although the optimum value must be determined empirically, a good rule of thumb is to begin with a gradient volume that is approximately 10–20 times the column volume. The slope can then be increased or decreased in order to optimize the resolution.

Except for optimizing gradient elution methods, which is a very important parameter in chromatographic analysis, another parameter of great significance is the mixing of the mobile-phase components.

There are two primary methods of mixing the mobile-phase components, known as "low-pressure mixing" and "high-pressure mixing." The first method employs electrically actuated solenoid valves located ahead of a single-solvent delivery system (pump). The precision of the gradient depends on the ability of the solenoid to reproducibly dispense solvents in segments of variable size (volume), depending on the composition desired. If reproducible retention times and stable detector baselines are to be obtained, these "segments of solvent plugs" must be well mixed into a homogenous mobile-phase stream before entering the chromatographic column.

The second method uses a separate solvent delivery device for each solvent, with each being capable of delivering smooth, precise flow rates of as low as a few microliters per minute. Gradients are formed by varying the delivery speeds and simply blending the concurrent solvent streams on the high-pressure side of the pumps.

Each method of gradient formation has advantages and disadvantages. The low-pressure gradient formation is preferred most of the time, because it uses only one pump, whereas the high-pressure method uses two pumps which might go wrong during use. Because low-pressure gradient systems have only one pump, they are, of course, less expensive. These systems require extensive degassing and have a large lag time (delay volume) in starting the gradient, whereas, in high-pressure systems, degassing is desired but not essential.

Moreover, low-pressure systems often use three or four solvents. This multiple-solvent blending might also be useful for the optimization of both isocratic and gradient elution methods. This is an advantage that the high-pressure system also has; when not using a gradient system, the operator has two independent isocratic pumps.

Gradient elution is ideal for separating certain kinds of sample which cannot be easily handled by isocratic methods, because of their wide k' range. Nevertheless, there is a strong bias against the use of gradient elution in many laboratories.

Some of the reasons for not preferring gradient elution are as follows: Gradient equipment is not available in some laboratories, because of its higher cost, and gradient elution is more complicated and makes both method development and routine analysis more difficult; the most important issue is that it is not compatible with some high-performance liquid chromatography (HPLC) detectors (e.g., refractive index detectors). Furthermore, gradient runs take longer, because of the need of column equilibration after each run. Baseline problems are more common with gradient elution and the solvent must be of high purity.

Although the disadvantages of gradient elution must be taken into serious consideration, many separations are only possible using gradient elution. The use of gradient elution for routine applications is suggested for the following kinds of sample:

1. Samples with a wide range of k'
2. Samples composed of large molecules >1000 in molecular weight
3. Samples containing late eluting interferences that can either foul the column or overlap subsequent chromatograms

Using gradient elution to develop HPLC methods has many advantages compared with using isocratic experiments. First, errors in solvent strength can be adjusted when changing from one solvent to another. Second, the ability to increase resolution during early exploratory runs is a distinct advantage when doing solvent mapping. Early bands often are severely overlapped in isocratic separations, so that it may not be clear how resolution is changing as separation conditions are varied. Gradient elution opens up the front of the chromatogram, allowing a better view of what is happening as conditions are varied (Fig. 2).

Third, using gradient elution runs during the initial stages of method development makes it easier to locate compounds that elute either very early or very late in the chromatogram. With isocratic separation, early-eluting compounds are often lost in the solvent front, whereas late-eluting compounds disappear into the baseline or

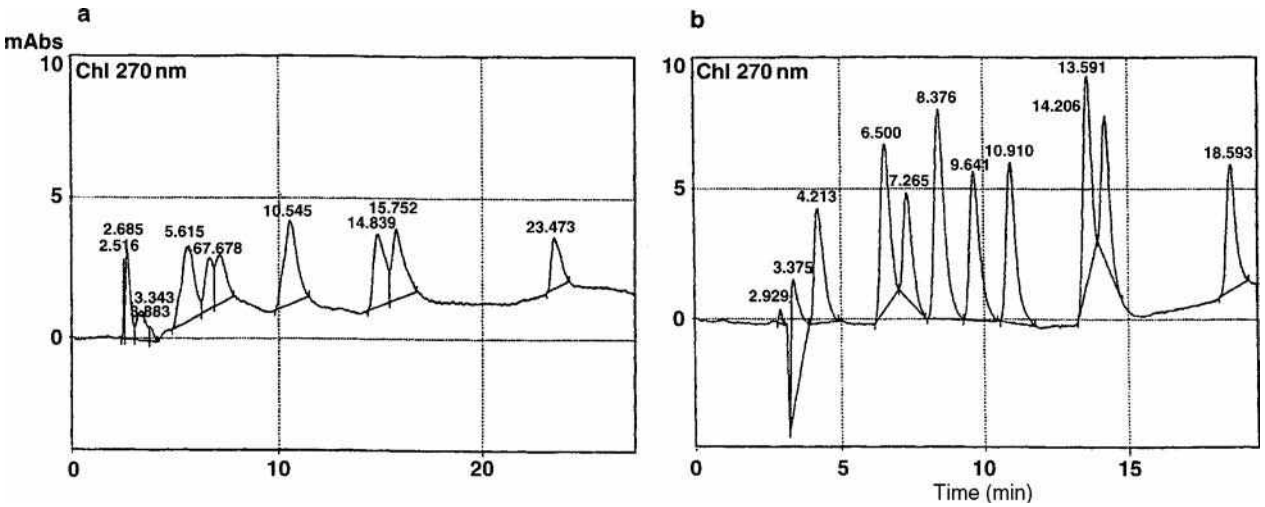

Fig. 2 HPLC analysis of eight methylxanthines: a, with isocratic elution; and b, with gradient elution.

overlap the next sample. Finally, gradient elution method development works for either gradient or isocratic elution.

In conclusion, gradient elution is not preferred as a quantitative technique because it is more complex than isocratic elution and, hence, more things can potentially go wrong. However, with proper control of operating parameters and good instrumentation, it is possible to obtain a separation with excellent quantitative results. This requires that the operator understand the hardware and determine that it is working correctly before attempting a separation. The ideal gradient system should be easy to operate, reproducible to provide consistent retention times, versatile to provide capability of generating various concave, convex, and linear gradient shapes, and convenient to provide a rapid turnaround time to initial eluent conditions (equilibration) for fast throughput from analysis to analysis.

Gradient HPLC: Gradient System Selection

Pavel Jandera
Department of Analytical Chemistry, University of Pardubice, Pardubice, Czech Republic

Abstract

Gradient elution is widely used for the separation of complex samples in reversed-phase high-performance liquid chromatography (HPLC) systems and ion-exchange systems. The theory of gradient elution has now been elaborated so that it allows predicting the retention and the resolution of sample compounds in reversed-phase, ion-exchange, and normal-phase systems for almost any combination of gradient profile and relationship between the retention and mobile-phase composition.

The most important sources of errors in the prediction and optimization of gradient elution are the gradient dwell volume and the preferential adsorption of the strong solvents, especially in normal-phase (adsorption) chromatography. The gradient dwell volume effects are more important in micro-LC techniques than in conventional analytical LC and may cause significant increase in the time of analysis, unless special instrumentation and (or) pre-column flow splitting is used, but their effects can be taken into account in predictive calculations. In normal-phase gradient HPLC, poor reproducibility may be caused by preferential adsorption of polar solvents from mixed mobile phases, which may cause significant deviations of the actual gradient profile from the preset program. Using carefully dried solvents and controlling the temperature, reproducibility of retention in normal-phase gradient elution can be largely improved.

The parameters of binary or ternary linear and non-linear gradients can be adjusted by predictive calculations to optimize the resolution and minimum separation time in various chromatographic systems. In addition to accurate calculations of the gradient elution data, simple procedures can be employed for rapid estimation of the effects of the gradient program, column geometry, or mobile-phase flow rate on the retention both in reversed-phase and in normal-phase gradient chromatography and for transfer of gradient methods between various instruments. In gradient elution, sample band broadening is largely suppressed with respect to isocratic operation, providing a higher number of separated peaks within the same separation time interval. Because of higher peak capacity, gradient elution is especially suitable for two-dimensional liquid chromatography, where increased peak capacity is of primary concern.

INTRODUCTION

Many high-performance liquid chromatography (HPLC) analyses can be performed at constant, isocratic, operating conditions using isocratic elution. However, isocratic elution with a mobile phase of fixed composition often does not yield a successful separation of complex samples containing compounds that differ widely in retention characteristics. To keep the time of analysis within acceptable limits, the retention factors [$k = (V_R/V_m - 1)$] of the most strongly retained sample components should usually be lower than 10 (V_R = retention volume, V_m = column holdup volume). For a satisfactory separation of both weakly and strongly retained sample compounds in a single run, operating conditions controlling retention, such as the composition or flow rate of the mobile phase, or the column temperature, should be varied during the chromatographic experiment. Flow programming in contemporary HPLC, using efficient small-particle columns, has only marginal effect on separation and is limited by the maximum instrumental pressure. Temperature programming is widely used in gas chromatography (GC), but rarely in HPLC, because a large rise in temperature during the run is required to significantly reduce retention. Solvent gradients are generally much more efficient to decrease the retention than programmed temperature. For example, retention factors k of low-molecular-weight analytes in reversed-phase LC (RPLC) decrease by a factor of 2–3 with a 10% increase in the concentration of organic solvent in aqueous–organic mobile phase, whereas an increase of temperature by 10°C usually leads to a decrease in k of non-ionic compounds by 10–20%. Furthermore, many commercial HPLC columns, especially with stationary phases bonded onto a silica gel support, are not stable at temperatures higher than 60°C. Also, only a few instruments that allow steep-enough temperature gradients are available because of a relatively slow response of the temperature inside the column to a change in the temperature setting in an air-heated thermostated compartment, especially with conventional analytical columns of 2 mm inner diameter or larger.

For these reasons, solvent gradients are most frequently used in contemporary HPLC. In gradient elution, the composition of the mobile phase is changed during the chromatographic run, either stepwise or continuously, to

increase the elution strength of the mobile phase, which allows decreasing the retention factors by 2 to 3 orders of magnitude in a single run. However, gradient elution requires more complicated equipment than isocratic HPLC, as two or more components of the mobile phase should be accurately mixed according to a preset time program; in addition, the selection of detectors is limited. Gradient runs generally take a longer time than isocratic elution because the column should be re-equilibrated to initial gradient conditions after each run.

The phenomena controlling gradient elution have often been misunderstood by many practicing chromatographers, who often consider it as subject to more experimental problems, less reproducible, slower, and more difficult to transfer from one instrument (laboratory) to another than isocratic elution, the reason being more complex equipment, more tedious method development, and more difficult interpretation of results. That is why some workers try to avoid gradient elution; however, by doing so they can miss undeniable benefits of this technique.

The main reasons for the use of gradient elution are the following:

- Improving the resolution of samples with wide range of retention.
- Increasing the number of peaks resolved within a fixed time of separation (increasing the peak capacity in single- or multidimensional LC).
- Separation of mixtures of compounds with high molecular weights such as synthetic polymers, proteins, and other biopolymers, whose retention changes markedly for small changes in the composition of mobile phases.
- Providing economic and fast generic separation methods that can be applied with confidence in development and control laboratories to a large number of samples of variable composition to provide important information in short time to synthetic chemists, either for fast sample screening or for generating impurity profiles.
- Using initial "scouting" gradient experiments for efficient development of final gradient or isocratic methods.
- Removing strongly retained interfering compounds in a separate sample pretreatment before analysis.
- Suppression of tailing peaks, especially for samples containing basic compounds.

Because of a higher number of experimental variables that may affect the retention, the effective use of gradient technique requires understanding how the gradient profile controls the separation. Some practitioners may be puzzled by observing that, for example, using a longer column or decreasing the flow rate of the mobile phase, while keeping other gradient conditions unchanged, may shorten the analysis time and decrease the resolution in gradient elution, contrary to the effects in isocratic HPLC. The theory developed in the past few decades can satisfactorily explain such "unexpected" results in gradient elution. Theoretical models describing the sample behavior under gradient conditions provide efficient tools for development and optimization of gradient HPLC methods.

PRINCIPLES OF GRADIENT ELUTION

Mobile-phase gradients can be formed outside the separation column by pumping and mixing the liquid components according to a preset time program (external gradients), or can be generated inside the column as a consequence of changing the equilibrium between the components adsorbed on the stationary phase and in the solution, induced by incoming mobile phase (internal gradients). Therefore, the second approach is suitable only for a limited number of separation cases and is generally not used, except for some ion chromatography systems with reagent-free eluent generators to produce hydroxide eluents for isocratic or gradient separations. The retention of non-ionic compounds in RPLC and normal-phase LC (NPLC) depends mainly on their polarities and the polarities of the stationary and mobile phases; hence, external polarity (solvent strength) gradients, prepared by mixing solvents of different polarities, are suitable for their separation. Solvent strength gradients are often useful for the separation of ionic compounds; however, the mobile phase should contain buffers or other ionic additives so that ionic strength or pH gradients can also be used for separations in ion-exchange (IE) or ion-pair gradient chromatography of ionic compounds.

Mobile-phase gradients in analytical HPLC can be classified using several criteria:

1. Number of mobile-phase components whose concentrations change with time:
   - Two-component (binary) gradients
   - Multicomponent (ternary, quaternary, etc.) gradients
   - Relay gradients, i.e., multicomponent gradients consisting of several subsequent steps with different solvents where the mobile phase changes from solvent A to solvent B in the first step, from solvent B to solvent C in the second step, etc.
2. Profile of the gradient:
   - Linear gradients
   - Non-linear gradients with curved profile (concave or convex, rarely used, mostly substituted by segmented gradients)
   - Step gradients, including several subsequent isocratic steps with increasing concentration of one or more strong eluting components of the mobile phase
   - Segmented gradients, including several subsequent steps, usually linear with different slopes

(ramps) or isocratic hold periods (most often at the end or at the beginning of elution, but also inserted between linear gradient steps)
- Reverse gradients with decreasing concentration of the strong mobile-phase component are often used to restore the initial conditions before the next sample injection.

3. Chromatographic mode and mobile phase:
   - RP solvent gradients—concentration(s) of one or more organic solvent(s) in water increase(s); nonpolar bonded columns
   - Non-aqueous RP solvent gradients—concentration(s) of one or more less polar organic solvent(s) in a more polar one increase(s)
   - Ion-pair RP solvent gradients in mobile phases containing ion-pair reagents
   - Ion-pair reagent concentration gradients in RP mode
   - RP pH gradients
   - RP decreasing ionic strength gradients (hydrophobic interaction chromatography, salting-out chromatography)
   - Ionic strength gradients in ion-exchange liquid chromatography (IELC) (may be combined with solvent gradients)
   - pH gradients in IELC (may be combined with solvent gradients)
   - NP solvent gradients—concentration(s) of one or more polar solvent(s) in a less polar one increase(s); non-aqueous mobile phases, polar adsorbent, or polar-bonded-phase columns
   - NP hydrophilic interaction chromatography gradients—concentration(s) of water (or of water and a more polar organic solvent) in a less polar solvent increase(s); aqueous mobile phases, polar adsorbent, or bonded-phase columns

Most frequent are simple continuous gradients, which can be characterized by three parameters: 1) the initial concentration; 2) the steepness (slope); and 3) the shape (curvature) of the gradient, which all affect the elution time and the spacing of the peaks in the chromatogram. A linear gradient profile is used almost exclusively in practice and can be described by Eq. 1:

$$\varphi = \mathrm{A} + \mathrm{B}'t = \mathrm{A} + \frac{\Delta\varphi}{t_G}t = \mathrm{A} + \frac{\mathrm{B}'}{\mathrm{F_m}}V = \mathrm{A} + \mathrm{B}V = \mathrm{A} + \frac{\Delta\varphi}{V_G}V \quad (1)$$

where A is the initial concentration φ of the strong solvent in the mobile phase at the start of the gradient, and B or B′ is the steepness (slope) of the gradient (i.e., the increase in φ in the time unit or in the volume unit of the mobile phase); V_G and t_G are the gradient volume and the gradient time during which the concentration φ is changed from the initial value A to the concentration $\varphi_G = \mathrm{A} + \Delta\varphi$ at the end of the gradient; and $\Delta\varphi$ is the gradient range. Curved gradients are often substituted by multiple linear segmented gradients consisting of several subsequent linear gradient steps with different slopes B.

The theory of gradient elution chromatography allows prediction of the elution behavior of sample compounds by calculating from their isocratic retention data (or from two initial gradient experiments) in RPLC, NPLC, and IELC systems. Unlike isocratic conditions, the retention factors change (decrease) during gradient elution and can be considered constant only in a very small (differential) volume of the mobile phase dV corresponding to migration along a differential part of the column holdup volume V_m, dV_m:

$$\mathrm{d}V = k \cdot \mathrm{d}V_m \quad (2)$$

The differential equation Eq. 2 can be solved after introducing the dependence of k on the volume of the eluate passed through the column from the start of the gradient run V. Any dependence of k on V can be divided into two parts: 1) a dependence of k on the concentration of a strong eluting component in the mobile phase φ controlled by the thermodynamics of the distribution process (the retention equation); and 2) the parameters of Eq. 1 describing the gradient profile, adjusted by the operator. A plethora of models for the description of retention in RPLC, IE, and NPLC have been suggested during the past 40 years, resulting in various retention Eqs. 1–3. For practical prediction and optimization of retention in gradient elution, the retention model can be rigorously theoretical, semiempirical or fully empirical.

RP GRADIENT LC

RP chromatography is, by far, the most widely used LC mode for the separation of complex mixtures based on different lipophilicities of sample compounds.[1] The effect of the volume fraction φ of the organic solvent in a binary aqueous–organic mobile phase on the retention factors k in RP chromatography can be very often described by a simple equation (Eq. 3):[1,2]

$$\log k = \log k_0 - m\varphi = a - m\varphi \quad (3)$$

Here, k_0 is the retention factor of the sample solute extrapolated to pure water as the mobile phase, and m characterizes the "solvent strength" (i.e., the change in log k per concentration unit of the organic solvent). Assuming the validity of Eq. 3, the retention volume V_R in RP gradient elution chromatography with linear gradients can be calculated from Eq. 4:[3]

$$V_R = \frac{1}{mB}\log\{2.31\ mB\ [V_m\ 10^{(a-mA)} - V_D] + 1\} + V_m + V_D \quad (4)$$

V_D is the so-called gradient dwell volume [i.e., the volume of the mobile phase contained in the instrument parts (mixer, filter, and tubing) between the pump and the column]. In an ideal case, linear concentration gradients in RPLC correspond to the linear solvent strength (LSS) gradients according to the model developed by Snyder and Dolan;[4] hence, Eq. 4 describes the retention data in LSS gradient elution.

In gradient elution of weak acids or bases, gradients of organic solvent (acetonitrile, methanol, or tetrahydrofuran) in buffered aqueous–organic mobile phases are most frequently used. The solvent affects the retention as in RP chromatography (RPC) of non-ionic compounds, except for some influence on the dissociation constants, but Eq. 4 is usually accurate enough for calculations of gradient retention volumes.

The pH gradients may be used for RPC separation of weak acids or bases, whose ionization and retention strongly depend on the pH of the mobile phase. The retention factor, k, of a non-dissociated acid or a base may be 10–20 times larger than that of their dissociated forms. However, pH gradients are generally less useful and more difficult to design than solvent gradients. Quasi-linear pH gradients can be accomplished by mixing universal buffers containing phosphoric, acetic, and boric acids as solvent A with sodium hydroxide as solvent B. An RP column should be stable over a wide range of pH; bidentate bonded silica columns, hybrid silica–organic polymer matrix columns, or columns based on modified zirconium dioxide support are generally suitable for pH gradients. Theoretical model of RP pH gradients enables numerical calculation of the retention times of weak acids or weak bases in LC with linear pH gradients.[5] The dependence of the dissociation constants on the concentration of organic solvent in the mobile phase may affect the accuracy of prediction.

Completely ionized substances can often be separated in ion-pair chromatography (IPC), where an ion-pair reagent with surface-active properties, containing a strongly acidic or strongly basic group and a bulky hydrocarbon part in their molecules, is added to aqueous–organic mobile phases to increase the retention and improve the peak symmetry of ionic samples. Adequate ion-pair reagent concentrations in IPC are between 10^{-4} and 10^{-3} mol. A major disadvantage of gradient IPC is slow column equilibration after changing the mobile phase. Complete washout of the adsorbed ion-pair reagent from the column may be difficult to achieve. Furthermore, increasing concentration of organic solvent during gradient elution affects the distribution equilibrium of the ion-pairing reagent between the stationary and the mobile phase, which may impair the accuracy of the predicted gradient data.

NP (ADSORPTION) GRADIENT LC

Normal-phase chromatography (NPC) is far less used than RPC, but it has several practical advantages: 1) because of lower viscosity, pressure drop across the column is lower than with aqueous–organic mobile phases used in RPC; 2) columns are usually more stable in organic than in aqueous–organic solvents; 3) columns packed with unmodified inorganic adsorbents are not subject to "bleeding," i.e., to gradual loss of the stationary phase, which decreases slowly the retention during the lifetime of a chemically bonded column; 4) some samples are more soluble or less likely to decompose in organic than in aqueous mobile phases; 5) because of fixed position of the adsorption sites, NPC is suitable for separation of various positional isomers or stereoisomers; 6) if sample pretreatment involves extraction into a non-polar solvent, direct injection onto an NPC column is less likely to cause problems than the injection onto an RPC column; 7) gradient NPC is more suitable than RPC for the separation of synthetic polymers insoluble in water, but it has lower selectivity for the separation of molecules differing in the hydrocarbon part. However, reproducible NP gradient operation requires strict control of temperature and of trace concentrations of water in non-aqueous mobile phases. Last but not the least, organic solvents are more expensive to purchase and dispose than water.

In NP chromatography, the elution strength of the mobile phase is proportional to its polarity, which is usually adjusted using binary mobile phases consisting of a weak (non-polar) solvent A and a stronger, more polar solvent B. Hence, the elution strength increases with increasing concentration of the polar solvent B. A simple equation (Eq. 5) can often adequately describe the experimental dependencies of the retention factors k of sample compounds on the volume fraction φ of a polar solvent B in a binary mobile phase consisting of two organic solvents with different polarities, if the sample solute is very strongly retained in the pure, less polar solvent:

$$k = k_0\ \varphi^{-m} \quad (5)$$

k_0 and m in Eq. 5 depend on the nature of the solute and on the chromatographic system, but are independent of the concentration of the strong solvent B in the mobile phase.

In NP gradient LC on polar adsorbents, the concentration of one (or more) polar solvent(s), B, in a non-polar solvent A increases. Assuming the validity of Eq. 5 in NP gradient chromatography with linear increase in the volume fraction of a polar solvent B, the elution volume V_R of a sample solute can be calculated from Eq. 6:[2]

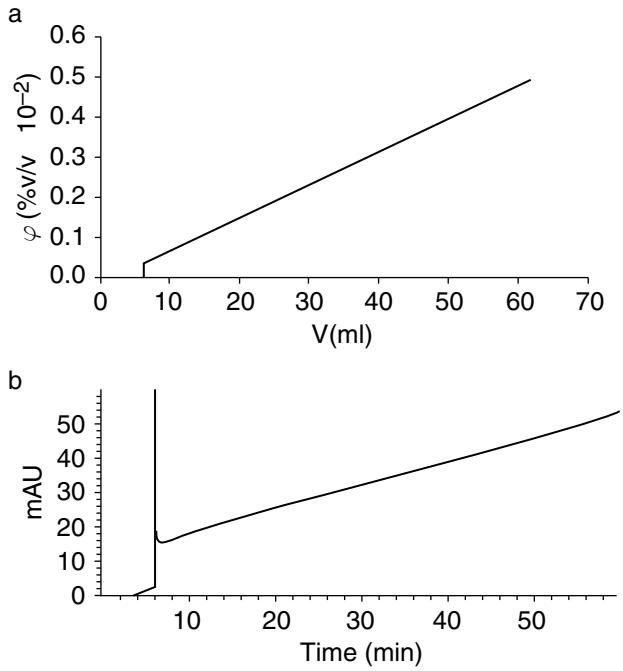

Fig. 1 Calculated breakthrough curves in NP gradient elution HPLC. Simulated calculation using the experimental isotherm data and assuming $N = 5000$. a) Gradient dwell volume = 0.50 ml. b) Record of the blank gradient detector trace showing the breakthrough of propan-2-ol at 6 min and a "ghost peak" of impurities displaced at the breakthrough volume. Column: silica gel Separon SGX (7.5 μm), 150 × 3.3 mm I.D., 1 ml/min, 40°C. Gradient: 0–50% 2-propanol in 30 min (φ = concentration of propan-2-ol in the eluate; V = volume of the eluate from the start of the gradient).

$$V_R = \frac{1}{B}\left[(m+1)B(k_0 V_m - V_D A^m) + A^{(m+1)}\right]^{\frac{1}{m+1}} - \frac{A}{B} + V_m + V_D \quad (6)$$

Here, as in Eq. 4, V_m is the column holdup volume and V_D is the gradient dwell volume.

Eq. 5 is applicable to systems where the solute retention is very high in the pure non-polar solvent. If this is not the case, the retention is better described by Eq. 7.[6]

$$k = (a + b\varphi)^{-m} \quad (7)$$

Here, a, b, and m are experimental constants depending on the solute and on the chromatographic system [$a = 1/(k_a)^m$, k_a is the retention factor in pure non-polar solvent]. Usually, Eq. 7 slightly improves the description of the experimental data with respect to Eq. 5. In NP systems where Eq. 7 applies under isocratic conditions, the elution volume V_R of a sample solute in NPLC with linear gradients described by Eq. 1 can be calculated using Eq. 8:[6]

$$V_R = \frac{1}{bB}\left[(m+1)bBV_m + (a + Ab)^{(m+1)}\right]^{\frac{1}{m+1}} - \frac{a + Ab}{bB} + V_m \quad (8)$$

In contrast to RP gradient elution, preferential adsorption of polar solvents from the mobile phase onto the surface of the polar adsorbent during a gradient run may lead to significant deviations of the actual gradient profile from the preset mobile-phase composition program and to a decrease in the reproducibility of the retention data (Fig. 1). Furthermore, because of the strong preferential adsorption of polar solvents, column re-equilibration times after the end of the gradient are often long in NPLC. This has been a reason for strong bias against the use of gradient elution in NP chromatography. To suppress these effects, which are most significant with gradients starting in pure non-polar solvents, gradients should be started, rather, at 3% or more than at a zero concentration of the polar solvent, if possible, and non-localizing polar solvents should be used, such as dichloromethane, dioxane, or *tert*-butyl methyl ether.

Water is much more strongly adsorbed than polar organic solvents on polar adsorbents; hence, even trace water concentrations in the mobile phase decrease the adsorbent activity and very significantly affect the retention. As the distribution equilibrium of water and other polar solvents between the polar adsorbent and an organic mobile phase is strongly affected by temperature, it is very important to work with a thermostated column. The reproducibility of the retention data in NP gradient LC can be considerably improved to the level comparable with RP gradient chromatography by keeping a constant temperature and adsorbent activity and by controlling the water content in the mobile phase best by using dehydrated solvents kept dry over activated molecular sieves and filtered before use.[6]

Aqueous–organic mobile phases are sometimes used in NP "hydrophilic interaction chromatography" (HILIC),[7] employing diol, aminopropyl, or specially designed HILIC (e.g., polyhydroxyethyl aspartamide)-bonded phases more often than unmodified silica. The retention increases as the polarity of analytes increases and as the amount of water, which is the most polar component in the mobile phase, decreases. This behavior is characteristic of NPC and opposite to RPC; Eq. 5 can often be used to describe the effect of the concentration of water in the mobile phase on the retention in HILIC. Hence, the retention in gradient HILIC with increasing concentration of water (usually starting at 1–10% water) can be described by Eq. 6. HILIC provides excellent separation selectivity for some strongly polar samples, such as some peptides and proteins, carbohydrates,

oligonucleotides, and so on, very weakly retained in RPC or very strongly retained in non-aqueous NPC.

IE GRADIENT LC

The IE process is based on the competition between the solute and the counterion in the mobile phase, which is essentially aqueous or aqueous–organic solution of a salt or buffer. Salt (ionic strength) gradients in IE chromatography are frequently used in the separation of complex peptides, proteins, and other biopolymer samples as a complementary technique to RP solvent gradient separations, often in a 2-D setup. The gradients usually start at a low salt (chloride, sulfate, etc.) concentration and typically run from 0.005 to 0.5 *M*. A buffer is used to control the pH; acetonitrile and methanol may be added to improve the resolution and urea to improve the solubility of proteins that are difficult to dissolve. Ion exchangers with weak hydrophobic matrices usually prevent protein denaturation in aqueous mobile phases.

The retention in IE chromatography can be described by a stoichiometric model as competition between the sample ions and the counterions in the mobile phase for IE sites in the stationary phase. Because this principle is similar to the competition between a non-ionic sample and a polar solvent for the adsorption centers in the competition/displacement model of NP chromatography on polar adsorbents, Eq. 5 can also be used to describe the effect of the ionic strength in the mobile phase on retention in isocratic IE chromatography, if φ has the meaning of the molar concentration of a salt (buffer) in the mobile phase. k_0 is the retention factor in the mobile phase containing 1 mol/L salt (buffer) and $m = x/y$ is the stoichiometric coefficient of IE, where x is the charge on the analyte and y is the charge of the eluent competing ion (counterion).[3] The exponent m is a measure of the decrease in retention for per unit change in concentration of counterions in the mobile phase and is proportional to the charge of analyte. k_0 depends on the IE capacity of the stationary phase and on the IE selectivity coefficient between the analyte ion and the competing counterion in the eluent, which is difficult to predict a priori. In practice, m and k_0 are determined on the basis of a limited number of experiments at different isocratic eluent compositions or scouting gradient runs.

Because of the validity of Eq. 5 in IE isocratic chromatography, elution times (volumes) in IE gradient chromatography can be predicted using Eq. 6, with A standing for the molar concentration of the counterion at the start of the gradient and B characterizing the gradient ramp as the change in the molar concentration of the counterion per volume unit of the mobile phase passed through the column. This gradient elution retention model for IE chromatography was proposed by Jandera and Churáček[2] and was later applied by Baba et al.[8] to the prediction and optimization in IE chromatography of polyphosphates and by Shellie et al.[9] in ion chromatography of various anions and cations.

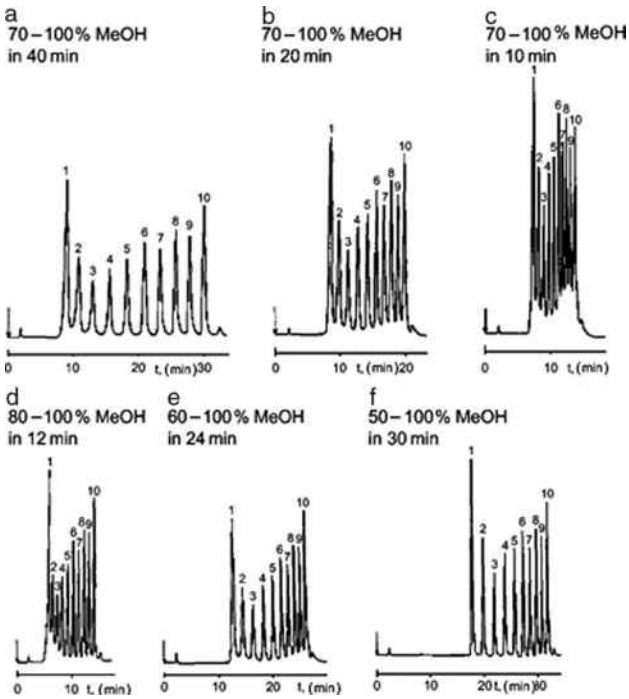

Fig. 2 RP gradient elution separation of 1,2-naphthoylenebenzimidazole alkylsulfonamides. Column: Lichrosorb RP-18, 10 μm (300 × 4 mm I.D.). Linear gradients of methanol in water with a constant gradient range but different gradient volumes (a–c), and with a constant gradient steepness (1.67% methanol/min) but different initial concentrations of methanol (d–f). Flow rate = 1 ml/min. The number of peaks agrees with the number of carbon atoms in alkyls.

The pH affects the degree of dissociation and hence the selectivity of separation of weak acids and bases. The change in ionization is greatest when pH is close to pK_a. If the pK_a values are known, the change in ionization and in retention of the sample compounds resulting from a change in pH can be predicted. The use of pH gradients to accomplish the separation of solutes differing in the degree of ionization is more frequently applied in IE than in RPC, especially for the separation of biopolymers such as proteins, which elute roughly in the order of their isoelectric points, p*I*. Protein molecules carry multiple negative charges and are strongly retained on an anion exchanger at a pH higher than p*I*, but as soon as the pH drops below the p*I* during gradient elution, the initially strongly retained protein gets positively charged and is released from the ion exchanger rapidly. Hence, proteins are focused in narrow bands during the separation and their elution occurs at the time when the instantaneous pH at the column outlet reaches the p*I* of the solute. The band shapes improve with respect to ionic strength gradients.

The formation of linear pH gradients in IE chromatography is more difficult than in RPLC, because the ion exchanger may show preferential adsorption for certain buffer components and consequently change the preset gradient. For this reason, IE materials with small IE capacities are required in combination with buffer components that are not adsorbed on the IE column. Ethanol is added to the buffer to reduce the adsorption. In combination with RP solvent gradient in second dimension, pH IE gradient in first dimension seems a promising emerging technique for 2-D separations of proteins. The dependence of the retention in gradient elution with pH gradients is less straightforward, so that the prediction of retention behavior is more difficult than with salt gradients.

EFFECTS OF GRADIENT PROFILE ON SEPARATION: COMPARISON WITH ISOCRATIC ELUTION

The gradient profile affects retention in a similar way as the concentration of the strong solvent in a binary mobile phase under isocratic conditions. This is illustrated in Fig. 2 for gradient elution RP chromatography separation of 10 homologous derivatives of *n*-alkylamines. At a constant gradient range (70–100% methanol), the steepness of the gradient decreases as the gradient time increases from 10 to 40 min; the resolution improves, but the retention times increase (the top three chromatograms). The bottom three chromatograms show the effect of the gradient range on the separation at a constant steepness of the gradient (1% methanol/0.6 min)—as the initial concentration increases from 50% to 80% methanol, both retention and resolution decrease. The retention times of early eluting compounds are affected more significantly by the initial concentration of the strong solvent (methanol) than by the gradient steepness. The examples in Fig. 2 illustrate the importance of appropriate adjustment of both the gradient range and the initial gradient concentration to keep the analysis time short.

Eqs. 4 and 6 show that, for comparable retention times, a less steep gradient should be used to compensate for a higher parameter m in Eqs. 3 and 4, which usually increases with increasing size of the molecule. This behavior has the following practical consequences for gradient elution of high molecular compounds: 1) macromolecules may have so large an m that a very small change in the concentration of the strong solvent may change the retention from very strong to practically no retention, so that isocratic separation of large molecules is difficult, if possible at all; 2) shallow gradients are usually required for separations of high molecular samples, so that the selection of a suitable combination of the gradient parameters A and B is more critical than for small molecules; and 3) samples with a broad range of molar masses may require a flatter gradient at the end of the chromatogram than at its start for regular band spacing (a convex gradient).

Under isocratic conditions, bandwidths increase for more strongly retained compounds, but the bandwidths in gradient elution chromatography are approximately constant for both early-eluting and late-eluting compounds. This is caused by increasing migration velocities of the bands along the column during gradient elution, so that all sample compounds are eventually eluted with very similar instantaneous retention factors k_e at the time they leave the column, which are approximately half the average retention factors (k^*) during the band migration along the column. The bandwidths decrease with steeper gradients (the three top chromatograms in Fig. 2). Because k_e values are usually significantly lower than the retention factors in isocratic LC, the peaks in gradient elution chromatography are generally narrower and higher, improving the detector response and the sensitivity of determination. However, the beneficial effect of gradient elution on increasing sensitivity is often counterbalanced by an increased baseline drift and noise in comparison with isocratic HPLC. To avoid this inconvenience, high-purity solvents and mobile-phase additives are generally used in gradient elution HPLC.

The bandwidths W_g in gradient elution can be determined by introducing the appropriate instantaneous retention factor k_e at the elution of the peak maximum calculated using an appropriate gradient retention equation (e.g., Eq. 4 or Eq. 6):

$$W_g = \frac{4V_m(1+k_e)}{\sqrt{N}}G \tag{9}$$

N is the number of theoretical plates determined under isocratic conditions; and V_m is the holdup volume of the column. It should be noted that the correct plate number value cannot be determined directly from a gradient elution chromatogram, as the retention factors k are continuously changing during the elution. G in Eq. 9 is the band compression factor, which accounts for additional band compression in gradient elution. This occurs because the trailing edge of the sample band moves along the column in a mobile phase with higher elution strength faster than the leading edge, migrating more slowly in a weaker mobile phase during gradient elution. Neglecting the additional band compression may lead up to 10–20% positive errors in the calculated bandwidths. A simplification adopted in the derivation of Eq. 9 by neglecting the effects of changing mobile-phase composition on the diffusion coefficients, which affects the band broadening, may cause errors in the calculated gradient bandwidths, which are generally estimated to be less than 1% for low molecular samples. For practical method development, neglecting band compression may be used as a "safety tolerance" to compensate for

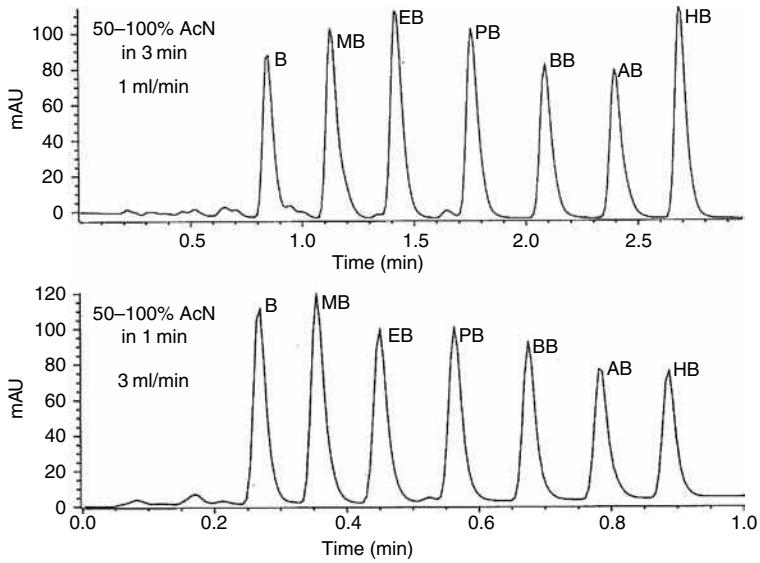

Fig. 3 Gradient elution RP separation of alkylbenzenes with gradient times adjusted to varying flow rate of the mobile phase. Linear gradients, 50–100% acetonitrile in 3 min at 1 ml/min (*top*) and 50–100% acetonitrile in 1 min at 3 ml/min (*bottom*). Conditions: Purospher Star RP-18e, 3 μm, column (30 × 4 mm I.D.), 40°C, detection UV, 254 nm; sample: B, benzene; MB, toluene; EB, ethylbenzene; PB, propylbenzene; BB, butylbenzene; AB, amylbenzene; HB, hexylbenzene.

additional band broadening effects caused by variation of the viscosity and diffusion coefficients during the gradient, or due to extracolumn band broadening.[10]

Combining the appropriate equations for the retention volumes of solutes 1 and 2 with adjacent bands and Eq. 9, for bandwidths, we can calculate the resolution in gradient HPLC as follows:

$$R_s = \frac{V_{R(2)} - V_{R(1)}}{W_g} \tag{10}$$

Here, $V_{R(1)}$ and $V_{R(2)}$ are the retention volumes of sample compounds with adjacent peaks.

TRANSFER OF GRADIENT METHODS BETWEEN DIFFERENT INSTRUMENTS, COLUMNS, AND SEPARATION CONDITIONS

Transfer of gradient methods between various instruments and columns with different geometry and/(or particle size is less straightforward than the transfer of isocratic HPLC methods, as changing column dimensions and flow rate affect the gradient volume (gradient ramp) and consequently not only the elution times and the column efficiency (plate number) but also the selectivity of separation may change. Hence, the gradient profile should be adapted to match any change in flow rate F_m, column length L, or diameter d_c by appropriate change in the gradient time t_G to keep the ratio V_m/V_G constant to obtain predictable results. The necessary changes in operation parameters can be calculated from Eq. 11 assuming a constant gradient concentration range [i.e., constant concentrations of the stronger solvent at the start (A) and at the end (φ_G) of the gradient]:

$$\frac{V_m}{V_G} = \frac{V_m}{t_G F_m} = \frac{d_c^2 l}{t_G F_m} = const \tag{11}$$

Eq. 11 shows that the number of column holdup volumes necessary to elute a sample compound, V_R/V_m, is directly proportional to the ratio of the gradient volume, V_G, and the holdup volume, V_m, which should be kept constant when changing column geometry or flow rate. This condition is similar to keeping a constant retention factor, k, at a constant mobile-phase composition and temperature. Hence, any change of column length, l, or diameter, d_c, at a constant gradient range $\Delta\phi$ should be compensated by appropriate change in the gradient time, t_G, or flow rate of the mobile phase, F_m, to keep the ratio V_m/V_G constant.[10] In this case, a change in operation conditions has the same impact on the column plate number, N, and time of separation as in isocratic chromatography. With two columns of different diameters, but the same length, the column holdup volumes are proportional to the second power of the column diameters.

Eq. 11 shows that the flow rate of the mobile phase should be adjusted in the proportion of changing V_m, to keep the separation time constant. Alternatively, the gradient time can be adjusted to keep the ratio $V_m/(t_G \times F_m)$ constant.[10] Clearly, the speed of separation increases at a higher flow rate, but to achieve the desired decrease in the separation time, the gradient time should be decreased in inverse proportion. Fig. 3 illustrates proportional decrease in the elution times with increasing flow rate at the gradient time adjusted in this way, in agreement with Eq. 11.

Fast generic gradient methods are required for high throughput in food safety control, in environmental analysis, and especially in pharmaceutical laboratories throughout the whole drug analysis process, including drug discovery screening, raw material analysis, impurity

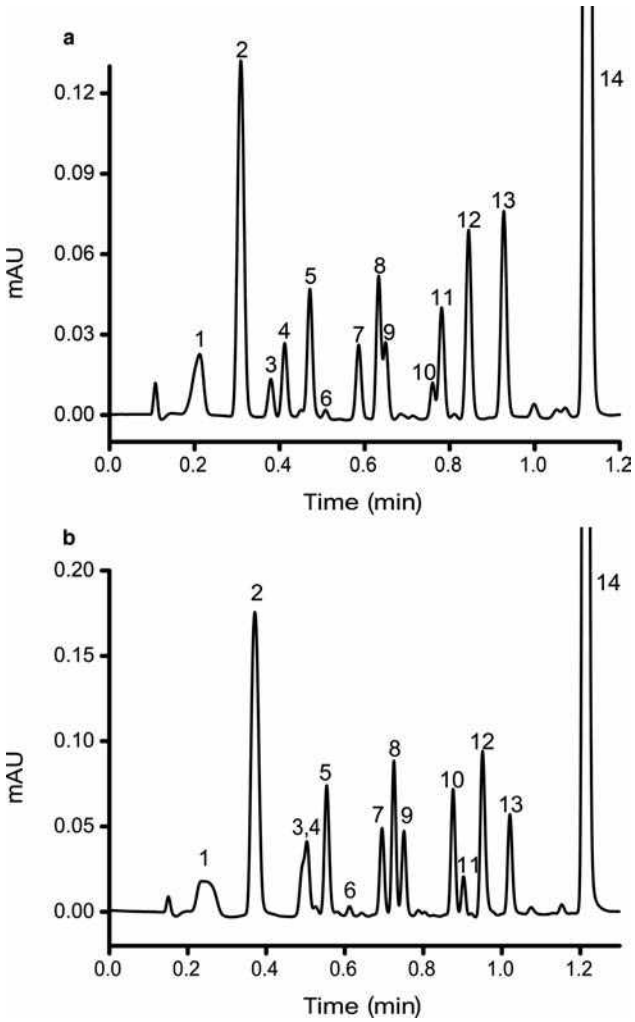

Fig. 4 High-pressure fast gradient separation of natural phenolic antioxidants. (a) Ascentis Express C18 column with fused core 2.7 μm C18 particles with a thin porous outer shell (0.5 μm), 30 × 3.0 mm I.D. at 1.5 ml/min, 53 MPa. (b) Acquity BEH Phenyl column with totally porous particles in 1.7 μm particles at 1.5 ml/min, 74 MPa, UV detection, 254 nm. Sample: 1, gallic acid; 2, protocatechine; 3, esculine; 4, chlorogenic acid; 5, caffeine; 6, epicatechine; 7, vanilline; 8, rutine; 9, sinapic acid; 10, hesperidine; 11, 4-hydroxycoumarine; 12, morine; 13, quercetine; 14, 7-hydroxyflavone.

profiling, pharmacokinetic studies, and final product stability tests. At a constant ratio of V_G/V_m, the resolution only slightly impairs when decreasing the column length, keeping a constant ratio of the column length to the mean particle diameter, l/d_p, but the time of separation decreases proportionally to l. Hence, much faster separations can be achieved on short columns packed with small particles, for example, with a 3 cm column packed with a 3 μm material, or even better with a 1 cm, 1 μm column, in comparison with conventional 5 cm, 5 μm columns. Very fast gradients with short columns require a modified LC instrument with minimized extracolumn volumes by using low-volume injectors and detector cells, fast autosamplers, detectors with a short time constant, high signal sampling rates, and flow splitting to decrease the effects of the gradient dwell volume. Over the last few years, instrumental systems suitable for fast gradient separations have become available, operating at considerably higher pressures up to 150 MPa. Monolithic columns or columns packed with non-porous or fused-core superficially porous particles offer decreased band broadening, yielding comparable efficiencies and separation times at lower operation pressures than fully porous particles of smaller particle size. Fig. 4 compares fast-gradient RP separation of 14 phenolic acids and flavones on a column with superficially porous fused-core particles (4a) and on a column with small totally porous particles, at a significantly higher pressure for comparable run time (4b). Separations can be further accelerated at high temperatures due to decreased viscosity of the mobile phase and lower pressure drop across the column.

The simple transfer rule of Eq. 11 does not take into account the differences between the instrumental gradient dwell volumes, V_D, in various commercial instruments, which may complicate the transfer of gradient methods, as more or less significant differences in the retention times and unexpected changes in the band spacing and sample separation may appear, due to the different migration of analytes along the column under isocratic conditions in the mobile phase contained in different dwell volumes before the actual start of the gradient. The effect of the dwell volume on the retention times of analytes increases with decreasing retention factor k_I at the start of gradient elution and with increasing ratio V_D/V_m and becomes very significant in the instrumental setup with the dwell volume comparable to or larger than the column holdup volume, which is more likely to occur in micro- or in capillary LC than in conventional analytical LC. Possibilities for correcting for different dwell volumes in the transfer of gradient methods are discussed in the section dealing with instrumental aspects of gradient elution.

TERNARY MOBILE-PHASE GRADIENTS

If the separation with binary gradients is unsatisfactory, ternary gradients can sometimes improve the selectivity by changing, simultaneously, the concentrations of two components with high elution strengths in a ternary mobile phase. For example, the early-eluting compounds show poor resolution with the gradients of methanol, but are better separated with gradients of acetonitrile in water, whereas the separation selectivity for the late-eluting compounds is better with a gradient of methanol than with gradients of acetonitrile in water.

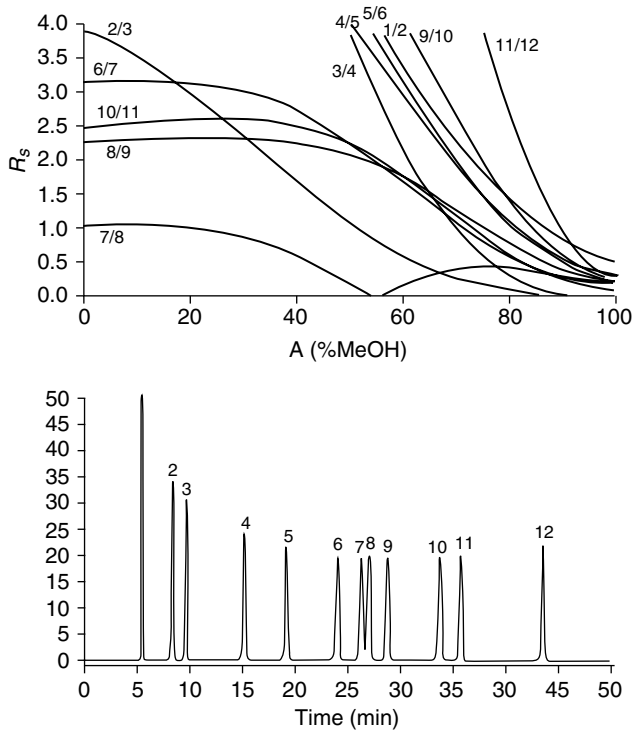

Fig. 5 *Top*: The resolution window diagram for RP gradient elution separation of phenylurea herbicides on a Separon SGX C18 7.5 μm column (150 × 3.3 mm I.D.) dependent on the initial concentration of methanol in water at the start of the gradient *A* with optimum gradient volume $V_G = 73$ ml. Column plate number $N = 5000$; sample compounds: 1, hydroxymetoxuron; 2, desphenuron; 3, phenuron; 4, metoxuron; 5, monuron; 6, monolinuron; 7, chlorotoluron; 8, metobromuron; 9, diuron; 10, linuron; 11, chlorobromuron; and 12, neburon. *Bottom*: The separation with optimized binary gradient from 24% to 100% methanol in water in 73 min. Flow rate = 1 ml/min; $T = 40°C$.

A ternary gradient with increasing concentration of methanol and simultaneously decreasing concentration of acetonitrile may improve the resolution of the sample.[6,11] Two specific types of ternary gradients are probably most useful in practice:

1. The "elution strength" (or "isoselective") ternary gradients, where the concentration ratio of two strong mobile-phase components is kept constant and the sum of their concentrations changes during the elution (so-called isoselective multisolvent gradient elution).
2. The "selectivity ternary gradients," where the sum of the concentrations of two strong mobile-phase components in the mobile phase is constant, but their concentration ratio changes during the elution.

OPTIMIZATION OF GRADIENT ELUTION

Gradient elution can be optimized using strategies common in isocratic HPLC. In RP gradient elution chromatography, the Dry-Lab G commercial software is probably the most popular tool for optimization of operating parameters.[7,12] Here, the retention data from two initial gradient runs are used to adjust, subsequently, the steepness and the range of the gradient, and, if necessary, other working parameters. This approach can be adapted to optimize segmented gradients.

Some parameters may show synergistic effects on the separation. Appropriate selection of the concentration of the strong solvent in the mobile phase at the start of the gradient A is equally important as adjusting the gradient steepness B because each parameter influences, very significantly, the resolution and the time of analysis. The gradient steepness and the initial concentration of the strong solvent can be optimized simultaneously, using the simplex method,[8,13] or a simple strategy employing a preset concentration of the strong solvent φ_G at the end of the gradient and gradient volume, V_G. Then, the steepness parameter B of the gradient depends on the initial concentration A, and the elution volumes V_R can be calculated as a function of a single parameter A:[6,11]

$$B = \frac{\varphi_G - A}{V_G} \tag{12}$$

The differences between the retention volumes of compounds with adjacent peaks or corresponding resolution R_s can be plotted vs. the initial concentration of the strong solvent A in the form of a "window diagram" to select the optimum A that provides the desired resolution for all adjacent bands in the chromatogram in the shortest time. With optimized A, the corresponding gradient steepness parameter *B* can be calculated for the preset gradient volume V_G and final concentration φ_G using Eq. 12. An example of the "window diagram" for optimization of NP gradient elution chromatography is shown in Fig. 5 (*top*), and the corresponding optimized separation is shown in Fig. 5 (*bottom*). In addition to the gradient steepness and initial concentration, the gradient shape can be adjusted for non-linear gradients or segmented gradients with several subsequent linear steps with different gradient steepness.

The composition of mixed mobile phases for ternary or quaternary "isoselective gradient elution" can be optimized using "overlapping resolution mapping" strategy to adjust optimum separation selectivity based on seven or more initial experiments with solvent mixtures of approximately equal elution strengths. Based on the retention data from the initial experiments, either 3-D diagrams or contour "resolution

maps" are constructed for all adjacent bands in a selectivity triangle space as a function of the concentration ratios of three solvents or two solvents and the pH of the mobile phase, from which the concentration ratio of the strong solvents that provides maximum resolution is selected.[14]

INSTRUMENTAL ASPECTS OF GRADIENT ELUTION CHROMATOGRAPHY

Even though the most common UV and fluorometric HPLC detectors can be used without problems in gradient elution if high-purity solvents are used as the mobile-phase components, some detectors are not compatible with gradient elution, such as the universal refractometric detector, which gives a response for almost all sample compounds, but also for the mobile-phase components. However, the only universal detector that can be used for gradient elution is the evaporative light-scattering (ELS) detector, which is less sensitive for UV-absorbing compounds than for the UV detector. As the ELS detector gives response to the stray light on solid particles of analytes after evaporation of the solvent from the nebulized column effluent, its use is restricted to volatile mobile phases and non-volatile analytes. Furthermore, this detector provides a non-linear concentration response. Mass spectrometric detection is ideally suited for gradient elution HPLC, as it combines the features of universality and specific detection, including possibilities of online mass spectral analysis of each peak.

Electrochemical detectors are generally incompatible with gradient elution, except for the multichannel coulometric CoulArray detector, which is controlled by a software compensating for the gradient baseline drift during the elution. This detector allows highly sensitive and selective detection of oxidizable or reducible compounds in gradient HPLC.

In micro-HPLC with narrow bore or capillary columns, lower flow rates should be used at comparable linear mobile-phase velocities. The flow rate should decrease in proportion

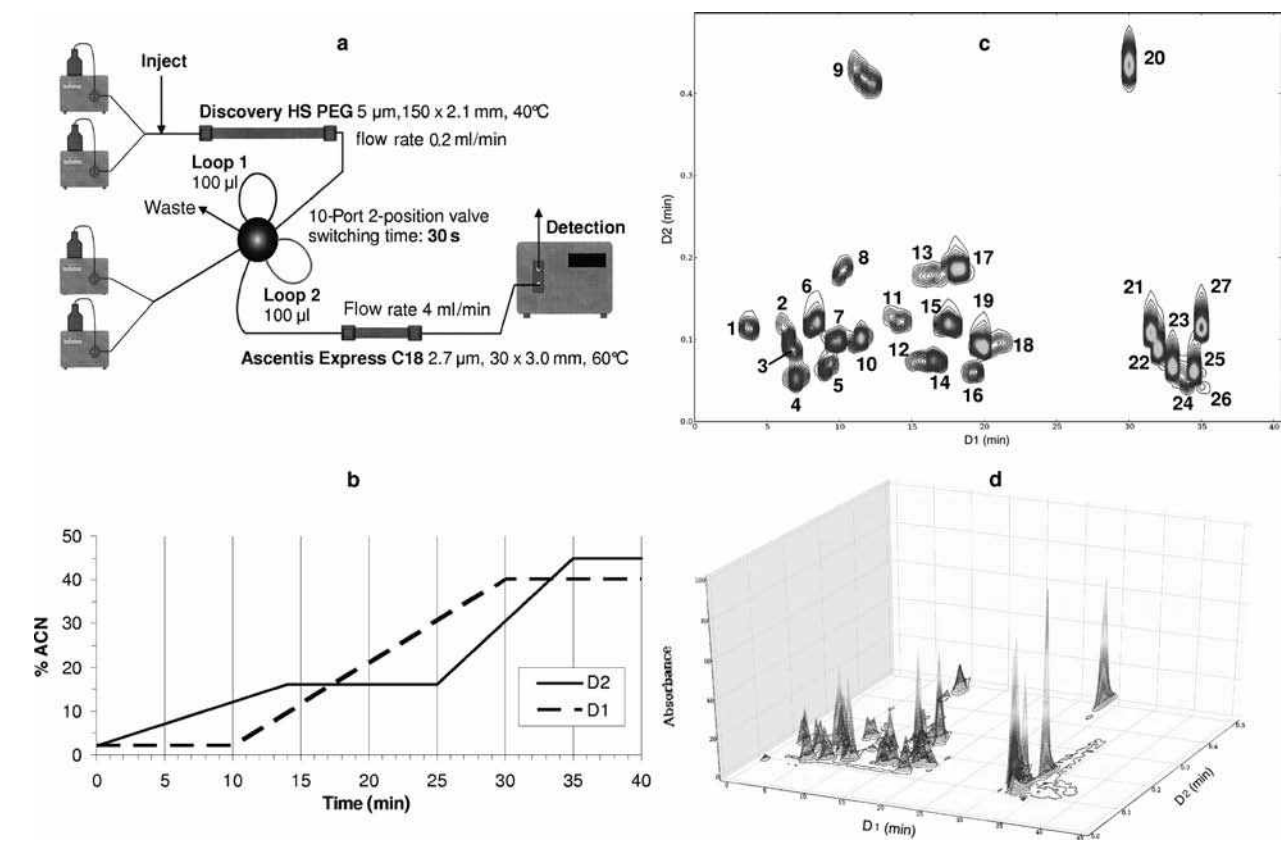

Fig. 6 Comprehensive LC × LC separation of phenolic acids and flavones using parallel gradients in the first and in the second dimension. D2 pressure = 400 bar. Compounds: 1, esculine; 2, 4-hydroxyphenylacetic acid; 3, chlorogenic acid; 4, gallic acid; 5, protocatechuic acid; 6, syringic acid; 7, vanillic acid; 8, salicylic acid; 9, hesperidine; 10, *p*-hydroxybenzoic acid; 11, sinapic acid; 12, (–)-epicatechine; 13, naringin; 14, caffeic acid; 15, ferulic acid; 16, (+)-catechin; 17, 4-hydroxycoumarin; 18, *p*-coumaric acid; 19, rutine; 20, flavone; 21, 7-hydroxyflavone; 22, hesperetin; 23, naringenin; 24, luteolin; 25, apigenin; 26, quercetin; 27, biochanin A.

to the second power of the column inner diameter, so that micro-LC columns with 1 mm I.D. require flow rates in the range of 30–100 μl/min, whereas capillary columns with 0.3–0.5 mm I.D. require flow rates between 1 and 10 μl/min, and capillary or nano-LC columns with 0.075–0.1 mm I.D. require flow rates in the range of hundreds of nanoliters per minute. Special miniaturized pump systems are required to accurately deliver the mobile phase at very low flow rates in isocratic LC. It is technically much more difficult to keep very low flow rates constant during a gradient run than in isocratic LC, and to simultaneously change accurately the volume proportions of the mixed solvents according to a preset time program. In contemporary micro-LC and capillary LC practice, concentration gradients can be achieved using sophisticated LC pumping systems for the delivery of microliter-per-minute gradients that are either flow-split or sampled. High-precision microflow reciprocating pumps using precolumn flow splitting can be used for delivery of flow rates ranging down to 50 nl/min in micro-LC and capillary LC systems. If a precolumn flow splitter is used, only a small part of the mixed mobile phase from the pump flows through the column, whereas a larger part is diverted through a bypass capillary. To avoid some problems connected with flow splitting, splitless systems with large inner volume syringe pumps for each solvent can be used, which deliver smooth flow. Mobile phase is not wasted and the systems are less affected by a change of the column backpressure in gradient runs where solvents with different viscosities are mixed. However, a change of mobile phase contained in the pump inner volume is time-consuming and such devices are rarely used in modern HPLC practice.

The instrumental errors that can decrease the reproducibility of gradient elution data may originate from imperfect functioning of gradient pumps, especially when volatile or viscous solvents are mixed. These errors are usually most significant in the initial parts and the final parts of the gradient where the proportions of the solvents mixed are lower than 1:20 and rounding of the gradient is observed; this can reduce the retention times of the bands eluting near the start of the gradient and increase the retention times of bands eluting near the end of the gradient. It is usually more significant in the instruments with larger volumes between the gradient mixer and the column inlet, i.e., the "gradient dwell volume" V_D. The dwell volume may be as high as a few milliliters with some instruments and may differ from one instrument to another. It can be determined from a "blank" gradient. Much more important than contributing to the rounding of the gradient, dwell volume increases the retention times, as the sample bands migrate a certain distance along the column under isocratic conditions in a mobile phase with a low elution strength, before the front of the gradient gets to the actual position of the sample zone in the column. The gradient delay due to the dwell volume can be relatively very significant in microcolumn gradient operation, especially in the system using precolumn flow splitting with 0.1 mm or lower I.D. capillaries.

When transferring gradient methods between instruments with different dwell volumes, these differences can be compensated for experimentally by programmed delayed sample injection after the start of the gradient elution, or by insertion of a "mixing chamber"—an additional piece of tubing or a small precolumn packed with an inert material in front of the injector to obtain equal dwell volumes with different instruments. Unfortunately, some LC workstations do not allow using delayed injection. Furthermore, it is not always possible to merge a makeup initial holdup time into the equilibration time between the subsequent runs in a sequence of analyses. Finally, a makeup gradient delay contributes to the run time and may be impractical with narrow-diameter columns.

To avoid difficulties when a gradient HPLC method is transferred between the instruments with different V_D values and to improve the precision of predictive calculations of the gradient elution data, the correction for the gradient dwell volume should be accounted for in calculations, using equations such as Eqs. 4, 6, or 8, as appropriate.[10]

GRADIENT ELUTION IN 2-D LC

Two-dimensional LC × LC systems essentially represent programming of stationary phases. The separation selectivity in the first dimension should largely differ from that in the second dimension. "Comprehensive" LC × LC technique represents a new emerging specific 2-D mode, where all sample compounds eluting from the first dimension are subjected to separation in the second dimension. The whole effluent from the first dimension is transferred into the second-dimension separation system in subsequent aliquot fractions collected in two alternating sampling loops of a 10-port (or 8-port) switching valve in multiple repeated cycles. The record of the detector at the outlet from the second-dimension column is transformed into a 2-D chromatogram, which is usually represented as a contour plot with the separation time in the second dimension plotted vs. the separation time in the first dimension. The separation time in the second dimension in comprehensive LC × LC is strictly limited, as the whole separation in the second dimension should be accomplished while the next fraction is collected from the first dimension by the fraction transfer cycle time from the first dimension, and every peak eluting from the first-dimension column should be sampled in several (at least three or four) subsequent fractions, to avoid loss of resolution achieved in the first dimension.

Gradient elution operation is a useful mean to suppress the band broadening and to increase the number of sample compounds separated and should be applied, if possible, in both dimensions.[15] Fig. 6 shows an example of comprehensive LC × LC separation of natural antioxidants with

simultaneous gradients on a first-dimension microcolumn and on a second-dimension short column.

CONCLUSIONS

The elution with solvent gradients is the most efficient technique for improving the separation of complex samples by programmed change of retention during the HPLC separation run. Understanding of the theoretical principles of gradient elution is important for rational method development, optimization, and transfer between different instrumental systems and column geometries in RP, IE, and NP modes. The gradient dwell volume of the system is the main instrumental factor complicating the method transfer and limiting rapid high resolution in gradient micro-HPLC. The most important recent advances in the instrumentation for gradient elution HPLC have resulted in the development of sophisticated instrumentation for gradient micro-HPLC, and the availability of universal ELS detection for compounds that do not contain chromophores or fluorophores and of a sensitive multichannel coulometric detection for gradient HPLC of electroactive compounds. Gradient elution is well suited for HPLC/mass spectrometry applications and for 2-D HPLC, especially in comprehensive LC × LC mode.

Headspace Sampling

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

Headspace sampling is usually employed to identify the volatile constituents of a complex matrix without actually taking a sample of the material itself. There are three variations of the technique: (a) static headspace sampling, (b) dynamic headspace sampling, and (c) purge and trapping.

DISCUSSION

The first technique, commonly used to monitor the condition of foodstuffs, particularly for detecting food deterioration (food deterioration is often accompanied by the characteristic generation of volatile products such as low-molecular-weight organic acids, alcohols, and ketones, etc.), involves first placing the sample in a flask or some other appropriate container and warming to about 40°C. Raising the temperature increases the distribution of the volatile substances of interest in the gas phase. A defined volume of the air above the material is withdrawn through an adsorption tube by means of a gas syringe. Graphitized carbon is often used as the adsorbing material, although other substances such as porous polymers can also be employed. Carbon adsorbents having relatively large surface areas (~100 m^2/g) are used for adsorbing low-molecular-weight materials, whereas for large molecules, adsorbents of lower surface areas are used (~5 m^2/g). After sampling, the adsorption trap is placed in an oven and connected to the chromatograph. The column is maintained at a low temperature (50°C or less) to allow the desorbed solutes to concentrate at the beginning of the column. The trap is then heated rapidly to about 300°C and a stream of carrier gas sweeps the desorbed solutes onto the column. When desorption is complete, the temperature of the column is programed up to an appropriate temperature and the components of the headspace sample are separated and quantitatively assayed. The proportions of each component in the gas phase will not be the same as that in the sample, as they are modified by the distribution coefficient. Thus, analyses will be comparative or relative, but not absolute.

The second analytical procedure is somewhat similar, but a continuous stream of gas is passed over the sample and through the trap. This produces a much larger sample of the volatile substances of interest and, thus, can often detect trace materials. The adsorbed components are desorbed by heat in the same manner and passed directly onto a gas chromatography (GC) column. The results are still determined by the distribution coefficient of each solute between the sample matrix and the air and, thus, the quantitative results remain comparative or relative, but not absolute.

The third method (purge and trap) is used for liquids and, in particular, for testing for water pollution by volatile solvents. In this method, air or nitrogen is bubbled through the water sample and then through the adsorbent tube. In this way, the substances of interest can be completely leached from the water; the results will give the total quantity of each solute in the original water sample. Thus, with this method, the results can be actual and not relative or comparative. The solutes are desorbed by heat in exactly the same way as the previous two methods, but provision is usually made to remove the water that is also collected before developing the separation.

A good example of the use of headspace analysis is in the quality control of tobacco. Despite the health concern in the United States, tobacco is an extremely valuable export and its quality needs to be carefully monitored. Tobacco can be flue cured, air cured, fire cured, or sun cured, but the quality of the product can often be monitored by analyzing the vapors in the headspace above the tobacco.

The headspace over tobacco can be sampled and analyzed using a solid-phase microextraction (SPME) technique. The apparatus used for SPME is shown in Fig. 1. The basic extraction device consists of a length of fused-silica fiber, coated with a suitable polymeric adsorbent, which is attached to the steel plunger contained in a protective holder. The steps that are taken to sample a vapor are depicted in Fig. 1. The sample is first placed in a small headspace vial and allowed to come to equilibrium with the air in the vial.[1] The needle of the syringe containing the fiber is then made to pierce the cap, and the plunger pressed to expose the fiber to the headspace vapor. The fiber is left in contact with air above the sample for periods that can range from 3 to 60 min, depending on the nature of the sample.[2]

The fiber is then removed from the vial[3] and then passed through the septum of the injection system of the gas chromatograph into the region surrounded by a heater (4). The plunger is again depressed and the fiber, now protruding into the heater, is rapidly heated to desorb the

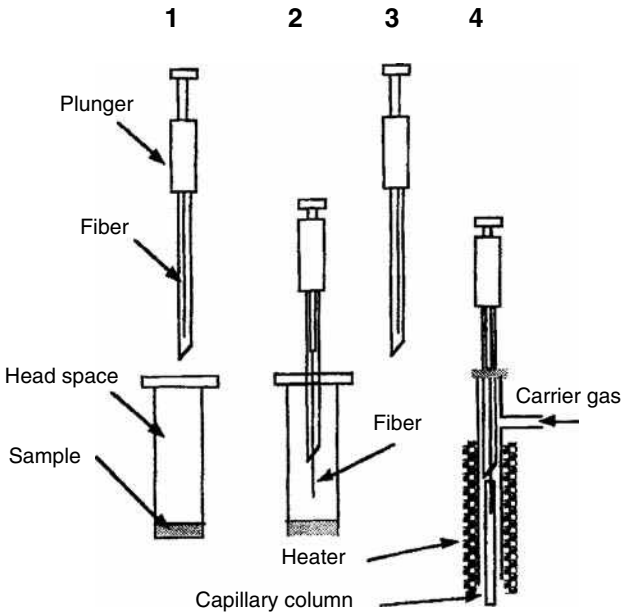

Fig. 1 The SPME apparatus.

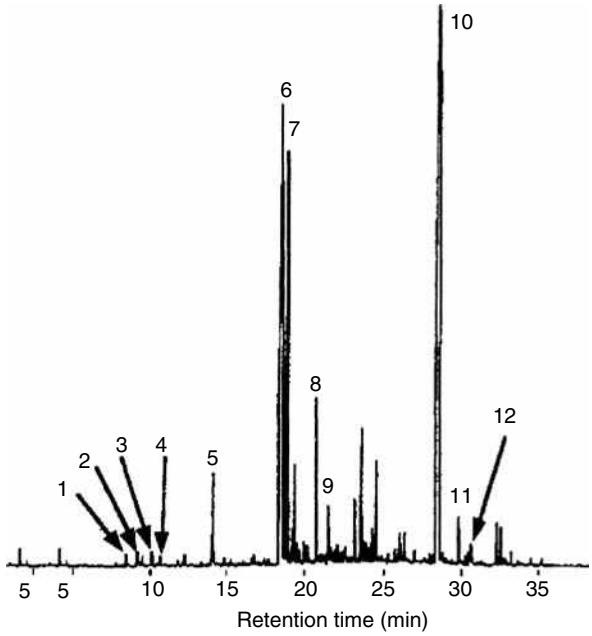

Fig. 2 A chromatogram of tobacco headspace. 1: Benzaldehyde; 2: 6-methyl-5-heptene-2-one; 3: phenylacetaldehyde; 4: ninanal; 5: menthol; 6: nicotine; 7: solanone; 8: geranyl acetone; 9: β-nicotyrine; 10: neophytadiene; 11: famesylacetone; 12: cembrene.

sample onto the GC column. In most cases, the column is kept cool so the components concentrate on the front of the column. When desorption is complete (a few seconds), the column can then be appropriately temperature programed to separate the components of the sample. A chromatogram of the headspace sample, taken over tobacco, is shown in Fig. 2. The actual experimental details were as follows. One gram of tobacco (12% moisture) is placed in a 20 ml headspace vial and 3.0 ml of 3 *M* potassium chloride solution is added. The fiber is coated with polydimethyl siloxane (a highly dispersive adsorbent) as a 100 μm film. The vial is heated to 95°C and the fiber is left in contact with the headspace for 30 min. The sample is then desorbed from the fiber for 1 min at 259°C. The separation can be carried out on a column 30 cm long with a 250 μm inner diameter, carrying a 0.25 μm-thick film of 5% phenylmethylsiloxane. The stationary phase is predominantly dispersive, with a slight capability of polar interactions with strong polarizing solute groups by the polarized aromatic nuclei of the phenyl groups. Helium can be used as the carrier gas, at 30 cm/sec. The column is held isothermally at 40°C for 1 min, then programed to 250°C at 6°C/min and held at 250°C for 2 min. It is seen that a clean separation of the components of the tobacco headspace is obtained and the resolution is quite adequate to compare tobaccos from different sources, tobaccos with different histories, and tobaccos of different quality.

Headspace Sampling in GC

Clayton B'Hymer
National Institute for Occupational Safety and Health, Centers for Disease Control and Prevention, U.S. Department of Health and Human Services, Cincinnati, Ohio, U.S.A.

Abstract
Headspace sampling is an important technique for the analysis of volatile compounds from a sample matrix that cannot readily be sampled by means of direct injection into a gas chromatograph (GC). Non-volatile liquid and solid samples can contaminate the injector of a GC; thus, there is the need for the indirect sampling technique of headspace analysis for volatile components existing within the sample matrix. Headspace sampling is a mature technique, spanning several decades, but new variations of the technique plus the extensive variety of commercial equipment available allow for its extensive use in solving many analytical problems encountered today. The three main techniques of headspace sampling are static, dynamic, and solid-solid-phase microexraction (SPME); they are described and a discussion of their advantages and limitations is included. Applications of headspace sampling are extensive; specific examples included in this discussion are the analysis of volatile compounds from complex biological matrices for toxicological studies, the detection of volatile biomarkers from chemical exposure, and the analysis for volatile impurities remaining in pharmaceutical compounds and products.

INTRODUCTION

Headspace sampling is a type of analysis in which the volatile analytes are separated from a sample matrix prior to their introduction into a gas chromatograph (GC). The gaseous phase or "headspace" above the sample matrix within a sealed system is collected and then analyzed by the GC. Headspace sampling represents an indirect method to measure volatile components of the sample matrix; that is, the gaseous phase above a sample matrix is measured, not the sample matrix itself. In the general technique, an aliquot of gas (vapor) phase sampled is in equilibrium with the liquid or solid phase of the sample matrix. In equilibrium, the distribution of the analytes between the two phases is dependent upon their partition coefficients; thus, the quantity of the original analyte in the sample can be determined from the analytical results of the headspace aliquot. Dynamic (purge-and-trap, P&T) and static headspace are the two main classic types of headspace sampling techniques performed today. In the last decade, solid-phase microextraction (SPME) has also been developed to sample headspace volatile. An additional equilibrium is established between the gas phase above the sample matrix and the solid-phase of the SPME fiber. Applications of headspace sampling are extensive and include the analysis of volatile components in the food and flavor industry, pharmaceuticals, cosmetics, biomarkers of chemical exposure or ingestion, environmental testing, and volatile monomers from plastics. Headspace sampling and analysis represent a broad analytical field with continued growth in numerous applications.

HISTORICAL BACKGROUND

Since the inception of GC analysis, the need to analyze volatile components from a non-volatile sample matrix has often been encountered. When a non-volatile sample matrix is directly introduced into a GC, the sample remains within the injector, thus contaminating it. Headspace sampling was a logical development to avoid this sample matrix problem. Headspace sampling was initially applied to other analytical techniques before use with GC, and this chronological description has been reported elsewhere.[1] The first apparent reported combination of headspace sampling with GC analysis was by Bovijn, Pirotte, and Berger[2] in 1958; they used the technique to monitor trace concentrations of hydrogen in water present in a power plant high-pressure boiler. The terms "headspace," "headspace sampling," and "headspace analysis" have been attributed to the food packaging industry where the gas layer above the food in sealed containers was described as the headspace. This terminology was first used in the early 1960s by Stahl and his coworkers while at McCormick & Company, Incorporated (Baltimore, Maryland, U.S.A.). In Stahl's work, the oxygen content within the headspace gases of metal food cans was determined by headspace sampling GC, and Stahl's work has been described within the historical context of headspace sampling.[1] Headspace analysis gained wide use within the food industry with the development of more sensitive detectors for GC in the late 1950s. Initial headspace sampling was performed manually using syringes, but automated instrumentation was

quickly devised by major manufacturers for commercial sale. The needs of forensic analysis have been one of the main driving forces in accurate quantitative headspace sampling instrumentation; exacting quantitative results have been demanded by the court system for blood alcohol analysis. Blood alcohol analysis has been a common application for headspace sampling for several decades. Regulatory requirements by the Food and Drug Administration in the United States and by the European drug regulatory agencies have also generated demand within the pharmaceutical industry for accurate quantitative measurements of residual solvents and volatile components of drug products.[3,4]

THE TYPES OF HEADSPACE SAMPLING

As mentioned in "Introduction," there are basically three headspace sampling techniques. Dynamic or P&T headspace sampling and static headspace sampling are the two classical techniques. SPME is the third headspace sampling technique that will be discussed. These three methodologies have been described extensively in the literature[1,3–5] and their basic designs are diagramed in Fig. 1. The sample matrices can be gas, liquid, or solid. Most often, liquids or liquid/solid mixtures are used because of better sample homogeneity and the relatively quick establishment of equilibrium of the gas phase above the sample matrix. Solid samples may require additional time for a volatile component to diffuse out of the solid matrix; residual solvents may be entrapped within a solid crystal structure. (The use of a dissolution solvent to release the analytes within a solid is done frequently in headspace analysis.) Finally, derivatization/reaction headspace sampling is a variation of headspace sampling and will also be discussed.

Dynamic Headspace Sampling

In dynamic headspace analysis, a continuous flow of gas is swept over the surface of the sample matrix. The sample may be heated during this cycle. The volatile components of the sample are swept into a trap where these analytes are accumulated prior to GC analysis (Fig. 1a). The trap consists of a column containing a sorbent such as Tenex®, Chromosorb®, Porapak®, Amerlite®, XAD resins, or activated carbon. Tenex is most often used because of its superior thermal stability. A rapid thermal desorption cycle of the trap is initiated, and a carrier gas takes the desorbed analytes into a GC for analysis. Cold trapping can be used as an alternative to the sorbent trap in dynamic headspace sampling. After collection of the volatile components, the cold trap is then heated and the analytes are introduced into the GC by a carrier gas. Other terminology and variations of dynamic headspace sampling are thermal desorption sampling (TDS) or direct thermal extraction. The last two sampling methods can involve more extreme heating cycles of the sample matrix.

Dynamic headspace sampling has several advantages over static headspace analysis. Dynamic headspace analysis is particularly suitable for the determination of volatile analytes at very low concentrations from the sample matrix. Lower detection limits are obtained because the "total" amount of a volatile substance can be extracted, trapped, and analyzed at one time. The detection limits for dynamic headspace sampling have been noted as being substantially lower than those for static headspace sampling.[6] Also, dynamic headspace sampling has the advantage of avoiding an equilibrium between the gas phase and the sample matrix, as is required with static headspace and SPME techniques. In the specific case of solid samples being thermally decomposed, an advantage of dynamic headspace analysis is that the use of a dissolution solvent and thus its associated peak can be avoided in the chromatogram.[7] The most frequently cited disadvantage of

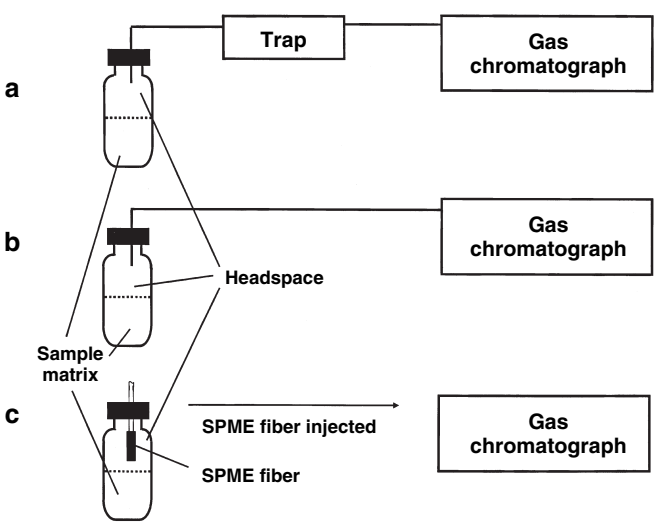

Fig. 1 Comparison of dynamic, static, and SPME headspace sampling. (a) Dynamic headspace sampling uses a sorbent or cold trap to concentrate volatile analytes before analysis by the GC. (b) Static headspace sampling uses direct transfer of a volume of gas from the headspace above the heated sample vial directly to the GC for analysis. Injection designs are illustrated in Fig. 2. (c) SPME headspace sampling uses a fiber support with solid-phase coating. The fiber is placed in the headspace and reaches equilibrium with the headspace volatile analytes. The SPME fiber is transferred by means of a syringe and thermally desorbed in the injector of the GC for analysis.

dynamic headspace sampling is the problem of artifact volatile collection in the trap. This is common for the P&T technique and can be minimized by complete desorption of the trap. This could include desorption cycles having higher temperatures or extending for longer periods to remove the artifacts. Numerous dynamic headspace sampling instruments are commercially available allowing for easy use of this technique.

Static Headspace Sampling

Static headspace analysis is probably the most widely practiced form of headspace analysis. In static headspace sampling, a liquid or solid sample is placed into a sealed vial. The vial is heated for a time until an equilibrium of the volatiles between the sample and the gas phase is reached. An aliquot of the headspace gas is sampled and injected into the GC for analysis. The basic physicochemical properties and gas laws are applied in this technique and need not be detailed in this entry. Higher temperatures will promote higher partial pressure and concentration of volatile compounds within the headspace of a given sample; polarity considerations of solutes vs. solvents will also come into play. In pharmaceutical testing, static headspace sampling is preferred when the liquid or solid samples are soluble (or extractable) in solvents such as water, benzyl alcohol, dimethyl formamide (DMF), or dimethyl sulfoxide (DMSO).[4,8] A liquid sample matrix offers a system in which the partitioning equilibrium is more readily established and reproducible. The repeated gas-extraction method first described by McAuliffe[9] can be used when the partition coefficients (the partition coefficient, *k*, equals the ratio of the concentration of the volatile analyte in the sample matrix divided by the concentration of the volatile in the gaseous headspace at equilibrium) and the equilibrium time are not well known. Kolb and Pospisil[10] popularized this technique, but referred to it as multiple-headspace extraction (MHE). In MHE, the headspace sample is extracted several times with a gas to obtain exponentially decreasing peak area responses. This allows for the calculation of the total residual solvent or volatile in the original sample, assuming that the thermodynamic equilibration was reached during the multiple extractions. Kolb and Pospisil[10] proposed MHE with solid or certain insoluble samples requiring external calibration. MHE as a headspace sampling technique has fallen out of current usage and is not very common today.

The main disadvantages of static headspace sampling over dynamic headspace sampling are in higher detection limits and lower sensitivity. Detection limits and sensitivity can be improved by pH control, salting-out or increasing the equilibrium temperature during sample heating.[11–15] Salting-out is done simply by adding an inorganic salt to an aqueous sample matrix. High salt concentrations in aqueous samples decrease the solubility of polar organic volatiles and thus promote their transfer into the headspace. Some common salts used for salting-out include ammonium chloride or sulfate, sodium chloride, citrate, or sulfate, magnesium sulfate, or potassium carbonate. The magnitude of the salting-out effect is not the same for all compounds. Generally, volatile polar compounds in aqueous matrices will experience the largest increase in partitioning into the gaseous headspace and have higher responses after the addition of a salt. Increasing the sample heating temperature will increase the analyte response until the boiling point temperature of the analytes is reached.[16] When water is chosen as the dissolution medium, non-polar analytes are enriched in the headspace and have higher GC responses, while polar analytes have lower GC responses. Dennis, Josephs, and Dokladalova[17] showed enrichment in the headspace up to a factor of 50 for trace non-polar solvents in water, while polar analyte responses in the headspace of polar sample matrices dropped by up to a factor of 4. Use of multiple internal standards may be necessary in static headspace sampling to match the solubility and partitioning of the analytes in the sample matrix. The purity of the dissolution solvent is another common problem encountered with static headspace sampling. A small impurity in the dissolution solvent might produce an interference peak in the chromatogram.

Instrumental design for static headspace samplers

Automated headspace systems have been offered by several manufacturers for many years, including Thermo Electron Corporation (San Jose, California, U.S.A.), PerkinElmer (Wellesley, Massachusetts, U.S.A.), Tekmar (Mason, Ohio, U.S.A.), and Agilent Technologies (Palo Alto, California, U.S.A.). There are essentially three injection techniques for static headspace sampling: gas-tight syringe, balanced-pressure, and pressure-loop injection (Fig. 2). All these techniques are used on commercial headspace systems and are described.

The gas-tight syringe injection technique can be done manually, although Thermo Electron-Finnigan offers some autosamplers that perform this technique. A syringe draws a sample of the headspace after equilibrium has been achieved above the sample; then the syringe is used to inject the headspace gases directly into a GC (Fig. 2A). Volatile sample loss can occur unless precautions are taken. The syringe must be heated correctly to ensure that no analytes condense inside the syringe; reproducibility problems can occur from sample loss using the syringe. Some sample loss may occur owing to the pressure changes between the heated headspace vial and the atmospheric conditions. Early static headspace analysis was performed manually using handheld gas-tight syringes, but reproducibility of injections and analyte condensation were significant problems until automated systems were available. The Finnigan TRACE model HS2000 headspace autosampler uses the gas-tight syringe design.

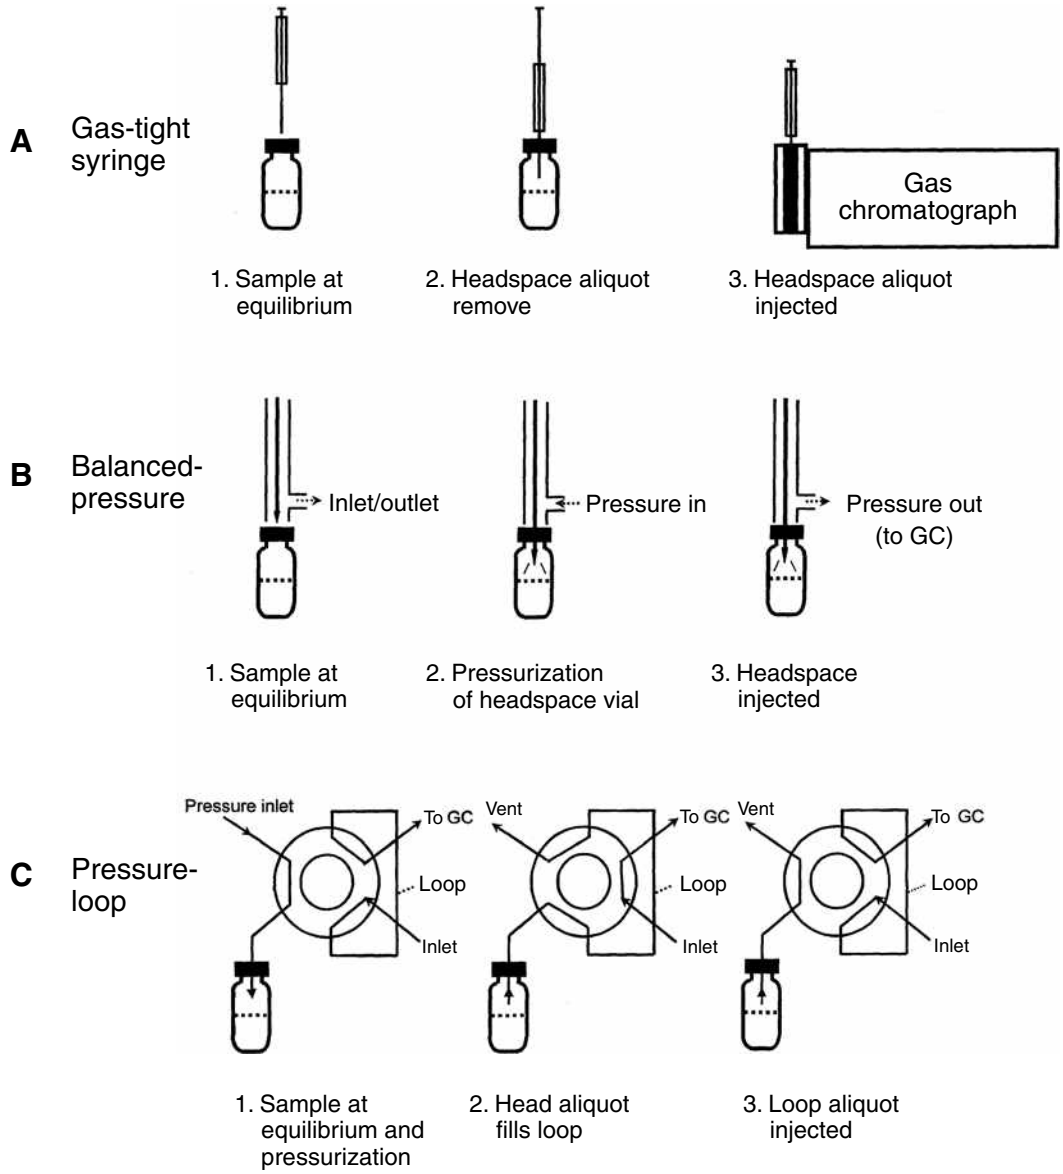

Fig. 2 The three designs of static headspace injection systems. (A) The gas-tight syringe system uses a syringe to collect and transfer a headspace aliquot to the GC. (B) The balanced-pressure system pressurizes the vial after thermal equilibrium, then releases the pressurized headspace into the GC. (C) The pressure-loop system pressurizes the headspace vial, fills a fixed-volume loop with a headspace aliquot, and then the loop contents are flushed into the GC.

The balanced-pressure injection entails the headspace vial being pressurized and allowed to reach an equilibrium; then a valve is switched to direct part of the sample into the transfer line and the GC for a specific time interval (Fig. 2B). The absolute volume of the sample injected into the GC is unknown because this technique uses a theoretical amount of time to inject the sample. A number of contact parts are minimized in this design which should in theory lessen the chance of analyte adsorption or condensation within the system. An example of an instrument utilizing the balanced-pressure technique is the Perkin-Elmer TurboMatrix model HS-40.

The pressure-loop system uses a known amount of sample, unlike the pressure-balance injection technique. After the sample vial has reached an equilibrium and has been pressurized, a fixed-volume loop is filled with an aliquot of the headspace gases. This sample loop is flushed with carrier gas and the volatile analytes are carried by means of the transfer line into the GC (Fig. 2C). Typically, this technique uses a six-port valve system much like those used on high-performance liquid chromatographic (HPLC) injection systems. Loop volumes are generally 1 ml or slightly larger. The loop is flushed between injections, but might cause ghost peaks because of sample carryover

from a previous analysis. Analyte condensation is minimized by heating the sample loop and transfer line, although adsorption problems are possible in the sample loop and various transfer lines. The pressure-loop system is noted for its good run-to-run reproducibility and precision of duplicate injections. The pressure-loop injection design is used by the Tekmar model 7000HT and by Agilent Technologies in their models G1888 and 7694E static headspace sampling systems.

SPME Headspace Sampling

In SPME headspace sampling, a small amount of extracting phase, a stationary phase (described as the solid phase), is coated on a support, most commonly a fused silica fiber. The extraction phase is placed in the headspace of a sealed vial containing the sample matrix and heated until a concentration equilibrium is reached. The analytes reach an equilibrium between the sample matrix, the headspace above the sample matrix, and the extraction solid phase of the SPME fiber (Fig. 1C). Once equilibrium is reached, continued exposure of the SPME fiber does not lead to any additional accumulation of the analytes. The fiber is usually attached to a sampling device, which is basically a syringe. The SPME fiber is attached to the plunger and is extended during sampling and withdrawn into the syringe before insertion into a GC. The fiber is extended into the inlet of a GC, and the volatile analytes are thermally desorbed from the extracting phase of the fiber and swept onto the GC column for analysis. The SPME sampling by direct contact or immersion with a liquid sample matrix has also been done to measure volatile components, but this technique is not true "headspace sampling" and will not be discussed here.

"Gas-tight" and "headspace injection" SPME are the two types of injection techniques used. In gas-tight SPME, only a small volume of headspace gas is removed from the sample vial for injection. In headspace injection SPME, a larger volume of headspace gas is removed from the sample vial along with the SPME fiber (see Fig. 3). Camarasu, Meqei-Szuts, and Varga[6] conducted extensive comparison tests of these techniques along with static headspace sampling of common solvents found in pharmaceutical products, which are listed in Table 1. Gas-tight SPME was found to be the most sensitive technique for acetonitrile, dichloromethane, and chloroform in the Camarasu study. This was attributed to the inherent selectivity of the SPME fiber (polydimethylsiloxane/divinylbenzene). Volatile residual solvents commonly found in pharmaceuticals were shown to have detection limits nearly two orders of magnitude lower when using gas-tight SPME over the detection limits determined for static headspace sampling GC.[6] The main limitation of SPME headspace sampling is in the capacity of the fiber itself. Overloading the SPME fiber is possible and the equilibrium time of both

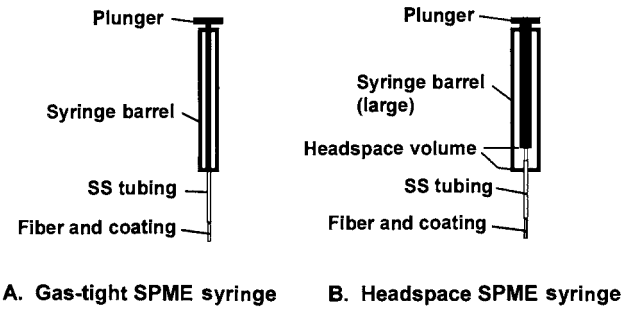

Fig. 3 Injection modes of solid-phase microextraction (SPME) using a manual syringe. (A) The gas-tight SPME samples a small volume of the sample headspace by using a small syringe. Most of the volatile analytes are collected on the coating of the SPME fiber. (B) Headspace SPME syringe collects a larger volume of the sample's headspace gases along with the volatile analytes collected on the SPME fiber. The headspace aliquot and the analytes adsorbed to the fiber are injected into the GC.

the headspace and the SPME fiber in the headspace must be experimentally determined.

Solid-phase microextraction headspace sampling has the advantage of concentrating the analytes, thus lowering detection limits of volatiles. In recent years, SPME headspace analysis has gained a solid reputation as a valid alternative to traditional headspace GC because of the simplicity of execution of the procedure and the low cost of the hardware.[18] Utilization of SPME headspace sampling is increasing with the availability of commercial devices. Supelco (Avondale, Pennsylvania, U.S.A.) has offered a manual syringe SPME system. Varian offers SPME capability in their Combi PAL autosampling system. Many autosampler designs can be adapted to SPME injection since it is analogous to the operation of a common hand held syringe. Another advantage of this technique is that SPME fibers can be cleaned easily and are ready for

Table 1 Detection limit comparison of headspace sampling methods (ng/ml).

Residual solvent	Headspace SPME (PDMS/DVB)	Gas-tight SPME (PDMS/DVB)	Static headspace
Acetonitrile	0.1	0.05	2
Benzene	0.01	0.01	0.1
Chloroform	0.01	0.007	7
1,2-Dichloroethylene	0.01	0.02	7
Dichloromethane	0.01	0.005	0.5
1,4-Dioxane	2	2	20
Trichloroethylene	0.01	0.01	7
Pyridine	0.05	0.7	30

reuse after thermal desorption which simplifies their adaptation to automation. SPME has been reviewed in the literature.[19,20]

Derivatization/Reaction Headspace

Chemical derivatization is a technique that can be used to increase the headspace sampling/chromatographic response of specific compounds which may lack volatility if not derivatized. Compounds with the capability of hydrogen bonding (i.e., alcohols, acids, amines) are difficult to volatilize and analyze by direct GC. Derivatization can be performed in the actual headspace sample vial to form the more volatile derivatized analyte which can, in turn, be sampled in the gaseous headspace. One common example is the use of methanol and boron trifluoride to derivatize fatty acids to the corresponding methyl esters. The major disadvantage of this approach is that the derivatization reagents and associated by-products from the derivatization reaction may be volatile and can partition into the headspace along with the desired derivatized compounds. This may cause difficulties with interfering peaks which might coelute with the compounds of interest. Pressures within the headspace/reaction vial may also cause problems by exceeding the pressure sealing abilities of the septum or the vial's structure.

EXAMPLE APPLICATIONS OF HEADSPACE SAMPLING IN GC

There are many areas in analytical chemistry which utilize headspace sampling and headspace analysis with GC. The role of food analysis in the historical development of headspace analysis has been briefly discussed in this entry. Headspace analysis is widely practiced in environmental analytical chemistry; it is often used in the analysis of volatile organic chemicals in water, waste water, and soil. Plastic materials testing for volatile monomers in finished plastic products has been performed using headspace analysis. Forensic chemists are using SPME headspace sampling for use in testing traces of residual accelerants from residue ash or post fire debris. SPME fibers are replacing the activated charcoal strips previously used in sampling headspace of collected fire debris. Dynamic, static, and SPME headspace analysis, as well as cryogenic focusing, have been used in arson analysis.[21,22] The three examples that will be briefly discussed for this entry will be clinical/toxicological analysis, industrial health and hygiene exposure analysis, and pharmaceutical analysis. Many more applications obviously exist and can be readily found in the literature.

Clinical/Toxicological Analysis

Clinical/toxicological analysis is another important area for headspace sampling including blood alcohol analysis, although forensic analysis of blood alcohol levels for court cases is one of the most common uses of headspace sampling. Clinical testing and testing of blood for volatile alcohol in support of toxicology studies are equally significant. Fig. 4 displays a chromatogram of typical blood alcohol analysis; in this particular example, rat blood was analyzed using manual syringe headspace sampling.[23] In addition to ethanol, longer chain alcohols were analyzed simultaneously using this procedure. Blood alcohol testing, in general, has been reviewed in the literature,[24] and headspace sampling offers an ideal technique for the analysis of volatile components. This is also true for many toxicological analyses where it is not possible to inject blood, tissue, or sample matrix directly into a GC. The Doizaki and Levitt[23] procedure cited above was also

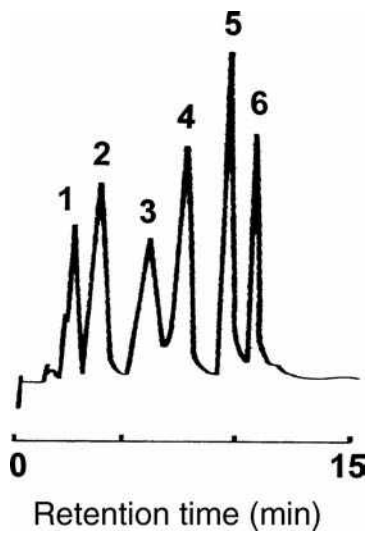

Fig. 4 Gas chromatogram of a standard alcohol mixture. The concentration of each alcohol is at 1000 nmol/ml aqueous solution. Peaks: 1) ethanol; 2) *n*-propanol; 3) 2-propen-1-ol (allyl alcohol); 4) *n*-butanol; 5) 3-methyl-1-butanol (isoamyl alcohol); 6) *n*-pentanol (*n*-amyl alcohol). Manual static headspace sampling was used with the following conditions: 0.2 ml aliquot of sample added to 9 ml serum bottle containing 200 mg of potassium carbonate and heated for 20 min at 70°C. A 0.2 ml headspace aliquot was injected. The Hewlett-Packard Model 5880 gas chromatograph was equipped with a cryogenic attachment (carbon dioxide cooling) and a 50 m × 0.2 mm (I.D.) Carbowax 20 *M* (HP) column. Initial column temperature was 20°C with a 6 min hold, then increased at a rate of 5–40°C/min, then increased at a rate of 10°C/min to a final temperature of 90°C and held for 5 min. A flame ionization detector (FID) was used.

applied in the determination of alcohols in human stool specimens.

Industrial Health and Hygiene Biomonitoring Exposure Analysis

Headspace sampling is being used to monitor the internal exposure of human subjects to chemicals in their work environment. Test methods have been devised to measure residual parent compounds or their metabolites (biomarkers for exposure) in human blood or urine samples taken from the exposed population. In one published work, a method to measure urinary 1- and 2-bromopropane was validated.[16] 1-Bromopropane is a commonly used industrial solvent, and 2-bromopropane is often found as an impurity component in industrial grade 1-bromopropane. 1-Bromopropane has numerous industrial applications including cleaning metal, optical instruments, and electronics, and as a component in spray adhesives. Both compounds are a health concern for exposed workers owing to their chronic toxicity. Because of the extensive use of 1-bromopropane in the industrial setting, workers can be exposed to 1-bromopropane in both vapor and liquid form, including by direct dermal contact. In the chromatogram displayed in Fig. 5, 1- and 2-bromopropane were analyzed using static headspace sampling of spiked urine samples.[16] Headspace sampling of adsorbent material used to monitor the workplace environment is also carried out. The other forms of headspace sampling are finding applications in the industrial health and hygiene monitoring field.

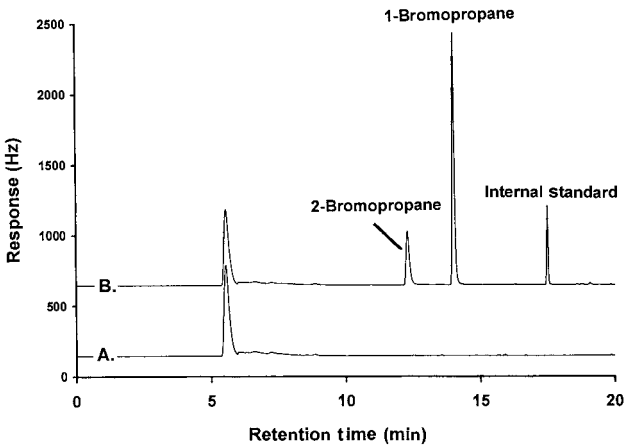

Fig. 5 Gas chromatograms of blank (a) and spiked (b) human urine samples containing 1-bromopropane, 2-bromopropane, and 1-bromobutane as the internal standard. Static headspace sampling was used with the following conditions: Tekmar model 7000 HT headspace sampler with a 1.0 ml sample loop and platen temperature of 75°C and a valve/loop temperature of 120°C. Sample equilibrium time was 34 min. The Agilent Technologies Model 6890 gas chromatograph was equipped with an Agilent J&W DB-1 (dimethylpolysiloxane) column with a 1 μm film thickness. Initial column temperature was 45°C with a 10 min hold, then increased at a rate of 12.5°C/min to a final temperature of 170°C. A microelectron capture detector (μ-ECD) was used.

Pharmaceutical Analysis

Pharmaceutical products are extensively tested for residual solvents, often using headspace analysis. Residual solvents in pharmaceuticals are generally volatile chemicals that are used in and are produced during the synthesis of drug substances or can exist in the excipients used in the production of drug formulations. These residual volatile chemicals can be remains from processing agents. Many of these volatile organic substances cannot be completely removed by standard manufacturing processes and are left behind, usually at low or trace levels. High levels of residual organic solvents can play a role in the physicochemical properties such as crystallinity of the bulk drug substance. Residual solvents also present a risk to human health because of their toxicity. Some odor problems have also been associated with finished drug products having high levels of residual volatiles. Therefore, the main purpose of pharmaceutical residual solvent testing is its use as a monitoring check for further drying of bulk drug substance or as a final check of a finished product. In Fig. 6, chromatograms from a headspace GC method to quantify the levels of various residual solvents in the bulk pharmaceutical product α-phenyl-1-(2-phenylethyl)-piperine methanol, a serotonin 5-HT2 receptor antagonist, are shown.[25] The solvents detected in this chromatogram are possibly present in bulk drugs since they were used in its synthetic route or used to recrystallize the final bulk product. Static headspace sampling was used for this specific chromatographic test method analysis, but dynamic headspace sampling has been applied to analytical problems within the pharmaceutical industry. SPME headspace sampling is a more recent development and has been applied to pharmaceutical residual solvent analysis.[6]

CONCLUSIONS AND FUTURE TRENDS

Headspace sampling in GC analysis is a highly useful technique and has been widely practiced in multiple analytical fields over the past four decades. The advantages of avoiding direct sampling of sample matrices that would contaminate the operation of a GC make headspace sampling a valuable technique. Coupling this sampling technique with today's greater availability of both more sensitive and more specific GC detectors including mass spectrometry will only lead to continued

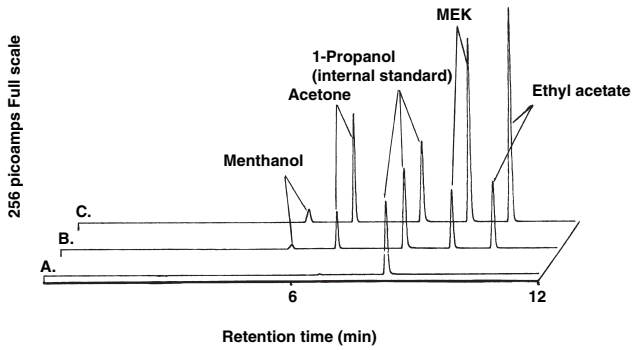

Fig. 6 Gas chromatograms of the drug substance α-phenyl-1-(2-phenylethyl)-piperine methanol, a serotonin 5-HT2 receptor antagonist, spiked with possible processing solvents. Three solvent levels are represented, a) 0% (w/w); b) 0.1% (w/w) spike; c) 0.3% (w/w) spike. Peaks: methanol; acetone; 1-propanol (internal standard); methyl ethyl ketone (MEK); ethyl acetate. The unspiked drug substance contained a low level of acetone of less than 0.01% (w/w). Static headspace sampling was used with the following conditions: Tekmar 7000 with 1.0 ml sample loop with a block temperature of 80°C and the loop temperature at 95°C. Sample equilibrium time was 40 min. The Hewlett-Packard Model 5890 gas chromatograph was equipped with a 60 × 0.32 mm (I.D.) Supelco SPB-1 (dimethylpolysiloxane) column with a 1 μm film thickness. The initial column temperature was 50°C with a 12 min hold, and then a post run at 100°C for 3 min. A flame ionization detector (FID) was used.

use and growth in the future. The use of SPME headspace sampling will certainly increase as commercial instrumentation becomes more available and the technique becomes more accepted in the different fields of analysis. Recent applications of headspace SPME have included the detection of volatile liver cancer biomarkers from blood samples[26] as well as the determination of volatile plant protection agents from soil samples.[27] Headspace SPME, along with the traditional forms of headspace sampling,[1,3–5,11] will undoubtedly continue to grow in use in the future. For a more detailed description of the general theory of headspace sampling GC analysis, see Hachenburg and Schmidt[11] as well as the various review articles in the literature.[3,4]

DISCLAIMERS

The findings and conclusions in this report are those of the authors and do not necessarily represent the views of the National Institute for Occupational Safety and Health (NIOSH). The mention of company names and/or products does not constitute endorsement by NIOSH.

Helium Detector

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

The outer group of electrons in the noble gases is complete, and as a consequence, collisions between noble gas atoms and electrons are perfectly elastic. It follows that if a high potential is set up between two electrodes in a noble gas and ionization is initiated by a suitable radioactive source, electrons will be accelerated toward the anode and will not be impeded by energy absorbed from collisions with the noble gas atoms. However, if the potential of the anode is high enough, the electrons will develop sufficient kinetic energy that, on collision with the noble gas atom, energy can be absorbed and a *metastable* atom can be produced. A metastable atom carries *no* charge, but adsorbs energy from collision with a high-energy electron by displacing an orbiting electron to an outer orbit.

DISCUSSION

Metastable helium atoms have an energy of 19.8 and 20.6 eV and thus can ionize and, consequently, detect all permanent gas molecules and, in fact, the molecules of all other volatile substances. A collision between a metastable atom and an organic molecule will result in the outer electron of the metastable atom collapsing back to its original orbit, followed by the expulsion of an electron from the organic molecule. The electrons produced by this process are collected at the anode and produce a large increase in anode current. However, when an ion is produced by collision between a metastable atom and an organic molecule, the electron, simultaneously produced, is also immediately accelerated toward the anode. This results in a further increase in metastable atoms and a consequent increase in the ionization of other organic molecules.

This cascade effect, unless controlled, results in an exponential increase in ion current. It is clear that the helium must be extremely pure or the production of metastable helium atoms would be quenched by traces of any other permanent gases that may be present.

Originally, a very complicated helium-purifying chain was necessary to ensure the helium detector's optimum operation. However, with high-purity helium becoming generally available, the helium detector is now a more practical system.

The metastable atoms that must be produced in the argon and helium detectors need not necessarily be generated from electrons induced by radioactive decay. Electrons can be generated by electric discharge or photometrically, which can then be accelerated in an inert gas atmosphere under an appropriate electrical potential to produce metastable atoms. This procedure is the basis of a highly sensitive helium detector that is depicted on the left-hand side of Fig. 1. The detector does not depend solely on metastable helium atoms for ionization and, for this reason, is called the helium discharge ionization detector (HDID).

The sensor consists of two cavities, one carrying a pair of electrodes across which a potential of about 550 V is applied. In the presence of helium, this potential initiates a gas discharge across the electrodes. The discharge gas passes into a second chamber that acts as the ionization chamber and any ions formed are collected by two plate electrodes having a potential difference of about 160 V. The column eluent enters the top of the ionization chamber and mixes with the helium from the discharge chamber and exits at the base of the ionization chamber.

In this particular detector, ionization probably occurs as a result of a number of processes. The electric discharge produces both electrons and photons. The electrons can be accelerated to produce metastable helium atoms which, in turn, can ionize the components in the column eluent. However, the photons generated in the discharge have, themselves, sufficient energy to ionize many eluent components and so ions will probably be produced by both mechanisms. It is possible that other ionization processes may also be involved, but the two mentioned are likely to account for the majority of the ions produced. The response of the detector is largely controlled by the collecting voltage and is very sensitive to traces of inert gases in the carrier gas. Peak reversal is often experienced at high collecting voltages, which may also indicate that some form of electron capturing may take place between the collecting electrodes. This peak reversal appears to be significantly reduced by the introduction of traces of neon in the helium carrier gas.

The helium discharge ionization detector has a high sensitivity toward the permanent gases and has been used very successfully for the analysis of trace components in ultrapure gases. It would appear that the detector response is linear over at least two, and possibly three, orders of magnitude, with a response index probably lying between

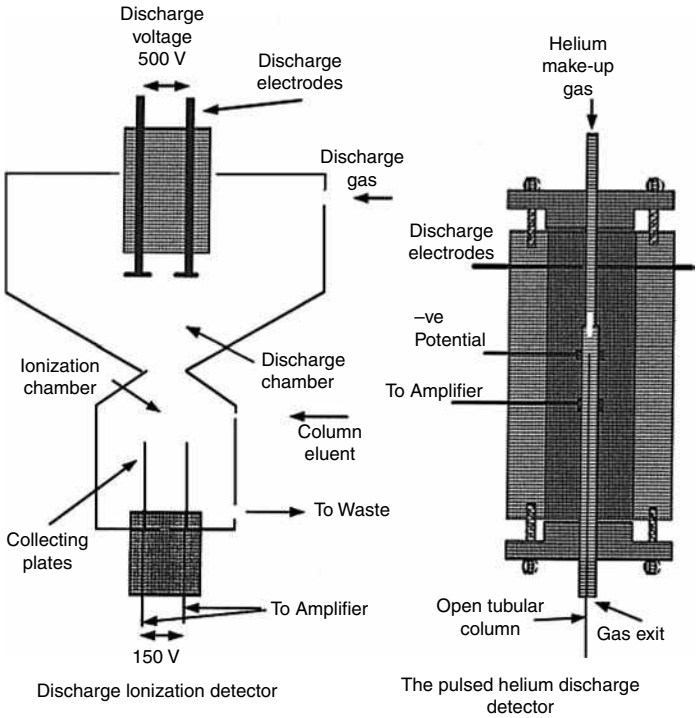

Fig. 1 The discharge ionization detector (courtesy of GOW-MAC Instruments) and the pulsed helium discharge detector (courtesy of Valco Instruments).

0.97 and 1.03. In any event, any slight non-linearity of the sensor can be corrected by an appropriate signal-modifying amplifier. The potential sensitivity of the detector to organic vapors appears to be about 1×10^{-13} g/ml.

THE PULSED HELIUM DISCHARGE DETECTOR

The pulsed helium discharge detector[1,2] is an extension of the helium detector, a diagram of which is shown on the right-hand side of Fig. 1. The detector has two sections: the upper section consisting of a tube 1.6 mm I.D. (where the discharge takes place) and the lower section, 3 mm I.D. (where reaction with metastable helium atoms and photons takes place). Helium makeup gas enters the top of the sensor and passes into the discharge section. The potential (about 20 V) applied across the discharge electrodes and for optimum performance is pulsed at about 3 kHz with a discharge pulse width of about 45 μs. The discharge produces electrons and high-energy photons (that can also produce electrons), and probably some metastable helium atoms. The photons and metastable helium atoms enter the reaction zone where they meet the eluent from the capillary column. The solute molecules are ionized and the electrons produced are collected at the lower electrode and measured by an appropriate high-impedance amplifier. The distance between the collecting electrodes is about 1.5 mm. The helium must be 99.9995 pure, otherwise permanent gas impurities quench the production of metastable atoms. The base current ranges from 1×10^{-9} to 5×10^{-9}A, the noise level is about 1.2×10^{-13}A, and the ionization efficiency is about 0.07%. It is claimed to be about 10 times more sensitive than the flame ionization detector and to have a linear dynamic range of 10^5. The pulsed helium discharge detector appears to be an attractive alternative to the flame ionization detector and would eliminate the need for three different gas supplies. It does, however, require equipment to provide specially purified helium, which diminishes the advantage of using a single gas.

Heterocyclic Bases: LC Analysis

Monika Waksmundzka-Hajnos
Department of Inorganic Chemistry, Medical University of Lublin, Lublin, Poland

INTRODUCTION

There are no absolute rules that formulate the influence of functional groups on pharmaceutical activities of compounds. However, it has been pointed out that an amine group or heterocyclic nitrogen atom possessing an aromatic ring causes an increase in a compound's biological activity. This is probably caused by the possibility of drug–receptor bonding, where electrostatic driving forces between ions present in the drug and receptor play the fundamental role. The presence of basic electron donor centers (amino group or heterocyclic nitrogen) makes possible their ionic interactions with acidic groups in proteins (–COOH), phospholipids, or nucleic acids (HPO_4^{2-}). Of course, other interactions, such as ion–dipole, dipole–dipole, induced dipole–dipole, H-bonds, and hydrophilic–hydrophobic specific interactions also play an important role in the fitting of drug molecules to the receptor. The chemical structures of drugs also play an important role in their solubility in body fluids and their transport through the lipid membranes of cells. Therefore, compounds possessing heterocyclic nitrogen are present in numerous drug groups. Examples of such drugs, their chemical structures, and pharmacological activities are presented in Table 1. Groups of alkaloids, which occur in plant organs with their pharmacological activities, are presented in Table 2.

STRUCTURE–CHROMATOGRAPHIC RETENTION RELATIONSHIPS

The relationship between the chemical structures of compounds and their chromatographic behavior has been considered by many scientists and was first reported by Martin in partition chromatography, where the partition coefficient is regarded as an additive value.[1] The hypothesis of the R_M additivity has raised worldwide discussion; hence, additivity rules were formulated. Deviation from the R_M additivity results from the complex character of the chromatographic process (change of a composition and volume proportions of phases), constitutional effects in molecules, because of reciprocal interactions of functional groups (internal hydrogen-bond effects, steric and electromeric effects) as well as ionization of substances.

Snyder[2] takes into consideration many factors influencing the value of adsorption energy of a molecule. Molecular planarity, steric hindrance, chemical interaction of adjacent functional groups (H-bonding), electronic interactions of some functional groups (induction and mesomeric effects), and simultaneous adsorption of two neighboring functional groups ("anchorage" effect of molecule on the adsorption sites especially on alumina surface) have been taken into account.

Retention in chromatographic systems can be connected with the properties of the chromatographed compounds. It should manifest itself in quantitative structure–retention relationships (QSRR) equations,[3] correlating retention parameters (log k) with the properties of analytes and chromatographic system revealed by molecular descriptors: dipolarity/polarizability, ability to donate H-bonds, measure of analyte H-bond accepting potency, analyte molecular volume, and others.

ADSORPTION CHROMATOGRAPHY

Silica Gel

The retention–mobile phase composition relationships for heterocyclic bases in systems involving silica/binary eluent can be expressed as the linear plots of log $k(R_M)$ vs. log X (X is the molar fraction of polar modifier in the eluent).[4] It proves a simple displacement model of retention of these substances in normal-phase systems. Slopes of log k vs. log X plots provide information about interactions of chromatographed substances with the adsorbent surface. Unit slopes, meaning single-point adsorption, are usually obtained for monofunctional heterocyclic bases (pyridine, quinoline, acridine without any functional groups). When unit slopes are obtained for bifunctional solutes, the complete delocalization of the weaker functional group takes place. It occurs for the apolar functional groups—for example, an alkyl chain. Sufficient adsorption energies of the two groups and suitable distance between the groups are two sufficient conditions of two-point adsorption for bifunctional heterocyclic bases (or other solutes). The experimental data indicate that for bases with two strongly polar functional groups, e.g., 4-aminopyridine, 5-hydroxyquinoline, 5-aminoquinoline, two-point adsorption on silica occurs.[4] When the functional groups in the solute molecule differ significantly in their adsorption energies, the localization of the stronger group and the resulting delocalization of the weaker group may cause a decrease of

Table 1 Structure and pharmacological activity of some heterocyclic base derivatives.

Drugs	Structure	Pharmacological activity
Benzodiazepine derivatives		Sedative, antiepileptic, hypnotic, anesthetic
1,4-Dihydropyridine derivatives		Ca-channel blocker, hypotensic
4-Aminoquinoline derivatives		Antiinflammatory, antimalarial
8-Hydroxyquinoline derivatives		Antiseptic
Acridine derivatives		Antiseptic
Barbiturates		Hypnotic, sedative, anesthetic
Thiobarbiturates		Anesthetic
Hydantoin derivatives		Antiepileptic
Quinoline derivatives		Anesthetic
Phenothiazine derivatives		Sedative, spasmolytic, antihistaminic

Piperidine derivatives		Neuroleptic, antidepressive, antihistaminic, psychotropic

Table 2 Alkaloids and their pharmacological activities.

Alkaloid type	Group of alkaloids	Main active alkaloids	Biological activity
Pyridine, piperidine	Nicotine and anabazine	Nicotine, anabazine, nornicotine	Synapotolytic, toxic
	Cortex granati	Isopelletierine and derivatives	Toxic, anthelmintic
	Lobeline group	Lobeline, isolobeline, sedamine	Synapsotropic, analeptic, secretolytic
	Arecoline	Arecoline	Anthelmintic, purgative
	Conium	Coniine, coniidine	Toxic, poisonous
	Lycopodium	Lycopodine and derivatives	Toxic, poisonous
	Quinolizidine	Lupanine, sparteine, cytisine, lobeline	Toxic, antiarrythmic
Tropane	Tropine	Tropine, hyoscyamine, atropine, scopolamine	Paraspasmolytic
	Ecgonine	Ecgonine, cocaine	Anesthetic
Isoquinoline	Benzylisoquinoline	Papaverine	Spasmolytic
	Aporphine	Glaucine, magnoflorine, boldine	Spasmolytic, hypotensic, choleretic
	Protoberberine	Berberine, narcotine, palmatine	Antibacterial, choleretic, analgetic, antiarrythmic
	Benzophenanthridine	Chelidonine, sanguinarine, chelerythrine	Choleretic, anesthetic, spasmolytic
	Protopine	Protopine, cryptopine	Antiarrythmic
	Morphinan	Morphine, codeine, thebaine	Narcotic, analgetic, spasmolytic
	Emetine	Emetine, cephaline	Antimicrobial (protozoa)
Indole	Indole alkaloids, *Catharanthus roseus*	Vincristine, vinblastine, vindesine	Anticancer, cytostatic
	β-carboline	Harman, harmine	Hallucinogenic, antiparkinsonian
	Yohimbine	Yohimbine, serpentine	Spasmolytic, hypotensic
	Reserpine	Reserpine, rescinnamine	Psychotropic, anxiolytic, antiarrythmic
	Eburamine	Vincamine	Hypotensic
	Strychnos	Strychnine, brucine	Analeptic, toxic, convulsant
	Ibogaine	Ajmaline, ibogaine	Antiarrythmic, psychotropic
	Secale cornutum	Ergotamine, ergocriptine, ergozine	α-Adrenolytic, spasmolytic, hypotensic
Purine		Caffeine, theophylline, theobromine	Analeptic, diuretic, spasmolytic
Steroidal	*Fritillaria* isosteroidal	Cevanine, jervine veratramine	Antitussive, tracheal, and bronchial relaxative
	Veratrum album	Protoveratrine A and B, veratramine, germine, veratrine, protoverine	Hypotensic, insecticidal
	Solanum	Solanine, tomatine, tomatidine, solanidine	Toxic, antifungal
Quinoline	*Cinchona*	Cinchonine, quinidine, quinine, cinchonidine	Antipyretic, antimalarial, antiarrythmic
Pyrrolizidine		Retronecine, heliotridine	Hepatotoxic, cancerogenic, cytotoxic

the slope, for example, for quinoline derivatives with a methoxy group in the meta or para position.

The slope of R_M vs. log c plots depends also on solvent strength. For the polar component of an eluent with low solvent strength (diethyl ether, methyl ethyl ketone), the slopes of methoxy and acetyl derivatives are greater than for stronger ones. The use of diethylamine as the eluent modifier leads to single-point adsorption of almost all heterocyclic bases investigated because the weaker group is unable to compete with the solvent for surface hydroxyl groups. Only basic groups such as $-NH_2$ in 4-aminopyridine, 3-aminopyridine, and 5-aminoquinoline can compete with diethylamine for surface hydroxyls, and the slopes for these solutes are approximately equal to 2.0.

Ortho substituted heterocyclic bases behave, on a silica surface, like monofunctional solutes and, in most cases, have slopes near unity [for example 2-acetylpyridine, 1-(pyridyl-2′)-ethan-1-ol], whereas the slope values for analogous para isomers are much higher. Also, 8-substituted derivatives of quinoline behave like ortho isomers (see 8-hydroxyquinoline). This is caused by the ortho effect—H-bond interactions of two neighboring polar groups (internally H-bonded groups), which cause their weaker adsorption and single-point interactions with surface silanols [compare slopes of 5-hydroxyquinoline and 8-hydroxyquinoline, 2-acetylpyridine and 4-acetylpyridine, 1-(pyridyl-2′)-ethan-1-ol and 1-(pyridyl-4′)-ethan-1-ol].[4]

Polar modifier influences separation selectivity of nitrogen bases on silica only to a small degree. Matyska and Soczewiński[5] compared separation selectivity of quinoline bases in equieluotropic eluent systems consisting of *n*-heptane and various modifiers (ethyl methyl ketone, ethyl acetate, diethyl ether, diisopropyl ether) and with chloroform and the same modifiers. They concluded that retention and separation selectivity of investigated nitrogen bases is, in most cases, similar. However, selectivity of separation of quinoline bases with two polar groups (hydroxy, amino derivatives) strongly depends on the modifier used as the eluent component.

Petrowitz compared adsorptive properties of alkyl- and halogen-derivatives of different solutes, and also heterocyclic bases. For example, methyl derivatives of pyridine behave in a different way on silica, depending on the group position. Thus, α- and γ-methylpyridine are strongly retained on silica because of hyperconjugation and formation of a double bond with increase of basicity of heterocyclic nitrogen, which does not occur in the β-isomer. It is also mentioned that in homologous series of pyridine alkyl-derivatives, a decrease of adsorption ability with the increase of the alkyl chain length is observed. When a pyridine or quinoline molecule has two functional groups (e.g., amino group in 2-position and methyl group in various positions), the adsorption affinity depends on steric hindrance of heterocyclic nitrogen by the neighboring methyl group. When retention behavior of quinolines with polar—hydroxy or amino group in the 8-position is observed, the methyl group in the 2-position significantly reduces the adsorption ability of molecules.

Retention behavior of halogenopyridines depends on the molecular mass of the halogen. The reduction of adsorption ability with an increase of halogen molecular mass is observed. The position of the halogen atom also has great meaning—a halogen neighboring the polar group or heterocyclic atom influences more adsorption ability and causes its decrease.

Alumina

Previous systematic investigations of organic compounds' adsorption from various chemical groups indicated analogies in the adsorption ability of silica and alumina.[6] However, alumina has heterogeneous surface active sites—electron donor oxygen atoms and electron acceptor aluminum ions. Numerous publications[7] have drawn attention to certain regularities in the adsorption onto alumina of the substituted pyridines and related aza aromatics. The contribution of the nitrogen atom in these adsorbates to total adsorption energy is markedly sensitive to the steric environment about the nitrogen atom. Klemm, Klopfstein, and Kelly stated[8] that the interaction between nitrogen and adsorbent is the result of charge-transfer complex formation. The presence of strong electron donor, as well as electron acceptor centers, favors especially considerable adsorption of molecules having, in adjacent positions, functional groups able to simultaneously interact with the surface aluminum ions produced by the formation of the chelate complex.[8] The same substances interact weakly with the silica surface. Retention behavior of hydroxyquinoline derivatives is quite different on alumina compared to silica.[1] 8-Hydroxyquinoline is strongly retained on the alumina surface due to anchorage of adjacent polar groups by the formation of a chelate with Al^{3+} ions, whereas, on a silica surface, it is weakly adsorbed. Rupture of an internal H-bond by methylation of the OH group leads to the increase of adsorption of methoxy derivative on silica, unlike alumina, on which 8-hydroxyquinoline is more strongly retained due to the anchorage effect than 8-methoxyquinoline (Table 3).[1] From the slopes of R_M

Table 3 R_F values of hydroxy and methoxy derivatives of quinoline on alumina and silica.

	R_F values in chromatographic systems			
	10% MeOH + B		40% AcOEt + Cx

Abbreviations: MeOH—methanol, B—benzene, AcOEt—ethyl acetate, Cx—cyclohexane.

vs. log X plots obtained for alumina in binary eluents, it is visible that in the case of the covering of a heterocyclic nitrogen by a methyl group or by a condensed ring, flat adsorption of the molecule is possible.

Magnesium Silicate—Florisil

Linear dependencies of R_M vs. log c of heterocyclic bases on Florisil layers indicate the displacement model of retention. It has been confirmed[1] that quinolines (methyl or benzo derivatives) are more strongly adsorbed onto Florisil than onto silica in non-aqueous *n*-heptane and polar modifier eluent systems. In spite of this, separation selectivity is better when Florisil is used (methylquinolines can be separated from dimethylquinolines and from quinoline). The influence of the neighboring methyl group in 8-methylquinoline on the decrease of adsorption affinity on Florisil is observed, as in the case of silica. The heterocyclic bases with a second electron acceptor group (6-nitroquinoline, 2-chloro-3-nitropyridine, 2-chloro-5-nitropyridine) are adsorbed more strongly onto Florisil active centers (OH groups and Mg^{2+} ions) than onto silica.[9]

Table 4 shows ΔR_M values for substituted quinolines in isoeluotropic eluent systems on different adsorbents.[10] The isoeluotropic series obtained for quinoline on various adsorbents is developed with solvents from different selectivity groups (Table 4). It is clearly seen that the highest ΔR_M values were obtained for quinoline bases on Florisil with dichloromethane, 2-propanol, and other modifiers, which proves highest selectivity of separation in this system.

Polar-Bonded Stationary Phases

Polar-bonded stationary phases, such as cyanopropyl, diol, or aminopropyl, bonded to a silica matrix, have moderate polarity and can be used in normal- and reversed-phase (RP) systems. The retention behavior of heterocyclic bases was also examined using these adsorbents by determination of R_M (log k) values of solutes by the use of eluents with various modifier concentrations.[1] It was statistically found that the Snyder–Soczewiński equation and Scott theory describe the retention of quinolines on polar-bonded stationary phases in normal-phase systems sufficiently well. It seems that results are consistent with a displacement model. The dispersive interactions between solute molecules and the polar component of an eluent seem also to have an important role.[1] Similarly, the retention–

eluent composition relationships for quinolines on such layers in RP systems using aqueous eluents can be represented by a semilogarithmic equation.[1]

The selectivity of separation of quinoline bases using normal-phase systems and polar-bonded stationary phases was compared by log k_1 – log k_2 correlations.[11] The values of regression coefficients for all correlation lines are relatively low. This results from different selectivities and mechanism of separation of the heterocyclic bases in the investigated systems. Fig. 1 is a graphical comparison of quinoline separation selectivity by the use of various systems as log k spectrum. It is seen that all polar-bonded stationary phases can be used for the separation of quinoline derivatives, especially with 2-propanol or tetrahydrofuran as eluent modifiers.

Application of Polar Adsorbents in Separation of Heterocyclic Bases

Polar adsorbents, especially silica, are widely used for the separation of alkaloids and basic drugs, such as barbiturates, benzodiazepines, and other pyridine and quinoline derivatives. Because of strong interactions of basic nitrogen with surface silanols, solvents with high eluent strength are used as mobile phases. In a review[12] describing thin-layer chromatography (TLC) analysis of benzodiazepines, there are more than 40 papers cited where the use of silica layers is reported. Mixtures of highly polar solvents—alcohols (MeOH, EtOH), chloroform, and mostly ammonium aqueous solutions or ethylenediamine as ionization suppressing agents are used as eluents. Moreover, basic components of an eluent can block the surface acidic silanols of silica. In a few cases, the use of a polyamide with various eluents and alkyl-bonded phases with aqueous eluents is reported. The use of similar chromatographic systems, e.g., silica/chloroform + alcohol (MeOH, EtOH, BuOH), is reported for analytical TLC of polyhydroxy–chromone and flavonoid alkaloids.[13] Cellulose, with multicomponent aqueous eluent, has also been used. There were no reports of high-performance liquid chromatography (HPLC) of flavonoid alkaloids until 2002. For the separation of polar chromone alkaloids, the use of silica with aqueous eluents containing ammonia is also reported.[13] Normal-phase systems can also be used for the isolation of chromone and flavonoid alkaloids using silica columns or preparative silica layers, mostly with gradient elution with chloroform + methanol. Because of the detection difficulty of polyhydroxy alkaloids (pyrrolidine, piperidine, pyrrolizidine, indolizidine, and nortropane classes) resulting from their lack of suitable chromophores for spectroscopic detection, analytical TLC is used for purity determination and detection in plant extracts and in pharmacokinetic studies.[14] Preparative planar chromatography has also been a separation method of choice for isolation of individual polyhydroxy alkaloids from mixtures. Silica gel, with combinations of chloroform, methanol, and aqueous ammonium, has been widely used for TLC in analytical, as well as on preparative, scale. *Cinchona*–quinoline alkaloids, mostly analyzed in RP systems, are also separated by normal-phase chromatography, mainly using bare silica columns or layers with mobile phases containing solvents such as chloroform, acetone, or ethyl acetate with alcohols as polarity adjusters and ammonia or diethylamine as ionization suppressors and silanol blockers.[15] Fig. 2 presents an example of the separation of isoquinoline alkaloids by use of two-dimensional TLC (2D-TLC) on a silica plate.[16]

RETENTION OF IONIZABLE WEAK BASES IN RPLC

HPLC separation of ionic samples is more complicated[17] than separation of non-ionic compounds. For regular ionic samples, three HPLC methods: reversed-phase, ion-pair, or ion-exchange chromatography (IEC) can be chosen. Because of its simplicity, reversed-phase chromatography (RPC) is usually the best starting point. If RPC separation proves inadequate, the addition of an ion-pairing reagent to the mobile phase or application of IEC can be considered.

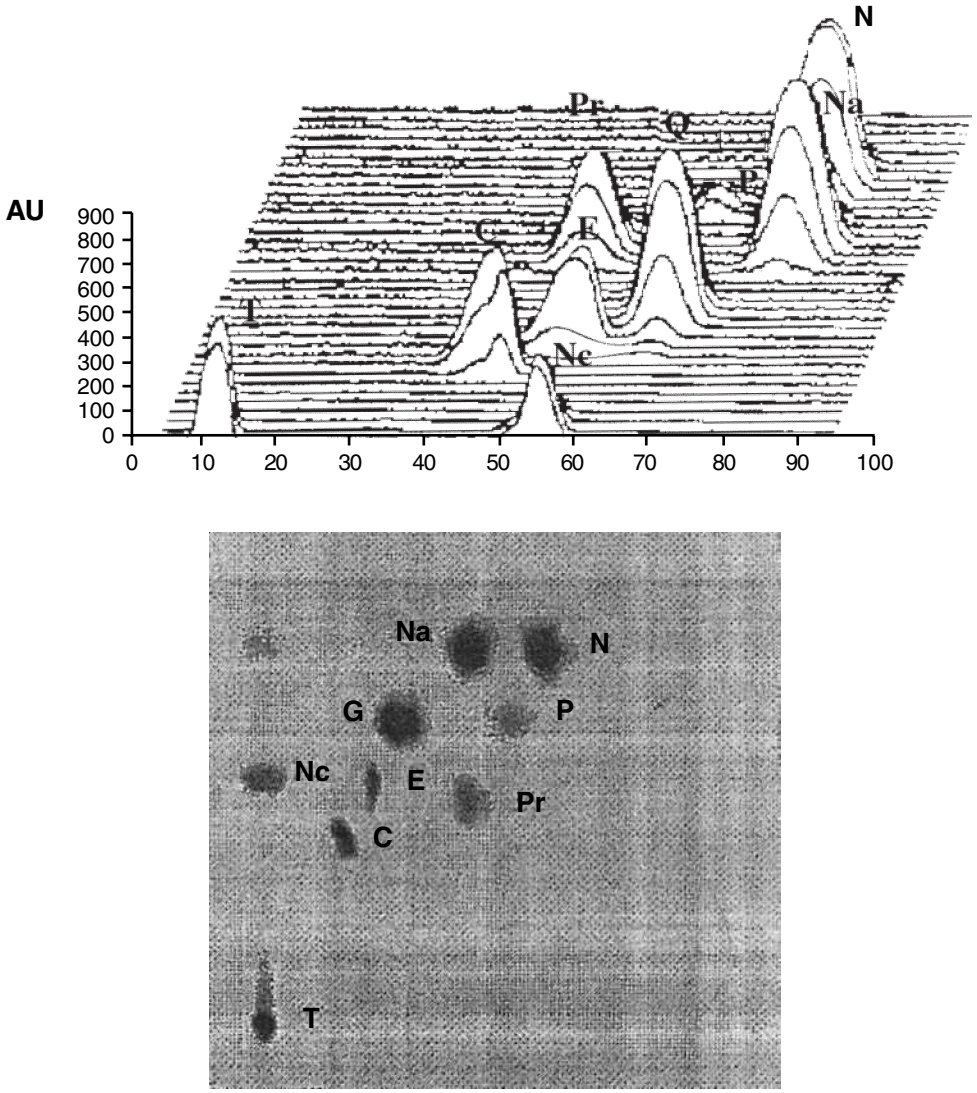

Fig. 2 Densitogram and videoscan from 2D-TLC of isoquinoline alkaloids separated on silica layer by use of aqueous methanol (8%) with 1% ammonia as the first direction eluent and multicomponent non-aqueous eluent with 0.1 *M* DEA as the second direction eluent. Planar Chromatogr.[16]

Separation Selectivity as a Function of pH and Mobile-Phase Composition

From the theory[18] for RP retention of ionic (e.g., basic) compounds as a function of pH, it can be assumed that a given solute (e.g., a heterocyclic base) exists in ionized (+) and non-ionized forms and its capacity factor k is given by:

$$k = k^0(1 - F^+) + k_1F^+ \quad (1)$$

where k_0 and k_1 refer to k values for non-ionized and ionic forms and F^+ is the fraction of ionized solute molecules for the case of a basic solute:

$$F^+ = 1/\{1 + (K_a/[H^+])\} \quad (2)$$

The dependencies of log k (R_M) as a function of pH for selected alkaloids are given in Fig. 3.[19]

The potential errors in the use of Eqs. 1 and 2 result from the following facts:[18] retention of solutes, especially protonated bases, by processes other than solvophobic interactions, e.g., with exposed silanols or metal contaminants;[20] change in K_a values as a function of ionic strength; solvophobic effect of ionic strength on solute retention; ion-pair interaction of sample ions with ionized buffer species; change in the sorption properties of the stationary phase (C_8 or C_{18}) as a result of changing ionization of silanols; a

change in buffer type, when more than one buffer type is needed to cover a given pH range.

It is maintained[18] that computer simulations based upon the theoretical model (Eqs. 1 and 2) are able to predict, accurately, retention and resolution of basic solutes as a function of pH. Predicted retention times and α values were significantly more difficult for the case of basic, rather than acidic, solutes, due to silanol effects (more significant for basic solutes).

As retention factors (k) can decrease by a factor of 10 or more for an ionized vs. a non-ionized compound, it is often necessary to combine pH optimization with variation of solvent strength (%B, φ) in order to maintain a reasonable k range for the effective separation ($1 < k < 20$).[18]

$$k = \mathrm{f}([\mathrm{H}^+], \varphi) \tag{3}$$

Because the capacity factor of a weak base is the average of capacity factors of individual forms BH^+ and B:

$$k = k_0\left(\frac{[\mathrm{BH}^+]}{[\mathrm{BH}^+] + [\mathrm{B}]}\right) + k_1\left(\frac{[\mathrm{B}]}{[\mathrm{BH}^+] + [\mathrm{B}]}\right) \tag{4}$$

it can be transformed to the equation:

$$k = \frac{k_0 + k_1[\mathrm{H}^+]/K_\mathrm{a}}{1 + [\mathrm{H}^+]/K_\mathrm{a}} \tag{5}$$

However, the problem is more complex because the acidity constant K_a as well as the retention factor of the protonated form k_0 and ionized form k_1 vary with the concentration of modifier in the aqueous mobile phase (φ), although the general form of Eq. 5 is maintained. This problem of the retention factor as the combined function of pH and modifier concentration in aqueous mobile phase has been analyzed by several researchers.[1]

Marques and Schoenmakers[21] took two approaches for weak acids; nevertheless, ionized base can be counted as cationic acid BH^+:

1. At constant pH, they describe k_0 and k_1 as a function of concentration of organic modifier in the mobile phase—φ, taking, from previous papers, the dependence of acidity constant as a function of φ:[22]

$$k = \delta + \frac{k_0(\varphi) + k_1(\varphi)[\mathrm{H}^+]/K_\mathrm{a}(\varphi)}{1 + [\mathrm{H}^+]/K_\mathrm{a}(\varphi)} \tag{6}$$

2. The second approach starts with:

$$\ln k = A + B\varphi + C\varphi^2 \tag{7}$$

where A is ln k for 0% modifier (methanol), which should be sigmoidal function of $[H^+]$, so that

$$A = \ln\left[\frac{k_0{}^\mathrm{w} + k_1{}^\mathrm{w}[\mathrm{H}^+]/K_\mathrm{a}{}^\mathrm{w}}{1 + [\mathrm{H}^+]/K_\mathrm{a}{}^\mathrm{w}}\right] \tag{8}$$

where $k_0{}^w$ is the capacity factor of B, $k_1{}^w$ is the capacity factor of BH^+, and $K_a{}^w$ is the acidity constant, all in pure water.

The first approach (Eq. 5) is realized assuming k_0, k_1, and K_a as different functions of mobile-phase composition: linear, quadratic, cubic (for K_a), and $\delta = 0$ or $\delta \neq 0$ (δ is the constant shift parameter). All the models (class 1 models) were verified experimentally. The model approaching ln k_0, ln k_1, and ln K_a as quadratic function of φ and $\delta = 0$

is, in the authors' opinion, the best compromise between precision and practicality.

The second approach is realized assuming k_0 as a sigmoidal function of $[H^+]$, the B parameter as quadratic, cubic, or sigmoidal function of $[H^+]$, and $C = 0$ or C as a linear function of $[H^+]$ and $\delta = 0$ or $\delta \neq 0$. All models were verified experimentally (class 2 models).

Models approaching k_0 as a sigmoidal function of $[H^+]$, B as cubic function of $[H^+]$, $C = 0$ and $\delta \neq 0$ or k_0 as sigmoidal function of $[H^+]$, B as quadratic, and C as a linear function of $[H^+]$ and $\delta \neq 0$ are adequate for practical purposes.

Retention as a Function of Ionic Strength of Eluent

The pH of the mobile phase is a major factor in the separation of ionizable compounds. As mentioned earlier, the most widely used model[18] considers the retention factor as an average of k_0 and k_1 according to the mole fraction of the neutral and ionic forms. The mole fraction depends on pK_a and pH of mobile phase. The pH of the mobile phase is taken to be the same as that of the aqueous fraction and this implies a false assumption. Even when pH is measured after mixing the buffer with the organic modifier, the potentiometric system, calibrated with aqueous standards, does not measure the true pH of the mobile phase.[23]

The second problem is that[21] pH should be taken from the activity of hydrogen ions, and the effect of activity coefficients γ can be neglected in water, but when the percentage of the organic modifier in the mobile phase increases, the activity coefficients decrease and cannot be neglected. Similarly, for the dissociation constant, the concentration should be changed by activities. From the Debye–Hückel definition, an activity coefficient depends on the ionic strength I of the solution.

The pH scale of any amphiprotic solvent is limited by zero and pK_{ap} values (K_{ap} is the autoprotolysis constant of medium); it differs in a mixed solvent, for example, methanol–water, where different proton-transfer equilibria occur. Ionizable solutes dissolved in these mixtures are differently solvated, show different dissociation constants, and the pH scale of the medium changes with mobile-phase composition.

Because the retention of ionic solutes depends on K_a, pH, and solvent strength, it depends on the activity coefficients of ions in the medium and, therefore, on its ionic strength.

Application of RP-HPLC Systems for Heterocyclic Base Analysis

Optimization in RP separation, and controlling the selectivity of basic samples, can be performed similarly as for non-ionic compounds by the variation of the solvent strength (%B) to obtain a satisfactory k range ($1 < k < 10$) or by change of the column type (C8, C18, phenyl, cyano). In applications of RP systems for the analysis of ionic compounds, the choice of suitable buffer is very important. Several properties such as buffer capacity, UV absorbance, and also solubility, stability, and interactions with the sample and chromatographic system, should be taken into account.

For RP separations when silica-based columns are used, the pH range of the mobile phase should be between 2 and 8. Therefore, for chromatographic analysis of heterocyclic bases, the following buffers may be used: phosphate buffer, (2.1–3.1, 6.2–8.2, and 11.3–13.3), acetate buffer (3.8–5.8), citrate buffer (2.1–6.4), carbonate buffer (3.8–5.8), formate buffer (2.8–4.8), and ammonia buffer (8.2–10.2) can be used.

Ionic samples, especially basic compounds, can interact with underivatized free silanols of silica-based alkyl-bonded columns. It appears that retention occurs by an ion-exchange process that involves protonated bases and ionized silanols. This case leads to increased retention, band tailing, and column-to-column irreproducibility. It is generally desirable to minimize these silanol interactions by an appropriate choice of experimental conditions. Silanol interactions can be reduced by selecting a column that is designed for basic samples with a reduced number of very acidic silanols that favor the retention process. The first method to reduce the silanol effect is the use of a low pH mobile phase ($2.0 < pH < 3.5$) to minimize the concentration of ionized silanols because, in this case, ionization of silanols is largely suppressed, giving rise to better peak shapes. The silanol effect can be further reduced by using a higher buffer concentration (> 10 mM) and the choice of buffer cations that are strongly held by the silanols ($Na^+ < K^+ < NH_4^+ <$ triethylammonium$^+ <$ dimethyloctylammonium$^+$) and, therefore, block sample retention by ionized silanols. Successful analysis of bases can be obtained even with classical RP-HPLC silicas by incorporation of amines into the mobile phases, which then compete with the analytes for column silanol sites. Working at high pH (e.g., $pH > 7.0$) for the separation of basic compounds is also recommended. Weak bases (e.g., pyridines) may be non-ionized at higher pH values and, thus, they may eliminate ionic interactions with acidic silanols. The problem, however, is with poor stability of silica-based columns, which are less stable for pHs over 6 and cannot be used at all for pH greater than 8. Only densely bonded alkyl end capped columns can be routinely used up to at least pH 11 when organic buffers and temperature under 40°C are used.

Reversed-phase HPLC is the method recommended for the screening of plant material, in which chromone alkaloids can be present.[13] Mostly C-18 columns were applied with aqueous mobile phases containing high concentrations of buffer at pH 4.5–6.5, modified with methanol or acetonitrile. Polyhydroxy alkaloids of the pyrrolidine, piperidine, pyrrolizidine, indolizidine, and tropane classes, because of their lack of a suitable chromophore, have rarely been analyzed

by conventional HPLC with UV detection. The detection problem could be surmounted by derivatization of the hydroxyl groups or by the use of other detection methods.[14] Amino columns, eluted with acetonitrile–water, or C-18 columns with buffered aqueous methanol with MS detection, were used for these purposes. Analysis of *Cinchona* alkaloids can also be performed by RP-HPLC, which is still the first choice for their separation.[15] Mostly, C-18 columns with aqueous mobile phases modified with methanol, acetonitrile, or tetrahydrofuran at acidic pH, have been used. The eluents with competitive amines to mask silanol effects were also used for the separations of *Cinchona* alkaloids.[17] Isosteroidal alkaloids, the main bioactive ingredient of *Fritillaria* species, do not display strong UV absorption and cannot be analyzed by conventional HPLC/UV. Systems with C18 columns and aqueous methanol containing amines were used when evaporative light-scattering detection was applied. Fig. 4 presents separation of isoquinoline alkaloid standards on a phenyl stationary phase with an eluent containing diethyl amine (DEA).[24]

A review describing methods of measurement of benzodiazepines in biological samples[1,25] also reports a number of examples of the use of HPLC with alkyl-bonded phases and aqueous eluents. Mainly, C-18 columns eluted with aqueous acetonitrile or methanol at low pH and UV detection, were used in benzodiazepine analyses.

RETENTION OF HETEROCYCLIC BASES IN RP ION-PAIR LC

Ion-pair and RP-HPLC share several features. The columns and mobile phases used for these separations are generally similar, differing mainly in the addition of an ion-pairing reagent to the mobile phase for ion-pair chromatography (IPC). If RPC method development is unable to provide an adequate separation due to poor band spacing, IPC provides an important additional selectivity option.[1]

Parameters Influencing the Retention and Selectivity in IP Systems

For the analysis of basic compounds, anionic ion-pairing reagents, such as sulfonic acids, alkyl sulfonates, and other acids such as *bis*-(2-ethylhexyl)-ortho-phosphoric acid (HDEHP), have been employed. When the concentration of the ion-pairing reagent gradually increases, then a distinct increase in retention of the analytes is observed, and in a limited range of concentrations, a linear relationship of log k and log of concentration of counterion is obtained[26,27] at the moment of approaching the saturation of surface concentration of hydrophobic counterions. Further increase of concentration does not lead to significant changes in retention even a decrease of retention is sometimes observed[1] (Fig. 5)[28]. The change of type and concentration of the counterion often causes variation in selectivity of separation.[29]

Additionally, the retention and selectivity in IP–RP systems can be controlled by the change of type and concentration of the organic modifier in the aqueous mobile phase[29] and the pH of the mobile phase,[1] which should be selected to obtain maximal ionization of solute molecules and ion-pairing reagent molecules for the possibility of forming an ion pair. For the basic solutes, analyses of the pH range 7.0–7.5 are often applied.

The stationary phase (the length of the alkyl chains bonded to the silica support) also influences the retention of hydrophobic ion pairs.

Similarly, as for RP-HPLC separations, selectivity can be additionally varied by solvent type (methanol, tetrahydrofuran, acetonitrile), buffer concentration, and temperature.[1]

RP–IP Systems in Analysis of Heterocyclic Bases

The comparison of separation of *Chelidonium majus* L. alkaloids on a cyanopropyl column, with a buffered aqueous mobile phase, without (a) and with IP reagent (b) is presented in Fig. 6.[30]

Some special problems for RP-IP-HPLC, such as positive and negative artifactual peaks appearing in a blank run, occur and can interfere in the development of the method and its routine use. Another problem in IP separations is slow column equilibration, which is slower when an ion-pair reagent is more hydrophobic. The slow equilibration of the column with many ion-pair reagents can create problems if a gradient elution is used under these conditions.

CHROMATOGRAPHY OF WEAK BASES USING ION-EXCHANGE SYSTEMS

Today, IEC is used infrequently in comparison with other chromatographic methods. In most cases, IPC is more convenient because of its higher column efficiency, more stable and reproducible columns, and easier control over selectivity and resolution. There are, however, cases for using IEC instead of RP- or IP-HPLC, especially when organic ions have poor UV absorbance and need other detection (conductivity or MS). Then, completely volatile components of mobile phase are required. In such cases, IEC with volatile buffers fulfil this requirement, whereas ion-pair reagents are not sufficiently volatile in most cases; also, when compounds are isolated or purified by HPLC separation, the removal of mobile phase is necessary. When multistep separation is required, the aqueous buffer–salt mobile phase used for ion-exchange allows direct injection of a sample fraction onto an RP column for the next step of separation. This may be difficult with IP systems.

For the separation of weak bases, cation-exchange columns are used, which have negatively charged groups (e.g., sulfonic or carboxylic) attached to the stationary phase. Two kinds of cation-exchange columns can be used: weak cation exchanger (WCX) or strong cation exchanger (SCX). The retention of basic compounds X^+ on such stationary phases (R^-) can be manifested by the equilibrium of an ion exchange:

$$X^+ + R^-K^+ \leftrightarrow X^+R^- + K^+ \quad (9)$$

where K^+ plays a role of counterion in mobile phase.

The increase of salt or buffer concentration in the mobile phase results in a decrease of the retention of sample compounds. Varying pH is usually a way to change the selectivity in IEC separations. Another way to change retention in IEC systems is the use of different counterions (displacers). Sometimes, the addition of organic modifiers, such as methanol or acetonitrile, is applied in IEC. This causes decreased retention of ionizable compounds.

There are several examples of the use of IEC systems for purification, isolation, and separation of heterocyclic bases. Based on ion-exchange SPE, a first and reliable procedure for the extraction of food tetrahydro-β-carboline, is accomplished on strong cation-exchange (SCX–benzenesulfonic acid cartridges) columns.[1] Water and/or alcoholic extracts of polyhydroxy alkaloids containing many other polar constituents are also purified by the use of resins.[14] The acidified aqueous solution is applied to the column and unretained neutral or acidic substances are eluted with water. The alkaloids, which

are bound to the resin, accompanied by any other non-alkaloidal basic compounds, are then displaced with dilute ammonium hydroxide. Thus, an extension of the ion-exchange purification process—column chromatography—can be used for isolation of alkaloids on a preparative scale.[14] Also, with HPLC analysis, cation-exchange columns can be used; especially when UV detection is impossible because of lack of suitable chromophores, amperometric detection for the analysis of polyhydroxy alkaloids is applied. In such cases, a cation-exchange column, Dionex CS3, eluted with hydrochloric acid, was used for the separation and detection.[14] In the case of MS detection, the use of a separation process with a cation-exchange column, with the elution using volatile eluents, is also preferred.[14] Ion chromatography using a Dionex cation-

exchange column, with the aqueous HCl as eluent, was applied to the analysis of theobromine and theophylline in foods and pharmaceutical preparations.[1]

CONCLUSIONS

It has been shown that there are many approaches to the separation of heterocyclic bases by chromatographic techniques. Normal-phase adsorption, reversed-phase, ion-pairing, and ion-exchange chromatographic methods have been reported extensively in the cited literature.

Highly Selective RP/HPLC: Polymer Grafting to Silica Surface

INTRODUCTION

Reversed-phase high-performance liquid chromatography (RP-HPLC) with, simply, octadecylated silica (ODS) and similar hydrophobized silicas, is the most popular method for analytical separation because of its wide applicability, with only slight modification of a mobile phase system. The separation mode is quite simple. It is usually understandable by the hydrophobic effect and partition coefficients of solutes, while highly-dense packing of organic phase on silica often brings selectivity increase based on a molecular slot effect.[1,2] However, if further specific selectivity is desired, even in RP-HPLC, its simple solution may be to immobilize a functional organic phase onto the silica surface, i.e., to develop new organic stationary phases. A typical example is seen in macrocyclic compound-immobilized silicas, such as those modified with porphyrin, cyclodextrin, and calixarene. In the case of porphyrin, its selectivity in HPLC is truly based on original functions derived from porphyrin.[3,4] Another solution can be expected by immobilization of a polymeric organic phase on silica. In this case, unexpected selectivity increase can be realized by a multiple-interaction mechanism, even if a polymer does not possess any macrocyclic structure. A typical example can be seen in poly(4-vinylpyridine)-grafted silicas.[5,6] The molecular-planarity selectivity towards polycyclic aromatic hydrocarbons (PAHs) compares to that in a porphyrin-immobilized silica in a reversed phase mode. In this entry, we introduce polymer-grafting onto silica as an organic stationary phase for highly selective HPLC.

ADVANTAGE OF POLYMER GRAFTING

Polymer-grafting onto silica can be usually carried out by activation of silica surface and subsequent radical polymerization with a vinyl monomer. However, we recommend preparing a polymer with a reactive terminal group at one side, and then immobilizing it onto the silica surface, as schematically illustrated in Fig. 1. This method gives us many advantages.

1. A polymer with a terminal reactive group can be obtained by one-step telomerization. By choosing monomer, a function of the resultant polymer can be tunable.
2. Usual spectroscopy is applicable for determination of the chemical structure before immobilization onto silica. The stereoregularity is also estimated by NMR spectroscopy.
3. Telomerization usually leads narrow polydispersity of degree of polymerization. This promises homogeneity as an organic phase.
4. Polymerization degree can be controlled by the initial molar ratio of a vinyl monomer to a telogen. This is an essentially important feature because large polymers cannot penetrate into the pores of silica and, thus, this causes heterogeneity in surface modification.

The first successful result was seen in the grafting of poly(octadecyl acrylate) onto silica and its application for separation of PAHs in a reversed phase mode.[7] The polymer is obtained by telomerization of octadecyl acrylate, initiated with 3-mercaptopropyltrimethoxysilane (Fig. 1). The following immobilization is carried out by mixing with porous silica in a suitable solvent. The resultant polymer-grafted silica shows, not only extremely high separation of PAHs, but also specific temperature dependency on the selectivity, which is induced by an ordered-to-disordered transition of the grafted polymer.[7] The detail is described later.

GRAFTING OF DISORDERED POLYMERS

A simple application of our grafting method is seen for polymerization of styrene,[8] methyl acrylate,[9]

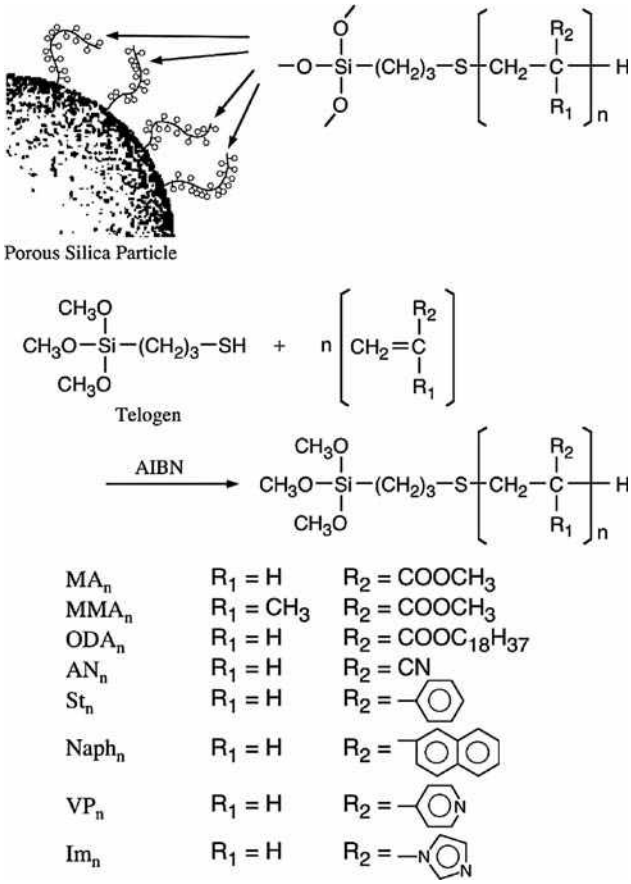

Fig. 1 Chemical structures of polymeric organic phases prepared by one-step telomerization. These polymers can be readily immobilized onto silica through the terminal methoxysilyl group.

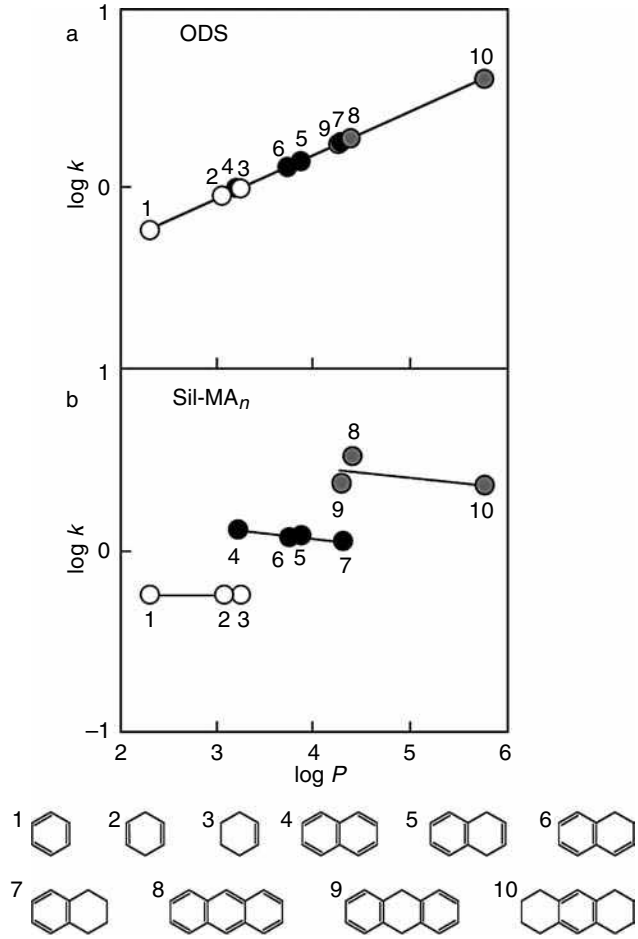

Fig. 2 Relationship between log k and log P with octadecylated silica (ODS) (a) and Sil-MA$_n$ (b). Mobile phases: (a) methanol–water (9:1); (b) methanol–water (7:3).

acrylonitrile,[5] etc. (Fig. 1). Radical polymerization of these monomers provides their random polymers. However, the polymer-grafted silicas showed unique features as RP-HPLC packing materials. For example, when the polystyrene-grafted silica (Sil-PSt$_n$, where n is the average degree of polymerization) is applied for separation of PAHs, both the retention and separation factors are higher than commercially available phenyl-bonded silicas. In addition, the elution peaks are comparably symmetrical, although conventional porous poly(styrene-divinylbenzene) packing materials showed remarkable peak-tailing. These desirable properties are attributable to the fact that Sil-PSt$_n$ does not include a cross-linking structure in the bonded phase, but rather fluid to be a liquid.

Poly(methyl acrylate)-grafted silica (Sil-MA$_n$) showed unexpectedly unique selectivity in a reversed phase mode.[9] The unusual nature of Sil-MA$_n$ is emphasized by Fig. 2. Octadecylated silica shows a good linearity in the log k–log P plots (Fig. 2a), indicating that the elution order is understandable by molecular hydrophobicity of solutes. On the other hand, Sil-MA$_n$ provides no similar result. As shown in Fig. 2b, it seems to show that Sil-MA$_n$, instead, recognizes the molecular size (i.e., the number of the rings). This unusual result should be explained by including π–π interaction derived from a carbonyl group of an acrylate moiety. This interaction is estimated by the ab initio MO/MP2 calculations[10,11] (Fig. 3) to be stronger than a benzene π–benzene π interaction,[12] and is also experimentally supported by a substitution effect.[13] Thus, it can be specified as a carbonyl-π interaction.

Similar specificities in HPLC have been realized with poly(4-vinylpyridine)[5,6] and poly(acrylonitrile).[5] The similarity of these polymers can be characterized by the fact that their residual groups include locally polarized moieties with π-electrons. Here, their uniqueness is summarized through the results of poly(4-vinylpyridine)-grafted silica (Sil-VP$_n$): Sil-VP$_n$ is less sensitive for molecular hydrophobicity of solutes, as shown in a typical chromatogram of Fig. 4A. This is proof of a great difference from ordinary ODS. On the contrary, higher retention and selectivity (Fig. 4C) are observed for PAHs or π-electron-containing substances, especially sensitive for difference of the molecular planarities of solutes

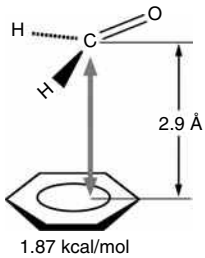

Fig. 3 Formaldehyde–benzene complex model by ab initio MO/MP2 calculations performed with the Gaussian 94 package.[11] The binding energy was calculated as a function of distance *R* between the carbon atom of formaldehyde and benzene plane, in which formaldehyde was removed perpendicularly to the benzene plane (plane-to-plane interaction) with the orientation fixed to that of the optimized geometry. A formaldehyde–benzene interaction (1.83 kcal/mol) is more effective than benzene–benzene[12] (0.49 kcal/mol in the parallel interaction) complex.

(Fig. 4E). In addition, Sil-VP$_n$ shows specificity for ortho-isomers[6] better than for para-isomers, as shown in Fig. 5A. This selectivity is often seen in adsorption chromatography, but it should be noted that a mobile phase is aqueous or composed of polar solvents. These uniquenesses will compensate us for limited applicability in ordinary ODS and other π-electron-containing stationary phases in a reversed phase mode. The simple application is cited in Fig. 5B and C, while ODS shows almost no separation for these substances.

When *N*-isopropylacrylamide (NIPAM) is chosen as a vinyl monomer and the resultant polymer is grafted onto silica, its HPLC behavior is temperature-dependent because poly(NIPAM) has a typically lower critical solution temperature (LCST) around 32°C in an aqueous solution (Fig. 6).[15,16] Above its LCST, the organic phase behaves as a hydrophobic surface, which is due to dehydration of the grafted polymer chain. Recently, the separations of amino acid phenylthiohydantoins[17] and bisphenol A[18] are achieved by using this temperature-responsive chromatography with an aqueous solution as the mobile phase.

GRAFTING OF ORDERED POLYMERS

Selectivity Increase Due to Ordering in Polymeric Organic Phase

It is difficult to control the stereoregularity of polymers in radical telomerization. However, the side chain ordering in the polymer can be realized if a long-chain alkyl compound is chosen as a vinyl monomer for telomerization. A preliminary example is reported with poly(octadecyl acrylate), ODA$_n$.[7] The resultant polymer can be easily grafted onto porous silica through a terminal trimethoxysilyl group. Toluene and tetrachloromethane are good solvents for this procedure.

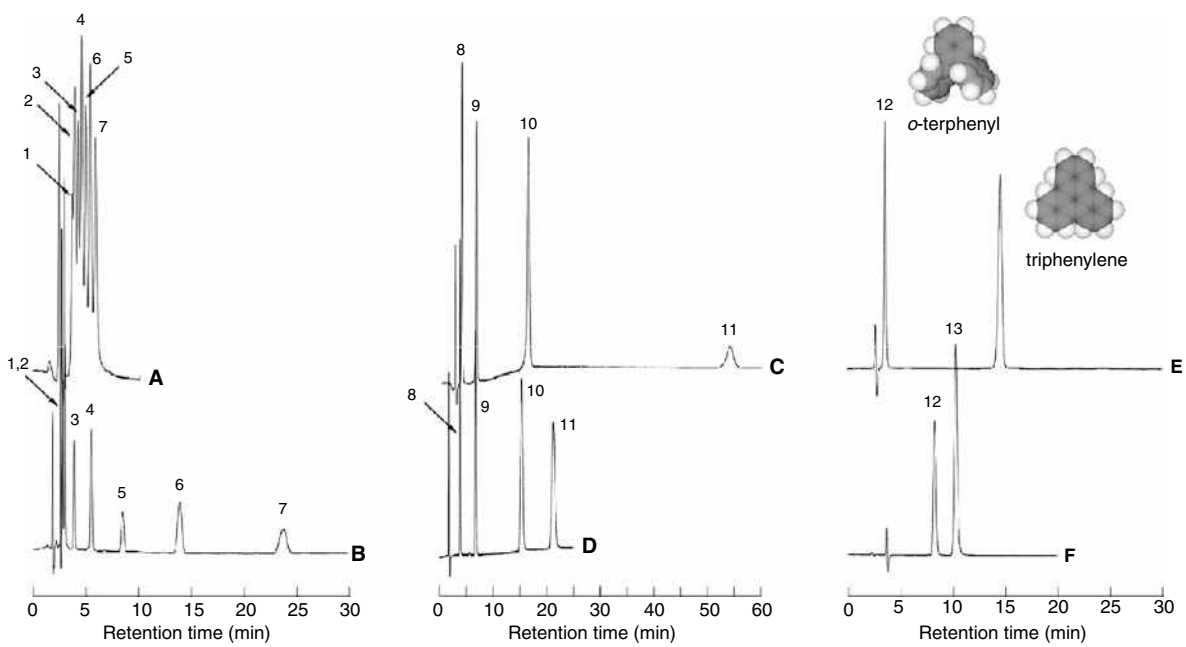

Fig. 4 Typical chromatograms with Sil-VP$_n$ (A, C and E) and ODS (B, D and F) at 30°C.[5] Mobile phase: (A), (B), (E) and (F), methanol–water (7:3); (C) and (D), methanol–water (7:3). Solutes: 1, toluene; 2, ethylbenzene; 4, hexylbenzene: 5, octylbenzene; 6, decylbenzene; 7, dodecylbenzene; 8, benzene; 9, naphthalene; 10, anthracene; 11, pyrene; 12, *O*-terphenyl; 13, triphenylene.

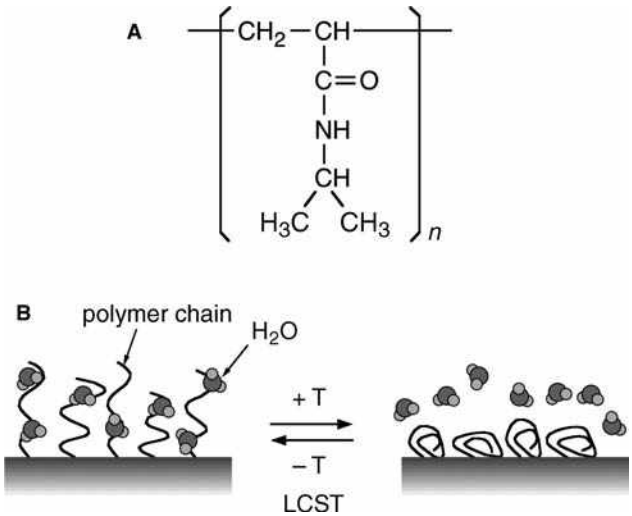

Fig. 6 A, Chemical structure of poly(*N*-isopropylacrylamide) and B, schematic illustration of temperature-responsive surface.

Poly(octadecyl acrylate) is characterized by differential scanning calorimetry (DSC)[19] and NMR spectroscopy.[20] The DSC thermogram shows a sharp endothermic peak (T_c) in both the heating and cooling processes. For example, the temperature of ODA_{27} (n=27) provides a peak around 49°C (T_{C_2}) with a shoulder (T_{C_1}) at 42–47°C in the heating process. Polarity microscopic observation indicated that T_{C_1} and T_{C_2} are assigned to crystalline-to-liquid crystalline and liquid crystalline-to-isotropic phase transitions, respectively. Similar phase transitions are also observed even after immobilization on silica. In a methanol–water (7:3) mixture as a mobile phase, a peak-top temperature (T_{C_2}) falls about 8°C, compared with the original T_{C_2}. This indicates that silica influences the orientation of bound ODA_{27}, but the bonded phase can maintain ordered structures and undergo crystalline-to-isotropic phase transition on silica, as illustrated in Fig. 7B.

The phase transition of ODA_n on silica can be also detected by a combination of suspension-state ^{1}H NMR and solid-state ^{13}C-CP/MAS-NMR spectroscopies.[20] For example, with a gradual increase in temperature, the intensity of proton signals (^{1}H NMR) of octadecyl moieties (mainly methylene groups) rises with a sharp inclination coincident with an endothermic peak in DSC thermogram, implying a relatively complete solid to liquid phase transition. In addition, the ratio of *trans*- to *gauche*-conformations can also be determined. This phase characterization method, in conjunction with conformation determination drawn from NMR spectroscopy, is important for a better understanding of the structure, dynamics, and separation behavior of organic layers grafted onto the silica surface. Interestingly, this method clarified that most of the octadecyl chains in the case of monomeric ODS, despite having

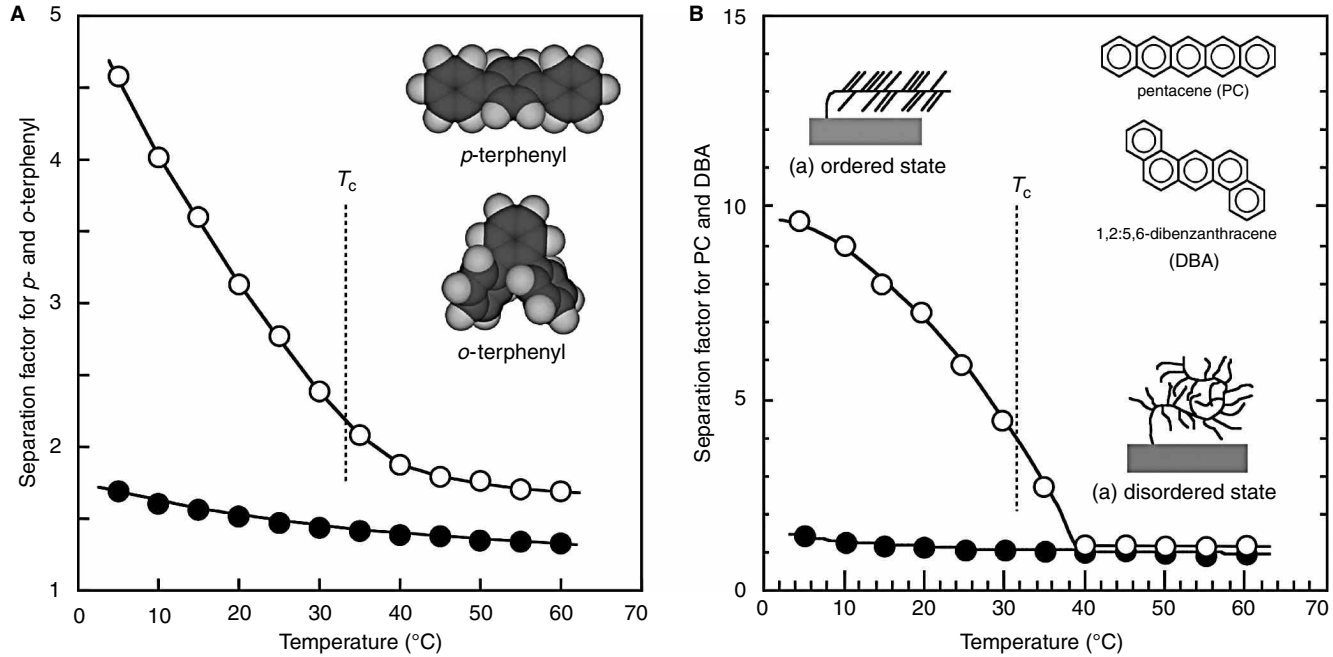

Fig. 7 Temperature dependencies on the separation factor with Sil-ODA$_n$ (open circles) and ODS (solid circles). Mobile phase: methanol (A); ethanol (B).

a gauche conformation, were still in a solid phase and only 12.3–18.5% of them have enough mobility to be considered as being in a liquid phase.[20]

Sil-ODA$_n$ shows ODS-related retention orders for usual hydrophobic solutes in a reversed phase mode, but the unique performance of Sil-ODA$_n$ is emphasized by temperature dependency. Sil-ODA$_n$ shows distinct bending in the plots of temperature vs. k in HPLC. T_c of Sil-ODA$_n$ observed completely agrees with the temperature of the bending point. This is accompanied by the remarkable selectivity change. A typical example is shown in Fig. 7. Both increases of the retention and separation factors always appear at temperature below T_c, where the physical state is in an ordered form. On the other hand, higher selectivity is clearly observed for PAHs vs. non-aromatic hydrocarbons. To clarify the separation mechanism of Sil-ODA$_n$, we have investigated the selectivity with geometrical isomers from various substituted azobenzene compounds.[13] As a result, it was found that the separation factor between the *trans*- and *cis*-isomers was remarkably dependent on the electron-donating property of the substituent group. This strongly suggests that bonded ODA$_n$ works as an electron-acceptor and a π–π interaction is brought by a carbonyl π moiety in ODA$_n$. As supporting this assumption, a carbonyl group-containing polymeric organic phase, Sil-MA$_n$ with neither a long-chain alkyl group nor any ordered structure shows no bending behavior in the temperature-selectivity plots, but also the separation factor is higher when compared with ODS.[13] In addition, the separation factor decreases with addition of acetone to a mobile phase, which can work as an inhibitor for a carbonyl π–benzene π interaction. No similar decrease is observed by 2-propanol. Theoretical study of a carbonyl π–benzene π interaction with a model system has also been done with ab inito calculation (Fig. 3).[10–12] Therefore, it is concluded that solute molecules are not incorporated into a crystalline (ordered) phase, but rather adsorbed onto the aligned carbonyl groups. On the other hand, the isotropic (disordered) bonded does not have such specificity. The solutes can partition into the bonded phase and, thus, the separation mode is similar to that of ODS.

Effect of Stereoregularity of Polymeric Organic Phase on Selectivity Increase

As briefly mentioned above, a stereoregularity of polymers is hardly controlled in a radical telomerization, although it would be an important factor to increase the selectivity. However, it is certain that stereoregularity can be influenced by solvent and temperature in a telomerization process. In support of this, when the telomerization is prepared in methanol, benzene, or cyclohexane, and then the resultant polymers, abbreviated as ODA$_n$-M, ODA$_n$-B and ODA$_n$-C respectively, are applied as organic stationary phases, significant selectivity difference is detected among them.[21] A typical example can be shown by the separation of a mixture of *m*- and *p*-terphenyls. These structural isomers are useful for evaluating the molecular shape selectivity because the molecular shape differs in planarity and length, but the hydrophobicity is similar. Therefore, a conventional RP-HPLC shows very low selectivity, e.g., α=1.1 and 1.3 in monomeric and polymeric ODSs, respectively, while complete separations (α=3.0–3.3) are observed in all Sil-ODA$_n$ at 0°C. Here, if the separation factor is compared with the results at 35°C, the solvent effect in the telomerization makes it clear. This difference can be explained by the fact that the phase transition temperature of ODA$_n$-M is a little higher (40°C in a peak-top temperature) than the others (35°C). This difference reflects the molecular orientation among the long-chain alkyl groups. The orientation of the side chain alkyl groups of ODA$_n$ can be also evaluated by the suspension-state ^{1}H NMR in methanol with the nanoprobe.[20] The octadecyl methylene peak is very small and broadened at 0°C, but the normalized intensity begins to increase distinctly around 30°C. This temperature is close to the phase transition temperature. This unusual increase of the intensity in ODA$_n$ can be explained by the fact that the mobility of octadecyl groups increases with the ordered-to-disordered transition, as shown in the DSC data. On the other hand, when ^{13}C NMR spectroscopy of ODA$_n$ is carried out in chloroform-d at room temperature, all ODA$_n$ provides nine distinct peaks in the range of 10–70 ppm. All peaks are assigned reasonably by considering electronegative forces of their neighboring moieties. On the basis of the assignment, it is estimated that ODA$_n$-C and ODA$_n$-B show relatively high polydispersity in the tacticity compared to ODA$_n$-M. This estimate agrees with the fact that the phase transition temperature of ODA$_n$-M is a little higher than the others. This study cannot confirm exact conformation of the carbonyl groups in ODA$_n$ but shows that the microenvironmental difference in polymer influences the resultant selectivity. Thisfinding is very valuable because it indicates that conformational control of the polymer main chain would lead to high selectivity in HPLC.

To discuss the effect of structural ordering of the polymer on selectivity, we have been focusing on secondary structures of poly(α-amino acid)s, i.e., polypeptides.[22,23] They provide rigid and exact conformations, such as α-helix and β-structure, spontaneously if polymerization is done with a purely chiral amino acid. The poly(L-alanine), poly(L-leucine), and poly(L-phenylalanine) with a terminal reactive trimethoxysilyl group can be prepared by the corresponding *N*-carboxyanhydrides and 3-aminopropyltrimethoxysilane as an initiator for polymerization. However, in this case, a

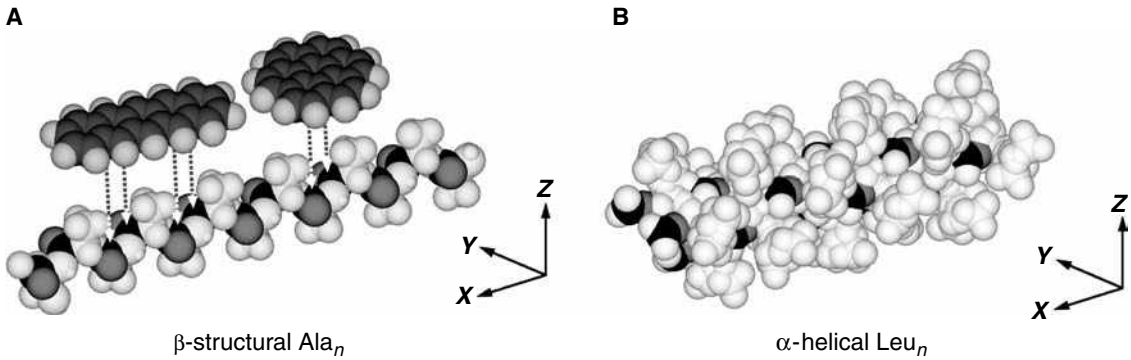

Fig. 8 CPK models of (A) β-structural Ala$_n$ and (B) α-helical Leu$_n$ derived from PEPCON. The black atoms present carbonyl carbons. A linear and planar solute such as pentacene provides more effective interaction area with the carbonyl groups one-dimensionally-aligned on the rigid main chain than a disk-like solute such as coronene (A). On the other hand, the carbonyl groups of Leu$_n$ are covered with their bulky residual groups (B).
Source: From Molecular-length and chiral discriminations by β-structural poly(L-alanine) on silica, in J. Chromatogr, A.[22]

serious problem is often accompanies the procedure. This is due to lower solubility of the resultant polypeptides and, particularly, becomes formidable with an increase of the polymerization degree. Therefore, grafting of polypeptides is usually carried out by immobilization of 3-aminopropyltrimethoxysilane onto porous silica and subsequent polymerization with *N*-carboxyanhydride initiated with the activated silica. The secondary structures of polypeptides on silica can usually be estimated by the absorption bands ascribed to an amide I and II in IR spectroscopy, because the strong absorption due to silica overlaps with that of an amide V. IR spectroscopy indicated that the main secondary structures of poly(L-alanine) and poly(L-leucine) on silica were the β-structure and the α-helix, respectively.[22]

When poly(L-alanine)-grafted silica is applied for separation of PAHs in a reversed phase mode, we can encounter various specific selectivities. For example, α=10.4 was obtained for a mixture of *p*- and *o*-terphenyls, while α=1.5 in ODS. Both *p*- and *o*-terphenyls possess the same numbers in carbon atoms and π-electrons, but the molecular planarity is entirely different. As indicated in the Corey-Pauling-Koltun (CPK) models of Fig. 7A, *p*-terphenyl is a little twisted (almost planar), but more slender (linear) than *o*-terphenyl. No similar enhancement of the selectivity is observed in poly(L-leucine)- and poly(L-phenylalanine)-grafted silica. These polypeptides show, rather, similarity to ODS: e.g., α=1.7 in poly(L-leucine)-grafted silica.

To explain the high selectivity of the poly(L-alanine) phase, we apply a multiple carbonyl π-to-benzene π interaction mechanism on highly-ordered structures. As shown in the schematic illustrations of Fig. 8, the carbonyl groups in the poly(L-alanine) main chain as a π-electron source are well-oriented because the peptide main chain is in a rigid β-form structure on silica. On the basis of these facts, we explain the multiple π–π interaction mechanism:

1. Polycyclic aromatic hydrocarbons can interact with the carbonyl groups. The methyl group of the poly(L-alanine) side chain does not prevent electrostatic interaction (Fig. 8A).
2. On the contrary, poly(l-leucine) does not offer a chance to provide this interaction because the residual isobutyl groups are too bulky to approach each other (Fig. 8B). Also, it should be noted that poly(L-leucine) provides only α-helices, even on silica and, thus, their carbonyl groups are absolutely covered with the bulky residual groups. As a result, the poly(L-leucine) phase showed only hydrophobicity recognition similar to ODS. The selectivity is close to that in ODS (α=1.5).
3. The carbonyl groups in poly(L-alanine) should be aligned unidimensionally along the β-structure form. This conformation promotes the multiple carbonyl-π interaction, which works more effectively with longer (slender and linear) PAHs than with shorter ones. Fig. 8A show that a longer and planar PAH, such as pentacene, yields higher contact points with poly(L-alanine) than a disk-like PAH such as coronene.

Multi-Anchoring Effect on Selectivity Increase

Porphyrin-derivatized bonded phases show unique shape selectivity, retaining planar PAHs.[3,4] Similar molecular-planarity selectivity is also observed in cholesteryl-10-undecenoate and 4,4′-dipentyldiphenyl bonded phases. These phases contain rigid structures and, thus, the limited mobility in their organic phases contributes to the molecular-shape selectivity. A similar effect on selectivity increase can be seen in the comparison of the retention behaviors between polymeric and

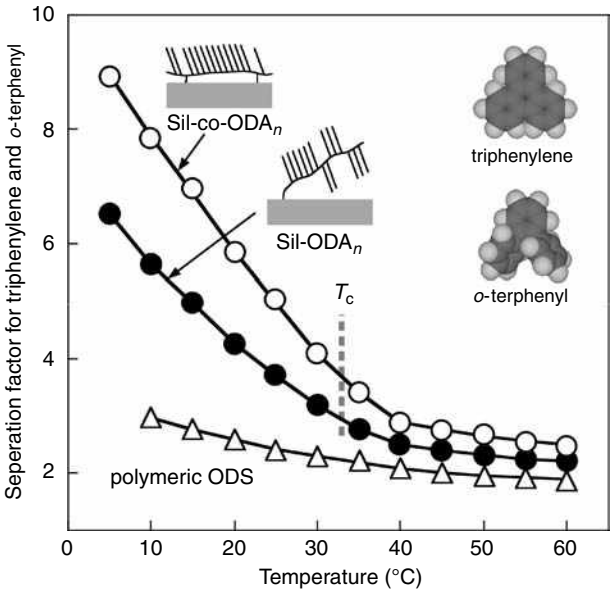

Fig. 9 Temperature dependencies of the separation factors between triphenylene and *o*-terphenyl with multi-anchored ODA$_n$ (open circles), Sil-ODA$_n$ (solid circles) and polymeric ODS (open triangles). Mobile phase: methanol–water=9:1.

monomeric ODSs.[2] Therefore, to increase the selectivity, decreasing molecular mobility of ODA$_n$ having plural reactive groups in the side chain has been synthesized and immobilized onto silica. This polymeric phase can be obtained by co-telomerization with γ-methacryloxypropyltrimethoxysilane. As expected, this polymer phase-immobilized silica showed better selectivity for PAHs: e.g., 1.4 times higher selectivity for the separation of triphenylene and *o*-terphenyl than Sil-ODA$_n$ (Fig. 9). This is a typical example that the immobilization method of polymer on support materials influences the resultant molecular-shape selectivity and, thus, this finding encourages us to investigate the multi-anchoring effect for various polymeric phases.

Application for Chiral Discrimination

It is well known that, for biologically active substances, one enantiomer shows different biological activity from the other. For example, the studies by Mori et al. on the relationship between optical purity and biological activity of insect pheromones have revealed that the biological activities were dramatically changed by their optical purities. Therefore, it is important to determine the absolute configuration and accurate optical purity of biologically active compounds.

For this purpose, a diastereomer method has been widely used for determination of the absolute configuration and optical purity and, thus, many diastereomerizing reagents have been developed for racemic amines, alcohols, and amino acids.[10,14] When this method is combined with RP-HPLC, it yields very convenient and quick analyses of enantiomer mixtures. Diastereomerizing reagents can be generally characterized by the fact that chromophoric groups are included for sensitive detection and chiral separation is realized by discriminating the hydrophobicity (or polarity) difference between the resulting diastereomers. Therefore, π–π interaction-supported RP-HPLC with ODA$_n$ would show much better discrimination for the resultant diastereomers, compared with ordinary ODS.

Fig. 10A shows a typical example for *N*-acyl amino acid diastereomerized with *N*-dansyl amino acid.[24] Diethyl phosphorocyanidate (DEPC) is adopted as a condensation reagent instead of conventional dicyclohexylcarbodiimide (DCC), to avoid racemization during the reaction. Fig. 10A shows the time course of chromatograms for the methyl ester of DL-phenylalanine diastereomerized by *N*-dansyl-L-proline with Sil-ODA$_n$. The chromatogram, a minute after addition of DEPC to the mixture of dl-phenylalanine and *N*-dansyl-L-proline, provided two new peaks with λ_{max} of 350 nm at 6.8 min and 8.5 min which are attributable to the absorption based on a dansyl group. It is also assigned that the first peak, at 6.8 min, has the same retention time as that obtained by the diastereomer of L-phenylalanine methyl ester with *N*-dansyl-L-proline. The selectivity in Sil-ODA$_n$ is temperature-dependent and much higher at temperature below T_c (α=1.45, −10°C) than that in ODS (α=1.16, −10°C).

Another good example is shown in Fig. 10B.[25] Ohrui et al., have developed the chiral labeling reagents, 2-(2,3-anthracenedicarboximide)cyclohexane carboxylic acid and 2-(2,3-anthracenedicarboximide)cyclohexanol to discriminate the diastereomers having chiral centers separated by more than four bonds. The use of these reagents made it possible to separate the branched fatty acids or alcohols having a branched methyl group by reversed phase HPLC with ODS. However, it was necessary to apply low column-temperature conditions (around −40°C) for their separation because the mobility of octadecyl groups in ODS should be remarkably reduced. To solve this problem, Sil-ODA$_n$ has been applied instead of conventional ODS because the ODA$_n$ phase is rigid and ordered in the side chain at temperatures below T_c.

Fig. 10B shows chromatograms for the diastereomers, *S,S,R*-**1** and *R,R,R*-**1** by HPLC with Sil-ODA$_n$ and ODS at 0°C.[25] No separation is observed in ODS, where it was necessary to apply lower column-temperature conditions for a substantial separation. Even each injection showed almost no separation at 0°C ($k_{R,R,R}$ and $k_{S,S,R}$=15.2 with ODS). On the contrary, complete separation is observed in Sil-ODA$_n$ ($k_{R,R,R}$=21.0, $k_{S,S,R}$=17.3, α=1.21). There is a

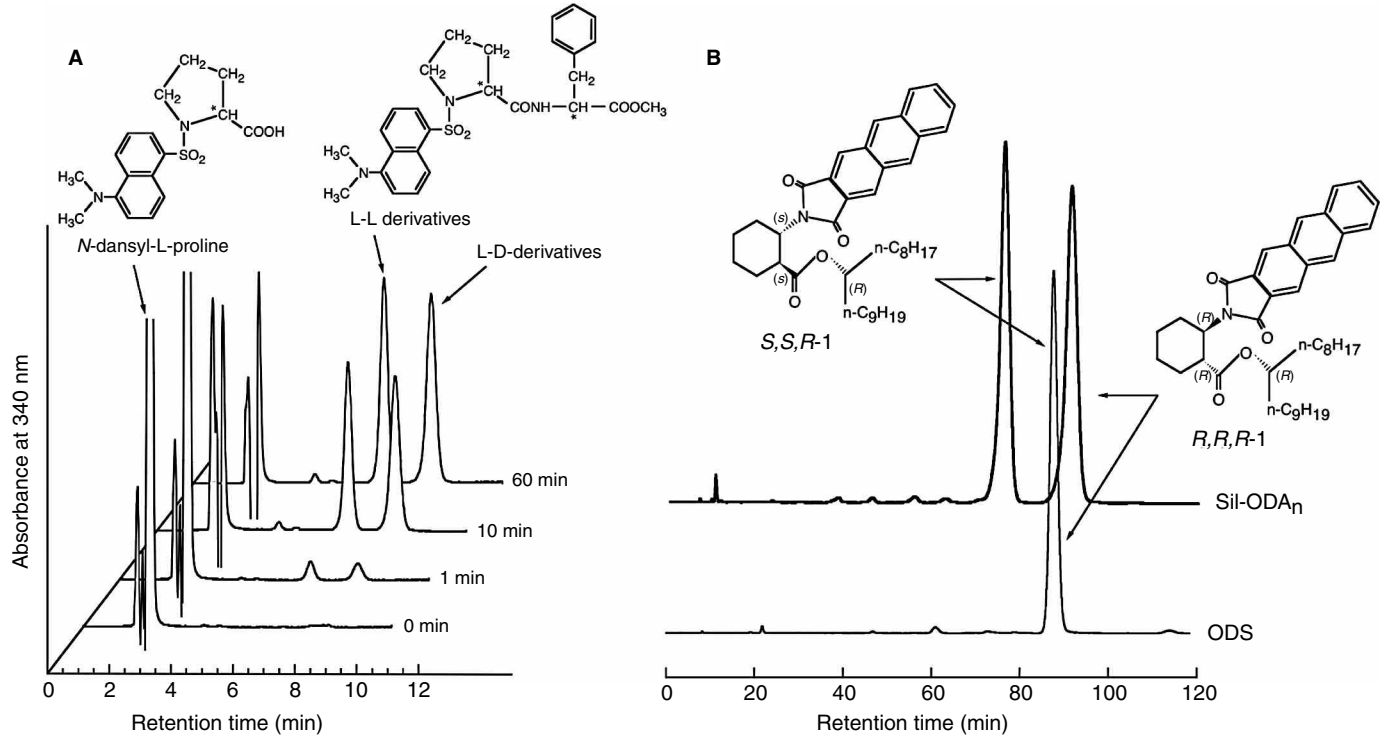

Fig. 10 (A) Time course of diastereomerization of dl-phenylalanine with *N*-dansyl-L-proline using DEPC[24] and (B) chromatograms of the mixture of *S*,*S*,*R*-**1** and *R*,*R*,*R*-**1** with Sil-ODA$_n$ and ODS.[25] Mobile phases: (A), methanol–water (7:3) at 25°C; (B), methanol at 0°C.

series of the Ohrui's reagents; then similar good results are always obtained with Sil-ODA$_n$, compared with ODS. This is due to the fact that the separation is supported with π–π interaction as well as a hydorophobic effect.

CONCLUSIONS

Lipid bilayer membrane systems, having gel (solvated crystalline state)-to-liquid crystalline phase transitions are attractive as specific organic media for separation chemistry. The first approach in HPLC was direct immobilization of a phosphatidylcholine lipid onto silica. This modified silica shows interesting selectivity against amino acids, but the separation mode is too complicated, due to the zwitterionic property of the immobilized molecule. In addition, no lipid membrane function is realized on the silica because of the direct immobilization with covalent bonding, which prohibits lateral diffusion of lipids from forming highly-ordered structures that lead to supramolecular functions of lipid membrane systems.

Sil-ODA$_n$ has been developed to address this question.[7] The ODA$_n$ phase does not make lipid membrane structures in an aqueous system, but it possesses similar functions, such as side-chain ordering and phase transition behavior between ordered and disordered states. However, the resultant selectivity in HPLC often excelled, better than expected. This is due to a sort of a side effect and, then, it may be called a polymeric effect, which promotes multiple interactions to increase the selectivity. Molecular ordering of functional groups particularly enhances it.

This entry has revealed that a grafting method is useful to direct a polymeric effect in HPLC. The advantage of this method is quite clear. Firstly, grafted polymers are not appreciably influenced by carrier particles. This feature is very important to maintain the original functions of polymers. For example, ODA$_n$ can undergo a phase transition, even after immobilization on silica. The other advantage is based on the fact that the functions of polymers are absolutely tunable by judicious selection of the monomer. Copolymerization would expand their versatility remarkably. Also, potential applicability of a polymer grafting method for surface modification must be limited to use in HPLC.

High-Temperature High-Resolution GC

Fernando M. Lanças

J.J.S. Moreira
Chromatography Laboratory, University of São Paulo, São Carlos, Brazil

INTRODUCTION

Gas chromatography (GC), in its early days, used packed columns with chemically inert solid supports coated with stationary phases. These columns presented low efficiency due to the wide range of particle sizes used, causing inhomogeneity in the packed bed and, consequently, high instability due to a poor deactivation and thermal instability at high-temperature operations.[1] This characteristic limited the use of the GC to only volatile and low-mass molecular compounds. The later development of columns with a stationary phase coated on the inner wall of the capillary provided a more inert environment. In this form, columns with higher thermal stability and more efficiency (higher N) were produced, allowing the analysis of semivolatile and medium molecular mass compounds. This technique was named high-resolution gas chromatography (HRGC).[1] The possibility of using thermally stable, highly efficient columns, stimulated scientists to search for new stationary phases and chemical manufacturing processes to produce capillary columns with high thermal stabilities, capable of operating at higher temperatures[2] (to 360°C).

Lipsky and McMurray[3] suggested, in their pioneering work on high-temperature high-resolution gas chromatography (HT-HRGC), the use of column temperatures equal to, or higher than, 360°C. However, other column temperature values have also been reported for this technique.[4]

The thermal stability of the high-temperature capillary columns allowed the analysis of higher molecular masses (more than 600 Da) and non-volatile compounds never before directly analyzed by gas chromatography.[2]

INSTRUMENTATION FOR HT-HRGC

The instrumentation used for HT-HRGC is the same as used for conventional GC, with only minor modifications.

Columns

The columns utilized in HT-HRGC are short (usually equal to, or shorter than, 10 m) coated with thin films (~ 0.1 μm or less) and having an inner diameter (I.D.) around 0.2 mm.[5]

A smaller inner diameter (e.g., 0.1 mm) can also be used, but with the inconvenience of limiting the work to more diluted samples in order to avoid column overload. On the other hand, this type of column permits carrier gas speeds higher than with columns of inner diameters in the range 0.2–0.3 mm. Columns with inner diameters equal to 0.1 mm exhibit fewer plates with the increment of the carrier gas speed, in contrast to the columns with equivalent characteristics, but of 0.3 mm I.D.[5] The increase of the carrier gas speed in smaller-I.D. columns performs an analysis in a shorter time, without undermining the efficiency of separation.[6]

Capillary columns, to be suitable to HT-HRGC, must be extremely robust and must be coated with a thin film of the stationary phase with the purpose of reducing the retention of the less volatile compounds and preventing stationary-phase bleed at high temperatures.[7]

Using such proper columns, elution of substances with carbon numbers in excess of *n*-C_{130} has been reported, at column temperatures of up to 430°C.[8]

Tubing Material for HT-HRGC Columns

There are four major types of materials being utilized to prepare columns for high-temperature capillary columns:[2]

1. Glass (borosilicate)
2. Polyimide-clad fused silica
3. Aluminum-clad fused silica
4. Metal-clad fused silica

Columns of aluminum-clad fused silica,[2,4] and metal-clad fused silica support temperatures up to 500°C, representing an advantage in comparison with borosilicate glass columns, with a temperature limit to 450°C, and columns of polyimide-clad fused silica for high temperature,[2,9] limited temperature to 400–420°C. On the other hand, aluminum-clad fused silica columns present leakage, principally in the connections, after a short time of use.[2,9] Polyimide-clad fused-silica

capillaries, after prolonged exposure to temperatures above 380°C, tend to break spontaneously at many points, thus losing the polyimide coating.[9] Borosilicate columns are inexpensive, being an alternative to fused silica for high-temperature applications. However, these columns have been reported to leak when coupled with retention gap and to mass spectrometry detectors.[2] An important alternative for HT-HRGC are HT metal-clad fused-silica columns which resist temperatures above 500°C for long-term exposure.[9]

Stationary Phases

The first results on HT-HRGC[3,10] were published in 1983, dealing with stationary-phase immobilization (polysiloxane –OH terminated). Due to the column instability, when submitted to high temperature, stationary-phase loss was common at that time. These works can be considered to be the precursor of high-temperature gas chromatography, because the phase immobilization process developed resulted in a series of OH-terminated polysiloxane phases compatible with the inner surfaces of borosilicate glass and fused-silica tubing. These phases are thermally stable and capable of withstanding elevated temperatures[11] used in HT-HRGC. After this report, many other articles dealing with the ideal stationary phase for high-temperature gas chromatography appeared. Non-polar stationary phases of the carborane–siloxane-type bonded phase (temperature range >480°C) and siloxane–silarylene copolymers suitable for HT-GC were developed[7] around 1988.

A medium-polarity stationary phase based on fluoralkyl–phenyl substitution, which is thermally stable up to 400°C, was reported,[12] and a CH_3O-terminated polydimethyl siloxane, diphenyl-substituted stationary phase made possible the analysis of complex high-molecular-mass mixtures such as free-base porphyrins and triglycerides using narrow-bore capillary columns.[5] Since these developments, a variety of stationary phases for analysis of specific analytes by HT-HRGC were found.[2]

Sample Introduction

The sampling and elution of such high-molecular-weight materials requires careful attention in order to avoid quantitative sample losses during the sample introduction step. In general, "cold" injection techniques are required for accurate non-discriminative sample transfer into the column. Cold on-column and programmed temperature (PT) split/splitless injection have been used with success for a large number of HT-HRGC analyses. In certain cases, however, significant losses of compounds above *n*-C_{60} have been observed with PT splitless injection.[13] This effect was identified as a time-based discrimination process caused by purging the PT inlet too soon after injection, resulting in incomplete sample vaporization.[14]

Actually, same articles show the possibility of use split injection[8] in HT-HRGC analyses of substances up to C_{78}. However, volatile materials from the septum accumulate at the head of the column during the cool-down portion of the temperature program. When the columns are reheated to analyze the next sample, these accumulated volatiles are eluted, producing peaks, a baseline rise, or both. This difficulty can be solved using commercial septa already available for HT-HRGC, which exhibit very low bleed levels.

DETECTORS

High-temperature high-resolution GC is a technique similar to conventional GC; however, it presents high column bleeding due to the high temperature to which the column is submitted. Selective detectors, when used in HT-HRGC, require special attention. As an example, the electron-capture detector (ECD) is a very sensitive detector and should not be used in HT-HRGC because of its ability to detect column bleeding. This fact limits the detectors used to a few, such as the flame ionization detector (FID), alkali-flame ionization detector (AFID), and mass spectrometry detector (MS). In HT-HRGC, these detectors usually need small adjustments; for example, the MS detector requires a special interface when used for HT-HRGC.[2]

HT-HRGC APPLICATION

High-temperature high-resolution GC has opened to many scientists the opportunity to analyze compounds of high molecular mass (600 Da or more) with similar efficiency to conventional high-resolution gas chromatography (HRGC). Actually, HT-HRGC has been applied to the analyses of compounds from several different areas.[15–18] As a general rule, this will avoid the time-consuming and usually expensive step of derivatization. In natural products, underivatized triterpenic compounds found in medicinal plants can be analyzed by this technique. The HT-HRGC analysis of triterpenes in aqueous alcoholic extracts of *Maytenus ilicifolia* and *M. aquifolium* leaves clearly allows the detection of the presence of friedelan-3-ol and friedelin and, therefore, allows distinguishing between the two varieties;[15] this differentiation is very important in pharmacological studies, because they present different biological activities.

Cyclopeptidic alkaloids (molecular mass ~ 600 Da), a class of important alkaloids which present biological

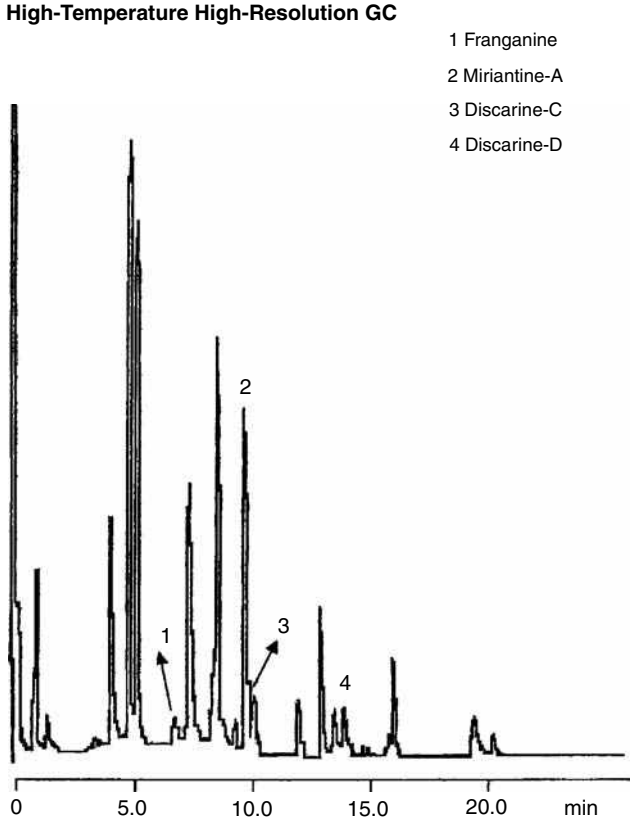

Fig. 1 Analysis of underivatized cyclopeptidic alkaloids in chloroform extract using HT-HRGC. Condition: fused-silica capillary column (6 m × 0.25 mm × 0.08 μm) coated with a LM-5 (5% phenyl, 95% polymethylsiloxane immobilized bonded phase) stationary phase. Temperature condition: column at 200°C (1 min), increased by 4°C/min, then 300°C (5 min); inlet: 250°C; FID detector: 310°C.

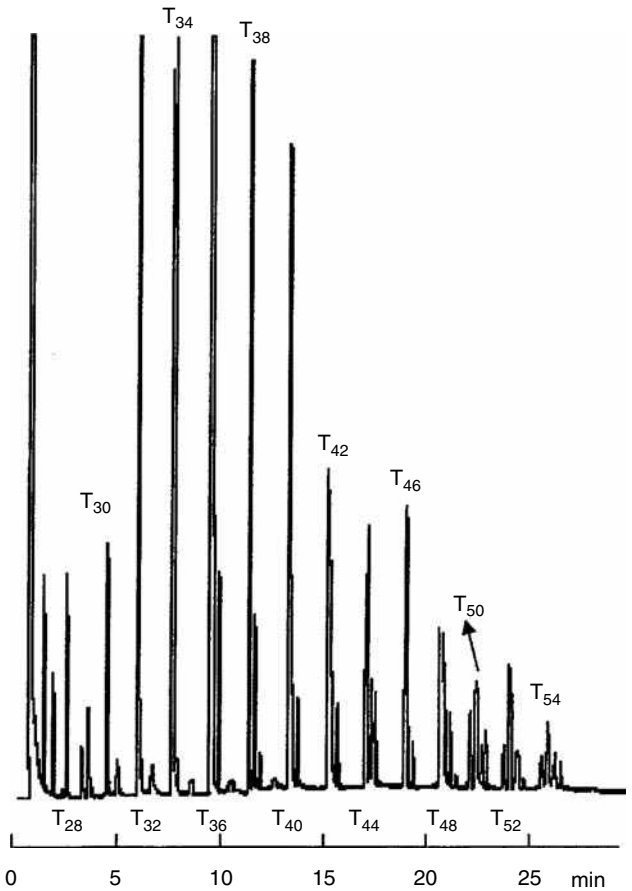

Fig. 2 Chromatogram of underivatized Palmist Oil (*Elaesis guineensis* L.) triacylglyceridic fraction using HT-HRGC. Condition: fused-silica capillary column (25 m × 0.25 mm × 0.1 μm) with the stationary phase OV-17-OH (50% phenyl, 50% methylpolysiloxane immobilized phase).Temperature condition: column at 350°C isothermic; injector: 360°C; FID detector: 380°C. T is the number of the underivatized triacilglyceride (e.g., T_{50} means a triacylglyceride having 50 carbon atoms).

activity,were analyzed by HT-HRGC without derivatization.[16] Fig. 1 illustrates the separation of cyclopeptidic alkaloids in the chloroform fraction. The following selected compounds were identified: (1) Franganine, (2) Miriantine-A, (3) Discarine-C, and (4) Discarine-D.

Triacylglycerides from animal and vegetable sources have been separated and identified by HT-HRGC and high-temperature gas chromatography coupled to mass spectrometry (HT-HRGC/MS). Fig. 2 shows the chromatographic profile of palm oil (*Elaeis guineensis* L.) by HT-HRGC, and the triacylglyceride compounds identification.[17]

The HT-HRGC/MS technique was also used as an important tool to identify and quantify cholesterol present in the total lipid extracts of archeological bones and teeth, constituents of a new source of paleodietary information.[19]

The detection of vanadium, nickel, and porphyrins in crude oils were analyzed by high-temperature gas chromatography–atomic emission spectroscopy (HT-GC–AES), presenting characteristic metal distributions of oils from different sources.[18] Other related applications of HT-HRGC, including the analysis of α, β, and γ cyclodextrins, antioxidants, and oligosaccharides.[2]

Considering that HT-HRGC is still a young separation technique and that it presents several attractive features, including the analysis of higher-molecular-weight compounds within short analysis times, without the necessity of sample derivatization, we can envisage a bright future for this technique, with many new applications being developed in the near future.

Histidine in Body Fluids: HPLC Determination

Toshiaki Miura

INTRODUCTION

Amino acids in biological samples have been principally determined by high-performance liquid chromatography (HPLC) with pre- or postcolumn chemical derivatization selective for a primary amino group. Although HPLC methods are applicable to the assay of all commonly encountered amino acids in biological samples, they are time-consuming and inadequate for the assay of a large number of samples when a specific amino acid is required to be assayed. In such cases, a rapid assay can be achieved by the use of a chemical derivatization that is selective for the individual amino acid, which renders the HPLC separation conditions to be very simple. As an example of such a case, this paper describes a rapid HPLC method for the determination of histidine in body fluids. The method is based on the separation by a reversed-phase, ion-pair chromatography followed by the selective postcolumn detection of histidine with fluorescence derivatization using *O*-phthalaldehyde (OPA).

SELECTIVE FLUORESCENCE DETECTION OF HISTIDINE WITH OPA

OPA has been known to give a fluorescent adduct with most primary amines in the presence of a thiol compound, but only with several biogenic amines such as histidine, histamine, and glutathione in the absence of a thiol compound in a neutral or alkaline medium. In the case of histidine, it gradually reacts with OPA alone in an alkaline medium, to give a relatively stable fluorescent adduct showing excitation and emission maxima at 360 and 440 nm, respectively.[1] Håkanson et al. optimized these reaction conditions and showed that the fluorescence intensity due to histidine reached a maximum 10 min after initiation of the reaction at pH 11.2–11.5, at 40°C. This fluorescence reaction is relatively selective for histidine and has been used in a batch method for the assay of histidine.[1]

On the other hand, we revealed the mechanistic pathway of the OPA-induced fluorescence reaction of histidine, as shown in Fig. 1.[2] In addition, we found that the fluorescent adduct of histidine rapidly forms in a neutral medium, although its stability is low.[3] These findings led us to optimize this fluorescence reaction for a postcolumn detection of histidine in its HPLC determination. Under the optimized conditions (for 30 sec at pH 7 and at 40°C), no significant fluorescence was observed with other biological substances, except for histamine and glutathione. The relative fluorescence intensities of histamine and glutathione were 14.4% and 11.8% of that given by histidine on a molar base, respectively.[3] Such high selectivity of this fluorescence reaction was reasonably explained by the fact that both the primary amino group and imidazole ring of histidine participate in the formation of the fluorescent adduct (Fig. 1).

Because the reaction temperature markedly influences the rates of formation and degradation of the fluorescent adduct, its precise control is an essential factor for the reproducibility of the postcolumn fluorescence detection. Therefore preheating of both the eluent and OPA reagent to a constant temperature of 40°C is required before their mixing, and these was achieved by insertion of preheater tubes for both the eluent and OPA reagent into the line. As described in the section "HPLC System and Conditions," the preheater tubes, as well as columns, resistor tube, and the reactor tube were placed in a column oven maintained at 40°C.

HPLC CONDITIONS FOR SEPARATION OF HISTIDINE

As described above, histamine and glutathione also show significant fluorescence in the postcolumn detection with OPA. The levels of glutathione are comparable or higher than those of histidine in many biological samples, such as liver, kidney, and blood (mainly in the erythrocytes). On the other hand, most biological samples normally contain histamine at markedly lower levels than histidine; in particular, the level of histamine in human serum or plasma is 10,000-fold lower than that of histidine. These facts indicate that the interfering biological substance is limited to glutathione in the HPLC method in the postcolumn fluorescence detection using OPA. Thus HPLC separation conditions had only to separate histidine from

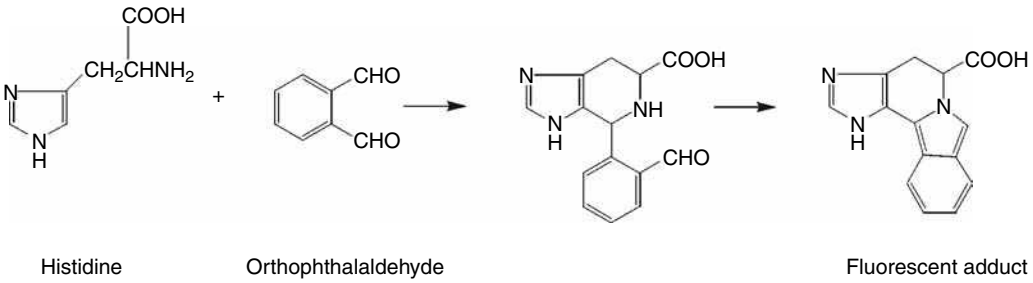

Fig. 1 Mechanistic pathway for the formation of fluorescent adduct in the reaction of histidine with *O*-phthalaldehyde.

glutathione, which was easily achieved by a reversed-phase ion-pair chromatography on an ODS short column with a 5 : 95 (v/v) mixture of methanol and sodium phosphate buffer (35 m*M*, pH 6.2) containing 5.3 m*M* sodium octanesulfonate, at a flow rate of 0.5 ml/min and at 40°C. Under these conditions, histidine and glutathione were eluted at 2.7 and 1.4 min, respectively (Fig. 2A).

DETERMINATION OF HISTIDINE IN BODY FLUIDS

HPLC System and Conditions

The HPLC system comprised an L-6000 pump (Hitachi, Tokyo, Japan) and an LC-9A pump (Shimadzu, Kyoto, Japan) for deliveries of an eluent and the OPA reagent, a DGU-12A degasser (Shimadzu), a Rheodyne Model 7725i sample injector (Rheodyne, Cotati, CA, USA), a CTO-10A column oven (Shimadzu), an F-1050 fluorescence detector equipped with a 12 μl square flow cell, and a D-2500 data processor (Hitachi). Separation was performed at 40°C with a Develosil ODS UG-3 column (30 × 4.6 mm I.D., 3 μm; Nomura Chemical, Seto, Japan) as an analytical column, which was protected by a guard-pak cartridge column (Develosil ODS UG-5, 10 × 4.0 mm I.D., 5 μm), and with a 1:19 (v/v) mixture of methanol and sodium phosphate buffer (35 m*M*, pH 6.2) containing 5.3 m*M* sodium octanesulfonate as an eluent. The OPA reagent was a 15:1 (v/v) mixture of 50 m*M* sodium phosphate buffer (pH 8.0) and 50 m*M* OPA in methanol. Both the eluent and OPA reagent were filtered through a 0.45 μm membrane filter (Millipore, Bedford, Massachusetts, U.S.A.) before use. The eluent was delivered to the column at a flow rate of 0.5 ml/min through a preheater tube (stainless-steel tube, 10 m × 0.8 mm I.D.). Ten microliters of the sample solution was introduced to the column. The eluate from the column was added with OPA reagent delivered at a flow rate of 0.5 ml/min to a mixing T-joint attached to the column through a preheater tube (stainless-steel tube, 10 m × 0.8 mm I.D.) and a resistor polytetrafluoroethylene (PTFE) tube (20 m × 0.25 mm I.D.). The mixture was passed through a reactor tube (coiled PTFE tube, 2.5 m × 0.5 mm I.D., coil diameter of 20 mm) and the generated fluorescence was detected at 435 nm with an excitation wavelength of 365 nm. All columns, preheater, resistor, and reactor tube were placed in the column oven which was maintained at 40°C.

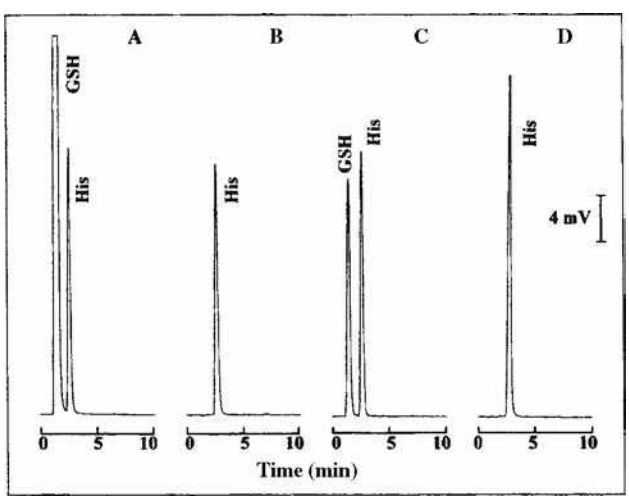

Fig. 2 Typical HPLC chromatograms of histidine. (A) Standard histidine and glutathione. Injected amounts: histidine (His), 5 pmol; glutathione (GSH), 500 pmol. (B) Human serum. (C) Human blood. (D) Human urine. (See the section "HPLC System and Conditions" for chromatographic conditions.)

Sample Preparation

Because of high selectivity of the postcolumn fluorescence detection with OPA, no sample pretreatment other than deproteinization was required for the assay of histidine in body fluids such as human serum, blood, and urine as follows:

- Human serum was mixed with an equal volume of 6% (w/v) perchloric acid and was vortexed several times. The mixture was centrifuged at 10,000 × *g* for 10 min at 4°C, then the supernatant was diluted 10-fold with water and was filtered through the 0.45 μm membrane filter. A portion of the filtrate was further diluted 10-fold with 0.01 *M* HCl for HPLC analysis.

- Heparinized human blood (1.0 ml) was mixed with water (0.9 ml) and 60% (w/v) perchloric acid (0.1 ml), vortexed, and then centrifuged at 4°C and 10,000 × *g* for 10 min. The supernatant (400 μl) was transferred to an Ultrafree-MC centrifugal filter unit (Durapore type, 0.22 μm) (Millipore) and centrifuged at 4°C and 10,000 × *g* for 1 min. A portion of the filtrate was diluted 200-fold with 0.01 *M* HCl and injected onto the HPLC column.
- Human urine was mixed with an equal volume of 6% (w/v) perchloric acid and was then filtered through the membrane filter. The filtrate was diluted 1000-fold with 0.01 *M* HCl and injected onto the HPLC column.

Evaluation of the Present HPLC Method

Fig. 2A shows the chromatogram of a 1:100 mixture of standard histidine and glutathione. The peak due to histidine was observed at 2.7 min with no interference from 100-fold excess of glutathione. The HPLC method gave a linear calibration curve ($r = 1.000$) over the range of 0.25–1000 pmol per injection (10 μl) with the coefficient of variation of 0.9% at 2 pmol ($n = 10$) and with the detection limit ($S/N = 8$) of 25 fmol.

Fig. 2B and D shows the typical chromatograms of deproteinized human serum and urine, respectively, which contain less glutathione than histidine. The high selectivity of the postcolumn detection made the chromatograms quite simple, where the peak due to histidine appeared as a sole peak. On the other hand, both glutathione and histidine were detected in human blood, which contains glutathione at a higher level than histidine (Fig. 2C).

Recoveries of the present HPLC method were tested by using a pooled human serum, blood, or urine, to which were added various amounts of histidine prior to the sample preparation. The mean recovery values were in the range of 101–104%. The values of histidine in human sera, blood, and urine, determined by the HPLC method, were 85.6 ± 15.0 μ*M* ($n = 47$, mean ± SD), 95.3 μ*M* ($n = 2$, 96.8 and 93.8 μ*M*), and 1.13 ± 0.48 mmol/mg of creatinine ($n = 10$, mean ± S.D.), respectively, which were in good agreement with their reported values. The coefficients of the day-to-day variation obtained with a pooled human serum, blood, or urine were below 1.0%.

CONCLUSIONS

Because of the high selectivity and sensitivity of the postcolumn fluorescence detection of histidine with OPA, the present HPLC method is applicable to a specific and rapid assay of histidine in human serum, blood, and urine after simple pretreatment. A recent paper demonstrated that the postcolumn detection with OPA was applicable to the simultaneous assays of histidine and its major metabolites (*cis*- and *trans*-urocanic acids) in human stratum corneum.[4] The postcolumn detection system was also applicable to the flow injection analysis (FIA) method for the assay of histidine in serum and urine. The FIA method enabled us to determine histidine in blood after pretreatment of the sample with *N*-ethylmaleimide (masking reagent of glutathione).[5] These methods are useful in the diagnosis of histidinanemia, one of hereditary metabolic disorders characterized by a virtual deficiency of histidine ammonia-lyase.

HPLC Column Maintenance

Sarah S. Chen
Analytical Science, GlaxoSmithKline, King of Prussia, Pennsylvania, U.S.A.

COLUMN CONFIGURATION

The high-performance liquid chromatography (HPLC) column usually consists of a stainless steel tubing packed with porous particles for separation. These particles are sealed in the tubing by HPLC column end fittings at each end. Porous frits close the ends of columns and retain the packing particles. Typically, 2 μm and 0.5 μm pore size stainless steel frits are used for 5 and 3 μm particles, respectively.[1] Many problems arising from stainless steel columns can be traced to the inlet stainless steel frit, which has a higher surface area than the column walls and can lead to sample adsorption. High backpressure, poor peak shapes, and low sample yields are indications of possible frit problems.

COLUMN PACKING MATERIALS

Silica-based packings are the most popular HPLC column because of their favorable physical and chemical properties.[2,3] The silica particles have high mechanical strength, narrow pore size, and particle size distributions. The surface of silica can be chemically modified with a large variety of bonded molecules having various functionalities. Silica-based packings are compatible with water and all organic solvents, and exhibit no swelling with change in solvents, in contrast to most polymer-based stationary phases.

Columns packed with porous, polymeric particles, such as divinylbenzene-cross-linked polystyrene, substituted methacrylates, and polyvinyl alcohols can also be used for HPLC method development,[4] as can modified alumina and zirconia stationary phases.[5,6]

COLUMN MAINTENANCE

Proper column maintenance is very important to ensure optimal performance and prolonged column lifetimes. There are common procedures that apply to all columns, e.g., avoiding mechanical or thermal shock. And, there are procedures that are column-specific, such as avoiding chloride-containing mobile phases to prevent "halide cracking" if the column tubing and frits are made of stainless steel (especially at low pH). Nonetheless, columns made with stainless steel tubing and packed with silica-based stationary phases are the most commonly used in HPLC. Thus, problems associated with these columns and how to prevent such problems by proper column maintenance will be discussed here.

How to Ensure Retention and Resolution Reproducibility with HPLC Columns

Reproducible retention and resolution are very important when developing routine methods. Changes in resolution and retention can be a function of the column quality, its mode of operation, instrumental effects, or variations in separation conditions. The first important step in maintaining retention reproducibility is through selection of a good quality column with a less acidic and highly purified support. Choosing a favorable mobile-phase condition (pH, buffer type and concentration, additives, etc.) that can eliminate surface silanol interactions when separating basic compounds is also very important for column retention reproducibility. There should be minimal variation in laboratory temperature (or column temperature) for retention and resolution reproducibility. Proper laboratory instrumentation and column storage conditions cannot be neglected either.

Poor retention reproducibility and tailing peaks often occur in poorly buffered mobile phases, owing to an inappropriately selected buffer, too low a buffer concentration, or a pH out of the effective range of a buffer. Increasing buffer concentration can minimize some of the problems. However, the buffer concentration must not be too high; otherwise, the buffer may not be miscible with the organic portion of the mobile phase. Other factors, such as tailing peaks, high backpressure, or loss of stationary phase will also result in poor retention reproducibility and will be discussed later.

How to Avoid Band Tailing

Band tailing leads inferior separations and reduced precision. Thus, conditions resulting in tailing or asymmetrical peaks should be avoided. Peak asymmetry or band tailing can arise from several sources: plugged column frits, void in the column, buildup of "garbage" on the column inlet, sample overload, solvent mismatch with sample, chemical or secondary interaction (many times silanol effects),

contaminating heavy metals, and excess void volume in the HPLC system.

Tailing peaks are common with heavily used columns. During use, columns can develop severe band tailing or even split peaks for a single component. Such effects usually arise from a void in the inlet of the column and/or a dirty or partially plugged inlet frit. The cause of the void can be either poorly packed columns that settle during use or dissolution of silica packing at high pH. Excessive system backpressure or pressure surges caused by poorly operating pumps or sample injection valves can also cause voiding. Voids can be eliminated by the addition of new packing material at the inlet end of the column. This can be done by carefully removing the end fitting from the column inlet. Packing material is then added in a slurry form to the void space. For the best results, packing material of the same type should be used. Old frits should be replaced with new ones of the same type before the end fitting is put back onto the column inlet. However, sometimes it is difficult to achieve the same column efficiency after such procedures.

The presence of strongly retained materials in "real-world" samples can result in peaks that are eluted long after the normal run time is over. These peaks can cause three kinds of problems in later runs. If the peaks are large and well behaved, they can show up in a subsequent run as very broad peaks. If the peaks are very small, they can elute under a peak of interest and cause distortion. It is also possible that peaks eluted late in a run can be small enough or so strongly retained that they appear only as a baseline bump. The development of broader tailing peaks during use may also indicate the buildup of strongly retained sample components (garbage) on the column. Purging the column with a strong solvent may eliminate this buildup. For reversed-phase columns, a 20-column-volume purge (about 50 ml for a 250 × 4.6 mm I.D. column) with 100% acetonitrile is often adequate. In case a stronger solvent is needed, a mixture of 96% dichloromethane and 4% methanol with 0.1% ammonium hydroxide is often effective. Since dichloromethane is not miscible with aqueous mobile phases, it is necessary to flush the reversed-phase column with acetonitrile prior to and after the use of dichloromethane. Methanol is used for normal-phase columns. Sometimes, it may be sufficient to flush the column once a day. If strongly retained materials are known to exist in the sample, it is a good idea to flush the column with a strong solvent at the end of each run sequence so that any strongly retained materials are flushed out before the next sample is analyzed.

How to Avoid High Backpressure

High backpressure is one of the most commonly encountered problems when performing HPLC analysis. Normal column backpressure is observed after a new column has been installed and equilibrated with the mobile phase. Unfortunately, this pressure often will increase with time of use because of particles collecting on the column inlet or outlet frit. These particles can be sample impurities, mobile-phase contaminants, or materials from the injector or autosampler rotor seal. Unfavorable buffer conditions, such as high pH, can dissolve silica particles. After the breakdown, small particles can clog the frit at the outlet of the column. The presence of small particles in the system can result in increased backpressure, split peaks, tailing, and eventually over-pressure shutdown. Most times, plugged frits can be eliminated by back flushing the column with a strong solvent. If this does not work, the plugged inlet frit can be replaced with a new frit without disturbing the packing. When replacing the inlet frit, additional packing material may be needed if a void is noticed at the column inlet. To reduce backpressure problems, samples should be cleaned before being injected. Sample treatment may include filtering the samples to remove particulates or using solid-phase extraction techniques to remove highly retained sample or matrix components. Only HPLC grade or superior solvents should be used for the mobile phase, and buffer solutions should be filtered and prefilters should be installed at the buffer reservoir. Rotor seals should be changed on a routine basis. Along with these preventative measures, it is advisable to use column prefilters, such as a guard column protection systems. Particles then build up on the inexpensive, replaceable frit in the prefilter, instead of the permanent frit at the head of the column. To choose a guard column for HPLC, it is best to choose one with the same type of stationary phase to match the analytical column. The length of a guard cartridge is usually 1 or 2 cm, with typical diameters ranging from 2.0 to 4.6 mm.

How to Prevent Loss of Stationary Phases

Column lifetime can be reduced significantly by loss of stationary phases during separations. Stationary/mobile phase combinations that lead to a rapid loss of bonded phase should be avoided. Column manufacturer's recommendations should be followed when using the column for separations. Commonly, reversed-phase columns with short-chain silane groups are the least stable, since the silane groups can be easily hydrolyzed with aggressive mobile phases (e.g., pH <2.0). Reversed-phase columns with longer alkyl groups, such as C_8 or C_{18} (Fig. 1), are usually considered relatively stable because of the inaccessibility of the surface Si–O–R. Polymeric C_8 and C_{18} are considered to be more stable than their monomeric counterparts. However, over long periods at very low or high pH, these columns can also lose bonded molecules. Use of sterically protected silane stationary phases will provide additional stability in aggressive low-pH environments.

The stability of the bonded organic ligand on a reversed-phase column depends on the type and acidity

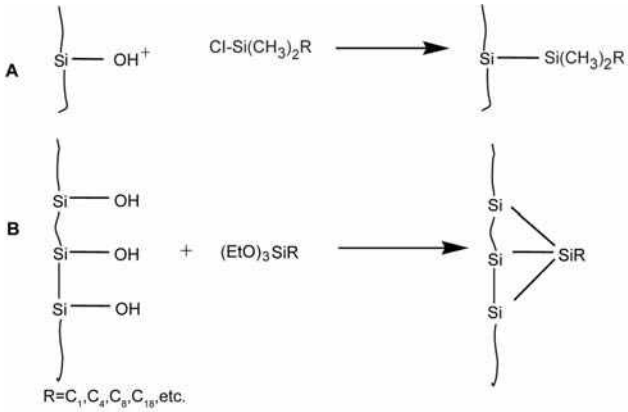

Fig. 1 Schematic diagram of monomeric (A) and polymeric (B) stationary phases for reversed-phase HPLC.

of the silica used as the support. Packings made with fully hydroxylated silicas with a homogeneous distribution of silanol groups show superior stability. Higher bonded-phase stability, apparently, can occur with columns made with highly purified silica supports having a lower surface acidity.

Loss of stationary phase from silica-based columns is accelerated at higher temperatures. Temperatures above ~40°C should be used with caution when operating at intermediate or high pH with phosphate buffers. Operation at pH < 3 and elevated temperatures can degrade the bonded stationary phase more rapidly and cause retention reproducibility problems. However, there are specially "end-capped" stationary phases available from several of column manufacturers that can withstand higher temperature with less hydrolysis.

Avoid using 100% aqueous mobile phase on reversed-phase columns

Unless specified by the manufacturer, 100% aqueous mobile phase should be avoided with a reversed-phase column such as C_{18} or C_8. Most reversed-phase columns exhibit decreased and poorly reproducible retention when operated with more than 98% aqueous conditions. This problem is explained as being the result of ligand collapse or incomplete wetting. When a C_{18} column is washed with water, the bonded phases are collapsed or incompletely wetted.[7] Subsequent flushing with mobile phase removes the wash solvent, but the stationary phase remains in the collapsed configuration, which causes a change in retention and selectivity. Therefore, it is advised that washing a reversed-phase column with water should be avoided. Furthermore, if the organic solvent content of a mobile phase is too low, the bonded material will tend to collapse onto itself to a low-energy conformation. This collapse/incomplete wetting could lead to abnormal chromatographic behavior and generally undesirable results. To avoid this phenomenon, scientists have used embedded polar phases, including amide or carbamate groups,[8–11] which presumably do not undergo phase collapse in 100% water and can withstand mobile phase with high aqueous content. If 100% aqueous mobile phase is needed for reversed-phase separation, columns with embedded polar groups should be used.

Other Factors in Column Maintenance

Storing a column in 100% organic solvent, such as acetonitrile, best preserves the performance and lifetime of bonded-phase columns. Storage with buffered solutions (particularly those containing high concentrations of water and alcohols) should be avoided. When buffers are used, columns should be flushed with 15–20 column volumes of the same aqueous/organic mobile phase without buffer before converting to 100% organic for storage. Columns should be capped tightly during storage, to prevent the packed bed from drying out. Bacterial growth often occurs in buffers and aqueous mobile phases that are prepared and stored at ambient temperature for more than a day. Particulates from this source can plug the column inlet and reduce column life significantly. As a result, mobile phases that are free of organic solvents should be discarded at the end of each day. Alternatively, 20% of organic modifier in the mobile phase retards bacterial growth. The organic modifier also assists in the mobile phase degassing process.

CONCLUSION

In general, mechanical and thermal shock of the column should be avoided to prevent disturbing column bed. Pressure surge in the system should also be avoided. Choosing a suitable buffer system is very critical to maintaining retention and resolution reproducibility, thus preventing the loss of stationary phase. Samples containing strongly retained components and particulates should be filtered before injection. The use of guard columns can reduce the "garbage" build-up at a column inlet and reduce the risk of high backpressure. It is good practice to flush the column frequently with a strong solvent after heavy use, and store in proper solvent.

HPLC Instrumentation: Troubleshooting

Ioannis N. Papadoyannis
Victoria F. Samanidou
Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece

INTRODUCTION

Despite the advances in technology and instrumentation, problems still arise when practicing high-performance liquid chromatography (HPLC), which cause headaches to chromatographers. During several stages of analysis, such as method development or routine operation, a variety of separation artifacts may be noticed. Pressure abnormalities, sample recovery, poor reproducibility, loss of resolution, instability, leaks, etc. are common problems.

General problems can be detected by smell, sight, or sound, although major symptoms in the liquid chromatography (LC) system show up as changes in the chromatogram, such as irregular peak shapes, extra peaks, negative peaks, varying retention times, and many others. It is well known that, if a picture is worth a thousand words, then a chromatogram, to a chromatographer, is equally valuable. Any chromatographer who has injected many samples into an LC system has occasionally confronted more than one of the abovementioned problems. Some problems can be corrected by changes in the equipment, whereas others require modification of the assay procedure. However, many of the common LC problems can be prevented with routine preventive maintenance.

Guides for troubleshooting HPLC instrumentation provide analysts and laboratory technicians with a readily available, very useful aid for solving operational problems of equipment and techniques. In order that the chromatographer effectively solves an arising problem in HPLC, he/she should be aware of the role of operating parameters, as these are indicators of system performance. Step-by-step troubleshooting protocols for each system component should be followed to isolate the problem and its cause.

OVERVIEW

This entry covers problem identification and procedures for solving them, as well as practices to maintain HPLC systems in good operating condition. It also guides users of HPLC equipment to investigate the source of a malfunction through each system component, from sample preparation to detection and integration.

PROBLEMS: CAUSES AND SOLUTIONS

In an HPLC system, problems can arise from many sources. Malfunction can be allocated to various points. Chromatographers should use not only their experience to locate problems but also all their senses (obviously, except taste) to identify LC problems. For example, a leak can be noticed by smell before it is actually seen. A strange noise indicates some kind of malfunction and a "hot" smell indicates an overheating module. Most problems, however, are identified by sight, and they can mainly be observed as changes in the chromatogram. As soon as the problem has been defined, actions should be taken to correct the malfunctioning component. The incident should be recorded, in a log book kept for this purpose, to help with further failure problems at a later time.

The HPLC user should know or learn what to look for and what to do to prevent HPLC problems and, finally, what can and should be done before calling a service technician. User's manuals, manufacturer's advice, books, articles in scientific journals, computer programs, and network sites can be used as resources for troubleshooting. A general rule is that one can know that a problem exists only when one knows how the system operates when it is working well. This means that keeping detailed records of system performance (log book) is very helpful.

Dolan (refer to "Bibliography") has very effectually set forth five rules of thumb for HPLC troubleshooting.

1. Do not change more than one thing at a time.
2. A problem is considered as problem when it occurs more than once.
3. A questionable system component should be substituted/replaced with one that is known to be working properly. Known good parts should be put back into service while all failed parts should be thrown away.
4. An experienced chromatographer should try to anticipate what will fail next.
5. Good records of maintenance and troubleshooting actions should be kept.

In HPLC instrumentation troubleshooting, problems can be classified as follows. Major HPLC problems are discussed under this paragraph, while an extended

summary of problem causes and remedy actions are tabulated in the respective tables.

Problems with the Chromatogram

Peak shape

Broad peaks, ghost peaks, pseudo peaks, negative peaks, peak doubling, peak fronting, peak tailing, spikes, no peaks. The major causes and their solutions are tabulated in Table 1.

Variable retention times

Retention time inconsistency (changing, increasing, decreasing), change in separation (loss of resolution). Table 2 summarizes their causes and solutions.

Baseline

Short-term noise, long-term noise, and drift. The causes of the baseline problems and their remedies are discussed in Table 3.

Pressure abnormalities

These include increased pressure, decreased pressure, unstable/fluctuating pressure, and high backpressure. Table 4 lists the major causes and their solutions.

Leaks

Leaks at various points, such as the column, fittings, the detector, the injection valve, or the pump. Table 5 summarizes their causes and solutions.

Change in quantitation

Including imprecision, change in selectivity, change in peak height–lack of sensitivity, poor sample recovery. Table 6 summarizes their causes and solutions.

Fig. 1 illustrates some of the changes that appear in the chromatogram as a result of the various problems.

Changes in the Chromatogram

Baseline

Baselines in chromatograms are not always smooth. On the contrary, a baseline may have spikes, noise, and other disturbances, indicating existing problems. Indeed, by magnifying the baseline, chromatographers can obtain information to recognize the problem and correct it. For example, trace contaminants in water, buffer, and reagents may cause peaks when using gradient elution.

Very often baseline problems are related to detector problems. Many detectors are available for HPLC systems. The most common are fixed and variable wavelength ultraviolet spectrophotometers, refractive index, and conductivity detectors. Electrochemical and fluorescence detectors are less frequently used, as they are more selective. Detector problems fall into two categories: electrical and mechanical/optical. The instrument manufacturer should correct electrical problems. Mechanical or optical problems can usually be traced to the flow cell; however, improvements in detector cell technology have made them more durable and easier to use. Detector-related problems include leaks, air bubbles, and cell contamination. These usually produce spikes or baseline noise on the chromatograms or decreased sensitivity. Some cells, especially those used in refractive index detectors, are sensitive to flow and pressure variations. Flow rates or backpressures that exceed the manufacturer's recommendation will break the cell window. Old or defective source lamps, as well as incorrect detector rise time, gain, or attenuation settings will reduce sensitivity and peak height. Faulty or reversed cable connections can also be the source of problems.

Electronic noise from fluorescent lights and other common sources is often called 60-cycle noise because it coincides with the 60-Hz frequency of the alternating current servicing the laboratory.

To isolate the origin of the problem due to the detector, the chromatographer may perform the "dry cell test": by disconnecting the detector from the column and then blowing the cell dry with dry nitrogen. Under these conditions no drift should be observed.

Ghost peaks

These peaks appear in a chromatogram due to contamination of mobile phase, injector, column, or strongly retained compounds from previous sample injections. When an autosampler is used, the problem is often referred to as "carryover." Flushing the injector and the column with strong solvent will remove interfering or late eluting compounds. To correct carryover problems, the chromatographer should change injection size, check wash solvent, increase wash solvent volume, adjust its pH value, use a portion of organic solvent, change a needle seal, injection loop, and check fitting assembly.

Ghost peaks in gradient runs can be avoided by increasing the equilibration time between analyses.

No peaks and negative peaks

If no peaks are observed, then the chromatographer should check the detector, the connections, the flow (leaks, pump function, air bubbles), the sample (for its stability), and

Table 1 Peak shape problems and remedies.

Peak shape
Fronting
1. Column overloaded. → Decrease sample amount or dilute sample.
2. Sample solvent incompatible with mobile phase. → Adjust solvent.
3. Nonresolved peak from another component. → Improve resolution by altering mobile or stationary phase.
4. Wrong pH value of mobile phase. → Adjust pH.
5. Channeling in column. → Replace or repack column.
Tailing
1. Secondary retention effects; residual silanol interactions. → Use ion pair reagent, or competing base or acid modifier. Triethylamine for basic compounds, acetate for acidic compounds.
2. Wrong pH value of mobile phase. → Adjust pH. For basic compounds lower pH usually provides more symmetric peaks.
3. Wrong stationary phase. → Change column.
4. Void at column inlet. → Repack top of column with stationary phase.
5. Wrong injection solvent. → Dissolve sample in mobile phase.
6. Interference in sample. → Check column performance with standards. Change mobile phase or stationary phase. Check selectivity.
7. Chelating solutes—trace metals in base silica. → Use high purity silica-based column with low trace-metal content, add EDTA or chelating compound to mobile phase; use polymeric column.
8. Unswept dead volume. → Minimize number of connections; ensure injector rotor seal is tight: ensure all compression fittings are correctly scaled.
9. Silica-based column-degradation at high temperature. → Reduce temperature to less than 50°C.
Double (split) peaks
1. Column voided. → Repack top of column with stationary phase; replace column.
2. Partially blocked frit. → Clean or replace the plugged frit. Install an in-line filter between pump and injector to remove solids from mobile phase or between injector and column to filter particulates from sample.
3. If only one peak is split co-eluting interfering components. → Use sample cleanup.
4. Sample solvent incompatible with mobile phase. → Inject samples in mobile phase.
5. Blocked frit. → Replace or clean frit, install 0.5 um porosity in-line filter between pump and injector to eliminate mobile-phase contaminants or between injector and column to eliminate sample contaminants.
6. Co-elution of interfering compound from previous injection. → Use sample cleanup; adjust selectivity by changing mobile or stationary phase. Flush column with strong solvent at end of ran; end gradient at higher solvent concentration.
7. Column overloaded. Sample volume too large. → Use higher-capacity stationary phase, increase column diameter, decrease sample amount.
8. Column void or channeling. → Replace column, or, if possible, open top endfitting and clean and fill void with glass beads or same column packing; repack column.
9. Injection solvent too strong. → Use weaker injection solvent or stronger mobile phase.
Broad peaks (all)
1. Large injection volume; detector operating outside linear dynamic range. → Injection of smaller sample volume or diluted sample (1 : 10).
2. High viscosity of mobile phase. → Change mobile phase, or increase column temperature. Change to lower viscosity solvent.
3. Poor column efficiency due to column void or column contaminated/worn out. → Repack top of column; replace column.
4. Incorrect detector settings. → Check settings and adjust.
5. Low mobile phase flow rate. → Increase flow rate.
6. Tubing too long or too wide; large extra column volume. → Use right tubing, shorten path. Use low- or zero-dead-volume endfittings and connectors; use smallest possible diameter of connecting tubing (<0.10 in. i.d.); connect tubing with matched fittings.
7. Leaks between column and detector. → Check for leaks.
8. Guard column contaminated/worn out. → Replace guard column.

(Continued)

Table 1 Peak shape problems and remedies. *(Continued)*

Peak shape
9. Retention times too long. → Use gradient elution or a stronger mobile phase for isocratic elution.
10. Too large volume of detector cell. → Use smaller cell volume.
11. Slow detector time constant → Adjust time constant to match peak width.
Broad peaks (some)
1. Late eluted peak from previous run. → Flush the column with a strong eluent after each run or end gradient at a higher concentration of strong solvent.
2. High molecular weight sample. → Optimize sample clean up.
Negative peaks
1. Highly UV absorbing mobile phase. → Change detection wavelength taking into account the UV cutoff of mobile phase solvents.
2. Refractive index of mobile phase is very different from RI of sample. → Change eluent.
3. Recorder connections. → Check polarity.
Ghost peaks
1. Dirty mobile phase. → Use HPLC grade solvents.
2. Carryover. Retained compound from previous injection. → Flush column with strong solvent to remove late eluting compounds. End gradient at higher solvent concentration.
3. Contamination of injector. → Flush injector.
4. Contamination of column. → Flush column with strong solvent.
5. Unknown interferences in sample. → Use sample cleanup or prefractionation before injection.
Spikes
1. Bubbles in mobile phase. → Degas mobile phase. Sparge it with helium (3–5 psi) during use; ensure that all fittings are tight; store column tightly capped.
2. Bubbles in detector. → Use back-pressure regulator at detector outlet.
Extra column dispersion
1. Wrong tubing dimensions. → Use short, small internal diameter (narrower) tubing between injector and column and between column and detector.
2. Detector overloaded. Outside linear dynamic range. → Use a low volume detector cell.
3. Large sample volume. → Inject small sample volumes.
No peaks
1. Detector off. → Check detector.
2. No flow. Pump off. → Start pump.
3. No sample. Sample deteriorated. → Check injector. Check sample stability.
4. Wrong settings on recorder or detector. → Check attenuation, gain, and detector wavelength.
5. Flow interrupted. → Check reservoirs, loop, degassing of mobile phase, and compatibility of mobile phase components.
6. Leaks. → Check fittings and pump for leaks and pump seals.
7. Air trapped in the system. → Prime pump.

settings on the detector (e.g., wrong wavelength), or integration.

Negative peaks are due to wrong polarity of recorder, or absorbance or refractive index of mobile phase higher than that of solute.

Peak tailing and peak fronting

Peak tailing (peak asymmetry factor >1.2). This is attributed to the wrong pH value, wrong column, wrong sample solvent (mobile phase is better to be used), void volumes at

Table 2 Retention time inconsistency.

Variable retention times

1. Leaks. → Check for loose fittings, pump leaks, seals.
2. Change in mobile phase composition. → Prepare new. Ensure that gradient system is delivering correct composition. Prevent evaporation.
3. Air trapped in pump. → Prime pump. Degas mobile phase—Sparge it with helium (3–5 psi) during use.
4. Overloading. → Dilute sample.
5. Sample dissolved in a solvent that is incompatible with the mobile phase. → Dissolve sample in the mobile phase.
6. Temperature fluctuations. → Use column oven.
7. Isocratic elution: Insufficient equilibration time. → Pass 10–15 column volumes of mobile phase through column for equilibration.
8. Gradient elution: Insufficient column regeneration time. → Increase equilibrating time.

Loss of resolution

1. Leak. Pump flow problems. → Check for leaks.
2. Obstructed guard or analytical column. → Replace guard column. Reverse analytical column and flush disconnected from the detector. Change inlet frit. Replace the column.
3. Improperly prepared mobile phase; contaminated mobile phase. → Prepare fresh mobile phase. Check pump-proportioning valve for malfunction.
4. Sample overloaded. → Dilute sample and reinject.
5. Extra column dead volume. → Check system plumbing and all connections for dead volume.
6. Injector problem. → Leaking injection valve or a damaged or blocked needle has to be corrected.
7. Temperature fluctuations. → Use column oven.

Table 3 Baseline.

Baseline

Regular noise

1. Air bubbles. → Prime pump. Degas solvent. Sparge mobile phase with helium during use.
2. Pump pulsations. → Use a pulse dampener.
3. Incomplete mixing. Malfunctioning proportioning valves. → Ensure complete mixing. Clean or replace the proportioning valve; partially remix solvents.
4. Other electronic equipment on the same line. → Check electronic equipment in line. Correct as necessary.
5. Leaks. → Check pump for leaks, salt build-up. Check fittings and pump seals.
6. Continuous-detector lamp problem or dirty flow cell. → Replace UV lamp (each should last 2000 hr); clean and flush flow-cell.

Irregular noise

1. Leaks. → Check fittings, pump seals, and pump for leaks.
2. Electronics. → Locate problem. Get servicing. Isolate detector and recorder electronically. Use a voltage stabilizer for the LC system or use an independent electrical circuit for the chromatography equipment.
3. Insufficient grounding. → Establish sufficient grounding.
4. Flow cell contamination. → Clean detector cell.
5. Detector lamp failing. → Replace detector lamp.
6. Mobile phase mixer inadequate or malfunctioning. → Repair or replace the mixer or mix off-line in case of isocratic elution.
7. Air bubbles in detector. → Install backpressure regulator after detector.
8. Occasional sharp spikes—external electrical interference. → Use voltage stabilizer for LC system; use independent electrical circuit.
9. Periodic-pump pulses. → Service or replace pulse damper; purge air from pump; clean or replace check valves.
10. Random-contamination buildup. → Flush column with strong solvent; clean up sample; use HPLC grade solvent.

Drift

1. Strongly retained materials. → Flush column with strong solvent.

(Continued)

Table 3 Baseline. *(Continued)*

Baseline
2. Default mixing. → Check mixer. Check flow rate and composition.
3. Air in the detector cell. → Clean cell. Use backpressure regulator at detector outlet.
4. Contamination of mobile phase. → Flush column with strong solvent; use HPLC grade solvents; clean-up sample.
5. Fluctuation of column temperature. → Use column oven.
6. Gradient elution. A. Positive direction. Absorbance of mobile phase B. → Add UV absorbing compound to mobile phase A. Negative direction. Absorbance of mobile phase A. → Add UV absorbing compound to mobile phase B.
7. Temperature at RI detector unstable. → Control changes in room temperature. Insulate column, use column oven, cover RI detector keeping it out of air currents.
8. Mobile phase not in equilibrium with column. → Allow more time for column equilibration.

Table 4 Pressure abnormalities.

Increased pressure

1. Blocked flow lines: Pump. Injector. Tubing. → Locate obstruction, by systematic disconnection of system components. Replace or clean blocked components.
2. Obstructed column or guard column, from particulate buildup at top of column. → Replace guard column. Reverse analytical column and flush disconnected from the detector. Change inlet frit. Replace the column. Filter sample.
3. Salt precipitation. → Ensure mobile phase compatibility with buffer concentration.
4. High viscosity of mobile phase. → Use solvent of lower viscosity or increase temperature.
5. Microbial growth in the column. → Store column with at least 25% organic solvent. Add 0.02% sodium azide to aqueous mobile phases, or use a mobile phase with at least 10% organic solvent.

Decreased pressure

1. Leaks in the system: Fittings not tight. → Check all connection for leaks. Tighten or replace fittings. Replace or clean check valves.
2. Piston seal(s) worn. → Replace piston seal(s).
3. Air trapped in pump. → Prime pump.
4. Mobile phase interrupted. Insufficient flow from pump. → Check reservoirs, loop, degassing of mobile phase, and compatibility of mobile phase components.

Unstable-fluctuating pressure

1. Air bubbles in pump. → Degas mobile phase—Sparge it with helium (3–5 psi) during use. Prime pump.
2. Leaks in pump check valve or seals. → Replace or clean check valves; replace pump seals.

High backpressure

1. Plugged frit, pre-filter, guard column; plugged inlet frit. → Backflush column/cartridge. Replace frit, pre-filter, guard column; replace endfitting or frit assembly.
2. Irreversibly retained contaminants on the column head. → Column cleaning/regeneration.
3. Precipitation of buffer. → Flush with water at low flow rate.
4. Precipitation or aggregation of proteins in column, particulate matter trapped by the top and/or bottom filter build-up of lipids, DNA, or other macromolecules non-specifically bound to the column microbial contamination. → Clean column, following column instructions with appropriate solvents, change top and/or bottom filter.
5. Column blocked with irreversibly adsorbed sample. → Improve sample cleanup; use guard column; reverse-flush column with strong solvent to dissolve blockage.
6. Column particle size too small (for example, 3 μm). → Use larger particle size (for example, 5 μm).
7. Microbial growth on column. → Use at least 10% organic modifier in mobile phase; use fresh buffer daily; add 0.02% sodium azide to aqueous mobile phase: store column in at least 25% organic solvent without buffer.
8. Mobile phase viscosity too high. → Use lower viscosity solvents or higher temperature. Replace frit or guard column.

(Continued)

Table 4 Pressure abnormalities. *(Continued)*

9.	Plugged frit in in-line filter or guard column; plugged inlet frit. → Replace end-fitting or frit assembly.
10.	Polymeric columns—solvent change causes swelling of packing. → Use correct solvent with column; change to proper solvent composition! Consult manufacturer's solvent-compatibility chart; use a column with a higher percentage of cross-linking.
11.	Salt precipitation (especially in reversed-phase chromatography with high concentration of organic solvent in mobile phase). → Ensure mobile phase compatibility with buffer concentration; decrease ionic strength and water-organic solvent ratio; premix mobile phase.
12.	When injector disconnected from column-blockage in injector. → Clean injector or replace rotor.

column inlet (the column may need repacking), as well as to active sites within the column which can be solved with the use of a competing basic or acidic modifier.

If only some of the peaks tail, secondary retention effects, such as residual silanol interactions, may take place. Another possibility is that a small peak is eluting on the tail of a larger peak. If all peaks tail, this may be due to a bad column or build up of contamination on the column inlet frit.

Peak fronting (peak asymmetry factor <0.9). This indicates that a small band is eluting before a large band, a wrong pH value of the mobile phase is used, an

Table 5 Leaks.

Leaks
Injector leaks
Rotor seal failure → Replace rotor seal.
Blocked loop → Clean or replace loop.
Loose injection-port seal → Tighten.
Waste line siphoning → Keep waste line above surface waste.
Waste line blockage → Replace waste line.
Column leaks.
Loose endfitting → Tighten endfitting.
Improper frit thickness → Use proper frit.
Detector leaks
Cell gasket failure → Prevent excessive backpressure; replace gasket.
Cracked cell window → Replace window.
Leaky fittings → Tighten or replace.
Blocked waste line → Replace waste line.
Leaky fittings
Loose fitting → Tighten.
Stripped fitting → Replace.
Overtightened fitting → Loosen and retighten; replace.
Dirty fitting → Disassemble and clean; replace.
Mismatched parts → Use parts from the same brand so that they match.
Leaks at pump
Loose check valves or fittings → Tighten.
Mixer seal failure → Replace mixer seal; replace mixer.
Pump seal failure → Repair or replace.
Pressure transducer failure → Repair or replace.
Pulse damper failure → Replace pulse damper.
Proportioning valve failure → Check diaphragms, replace if leaky; check for fitting damage, replace.
Purge valve → Tighten valve; replace purge valve.

Table 6 Imprecision.

Change in selectivity

1. Not enough sample is injected. → Increase amount of injected sample.
2. Sample loop of injector is underfilled. → Overfill loop with sample.
3. Sample is lost during sample preparation. → Optimize sample preparation.
4. Autosampler line is blocked. → Clean blockage.
5. Detector attenuation is set too high. → Reduce detector attenuation.
6. Peaks are outside detector's linear range. → Dilute or enrich sample to reach linear range of detector.
7. Column is worn out. → Replace column.
8. Column temperature is altered. → Use column oven to maintain constant temperature.

Change in height–lack of sensitivity

1. Sample deterioration. → Use fresh sample.
2. Leak. → Check for pump leaks and fittings.
3. Nonreproducible sample volume. → Ensure loop is completely filled. Check autosampler. Check flow and clear any blockages.
4. Low detector response. → Check detector settings and operating conditions.
5. Detector attenuation is set too high. → Reduce detector attenuation.
6. Sample is lost during preparation. → Optimize sample preparation. Use internal standard during sample preparation.
7. Peaks are outside the linear range of the detector. → Dilute of enrich the sample until concentration is within the linear range of the detector.
8. First few sample injections—sample adsorption in injector sample loop or column. → Condition loop and column with concentrated sample.
9. Injector sample loop is underfilled. → Overfill loop with sample.
10. Not enough sample is injected. → Increase amount of sample injected.
11. Peaks are outside detector's linear range. → Dilute or concentrate sample to bring detector response into linear range.

Imprecision

1. Operator dependence during sample processing and clean-up. → Check all steps for errors.
2. Sample injection. → Check autosampler; fill loop completely.
3. Detection. → Clean flow-cell. Improve signal-to-noise ratio.
4. Separation. → Improve resolution.
5. Data processing and calibration. → Use internal standard. Calibrate frequently.

Poor sample recovery

1. Absorption or adsorption of proteins. → Reduce non-specific interactions by changing HPLC mode; add protein-solubilizing agent, strong acid or base (with polymeric columns only), or detergent such as SDS to mobile phase.
2. Adsorption or chemisorption on column packing or on different hardware components. → Increase mobile phase strength; add competing base (for basic compounds) or use base-deactivated packing; ensure no reactive groups are present; use inert tubing and flow-path components, e.g., PEEK.
3. Irreversible adsorption on active-sites (less than 90% yield). → For basic compounds use end-capped, base-deactivated, sterically protected, high coverage, or polymeric reversed-phase. → For acidic compounds use endcapped or polymeric packing; acidify mobile phase.

overloaded column, a void volume at the inlet, or that the sample solvent is incompatible with the mobile phase.

Double peaks, rounded peaks, and broad peaks

A void volume in the column, or a partially blocked frit can possibly cause double or split peaks. In case that only one peak is a doublet, then co-eluting compounds may be present.

Rounded peaks are attributed to high concentrations (the detector response being outside the linear dynamic range), wrong sample solvent, or too high a setting of the detector or integrator time constant.

Problem No. 1: No Peaks/Very Small Peaks

Normal

794-0747

1. Detector lamp off.	1. Tum lamp on.
2. Loose/broken wire between detector and integrator or recorder.	2. Check electrical connections and cables.
3. No mobile-phase flow.	3. See “No Flow” (Problem No. 2).
4. No sample/deteriorated sample/wrong sample.	4. Be sure automatic sampler vials have sufficient liquid and no air bubbles in the sample. Evaluate system performance with fresh standard to confirm sample as source of problem.
5. Settings too high on detector or recorder.	5. Check attenuation or gain settings. Check lamp status. Auto-zero if necessary.

Problem

794-0748

Problem

794-0749

Problem No. 2: No Flow

Normal

794-0747

1. Pump off.	1. Start pump.
2. Flow interrupted/obstructed.	2. Check mobile-phase level in reservoir(s). Check flow throughout system. Examine sample loop for obstruction or air lock. Make sure mobile phase components are miscible and mobile phase is properly degassed.
3. Leak.	3. Check system for loose fittings. Check pump for leaks, salt buildup, unusual noises. Change pump seals if necessary.
4. Air trapped in pump head. (Revealed by pressure fluctuations.)	4. Disconnect tubing at guard column (if present) or analytical column inlet. Check for flow. Purge pump at high flow rate (e.g., 5–10 ml/min), prime system if necessary. (Prime each pump head separately.) If system has check valve, loosen valve to allow air to escape. If problem persists, flush system with 100% methanol or isopropanol. If problem still persists, contact system manufacturer.

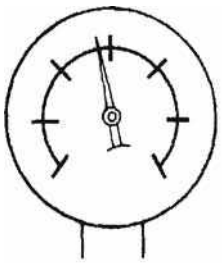
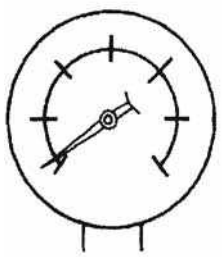
Problem No. 3: No Pressure/Pressure Lower Than Usual

Normal



794-0750

Problem

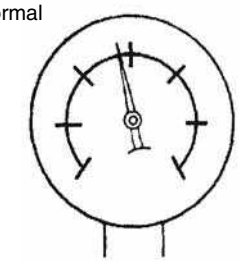


794-0751

1. Leak.	1. Check system for loose fittings. Check pump for leaks, salt buildup, unusual noises. Change pump seals if necessary.
2. Mobile-phase flow interrupted/ obstructed.	2. Check mobile phase level in reservoir(s). Check flow throughout system. Examine sample loop for obstruction or air lock. Make sure mobile phase components are miscible and mobile phase is properly degassed.
3. Ait trapped in pump head. (Revealed by pressure fluctuations.)	3. Disconnect tubing at guard column (if present) or analytical column inlet. Check for flow. Purge pump at high flow rate (e.g., 10 ml/min), prime system if necessary. (Prime each pump head separately.) If system has check valve, loosen valve to allow air to escape.
4. Leak at column inlet end fitting.	4. Reconnect column and pump solvent at double the flow rate. If pressure is still low, check for leaks at inlet fitting or column end fitting.
5. Air trapped elsewhere in system.	5. Disconnect guard and analytical column and purge system. Reconnect column(s). If problem persists, flush system with 100% methanol or isopropanol.
6. Worn pump seal causing leaks around pump head.	6. Replace seal. If problem persists, replace piston and seal.
7. Faulty check valve.	7. Rebuild or replace valve.
8. Faulty pump seals.	8. Replace seals.

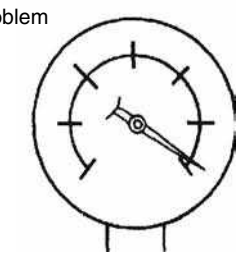
Problem No. 4: Pressure Higher Than Usual

Normal



794-0750

Problem

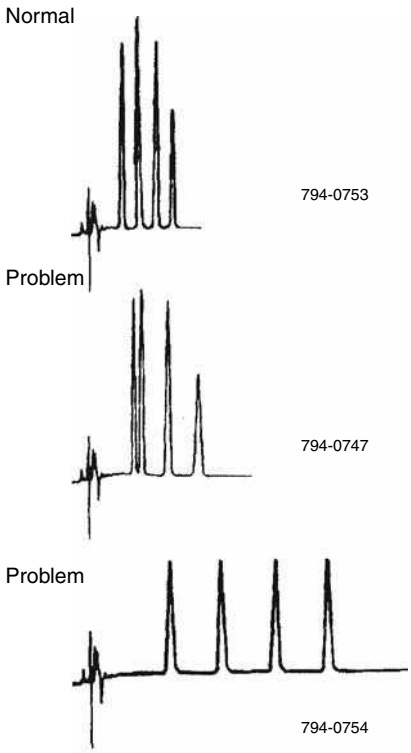


794-0752

1. Problem in pump, injector, in-line filter, or tubing.	1. Remove guard column and analytical column from system. Replace with unions and 0.010˝ I.D. or larger tubing to reconnect injector to detector. Run pump at 2–5 ml/min. If pressure is minimal, see Cause 2. If not, isolate cause by systematically eliminating system components, starting with detector, then in-line filter, and working back to pump. Replace filter in pump if present.
2. Obstructed guard column or analytical column.	2. Remove guard column (if present) and check pressure. Replace guard column if necessary. If analytical column is obstructed, reverse and flush the column, while disconnected from the detector (page 14). If problem persists, column may be clogged with strongly retained contaminants. Use appropriate restoration procedure (Table 2, page 14). If problem still persists, change inlet frit (page 16) or replace column.

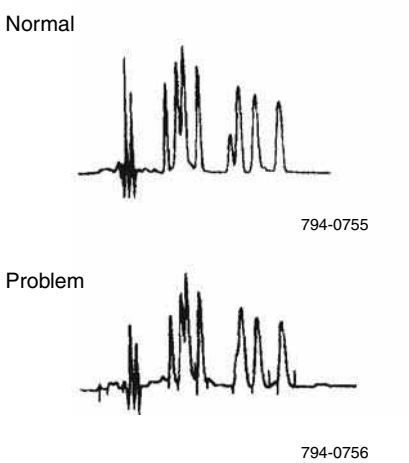
Fig. 1 (*Continued*)

Problem No. 5: Variable Retention Times



1. Leak.	1. Check system for loose fittings. Check pump for leaks, salt buildup, unusual noises. Change pump seals if necessary.
2. Change in mobile-phase composition. (Small changes can lead to large changes in retention times.)	2. Check make-up of mobile phase. If mobile phase is machine mixed using proportioning values, hand mix and supply from one reservoir.
3. Air trapped in pump. (Retention times increase and decrease at random times.)	3. Purge air from pump head or check valves. Change pump seals if necessary. Be sure mobile phase is degassed.
4. Column temperature fluctuations (especially evident in ion-exchange systems).	4. Use reliable column oven. (Note: higher column temperatures increase column efficiency. For optimum results, heat eluant before introducing it onto column.)
5. Column overloading. (Retention times usually decrease as mass of solute injected on column exceeds column capacity.)	5. Inject smaller volume (e.g., 10 µl vs. 100 µl) or inject the same volume after 1:10 or 1:100 dilutions of sample.
6. Sample solvent incompatible with mobile phase.	6. Adjust solvent. Whenever possible, inject samples in mobile phase.
7. Column problem. (Not a common cause of erratic retention. As a column ages, retention times *gradually* decrease.)	7. Substitute new column of same type to confirm column as cause. Discard old column if restoration procedures fail (see page 14).

Problem No. 6: Loss of Resolution



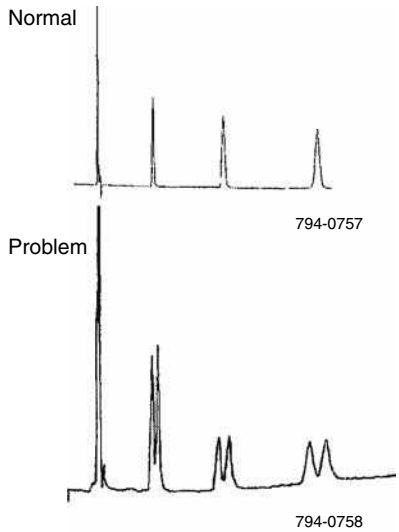
1. Mobile phase contaminated/ deteriorated (causing retention times and/or selectivity to change).	1. Prepare fresh mobile phase (page 2).
2. Obstructed guard or analytical column.	2. Remove guard column (if present) and attempt analysis. Replace guard column if necessary. If analytical column is obstructed, reverse and flush (page 14). If problem persists, column may be clogged with strongly retained contaminants. Use appropriate restoration procedure (Table 2, page 14). If problem still persists, change inlet frit (page 16) or replace column.

Fig. 1 (*Continued*)

Additionally, these peak-related problems may be attributed to column overload, too long or too wide tubing, column contamination, low flow rate, etc.

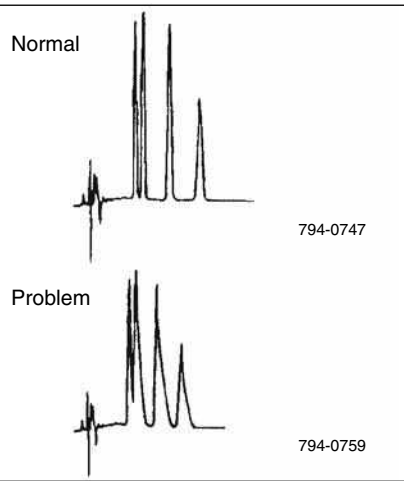
If all peaks are broadened, possible causes include a large sample volume injected, or a viscous mobile phase, or a column that has lost its efficiency, possibly due to the presence of a column void. If only some peaks are broadened, then a peak from a previous run may be eluted late, or a high molecular mass sample, e.g., a protein or a polymer is present.

Problem No. 7: Split Peaks



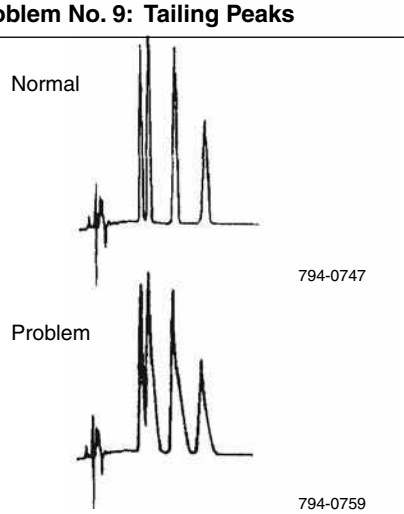
1. Contamination on guard or analytical column inlet.	1. Remove guard column (if present) and attempt analysis. Replace guard column if necessary. If analytical column is obstructed, reverse and flush (page 14). If problem persists, column may be clogged with strongly retained contaminants. Use appropriate restoration procedure (Table 2, page 14). If problem still persists, inlet frit is probably (partially) plugged. Change frit (page 16) or replace column.
2. Partially blocked frit.	2. Replace frit (see above)
3. Small (uneven) void at column inlet.	3. Repack top of column with pellicular particles of same bonded phase functionality. Continue using the column in reverse flow direction.
4. Sample solvent incompatible with mobile phase.	4. Adjust solvent. Whenever possible, inject samples in mobile phase.

Problem No. 8: Peaks Tail on Initial and Later Injections



1. Sample reacting with active sites.	1. First check column performance with standard column test mixture. If results for test mix are good, add ion pair reagent or competing base or acid modifier (page 2).
2. Wrong mobile phase pH.	2. Adjust pH. For basic compounds, lower pH usually provides more symmetric peaks.
3. Wrong column type.	3. Try another column type (e.g., deactivated column for basic compounds).
4. Small (uneven) void at column inlet.	4. See Problem No. 7.
5. Wrong injection solvent.	5. Peaks can tail when sample is injected in stronger solvent than mobile phase. Dissolve sample in mobile phase.

Problem No. 9: Tailing Peaks

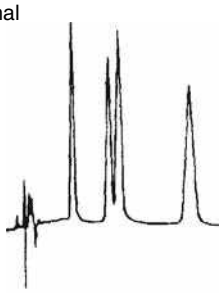


1. Guard or analytical column contaminated/worn out.	1. Remove guard column (if present) and attempt analysis. Replace guard column if necessary. If analytical column is source of problem, use appropriate restoration procedure (Table 2, page 14). If problem persists, replace column.
2. Mobile phase contaminated/ deteriorated.	2. Check make-up of mobile phase (page 2).
3. Interfering components in sample.	3. Check column performance with standards.

Fig. 1 (*Continued*)

Problem No. 10: Fronting Peaks

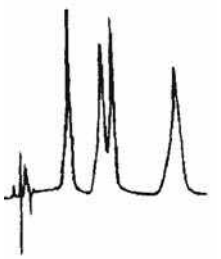
Normal



794-0760

1. Column overloaded.	1. Inject smaller volume (e.g., 10 µl vs. 100 µl). Dilute the sample 1:10 or 1:100 fold in case of mass overload.
2. Sample solvent incompatible with mobile phase.	2. Adjust solvent. Whenever possible, inject samples in mobile phase. Flush polar bonded phase column with 50 column volumes HPLC grade ethyl acetate at 2–3 times the standard flow rate, then with intermediate polarity solvent prior to analysis.
3. Shoulder or gradual baseline rise before a main peak may be another sample component.	3. Increase efficiency or change selectivity of system to improve resolution. Try another column type if necessary (e.g., switch from nonpolar C18 to polar cyano phase).

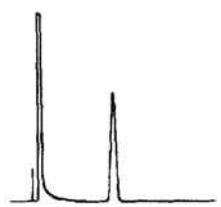
Problem



794-0761

Problem No. 11: Rounded Peaks

Normal



794-0762

1. Detector operating outside linear dynamic range.	1. Reduce sample volume and/or concentration.
2. Recorder gain set too low.	2. Adjust gain.
3. Column overloaded.	3. Inject smaller volume (e.g., 10 µl vs. 100 µl) or 1:10 or 1:100 dilution of sample.
4. Sample-column interaction.	4. Change buffer strength, pH, or mobile phase composition. If necessary, raise column temperature or change column type. (Analysis of solute structure may help predict interaction.)
5. Detector and/or recorder time constants are set too high.	5. Reduce settings to lowest values or values at which no further improvements are seen.

Problem

794-0763

Fig. 1 (*Continued*)

System peaks

A system peak is a peak that originates from the chromatographic system itself, i.e., mobile phase and column, and not from the sample. Its appearance and size are sensitive to the sample composition, but its origins are generally the mobile phase components.

When a mobile phase is introduced to a column, its components undergo distribution until equilibrium is attained. Injection of a sample different from the mobile phase causes a small equilibrium perturbation at the column head. The equilibrium of each component of the mobile phase can be disturbed and, thereby, manifested by one system peak for each mobile phase additive, using the appropriate detection conditions.

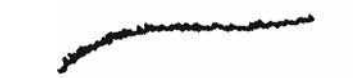
System peaks are most often recognized as a pair of peaks, one positive and the other negative, which represent enrichment and depletion zones eluted from the column. They may vary in retention time and size, depending on the sample matrix, injection volume, mobile-phase composition, and the stationary phase. Dissolving samples in the mobile phase is the best way to minimize system peak effects. System peaks are especially important in ion-pairing chromatography and in ion chromatography. In the latter, they are pH dependent and they often interfere with sample components.

Problem No. 12: Baseline Drift

Normal

794-0748

Problem



794-0764

1. Column temperature fluctuation. (Even small changes cause cyclic baseline rise and fall. Most often affects refractive index and conductivity detectors, UV detectors at high sensitivity or in indirect photometric mode.)	1. Control column and mobile-phase temperature, use heat exchanger before detector.
2. Non-homogeneous mobile phase. (Drift usually to higher absorbance, rather than cyclic pattern from temperature fluctuation.)	2. Use HPLC grade solvents, high purity salts, and additives. Degas mobile phase before use, sparge with helium during use.
3. Contaminant or air buildup in detector cell.	3. Flush cell with methanol or other strong solvent. If necessary, clean cell with 1 N HNO_3 (never with HCl and never use nitric acid with PEEK tubing or fittings.)
4. Plugged outlet line after detector, (High pressure cracks cell window, producing noisy baseline.)	4. Unplug or replace line. Refer to detector manual to replace window.
5. Mobile phase mixing problem or change in flow rate.	5. Correct composition/flow rate. To avoid problem, routinely monitor composition and flow rate.
6. Slow column equilibration, especially when changing mobile phase.	6. Flush column with intermediate strength solvent, run 10–20 column volumes of new mobile phase through column before analysis.
7. Mobile phase contaminated, deteriorated, or not prepared from high quality chemicals.	7. Check make-up of mobile phase (page 2).
8. Strongly retained materials in sample (high k') can elute as very broad peaks and appear to be a rising baseline. (Gradient analyses can aggravate problem.)	8. Use guard column. If necessary, flush column with strong solvent between injections or periodically during analysis.
9. Detector (UV) not set at absorbance maximum but at slope of curve.	9. Change wavelength to UV absorbance maximum.

Problem No. 13: Baseline Noise (regular)

Normal

794-0748

Problem

794-0765

1. Air in mobile phase, detector cell, or pump.	1. Degas mobile phase. Flush system to remove air from detector cell or pump.
2. Pump pulsations.	2. Incorporate pulse damper into system.
3. Incomplete mobile phase mixing.	3. Mix mobile phase by hand or use less viscous solvent.
4. Temperature effect (column at high temperature, detector unheated).	4. Reduce differential or add heat exchanger.
5. Other electronic equipment on same line.	5. Isolate LC, detector, recorder to determine if source of problem is external. Correct as necessary.
6. Leak.	6. Check system for loose fittings. Check pump for leaks, salt buildup, unusual noises. Change pump seals if necessary.

Fig. 1 (*Continued*)

Pressure abnormalities

Lower pressure than anticipated is observed due to leaks, insufficient flow from the pump, air bubbles, and worn pump seals. Fluctuating pressure is attributed to air trapped in the pump, or leaking pump check valves or seals. Higher pressure than anticipated is due to blocked flow lines, particulate build up at the head of the column, or buffer

Problem No. 14: Baseline Noise (irregular)

Normal

794-0748

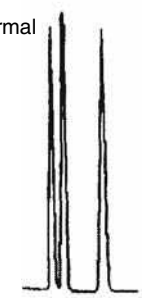
Problem

794-0766

1. Leak.	1. Check system for loose fittings. Check pump for leaks, salt buildup, unusual noises. Change pump seals if necessary.
2. Mobile phase contaminated, deteriorated, or prepared from low quality materials.	2. Check make-up of mobile phase. (page 2).
3. Detector/recorder electronics.	3. Isolate detector and recorder electronically. Refer to instruction manual to correct problem.
4. Air trapped in system.	4. Flush system with strong solvent.
5. Air bubbles in detector.	5. Purge detector. Install back pressure regulator after detector. Check the instrument manual, particularly for RI detectors (excessive backpressure can cause the flow cell to crack).
6. Detector cell contaminated. (Even small amounts of contaminants can cause noise.)	6. Clean cell.
7. Weak detector lamp.	7. Replace lamp.
8. Column-leaking silica or packing material.	8. Replace column and clean system.

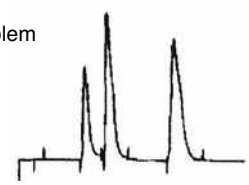
Problem No. 15: Broad Peaks

Normal



794-0767

Problem



794-0768

1. Mobile-phase composition changed.	1. Prepare new mobile phase.
2. Mobile-phase flow rate too low.	2. Adjust flow rate.
3. Leak (especially between column and detector).	3. Check system for loose fittings. Check pump for leaks, salt buildup, and unusual noises. Change pump seals if necessary.
4. Detector settings incorrect.	4. Adjust settings.
5. Extra-column effects:	
a. Column overloaded	5. a. Inject smaller volume (e.g., 10 µl vs. 100 µl) or 1:10 and 1:100 dilutions of sample.
b. Detector response time or cell volume too large.	b. Reduce response time or use smaller cell.
c. Tubing between column and detector too long or I.D. too large.	c. Use as short a piece of 0.007–0.010" I.D. tubing as practical.
d. Recorder response time too high.	d. Reduce response time.
6. Buffer concentration too low.	6. Increase concentration.
7. Guard column contaminated/worn out.	7. Replace guard column.
8. Column contaminated/worn out.	8. Replace column with new one of same type. If new column does not provide narrow peaks, flush old column (Table 2, page 14), then retest.
9. Void at column inlet.	9. Replace column or open inlet end and fill void (page 16).
10. Peak represents two or more poorly resolved compounds.	10. Change column type to improve separation.
11. Column temperature too low.	11. Increase temperature. Do not exceed 75°C unless higher temperatures are acceptable to column manufacturer.

Fig. 1 (*Continued*)

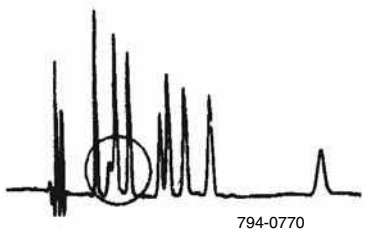
salt precipitation. To locate blockage, components should be systematically disconnected, starting from the detector-end to column-end. Once the blocked component is located, it must be either cleaned or replaced. Back flushing of column will help to remove particulates at the top of column, thus reducing pressure. If buffers are used, their compatibility with the mobile phase should be checked to avoid precipitation within the system.

Problem No. 16: Change in Peak Height (one or more peaks)

Normal

794-0769

Problem

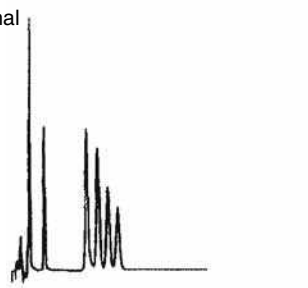


794-0770

1. One or more sample components deteriorated or column activity changed.	1. Use fresh sample or standard to confirm sample as source of problem. If some or all peaks are still smaller than expected, replace column. If new column improves analysis, try to restore the old column, following appropriate procedure (Table 2, page 14). If performance does not improve, discard old column.
2. Leak especially between injection port and column inlet. (Retention also would change.)	2. Check system for loose fittings. Check pump for leaks, salt buildup, unusual noises. Change pump seals if necessary.
3. Inconsistent sample Volume.	3. Be sure samples are consistent. For fixed volume sample loop, use 2–3 times loop volume to ensure loop is completely filled. Be sure automatic sampler vials contain sufficient sample and no air bubbles. Check syringe-type injectors for air in systems with wash or flushing step, be sure wash solution does not precipitate sample components.
4. Detector or recorder setting changed.	4. Check settings.
5. Weak detector lamp.	5. Replace lamp.
6. Contamination in detector cell.	6. Clean cell.

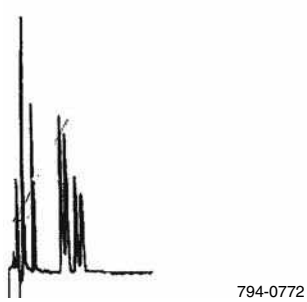
Problem No. 17: Change in Selectivity

Normal



794-0771

Problem



794-0772

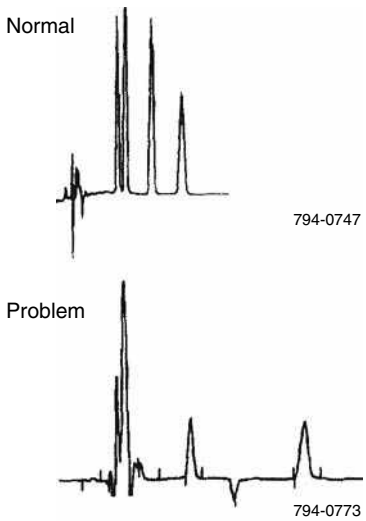
1. Increase of decrease solvent ionic strength, pH, or additive concentration (especially affects ionic solutes).	1. Check make-up of mobile phase (page 2).
2. Column changed, new column has different selectivity from that of old column.	2. Confirm identity of column packing. For reproducible analyses, use same column type. Establish whether change took place gradually. If so, bonded phase may have stripped. Column activity may have changed, or column may be contaminated.
3. Sample injected in incorrect solvent or excessive amount (100–200 µl) of strong solvent.	3. Adjust solvent. Whenever possible, inject sample in mobile phase.
4. Column temperature change.	4. Adjust temperature. If needed, use column oven to maintain constant temperature.

Fig. 1 (*Continued*)

Change on separation (loss of resolution) and changes in height

Changes in separation, implying a loss of resolution, are attributed to leaks or an obstructed column. Change in height originates from sample deterioration, leaks, non-reproducible sample volumes, and low detector response. A fresh sample should be checked, as well as detector settings and operating conditions.

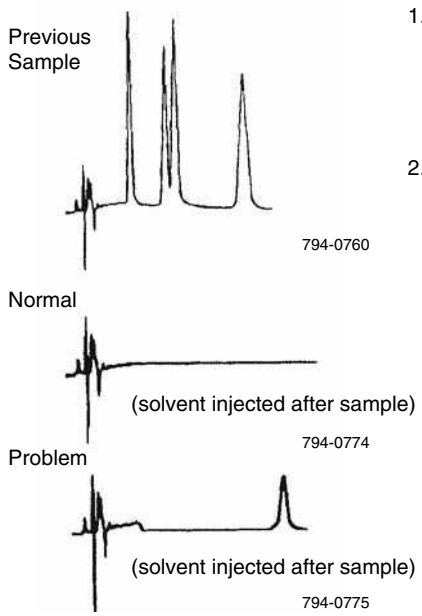
Problem No. 18: Negative Peak(s)



1. Recorder leads reversed.
2. Refractive index of solute less than that of mobile phase (RI detector).
3. Sample solvent and mobile phase differ greatly in composition (vacancy peaks).
4. Mobile phase more absorptive than sample components to UV wavelength.

1. Check polarity.
2. Use mobile phase with lower refractive index, or reverse recorder leads.
3. Adjust or change sample solvent. Dilute sample in mobile phase whenever possible.
4. a. Change polarity when using indirect UV detection, or
   b. Change UV wavelength or use mobile phase that does not adsorb chosen wavelength.

Problem No. 19: Ghost Peak



1. Contamination in injector or column.
2. Late-eluting peak (usually broad) present in sample.

1. Flush injector between analyses (a good routine practice). If necessary, run strong solvent through column to remove late eluters. Include final wash step in gradient analyses, to remove strongly retained compounds.
2. a. Check sample preparation.
   b. Include (step) gradient to quickly elute component.

Fig. 1 (*Continued*)

Leaks

Leaks can be detected visually or by smell before even a pressure decrease is noticed. They can take place in different positions in the LC system, such as the column, the pump, the injection valve, or the detector. In case of leaks at the column or fittings, a leaky fitting should be tightened or replaced. The detector seal should be replaced if there is a leak at the detector.

A worn or scratched valve rotor in the injection valve should be replaced to prevent leaks in the injection valve.

In case of pump seal failure, pump seals should be replaced, or the piston should be checked for scratches and should be replaced if necessary.

Sample introduction

Problems with the sample introduction may arise both in manual injection and during autosampling. Table 7 summarizes the problems related to sample introduction.

In the case of autosamplers, although they are considered as time saving devices, their function is associated with some

Table 7 Problems related to sample introduction.

Manual injector problems
Damaged rotor seal → Rebuild or replace valve.
Rotor too tight → Adjust rotor tension.
Valve misaligned → Adjust alignment.
Blocked loop → Replace loop.
Dirty syringe → Clean or replace syringe.
Blocked lines → Clean or replace lines.
Autoinjector problems
No air pressure → Supply proper pressure.
Rotor too tight → Adjust.
Valve misaligned → Adjust alignment.
Blockage → Clean or replace blocked portion.
Jammed mechanism → See service manual.
Faulty controller → Repair or replace controller.
Carryover problems → 1. Replace blank. 2. Change injection size. 3. Check fitting assembly and washing mechanism. 4. Use fresh wash solvent. 5. Increase wash volume. 6. Use more organic solvent in wash. 7. Adjust wash pH. 8. Change injection solvent. 9. Change needle seal, injection loop. 10. Replace valve.

common problems. For example, needle depth adjustment is very critical when there is not enough sample available; a needle blockage may occur from a septum. Another common problem related to the autosampler is carryover that causes the appearance of a peak in a blank injection following injection of a high concentration of sample. Sample stability is a figure of merit that certainly has to be evaluated to avoid imprecision and lack of sensitivity.

PREVENTIVE MAINTENANCE

Many of the problems that the chromatographer encounters can be avoided if preventive maintenance is performed in routine operation, in every step of chromatographic analysis, from sample preparation to the final step of an analysis.

Precautions regarding the use of the analytical columns, as well as the operation of each module, e.g., the pump, the detector, etc. may help keep away or postpone most of the abovementioned problems related to HPLC instrumentation.

Preventive Maintenance During Sample Preparation

As already mentioned, many problems concerning increased pressure and backpressure are due to plugged frits or system clogging from a sample matrix particulates or salt precipitation.

Preventive actions include the following:

1. Sample filtration to ensure it contains no solids.
2. Sample dissolution in the mobile phase or solvent weaker than the mobile phase.
3. Use of reduced sample volumes, whenever possible.

Mobile phase inlet filters, pre-injector and pre-column filters, saturator columns, and guard columns greatly reduce problems associated with complex separations.

Moreover, all solvents should be filtered through 0.2 μm filters, while particulates from samples can be removed by filtration through 0.45 or 0.2 μm syringe filters.

Bacterial Growth Precautions

Bacteria that grow in water reservoirs can yield by-products such as metabolites and dead bacteria, thus producing ghost peaks. Adding organic solvent to the aqueous part of the mobile phase, at a percentage of $> 20\%$ or sodium azide 0.04% will prevent bacterial growth.

Sources of Contamination

Numerous sources of contamination should be taken into account: air particles from the laboratory environment, phthalates from plastic stoppers, plasticizers from plastic containers, detergents and cleaning agents from sample containers and glassware, stabilizing agents and additives from solvents, reagents and chemicals solvent impurities, purified water, and microorganisms. The use of reagent blanks (sample matrix is water in this case) and matrix blanks may help to monitor an analysis on a day-to-day basis.

The compatibility of an organic solvent with a buffer in the mobile phase must be checked as the buffer salts can be easily precipitated when using online mixing, thus causing frit blockage, check valve malfunction, and other problems.

Good Column Practice: Column Protection

The most common problem associated with analytical columns is column deterioration. Deterioration may appear as poor peak shapes, split peaks, shoulders, loss of resolution, decreased retention times, and high backpressure. These symptoms indicate contaminants that have accumulated on the frit or column inlet, or there are voids, channels, or a depression in the packing bed. Deterioration is more evident in higher efficiency columns. For example, a column with 3 μm packing is more susceptible to plugging than one with 5 or 10 μm packing. Proper column protection and sample preparation are essential to prolong a column's life and obtain its best performance.

Filters and guard columns prevent particles and strongly retained compounds from accumulating on the analytical column. Silica particles in a saturator column dissolve in high pH mobile phases, protecting the silica-based packing in the analytical column. The useful life of these disposable products depends on mobile phase composition, sample purity, pH value within the recommended range, etc. As these devices become contaminated or plugged with particles, pressure increases and peaks broaden or split.

Keeping records of column backpressure and important chromatographic parameters [number of theoretical plates (N), peak asymmetry factor (As), retention factor (k'), resolution factor (Rs)] helps to monitor the required column performance, while storage in the appropriate organic solvent extends column lifetime. Table 8 presents the preventive actions for column protection.

Lamp Failure

Many detectors track the number of hours the lamp is ignited. Although the lamp life may vary, the detector's meter reading can be a helpful guide for troubleshooting. Lamps can sometimes operate for more than 2000 hr. To distinguish a lamp problem from air bubbles, one should stop the mobile-phase flow. A lamp problem will persist when the flow is stopped, whereas, if the problem is due to the presence of a bubble, the baseline remains steady on- or off-scale. If the bubble stops in the flow cell, it causes a dramatic baseline shift, usually off-scale.

Solvent degassing and backpressure regulators after the detector minimize bubble formation. It is a helpful practice to perform blank runs every day to provide reference data that can be consulted at a later date.

Spikes in chromatograms can come from many sources, such as aging detector lamps or bubbles in the flow cell; both

Table 8 Preventive maintenance for HPLC instrumentation.

Preventive maintenance for HPLC columns	Preventive maintenance to avoid high backpressures	General preventive maintenance
Filter solvents before use.	Use HPLC or analytical grade buffers, freshly prepared, filtered and degassed before use.	Filtering mobile phase prevents often replacing inlet frits and check valves.
Use in-line filters for all columns, and guard columns for dirty samples; pre-treat dirty samples, remove particulates.	Filter or centrifuge the sample to remove particulate matter. Turbid samples should not be injected onto column.	Degassing mobile phase prevents bubble formation.
Check samples for compatibility with mobile phase.	Set the maximum backpressure of the pumps at or slightly below the value suggested in the column instructions so that in case of increased pressure, the system will turn off before any damage occurs.	Inlet frits prevent check valve failure.
Avoid extreme column temperatures. Keep column temperature below 60°C.	Use the recommended flow rates for the column.	Rotor seal wear should not be over-tightened.
Flush column frequently/daily with strong solvent. Use stronger solvent protocol for dirty samples.	Ethanol, glycerol, high salt, urea, and cause increases in back pressure—reduce flow rate accordingly.	Sample filtration prevents injector function, frit blockage.
Keep the mobile phase pH between 3 and 7. If operating outside of this pH range use a precolumn.	When performing the separation at low temperatures, e.g., at 4°C, the recommended flow rate should be reduced by 50%.	In line filters or guard column prevent frit blockage.
Use fresh buffer solutions and aqueous mobile phases or treat them with sodium azide.	Wash the chromatography column thoroughly at the end of each separation.	Use of guard column or pre-column help avoiding void at top of column.
To prepare column for storage purge column of buffers and leave in appropriate solvent. Cap tightly.	Clean columns when needed, following the column instructions.	The use of restrictor after cell prevents bubble formation in cell.
Prevent microbial growth when storing columns by using 50–100 % organic/water mixtures or adding azide to gel filtration columns.	Maintain a log of each chromatographic run, including buffer composition, flow rate, observed back-pressure (before and after sample application), sample composition, binding, and elution conditions.	Flushing buffer from LC prevents corrosive abrasive damage.
Avoid physically mishandling columns: banging, dropping, or over-tightening fittings.	Monitor column efficiency via regular column testing (i.e., acetone tests, function tests).	Keeping spare parts in lab can reduce waiting time intervals.

can be easily corrected. External electrical noise sources, such as ovens, refrigerators, cellular telephones, and fluorescent lights, and other possible noise sources such as system electronics or from external electronic sources, and laboratory power feed may be beyond a chromatographer's control.

Having an unused spare detector lamp available makes checking the problems attributed to the lamp performance an easy task.

Preventing and Solving Common Hardware Problems

Special care can be taken to avoid high backpressure in the LC system. Preventive actions to this end, as well as general preventive maintenance practices that can generally help reduce the failure rate, are summarized in Table 8.

Preventing leaks

Leaks are a common problem in HPLC analysis. Their occurrence can be minimized by avoiding interchanging hardware and fittings from different manufacturers. Incompatible fittings can be forced to fit initially, but repeated connections may eventually leak. If interchanging is unavoidable, the appropriate adapters should be used and all connections should be checked for leaks before proceeding.

Highly concentrated salts (>0.2 *M*) and caustic mobile phases can reduce pump seal efficiency. The lifetime of injector rotor seals also depends on mobile phase conditions, e.g., operation at high pH. In some cases, prolonged use of ion pair reagents has a lubricating effect on pump pistons that may produce small leaks at the piston seal. Some seals do not perform well with certain solvents.

Instrument manufacturers' specifications should be consulted before using a pump under adverse conditions. To replace seals, refer to the maintenance section of the manufacturer's pump manual.

Unclogging the Column Frit

A clogged column frit is another common HPLC problem. To minimize this problem from the start, the use of a pre-column filter and/or guard column is recommended. To clean the clogged inlet frit, the column must be disconnected and reversed. Then it should be connected to the pump (but not to the detector), and solvent should be pumped through it at twice the standard flow rate. About 5–10 column volumes of solvent should be sufficient to remove small amounts of particulate material from the inlet frit. The performance of the cleaned column has to be evaluated by using a standard test mixture. It should be noted, however, that some columns are designated by the manufacturer as not to be used in a reverse flow mode. Of course, if the plugging prevents the column from being used anyway, then reverse flow treatment is an acceptable action.

Filling a Void/Replacing a Frit at the Column Inlet

Sometimes, neither solvent flushing nor restoration procedures restore a column's performance. If the column is proved to be the problem source, a void in the packing or a persistent obstruction on the inlet frit may exist. In this case, replacing the frit and/or topping the column with slurry of the sorbent material in a volatile solvent, e.g., acetone, to fill the void, may help.

Mobile Phase

Contamination of mobile-phase reservoirs can often become a possible source of problems such as blocked frits, irregular pump performance, extra peaks, or noise in the chromatogram. Mobile phase degassing by helium sparging, sonication, and vacuum or heating (mostly in case of electrochemical detection) prior to, or during, use prevents air bubble formation.

Manually mixed mobile phases can be adequately degassed before pumping. However, if mixing takes place in the LC equipment, solvents must be simultaneously degassed. Besides bubble formation, oxygen is the primary problem interfering with detector response. In UV detectors, oxygen can cause a significant baseline rise. In fluorescence detectors, oxygen can adversely affect sensitivity by quenching sample fluorescence. Also, oxygen-free mobile phase is required for electrochemical detectors in the reductive mode.

Degassing is not required only in some cases of normal phase LC or non-aqueous SEC due to not significantly different solubility of air in the solvents used (e.g., hexane, toluene, dichloromethane, etc.).

Another case where degassing is not necessary is when high-pressure mixing is performed, where mobile phase components are mixed after the pump, at the high pressure side of the pump, so that gas is kept dissolved in solution by the high pressure.

Keeping Accurate Records

Most problems do not occur suddenly; rather, they usually develop gradually. Accurate record keeping, then, is of paramount importance in detecting and solving many gradually developing problems. When using a new column for the first time, it should be evaluated initially and at regular intervals thereafter. By keeping a written history of column efficiency, mobile phases used, lamp current, pump performance, etc. the chromatographer can monitor a system's performance.

Records also help prevent mistakes, such as introducing water into a silica column, or precipitating buffer in the system by adding too much organic solvent. Many analysts occasionally modify their HPLC systems for a variety of reasons. Reliable records are the best way to ensure that a modification does not introduce problems. For problems relating to pumps, detectors, automatic samplers, and data systems, instrument manuals provide suitable troubleshooting guides.

Referring to the maintenance and troubleshooting sections of an instrument's manual is highly recommended. Many individuals consult manuals only after a catastrophic failure and then only when all other problem-solving approaches have been exhausted. Modern HPLC systems often have self-diagnostic capabilities that help isolate the problem area within the instrument.

CONCLUSIONS

The common problems in HPLC concern pressure (high, low, or unstable, or none), leaks, quantitation (detection problems, injection problems, sample problems or data-system problems), chromatogram (peak shape), and hardware.

Troubleshooting HPLC instrumentation guides provide a systematic approach to isolating and correcting common HPLC problems. Referring to the maintenance and troubleshooting sections of instrument manuals is strongly recommended. Modern HPLC systems often have simple self-diagnostic capabilities that help isolate the problem area within the instrument.

It is good practice to run quality control samples (samples spiked at known levels) randomly among samples of unknown assay levels.

Performing a system suitability test each day provides a good assay reference.

Preventive maintenance helps the chromatographer to reduce instrument downtime, allowing for more efficiency and cost effectiveness in the HPLC laboratory.

HPLC Instrumentation: Validation

Ioannis N. Papadoyannis
Victoria F. Samanidou
Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece

INTRODUCTION

Validation is the process of providing documented evidence that an instrument, a system, a method, a product, or a procedure performs as expected within specified design parameters and requirements so that the obtained results are reliable. Validation efforts should be broken down into separate components addressing the equipment—both the instrument and the computer controlling it—and the analytical method run on that equipment. After these have been separately verified, they should be checked together to confirm the expected performance limits of the system (system suitability testing, SST). Fig. 1 illustrates the basic validation steps with regard to computerized high-performance liquid chromatography (HPLC) equipment.

The need for validation in analytical laboratories may originate from regulations such as current Good Manufacturing Practices (cGMP), Good Laboratory Practice (GLP), and Good Clinical Practices (GCP); or quality and accreditation standards such as the International Standardization Organization (ISO) 9000 series, ISO 17025, and the European Norm (EN 45001), *United States Pharmacopoeia* (USP), Food and Drug Administration (FDA), and Environmental Protection Agency (EPA). All regulations require instruments to be calibrated, well maintained, and suitable for their intended use. However, validation of equipment and analytical methods is necessary not only because of the regulations and accreditation standards, but also as a prerequisite in terms of any *good analytical practice*.

OVERVIEW

Validation is a regular process that starts before an instrument is placed online and continues long after method development and transfer. It consists of at least three stages, each being critical to the overall description of the process:

- Phase 1. Instrument or equipment qualification, including computer qualification. Individual modules of equipment (hardware and firmware) have to be separately validated, as well as the entire system. Validation of computer systems includes the evaluation of hardware and software.
- Phase 2. Analytical method validation prior to routine use and after changing method parameters.
- Phase 3. Analytical system suitability testing, which combines instrument, computer, and method. When the equipment and a particular method have been selected and validated, the equipment for that method goes through an SST prior to, and within, sample analyses, or practically on a day-to-day basis.

Information about validation procedures concerning HPLC instrumentation and guidelines are discussed in the following sections.

EQUIPMENT VALIDATION OR QUALIFICATION

Validation of HPLC instrumentation, also called "qualification," is the procedure that ensures that the instrument is qualified; that is, that its performance complies with the method's predetermined requirements, providing reliable and valid results. Modern HPLC systems are computerized, generally consisting of analytical hardware, computer hardware, peripherals, and software.

Validation of instrument hardware includes testing according to documented specifications. If HPLC instruments consist of several modules, individual modules (modular validation), as well as the entire system (holistic validation), should be validated. However, the latter is preferred, as individual module tests should be performed as part of the diagnosis if the system fails.

The equipment used in a study should be tested on site before it is used the first time, within certain time intervals, and after repairs. It should be periodically inspected, cleaned, maintained, and calibrated according to the standard operating procedures (SOPs). Records of these activities should be maintained.

Qualification of HPLC equipment (equipment qualification, EQ) begins at the vendor's site. During this stage, the instrument and software are developed, designed, and produced in a validated environment according to GLP, cGMP, and/or ISO 9000 standards, preferably ISO 9001; ISO 9002 or 9003 are insufficient because they do not cover development.

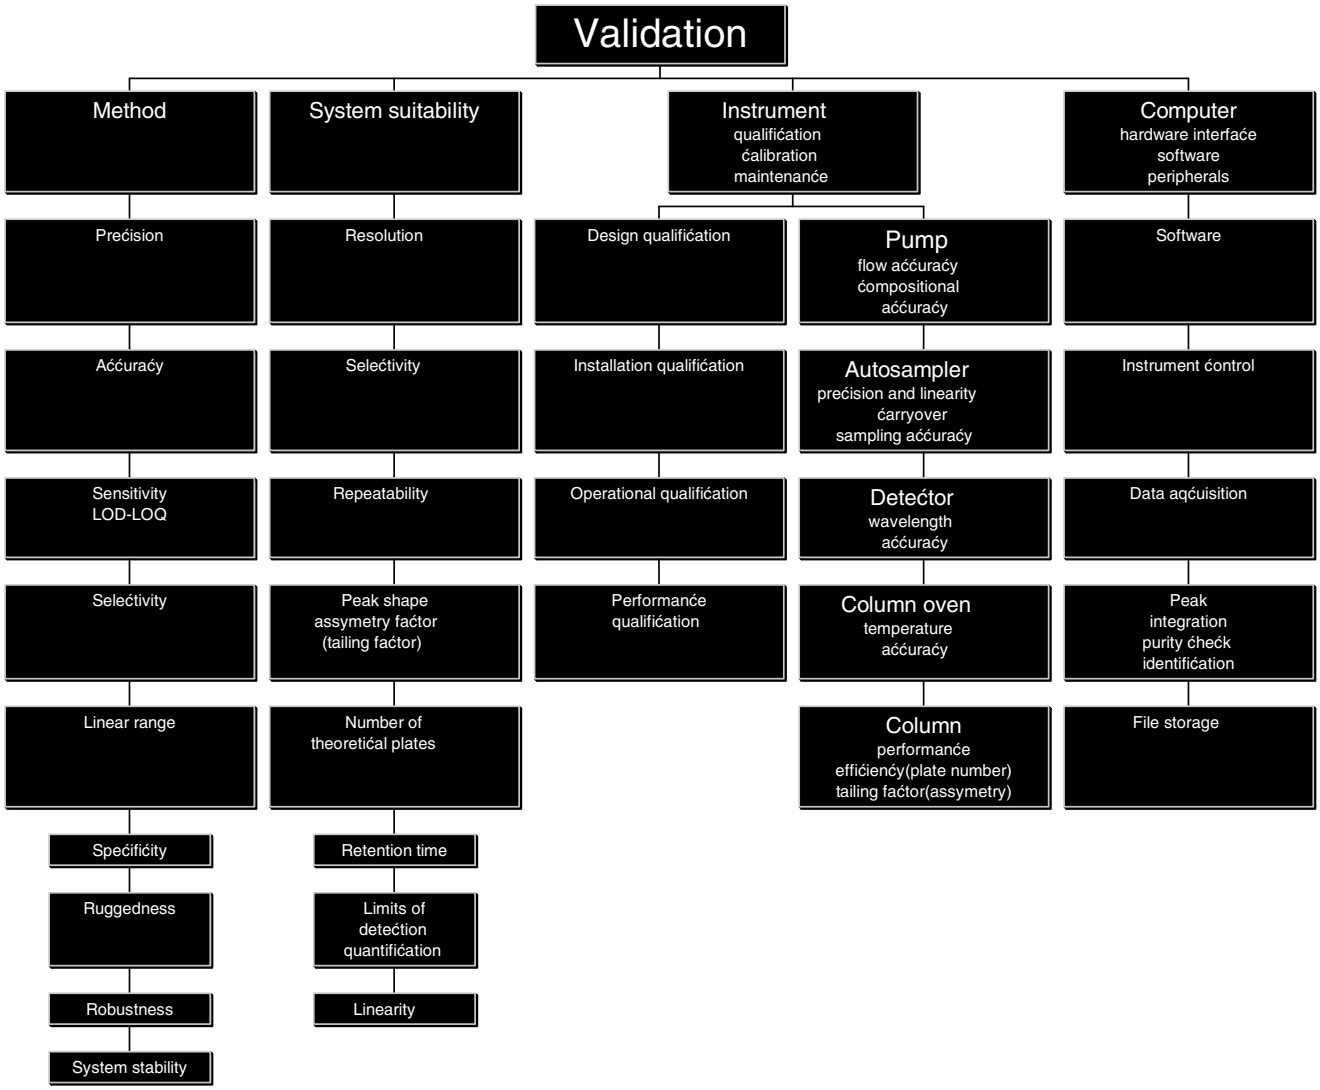

Fig. 1 Basic validation steps in an analytical laboratory.

Qualification can be subdivided into four stages: 1) design qualification (DQ); 2) installation qualification (IQ); 3) operational qualification (OQ); and 4) performance qualification (PQ).

Design Qualification (DQ)

DQ covers setting of user requirements, as well as functional and performance specifications. DQ should ensure that the instrument has all the necessary functions and performance criteria that will enable it to be successfully used for the intended application. DQ includes: 1) Description of the intended use of the equipment; 2) selection of the analysis technique, selection of the technical, environmental, and safety specifications, and final selection of the supplier and equipment; and 3) development and documentation of final functional and operational specifications.

Installation Qualification (IQ)

IQ establishes that the instrument is received as designed and specified, that it is properly installed in the selected environment, and that this environment is suitable for the operation and use of the instrument. During installation, one should: 1) Compare the equipment, as received, with the purchase order; 2) check documentation for completeness or for any damage; 3) install hardware (computer, equipment, fittings and tubings for fluid connections, columns in HPLC, power cables, and instrument control cables); 4) install software on the computer following the manufacturer's recommendation, and verify correct software installation; 5) make a backup copy of the software; 6) configure peripherals, e.g., equipment modules; 7) switch on the instrument and check for any error messages; 8) identify all hardwares and make a list with a description of each; 9) list equipment manuals and SOPs;

10) inject and qualitatively evaluate a standard; and 11) prepare an installation report describing how and by whom the instrument was installed.

Operational Qualification (OQ)

OQ, or acceptance testing, is the process of demonstrating that the whole instrument or its modules will function according to its operational specification, in the selected environment, according to previously defined functional and performance specifications ("acceptance criteria"). This procedure can be performed to the extent of the self-diagnostics routine test or to a more detailed procedure regarding flow-rate, injector precision, or wavelength accuracy. It can be carried out by the user or the vendor on behalf of the user.

Performance Qualification (PQ)

PQ is the process of testing and calibrating the instrument before and during routine use to verify system performance. This test is repeatedly executed to ensure that the entire system generates valid results and performs as intended, throughout representative or anticipated operating ranges. The criteria of PQ should also be used for revalidation later. After the instrument is placed online in the laboratory, and after a period of use, regulations require maintenance, followed by calibration and standardization. Each laboratory should have SOPs that define the period of use (usually a reasonable time interval in which the instrument properly operates). Records should be kept to track instrument maintenance.

The frequency of PQ depends on the type of instrument, on the stability of the performance parameters, on the specified acceptance criteria, and on the use of the equipment. The test frequency for PQ is much higher than for OQ. PQ is always performed under similar conditions to establish a routine sample analysis; that is, using the same column, the same analysis conditions, and the same test compounds. PQ should be performed on a daily basis or whenever the instrument is used. For a liquid chromatograph, the most important unit may be the chromatographic column or the detector's lamp condition. The test criteria and frequency should be determined during the development and validation of the analytical method. In practice, PQ can mean SST, where critical system performance characteristics are measured and compared with documented, preset limits. An example sequence for PQ includes: 1) definition of the performance criteria and test procedures; 2) selection of critical parameters: precision of the peak area/height, precision of retention times, resolution between two peaks, peak width at half height or peak tailing, limit of detection (LOD), and limit of quantitation (LOQ), wavelength accuracy of a UV/Visible detector; 3) definition of the frequency, e.g., every day, every time the system is used, before, between, and after a series of runs; 4) specification of corrective actions in case the system does not meet the criteria.

DQ should always be performed by the user, whereas IQ for large, complex, and high-cost instruments should be performed by the vendor. In some cases, warranty is lost if the user installs the system. OQ can be performed by either the user or the vendor. The decision mainly depends on the available resources at the user's site, and on the vendor's capability to offer such a service with high quality. PQ should always be performed by the user because it is very application-specific and the vendor may not be familiar with the method. As PQ should be performed on a daily basis, this practically limits this task to the user anyway. On completion of equipment qualification, detailed documentation should be available, considering qualification checklist, procedures for testing, qualification test reports with signatures and dates, PQ test procedures, and representative results.

Computer Validation/Qualification

Computer validation/qualification refers to computer hardware, peripherals, and software validation, the latter including operating software, e.g., Microsoft Windows, MS-DOS, and the application HPLC software. In the hardware, the most important unit to validate is the analog-to-digital converter (ADC) because it converts input voltage into numeric data. Software, however, is very difficult to validate because of its complex structure. For this reason, the vendor should check, validate, and document software according to Computer-Aided Software Engineering (CASE) principles. After installation, software validation can be performed with regard to the integrity of program code and data, as well as the data security, with special software packages; this can be automatically checked at power on. On the other hand, comprehensive validation of a data system is beyond the capability expected from many chromatography laboratories. The only parts of the software package that is created after installation are user-written programs (macros); they should be tested, ensuring security of data with restricted access to data and regular backup copies, documenting every change made either on the data acquisition system computer or software. Computer systems should be validated during, and at the end of, the development process and after software updates.

Equipment validated under a specified set of conditions must be revalidated whenever there is a change in those conditions. For example, changes in application software may influence the correct functioning of the computer system. Revalidation refers to those items of the system that are affected by the change.

HPLC INSTRUMENTATION QUALIFICATION

Instrument hardware should be validated for its intended use before and during its operation as part of the overall

validation process; that is, prior to routine use, after repair, and at regular time intervals.

The main qualification tests applied to HPLC instrumentation concern:

- The injection system (usually an autosampler). The parameters that have to be checked are precision and accuracy.
- The pump. The parameters that have to be checked are flow-rate precision, flow-rate accuracy, and stability regarding an isocratic pump. Gradient delay volume and gradient mixing volume, repeatability of the gradient, and mixing and proportioning accuracy are important when a gradient pump is used.
- The detector. The parameters that have to be checked are wavelength accuracy detection, refractive index sensitivity, linearity, spectral quality (PDAD) short-term or long-term noise, drift, and flow sensitivity.
- Column efficiency.
- Within-day and between-day reproducibility of the whole chromatographic system.

The first step is to establish internal specifications; then, compare the obtained results with the manufacturer's specifications; and, finally, interpret the differences. Within-day and interday reproducibility is the minimum test for routine use. Chromatographic systems should be tested for suitability to the performance criteria of the method on a daily basis before and during routine application. An HPLC system should be tested before each single sample analysis, or, if a series of samples are analyzed within a sequence, before each sequence.

Retention time, peak height or area, resolution, and peak shape are the data used to monitor the performance of the HPLC system. Peak shape is one of the first things that experienced chromatographers notice when looking at a chromatogram. Ideal chromatographic peaks are Gaussian-shaped; however, in practice, most peaks show some peak tailing, which is measured by using the asymmetry factor or the USP tailing factor as described in Fig. 2A. Column plate number, N, is the most common parameter to describe the shape of the peak. Resolution R_s, as described in Fig. 2B, is the measure of separation of two peaks, as well as of the efficiency of the column.

The frequency of the control sample analysis depends on the nature of the analysis. Successful analysis of the control samples assures that the system is performing as expected under the SOP. Validation of HPLC equipment assures that valid measurements are obtained. The quality of the analytical data can be maintained by keeping, in a safe place, records of the actual instrument conditions at the time the measurements were made. Backups should also be maintained.

The tests can be performed by using a typical C_{18} analytical column, 250 × 4 or 250 × 4.6 mm, and a mobile phase consisting of water–methanol or water–acetonitrile mixture. The analysis should concern compounds similar to those used for testing the performance of C_{18} columns (e.g., phenol) or compounds used for routine analysis in the laboratory. New columns must be checked for performance. Records of its chromatographic parameters must be kept.

Modular Calibration: Detector Performance

The refractive index sensitivity affects gradient analysis and should be checked by measuring the absorbance when the cell is filled with methanol ($n = 1.329$) and cyclohexane ($n = 1.427$) at 270 nm.

Noise and drift are measured in static (dry detector cell) and in dynamic mode at different wavelengths, e.g., 200, 254, and 390 nm. The change in the absorbance as a function of flow rate at the same wavelengths reflects flow sensitivity. Noise is expressed in AU/cm, drift in AU/hr, and flow sensitivity in AU min/ml. Some equipment units can automatically perform calibration for accuracy. For example, some HPLC/UV/Visible detectors include holmium oxide filters for measurement and calibration of the wavelength accuracy.

The characteristics of an equipment may change over time, e.g., UV detector lamps lose intensity, or pump piston seals abrade, or short-term noise affecting the LOD is increased because of flow cell contamination. These changes will have a direct impact on the performance of the HPLC instrument. The frequency of performance tests will be determined by experience and is based on need, type, and history of equipment performance. Intervals between the checks should be shorter than the time the instrument drifts outside acceptable limits. New instruments need to be checked more frequently, and, if the instrument meets the performance specifications, the time interval can be increased.

Long-term noise can be erroneously considered as late-eluting peaks, while drift affects the obtained data when the instrument is running over a long time period. Flow sensitivity affects flow rate and gradient programs using constant pressure pumps.

Photodiode array (PDA) or variable UV/Visible detector

A number of reference chemicals with well-defined UV spectra have been used for detector wavelength calibration, e.g., uracil, erbium perchlorate, holmium oxide, caffeine, etc.

Pump

The accuracy and stability of the pump flow rate can be checked at 1 ml/min, with the column in place, by measuring the time required to fill a 10 ml volumetric flask at the detector outlet. Other flow rates can be tested if

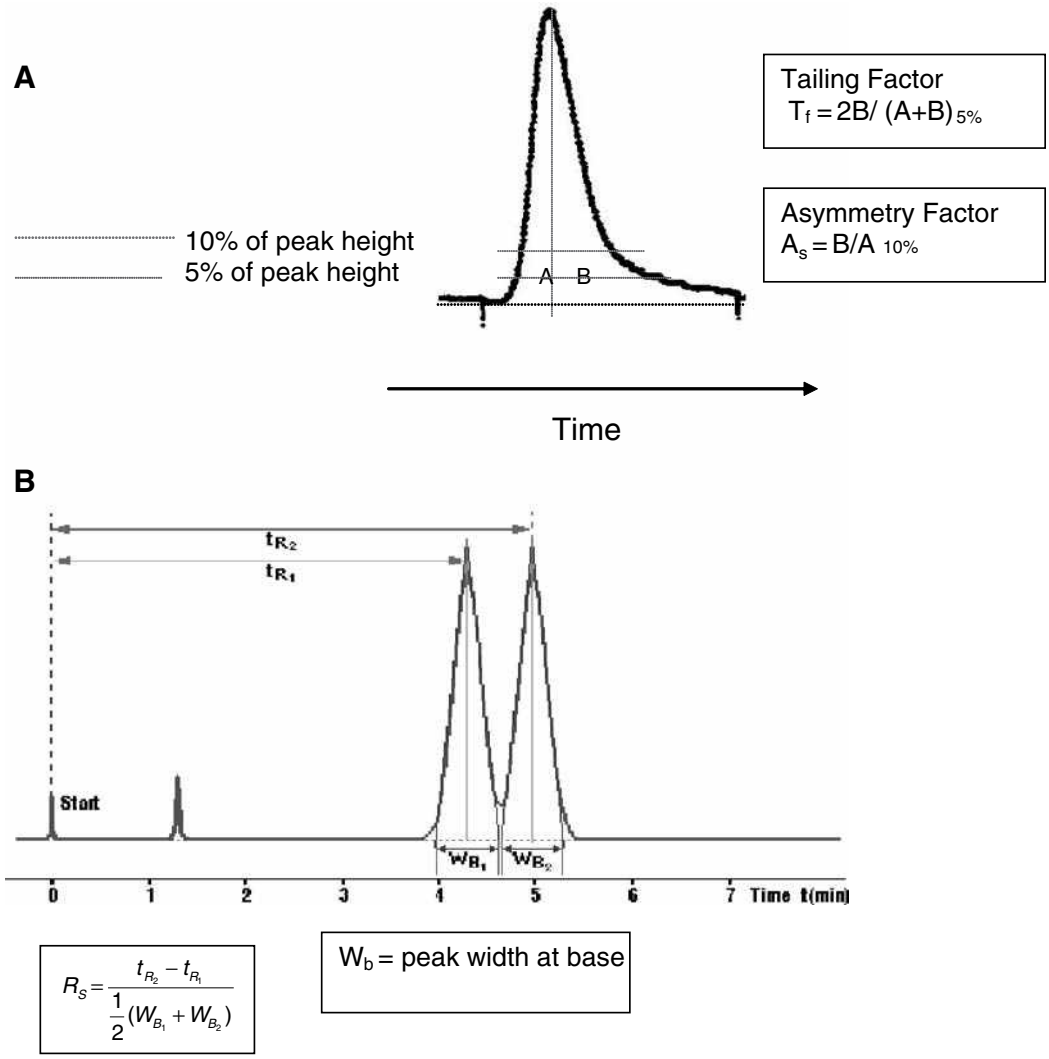

Fig. 2 (A) Measurement of peak tailing using USP tailing factor and peak asymmetry factor. (B) Peak resolution.
Source: From Merck HPLC Tutorial.

analyses with narrow bore or fast liquid chromatography (LC) are routinely performed. An acceptance criterion is 1.00 ± 0.05 ml/min. Flow-rate variations affect retention times.

Gradient pumps

Gradient delay volume, gradient mixing volume, and mixing and proportioning accuracy should be evaluated. These tests are executed by replacing the column with short tubing and filling the reservoirs with water and aqueous phenol solution. Increasing and decreasing steps must be used. The abovementioned parameters affect R_t and the selectivity of the separation. This is especially important when the gradient method has to be transferred from one system to another. Repeatability of the gradient analysis, important for the precision of the gradient method, is assessed by calculating the RSD of the peak area and retention times for replicate analysis of a control compound solution. Compositional accuracy is determined by making 5 min step gradients from water in one solvent line to 0.1% acetone in water in a second solvent line. The absorbance of each step against that of the 100% step is measured. A higher flow rate of 2 ml/min can be used to sharpen the step definition and increase test robustness. All four solvent lines are checked in a 1 hr solvent program.

Gradient methods in HPLC depend on the dwell volume, V_d, i.e., the volume between the point of mixing eluents A and B and the column inlet, including the loop of the injector. This volume differs from instrument to instrument, so that a method can be transferred only if this volume is well defined. When there is a significant difference in dwell volume between the two systems, retention times and resolution are dramatically different. So one must be state in which range of V_d the method is still valid.

Autosampler

Autosampler precision can be checked by replicate injections of a control sample, with wash injection intervals between every two sample injections. The repeatability of peak areas, mathematically expressed as RSD, is used as a criterion for autosampler precision. For example, when 10 consecutive injections of 10 μl of a solution are performed, the expected RSD for peak area precision ranges from 0.5% to 1.0%. Single injections of different volumes, such as 5, 10, 50, or 80 μl, can also be used, simultaneously checking the linearity of the injector, the detector, and the data system. Another approach to qualify the autosampler involves the gravimetric determination of the average volume of water per injection withdrawn from a tared vial after six 50 μl injections. The procedure takes less than 10 min and has an acceptance criterion of 50 ± 2 μl.

The same experiment can be used for the assessment of flow-rate precision by evaluating the repeatability of retention times for the examined compounds, expressed again as RSD. Both terms, flow-rate and injection volume precision, affect the precision of the results of the analysis. Carryover problems can be identified in the wash chromatograms at maximum detector sensitivity. They can be checked by multiple analyses of high-concentration samples followed by blank injections.

Column oven

A temperature accuracy test of the column oven, using a calibrated thermal probe, is used with an acceptance criterion of $35 \pm 2°C$.

Column

Two peaks are considered resolved if the R_s value is > 1.5. For multicomponent mixtures, a number of R_s values may have to be considered. The resolution between the most critical peaks may solely be considered as an indicator of the quality of the separation. Typical values for R_s range from 1.5 to 2.0 for critical resolution.

Computer

A computer associated with an HPLC equipment may control the instrument or part of it, e.g., the photodiode array detector, or acquire data generated by the instrument, such as the peak area of analytes.

- Software functions: For an automated HPLC analysis, required software functions include instrument control, data acquisition, peak integration, peak purity checks, compound identification through spectral libraries, quantitation, file storage and retrieval, and a printout of methods and data.
- Hardware interface: Determining the true performance of an electronic interface of a chromatography data system requires special instrumentation that is not generally found in a chromatographic laboratory. Testing procedure is similar to that of calibrating any electronic instrument.

The equipment hardware and computer software should be developed and validated according to a documented procedure, e.g., according to a product life cycle. The vendor should have a documented and certified quality system, e.g., ISO 9001. Quality must be designed and programmed into software prior to, and during, its development phases by following written development standards, including the use of appropriate test plans and methods.

Correct functioning of software and computer systems should be verified after installation and before routine use. Operational qualification for software and computer systems is more difficult than for hardware, as 1) it is more difficult to define specifications, test procedures, and acceptance criteria; and 2) there are hardly any guidelines available on OQ of software and computer systems. Because of these problems, there is even more uncertainty for software and computer systems than for equipment hardware.

The type of testing required for the qualification of software and computer systems depends very much on the type and complexity of software, i.e., if the software and computer hardware are supplied by one vendor, or computer systems that are interconnected and/or interfaced to analytical systems, or if the software are developed in the user's laboratory in addition to a vendor-supplied package (e.g., a macro).

ANALYTICAL METHOD VALIDATION

After equipment validation, the next step is analytical method validation, which covers testing of significant method characteristics according to good analytical practice guidelines. The validation of an HPLC method is the procedure that gives the chromatographer information to determine whether the system is operating as it should, providing accurate, precise, and reliable analytical data in a specific situation, meeting the preestablished specifications.

The validity of a specific method should be demonstrated in laboratory experiments by using samples or standards that are similar to the unknown samples that will be routinely analyzed. Chromatographic methods need to be validated before the first routine use. To obtain the most accurate results, all of the variables of the method should be considered, such as sampling, sample preparation, chromatographic separation, detection, and data

evaluation, using the same matrix as that of the intended sample. The proposed procedure must go through a rigorous process of validation. All validation experiments should be documented in a formal report.

Although the need to validate analytical methods is clear, the procedure for performing the validation is not clearly defined in terms of the validation parameters to be used, the specific procedures to be used in evaluating a particular parameter, and the appropriate acceptance criteria for a particular parameter.

Successful completion of the validation results in a method that can reliably be used to characterize "real samples." Ongoing validation activities may also be necessary during the routine utilization of an analytical procedure, as well as the revalidation of the analytical procedure, as certain operational aspects of the method are changed during its routine and continuous application.

Validation Parameter Guidelines for Method Validation

After the method has been developed, its performance must be validated with respect to different performance parameters. To determine which operational parameters should be included in a formal validation protocol, the chemical literature may be used to assess the practical state of the art among the practitioners of the desired methodology. Alternatively, existing guidelines published by organizations with recognized authority may be examined. Regulatory agencies and published literature provide the criteria for what constitutes a validated chromatographic method. The USP, for example, has published specific guidelines for method validation regarding pharmaceuticals. However, there are no official guidelines referring to biological fluids.

An attempt for harmonization was made at the International Conference on Harmonization (ICH) in 1995 and 1996 by representatives from the industry and regulatory agencies from the United States, Europe, and Japan, who defined parameters, requirements, and, to some extent, also methodology, for analytical methods validation.

In 1990, the USP 22 guideline listed eight individual parameters that must be investigated and documented in order to validate a method: 1) Accuracy; 2) precision; 3) limit of detection; 4) limit of quantification; 5) selectivity; 6) range; 7) linearity; and 8) ruggedness.

In 1995, USP 23 changed these parameters to some extent. Selectivity is now explicitly referred to as specificity, linearity and range were combined, and robustness was broken out of ruggedness. Ruggedness retains its original definition of day-to-day, instrument-to-instrument, operator-to-operator, etc. reproducibility. The robustness of an HPLC method is defined as a measure of its capacity to remain unaffected by small but deliberate variations in method parameters and provides an indication of its reliability during normal usage. So USP 23 includes: 1) Accuracy; 2) precision; 3) limit of detection; 4) limit of quantification; 5) specificity; 6) linearity and range; 7) ruggedness(*); 8) robustness(*). The asterisk is indicating that the terminology is included in an ICH publication, but they are not part of required parameters.

The definitions of these parameters and the indicative acceptance criteria are discussed in the following paragraphs. Each of the above-listed parameters is evaluated in terms of validating an HPLC method. The procedures for performing the validation must be presented in a complete, well-defined, practical, and understandable format. Once the validation is complete, an investigator must be able to interpret the results. The acceptance criteria allow the researcher to definitely determine, by comparing method performance data to the criteria, whether the method under evaluation is performing in a valid manner. These criteria should be universally applicable, numerically and mathematically explicit, complete, and achievable.

Accuracy and Recovery

The accuracy of an analytical method is the degree of agreement of results generated by the method to the true value or a conventional true value. Accuracy can be assessed by applying the analytical method to samples or mixtures of sample matrix components to which known amounts of the analyte have been added, above and below the normal levels expected in the samples. Method accuracy is the agreement between the difference in the measured analyte concentrations of the fortified (spiked) and unfortified samples and the known amount of analyte added to the fortified sample.

Comparison of the method's results can be performed by using an established reference method, assuming that the latter is free from systematic errors. Second, accuracy can be measured by analyzing a certified reference material, and comparing the measured value with the true value as supplied with the material. If such reference material is not available, a blank sample matrix can be spiked with a known concentration that should cover the range of concern, including one concentration close to the quantitation limit. The expected recovery depends on the sample matrix, on the sample processing procedure, and on the analyte concentration. Recoveries can be determined by either external or internal standard methods. Although it is desirable to attain a recovery close to 100%, other values such as not less than 50%, 80%, and 90% have been used as limits. Quantification by external standard is the most straightforward approach because the peak response of the standard is compared to the peak response of the sample. The standard solution concentration should be close to that expected in the sample solution. Precise control of the injection volume is mandatory because it influences the

accuracy. Peak response is measured as either peak height or peak area.

For the internal standard method, a substance is added at the earliest possible point in the analytical scheme to compensate for sample losses during extraction, cleanup, and final chromatographic analysis. The internal standard must be completely resolved from all other peaks in the chromatogram, having chemical and physical properties as similar as possible to those of the analyte of interest, so that the detector response is similar to the solute to be quantified. However, it is sometimes difficult to find the proper internal standard, as this must be stable over the time of the measurement period, absent from real samples, not reactive with the analytes, and eluted within a reasonable retention time. Analogs, homologs, and isomers are usually preferred. In the presence of analytes with different chemical or physical properties, two or more internal standards representing these analytes should be used.

Reagent blank, internal standard blank, solvent blank, and compound blank samples must also be analyzed for accurate qualitative and quantitative results.

Procedural guidelines for accuracy determination include replicate analysis, e.g., three to six assays, at five levels, over the range from 80% of the lowest expected assay value to 120% of the highest expected assay value, or from 75% to 125% of label claim, six samples of drug in the matrix spanning 50% to 150% of the expected content. At minimum, three concentrations must be used within the analytical range (extremes and midpoint of expected or near quantitation limit, center of range, and upper bound of standard curve).

For trace level analyses, acceptance criteria include 60–110% recovery for concentrations below 100 ppb, 80–100% recovery for concentrations above 100 ppb, and 70–120% for concentrations below 1 ppm. In biological samples, method accuracy for discovery phase investigations should be $\pm 20\%$ of actual, with recoveries of $\pm 10\%$ being necessary in preclinical and clinical studies. Alternatively, it is recommended that the mean recovery value should be within $\pm 15\%$ of actual, except at the quantitation limit where $\pm 20\%$ is acceptable.

Precision and Reproducibility

The precision of a method is the extent of agreement among individual test results, when the procedure is repeatedly applied to multiple samplings. Precision can be divided into three categories: 1) Repeatability; 2) intermediate precision; and 3) reproducibility.

Repeatability (intra-assay or within-day precision) is obtained when the analysis is carried out in one laboratory by one operator, using one piece of equipment over a relatively short time span. It reflects the variation in replicate procedures performed within a short time period, with the same operational conditions.

At least five or six determinations of three different matrices at two to three concentrations should be performed and expressed by the RSD. The acceptance criteria for precision depend on the type of analysis. While a precision of better than 1% RSD is easily achieved for compound analysis in pharmaceutical quality control, the precision may be at levels of 10–15% for biological samples. For environmental and food samples, the precision is very much dependent on the sample matrix, the analyte concentration, and the analysis technique, varying between 2% and 20%.

Intermediate precision is defined by ICH as "the long-term variability" of the measurement process, and is determined by comparing the results of a method run within a single laboratory over a number of weeks. A method's intermediate precision may reflect disagreement in results obtained by different operators, from different instruments, with standards and reagents from different suppliers, with columns from different batches, or a combination of these. The objective of intermediate precision validation is to verify that, in the same laboratory, the method will provide the same results after finishing the method development.

Reproducibility, as defined by ICH, represents the precision obtained between laboratories with the objective of verifying if the method will provide the same results in different laboratories. The reproducibility of an analytical method is determined by analyzing aliquots from homogeneous lots in different laboratories with different analysts, and by using operational and environmental conditions that may differ from, but are still within the specified, parameters of the method (interlaboratory tests). Various parameters affect reproducibility. These include differences in room environment (temperature and humidity), operators with different experience, equipment with different characteristics (e.g., delay volume of an HPLC system), variations in material and instrument conditions (e.g., in HPLC), mobile phases composition, pH, flow rate of mobile phase, columns from different suppliers or different batches, solvents, reagents, and other material with different quality.

Reproducibility is defined as the long-term variability of the measurement process, which may be determined for a method run, within a single laboratory, but on different days. Reproducibility also applies to a method, either run by different operators, different instruments, or a combination of the above. The reproducibility standard deviation is typically twofold to threefold larger than that for repeatability. Precision is often expressed relative to 1 day as intraday (within-day) precision or relative to a period of days, as interday (between days) precision. Reproducibility, in the sense of intralaboratory precision, is related to the procedure being performed at two or more laboratories as in, e.g., a collaborative study.

Precision in retention times and peak area or height is a major criterion of a separation system. Retention-time precision is important because R_t is the primary means

for peak identification. It is also an important performance criterion and diagnostic for an LC pump and a column.

Precision of peak areas or heights is important because they are used for calculating amounts during quantification. It is also the most important performance criterion for an LC injection system. Precision should be determined using a minimum of five replicate chromatograms. For bioanalytical samples, precision is studied at least at low, medium, and high concentrations. This is repeated on separate days to calculate intraday and interday precision.

Precision reflects a procedure's ability to reproduce the same, but not necessarily the correct or expected, result each time it is correctly performed. Precision is assessed by repetitively injecting a number of samples and statistically evaluating the resulting data. Important issues related to the precision determination include the number of replicates required and the type of sample to be tested. For the determination of repeatability, recommendations include: 1) Five to ten replicates for release or stability assays; 2) duplicate measurements made on 10 samples at each of three different analyte levels; 3) five replicates at three levels (limit of quantitation, midrange, and upper calibration bound); 4) replicate samples at analyte levels of 80–120% of expected for dosage forms and drug substance tests.

For intermediate precision, the repeatability experiments should be performed on 2, 3–5, or at least 10 separate days. To assess reproducibility, the experiments have to be performed in at least two laboratories.

System precision should be $\leq$1–2% relative standard deviation (RSD) (or higher for low-level impurities). The repeatability is generally 1/2 to 1/3 of the reproducibility. However, for biological samples, an RSD of 10–15% should be acceptable as the minimum precision.

Systematic errors result from sources traced to the methodology, the instrument, or the operator. These affect both the accuracy and the precision of the measurement. Random errors affect the precision and are difficult to eliminate as they result from random fluctuations in the measured signal because of noise and other factors. The imprecision of the entire procedure is often dominated by the random errors of the most imprecise step. The difference between an accurate and a precise method is illustrated in Fig. 3.

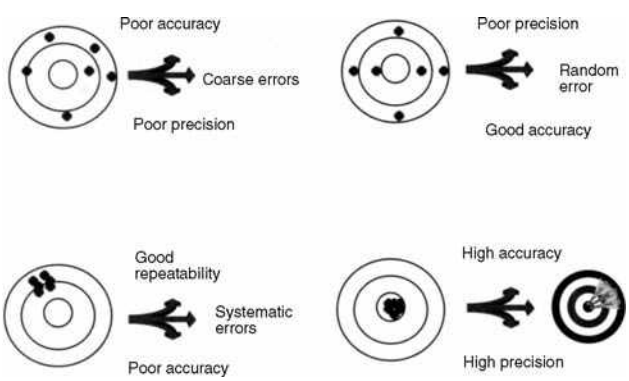

Fig. 3 Comparison of precision and accuracy parameters of an analytical method.

Selectivity–Specificity

The terms selectivity and specificity are often interchangeably used. The term specificity generally refers to a method that produces a response for a single analyte only, while the term selective refers to a method that provides responses for a number of chemical entities that may or may not be distinguished from each other. Because there are very few methods that respond to only one analyte, the term selectivity is usually more appropriate. The USP defines selectivity of an analytical method as its ability to accurately measure an analyte in the presence of interferences, such as synthetic precursors, excipients, enantiomers, and known (or likely) degradation products that may be expected to be present in the sample matrix.

Selectivity in HPLC is obtained by setting optimal chromatographic conditions, such as mobile phase composition, column temperature, and detector wavelength. There are a variety of ways to validate selectivity. One approach is to demonstrate a lack of response in the blank biological matrix. A second approach is to check whether the intercept of the calibration curve is significantly different from zero.

Peak purity is one important parameter in chromatography to determine whether the peaks within a sample chromatogram are pure or if it consists of more than one compound. To determine the homogeneity of a chromatographic analyte response, the use of UV/Visible photodiode-array detector (PDAD) and mass spectrometers is recommended, acquiring spectra during the entire chromatogram. The acquired spectra are normalized and overlaid for graphical presentation; if they are different, then the peak consists of at least two compounds. Usually, the simplest and most frequently used peak purity algorithm compares three spectra across a peak: On the upslope, at the peak apex, and on the downslope.

Specificity relates to the ability of a method to measure only what it is intended to be measured with a requisite level of accuracy and precision, although the sample may contain other related compounds. The most commonly cited specificity evaluation procedure is the analysis of a placebo, wherein the sample matrix without the analyte is analyzed and the resulting system response is examined for the presence of responses, which interfere or overlap with that of the analyte of interest. Other procedures for specificity include: 1) Peak reanalysis, wherein the peak of interest is collected and reanalyzed by different chromatographic conditions or with methods that are sensitive to analyte structure; 2) collaboration, in which the sample is quantitatively analyzed using two or more detection or

separation strategies, and the results compared; 3) use of detectors (e.g., MS or PDAD to assess peak purity).

Linearity and Range

The linearity of an analytical method is its ability to extract test results that are directly, or by means of well-defined mathematical transformations, proportional to the concentration of analytes in samples within a given range. In chromatography, peak parameters are related to analyte concentration via standardization procedures. This relationship is then used to convert a sample's peak parameter to its analyte concentration. Linearity is determined by a series of three to six injections of five or more standards, whose concentrations span over the range of expected concentrations, or 80% of the lowest expected level to120% of the highest expected level, or 50–150% or 10–200% of the expected working range, or 25–125% of the target range specified. The response should be directly or, by means of a well-defined mathematical calculation, proportional to the concentrations of the analytes. A linear regression equation applied to the results should have an intercept not significantly different from zero; otherwise, it should be demonstrated that there is no effect on the accuracy of the method. Frequently, the linearity is graphically evaluated in addition to, or alternatively to, mathematical evaluation.

The correlation coefficient of the best linear least squares regression model should be between 0.98 and 1.00 or greater than 0.999 with the slope and intercept reported. However, there is no rule stating that the relationship between instrumental response and analyte concentration must be directly linear for a procedure to be valid. The desire to have a linear relationship reflects the practical consideration that a linear relationship can be accurately described with fewer standards than a nonlinear relationship, and the subjective expectation that a linear relationship is more rugged than a more complicated, nonlinear relationship.

A method's range is linked to its linearity. The range is the interval between the lower and upper analyte concentration, for which it has been demonstrated that the analytical procedure has a suitable level of accuracy, precision, and linearity. The range is expressed in the same units as the analytical method's results (e.g., ng/μl, ppb, %, etc).

Limits of Sensitivity: Limit of Detection and Limit of Quantitation

Sensitivity is the ability of a method to reliably respond in a consistently recognizable manner to decreasingly smaller amounts of analyte. Frequently utilized measures of sensitivity are the limit of detection (LOD) and the limit of quantitation (LOQ). For chromatographic procedures, LOD is the lowest concentration of analyte that can be detected above the baseline detector noise at the most sensitive instrument setting, but not necessarily quantified. In chromatographic practice, the detection limit is the injected amount that results in a peak with a height twice or three times as high as the baseline noise.

The LOD can be determined either directly or from other validation data. Its direct measurement involves an analysis of the method's peak-to-peak baseline noise or an analysis of the variation in the method's blank response. In either case, LOD is calculated as either two or three times the variation in measured response, where the factors are associated with the 95% and 99% confidence intervals for a normal distribution. Practically, LOD can be measured by the serial dilution of samples until the peak can no longer be observed. LOD can be estimated as the value of the linear calibration curve's *y* intercept.

The LOQ is the minimum injected amount that gives precise measurements in chromatography, typically requiring peak heights 10 to 20 times higher than baseline noise. Another approach is the EURACHEM: A number of samples with decreasing amounts of the analyte are injected six times. The calculated RSD% of the precision is plotted against the analyte amount. The amount that corresponds to the previously defined required precision is equal to the LOQ. Alternatively, LOQ is the lowest injected amount of analyte, which results in a reproducible measurement of peak areas and can be reproducibly quantitated above the baseline noise. Peak heights are typically required to be about 10 to 20 times higher than baseline noise. Quantitation implies that the measurement possess a specified accuracy and precision. In some applications, LOQ is defined as the smallest concentration included in the standard curve.

The baseline response method for estimating LOQ involves the following procedure: The chromatogram resulting from a blank injection is examined over a range of 20 peak widths and the noise is measured as either the largest peak-to-peak fluctuation or as the largest deviation (positive or negative) from the mean response. The LOQ is then calculated as the product of 10 times the measured deviation and the calibration curve slope. The LOQ can also be determined as the lowest analyte concentration for which duplicate injections result in a $\%RSD \leq 2\%$. In routine applications, it has been recommended that LOQ should be within the working linear concentration range and that a specification limit should be no lower than twice the LOQ. For clinical applications, the LOQ should be at least 10% of the minimum effective concentration.

Ruggedness

It is generally expected that an analytical method will perform in an acceptable manner each time it is used. While a consideration of method ruggedness is a necessary part of any method's validation, it is a critical issue for compendial methods because of their widespread use in many different laboratories.

Ruggedness establishes a method's ability to effectively perform in the face of variations on operational and environmental conditions, which can reasonably be expected to occur whenever the method is applied. More specifically, ruggedness is the reproducibility of test results obtained by the analysis of samples under a variety of normal test conditions such as different laboratories, analysts, instruments, reagent lots, elapsed assay times, temperatures, etc. Thus, ruggedness addresses unintentional variation in the method introduced by its application, at different times, by different people, at different locations, using different instrumentation and materials. A rugged method will be able to withstand minor operating or performance changes and has built-in buffers against typical procedural abuses, such as differences in care, technique, equipment, and conditions.

For the determination of the method's ruggedness within a laboratory, a number of chromatographic parameters, e.g., flow rate, column temperature, detection wavelength, or mobile phase composition is varied within a realistic range, and the quantitative influence of the variables is determined. If the influence of the parameter is within a previously specified tolerance range, the parameter is said to be within the method's ruggedness range. Clearly, ruggedness is assessed by analyzing aliquots from homogeneous sample lots using operational and environmental conditions that differ, but are still within the method's specified operating range. The ruggedness test should be performed at several values of each operational parameter that affects method performance, e.g., mobile phase flow rate and composition, (pH, buffer concentration, ion pairing reagent concentration, percent organic phase, column temperature, injection volume, gradient dwell time, column lots or column manufacturers, different room temperature and humidity in separate laboratories, detection wavelength, analysts with different experience, instruments from various vendors, reagents from different suppliers, columns from different batches, sample and standard preparation procedures, and operating temperature. For operator-related ruggedness, a number of analysts, e.g., three to five, perform one assay per day for 3 days. The utilization of statistically designed experiments (e.g., nested ANOVA) to establish the ruggedness of an assay is recommended.

In ruggedness assessment regarding the column, the specificity (selectivity) of at least three columns, from three different batches, supplied by one column manufacturer must be checked. A similar column from another manufacturer should also be evaluated. Variability also arises from the degradation of the column over its lifetime. Even columns with the same material and dimensions may vary in performance and selectivity. If columns are packed in the laboratory, they should be tested before they are first used. Columns purchased from vendors should be supplied with test certificates.

The quantitative measure of a method's ruggedness is the precision behavior it exhibits over the course of the various operational scenarios, examined during the validation exercise. Generally, a rugged method's reproducibility is two to three times greater than the method's repeatability (inherent method precision under "normal" controlled operating conditions).

Robustness

Robustness tests examine the effect operational parameters have on the analysis results. For the determination of a method's robustness, a number of chromatographic parameters (e.g., flow rate, column temperature, injection volume, detection wavelength, or mobile phase composition) are varied within a realistic range and the quantitative influence of the variables is determined. If the influence of the parameter is within a previously specified tolerance, the parameter is said to be within the method's robustness range. Obtaining data on these effects will allow one to judge whether a method needs to be revalidated when one or more of parameters are changed, for example, to compensate for column performance over time.

The difference between ruggedness and robustness is that the former is related to unintentional variation in a method because of its use in varying analytical situations, although the latter is the procedure's capacity to remain unaffected by small but deliberate variations in method parameters. Thus, robustness is a measure of the procedure's reliability during normal usage. Although it is time-consuming, thorough robustness studies will help to avoid unexpected results in subsequent applications of the method. While data for robustness is not usually submitted in regulatory product applications, a robustness evaluation is recommended. Clearly, a robust method is one that is operationally immune to commonly encountered but relatively minor variations in its critical operating parameters.

It has been suggested that, in order to determine robustness, a method's critical operational variables should be identified by breaking the testing process into unit operations and then assessing the potential variability of each operation. Unit operations might include: 1) Analytical solution preparation—amount of material used, volumes of solvent used, dissolution times and conditions, and solvent used; 2) variation in the tested product (inhomogeneity, aging); 3) instrumental analysis—detection wavelength, mobile phase composition and flow rate, and column use history.

Stability

Many solutes readily decompose prior to chromatographic investigations, e.g., during the preparation of the sample solutions, during extraction, cleanup, phase transfer, and during storage of prepared vials (in refrigerators or in an automatic sampler). Under these circumstances, method

development should investigate the stability of the analytes.

The term "system stability" is a measure of the bias in assay results generated during a preselected time interval, e.g., every hour up to 10 hr, using a single solution. Stability should be determined by replicate analysis of the sample solution and the relative standard deviation calculated. The assay results obtained in different time intervals should not exceed more than 20% of the corresponding value of the system precision. If the value is higher on plotting the assay results as a function of time, the maximum duration of the usability of the sample solution can be calculated.

The effect of long-term storage and freeze–thaw cycles can be investigated by analyzing a spiked sample immediately upon preparation and on subsequent days of the anticipated storage period. A minimum of two cycles at two concentrations should be studied in duplicate. If the integrity of the drug is affected by freezing and thawing, spiked samples should be stored in individual containers and appropriate caution should be employed for study samples.

In most routine applications, solutions are not immediately used after preparation, but may be stored under specified conditions prior to use. Verifying solution stability is an important aspect of method validation; specifically, a valid method is one for which all related and analytical solutions are stable over the period typically required for their utilization or analysis. To address stability, the analytical solutions should be prepared, assayed, allowed to stand (in accordance with the method's protocol or specification) for a length of time equal to the anticipated maximum analysis time, and then reassayed. For analytical procedures involving overnight runs, up to three to four sample solutions over the working concentration range should be repetitively analyzed over the course of at least 16 hr. In such evaluations, the analytical solution is stable if all concentration values obtained before and after storage agree to within three times the system precision. Additionally, no new peaks should appear, nor should existing peaks be lost, from the chromatograms of the first and last sample injection. The stability of a solution must be checked for at least 16 hr, especially when an autosampler is used.

The preparation and execution should follow a validation protocol, preferably written in a step-by-step instructional format. Once the validation protocol is completed, the validation report should be prepared, including data listed in Table 1.

There are no official guidelines on the sequence of validation experiments and the optimal sequence can depend on the method itself. A potentially useful sequence for a liquid chromatographic method is: 1) Selectivity of standards (optimizing separation and detection of standard mixtures); 2) precision of retention times and peak areas; 3) linearity, limit of quantitation, limit of detection, range; 4) selectivity with real samples; 5) trueness or accuracy, at different concentrations; 6) ruggedness.

Table 1 Parameters to be included in a validation report.

1. Objective and scope of the method (applicability, type).
2. Type of compounds and matrix.
3. Detailed chemicals, reagents, reference standards, and control sample preparations.
4. Procedures for quality checks of standards and chemicals used.
5. Safety considerations.
6. Method parameters.
7. Critical parameters indicated from robustness testing.
8. Listing of equipment and its functional and performance requirements, e.g., cell dimensions, baseline noise, and column temperature range.
9. Detailed conditions on how the experiments were conducted, including sample preparation.
10. Statistical procedures and representative calculations.
11. Procedures for quality control in the routine (e.g., system suitability tests).
12. Representative plots, e.g., chromatograms, spectra, and calibration curves.
13. Method acceptance limit performance data.
14. The expected uncertainty of measurement results.
15. Criteria for revalidation.
16. Analyst who developed and initially validated the method.
17. Summary and conclusions.

The more time-consuming experiments, such as accuracy and ruggedness, are put toward the end. Some of the parameters can be measured in combined experiments. For example, when the precision of peak areas is measured over the full concentration range, the data can be used to validate the linearity.

Revalidation

Once the method is validated, any modification requires revalidation to demonstrate that it still works as defined. If the new parameter is within the tolerance range of the method as specified during the ruggedness test of method validation, the method does not need to be revalidated. In other cases, it should go through revalidation. With the system suitability software frequently offered by analytical equipment vendors, methods can be automatically revalidated with little operator interaction. The validation can be performed overnight.

Operating ranges should be defined for each method based on experience with similar methods, or they should be investigated during robustness studies. Availability of such operating ranges makes it easier to decide when a method should be revalidated. Part or full revalidation may also be considered if SST or the results of quality control

Table 2 Method changes and revalidation tests required.

Method characteristics changed	Performance parameters to revalidate
Instrument changes	Linearity (working range), LOD, LOQ, system precision.
Product changes	Selectivity, accuracy, precision.
Sample preparation procedure (same solvent, same concentration range)	Accuracy, recovery, precision, ruggedness
Sample preparation procedure (different solvent, different concentration range)	Complete reassessment of all previously used validation parameters.
Analyst changes	Qualification testing (perform retests, side-by-side collaborative studies).
Chromatographic change (e.g., column, mobile phase)	Selectivity, linearity, LOD/LOQ, system precision.
Extraction solvent, buffer, back extraction, matrix or injection solvent	Linearity, recovery, LOQ, intrabatch precision and accuracy, in-process solution stability. Additionally, if injection solvent is changed, processed sample stability should be checked, but recovery or in-process stability checks are not necessary.
Chromatographic conditions [column, mobile phase composition, detector type or monitoring condition (e.g., wavelength) change]	Linearity, selectivity, and intrabatch precision and accuracy (recovery not necessary).
Extending the upper end or reducing calibration curve range	Linearity, LOQ (if reduced), lower end of the intrabatch precision and accuracy at revised upper or lower levels.
Internal standard.	Selectivity, intrabatch precision and accuracy, recovery.

sample analysis are out of preset acceptance criteria and the source of the error cannot be tracked back to instruments or anything else.

For HPLC methods, significant changes could occur, and the recommended parameters for revalidation are summarized in Table 2. For bioanalytical methods, precision, accuracy, and limit of quantitation are considered to be the minimum revalidation tests.

SYSTEM SUITABILITY TESTING

Daily, prior to the sample analyses, the analyst must establish that the HPLC system and procedure are capable of providing data of acceptable quality. The validation procedure of an analytical system combining the analytical method and instrument performance is referred to as system suitability testing. The objective of an SST is to assess if the chromatograph or its modules, i.e., the column, the mobile phase, the detector lamp, etc. perform as required for a particular analytical run and can generate results of acceptable accuracy and precision or should be replaced before samples are committed for analysis. System suitability testing provides the analyst with diagnostic information by warning that part of the process is likely to be out of control. It typically represents a subset of the method validation procedure.

The requirements for SST are usually developed after method development and validation have been completed, giving information about acceptable system operation by comparing observed performance vs. previously established criteria or guidelines.

Critical issues of concern include the identification of performance characteristics that need to be monitored and the frequency of test execution. In general, intervals between tests should be shorter than the observed time in which the system drifts outside of acceptable levels: In most cases, at the beginning and at the end of a run, or in a more thorough approach, a quality control sample is run for every 10 samples. Additionally, an SST evaluation is performed each time an instrument malfunction has been observed during the course of a run. The final decision is based on the experience of the analyst depending on need, as well as previous performance of the equipment. In case the system is in continuous use for the same analysis, it may be sufficient to perform an abbreviated SST check each day. Full SST should be performed each time the system is assembled for the assay.

Quality control samples at three concentrations (low, middle, and high) around the expected range can be used to assess accuracy by two to five injections. The acceptance criteria established for the SST evaluation must balance the need to ensure adequate performance with the practical reality of performing chemical analyses. This means that they must be sufficiently tight, but not so restrictive that acceptable systems fail to pass. Some examples of the acceptance criteria are summarized in Table 3.

Table 3 Recommended system suitability testing acceptance criteria.

Parameter	Assay type	Acceptance criterion
Capacity factor	General	2–8
factor	Trace	1–3
	Stability indicating	> 4
Selectivity	General	1.05–2.0
Retention time	General	< 0.1 min
Resolution	General	> 2.0
	Quantitative analysis	> 1.5
	Biologicals	> 1.2
Plate count (*N*)	General	> 2000
Precision	General	%RSD < 1.5%
	Biologicals	%RSD < 5%
	Trace	%RSD 5–15%
Tailing factor	General	1.5–2.0

Source: From Chromatographic method validation: A review of current practices and procedures. Part III. Ruggedness, revalidation and system suitability, in J. Liq. Chromatogr.[2]

System suitability testing parameters regarding HPLC methods reflect problems associated with the performance of chromatographic procedures, e.g., flow irregularity, injection irreproducibility, system plumbing problems, detector misalignment or malfunction, wavelength accuracy, oven temperature, column malfunction, and mispreparation of analytical solutions regarding mobile phase, standard solutions, or samples. Detailed records of maintenance and changes must be kept. Documentation can be accomplished by using software especially designed for the task. The same software can be used to troubleshoot the method.

To obtain a good and acceptable analytical result, two requirements must be met: 1) The method has to be adequate; and 2) the execution has to be adequate.

The simplest form of an HPLC SST involves comparison of the chromatogram with a standard one, allowing comparison of the peak shape and the peak width baseline resolution. Additional parameters that can be experimentally calculated to provide quantitative SST report include the number of theoretical plates, separation factor, resolution, tailing or peak asymmetry factor, accuracy, and precision (RSD of six measurements). Resolution may also be combined with a selectivity test to check the resolution of the analytes from components present in the sample matrix. If matrix components interfere with a method, a matrix blank may be included in the SST. Peak shape and asymmetry, or tailing factor, can have a major impact on the performance of a quantitative method, especially at low amounts or concentrations, and may vary over the lifetime of a column.

The number of theoretical plates can provide the historical data needed to determine if the column needs to be replaced, based on scientific reasoning, and not simply a by a judgment that the column does not work.

Retention times tend to vary over time because of a number of causes, e.g., differences between batches of mobile phase, column performance and different columns, and ambient temperatures of laboratories. The RSD of retention time, especially important because it is used for peak identification, is influenced by: 1) Pump flow; 2) composition precision; 3) mobile-phase composition of solvent delivery systems; and 4) column temperature. Imprecise retention time indicates problems within the HPLC system such as piston seals, check valves, etc.

Signal-to-noise (S/N) ratio may become important when measuring analytes at low concentrations. Related to this measurement may be the limits of detection (LOD) or quantification (LOQ), which may be of particular importance in trace analysis. For methods determining analytes over a large concentration range, a linearity test can be incorporated into the SST.

The RSD of the peak area is influenced by: 1) Injection mode and volume; 2) pump flow and pulsation; 3) detector noise, drift, and response; and 4) sampling rate and integration parameters of the data system.

Additional checks should be performed in some cases; this could be a routine check of the wavelength accuracy, the baseline noise, and the intensity of the UV lamp.

Automation of the System Suitability Testing

Modern data-acquisition systems can offer SSTs with the basic software, leaving the analyst to fill in the required parameters. Storing chromatograms and multiple plotting of chromatograms over time provides a chromatographer with the ability to see the historical performance of the analytical column for the past week, month, or even the column's lifetime.

CONCLUSIONS

A successful chromatographic analysis depends on the precise performance of the HPLC instrumentation, i.e., control of pressure, the composition of mobile phase, the performance of the analytical column, the detector, the injector or autosampler, and the electronic data handling system.

Validation is the process of confirming that the analytical equipment, method, or system for a specific test is suitable for its intended use. Methods need to be validated before their introduction into routine use and revalidated whenever there is a change (outside the original scope of the method) in any parameter of the method.

In accordance with GLP, a chromatographic procedure must 1) exactly follow a protocol; 2) be conducted by a qualified personnel; 3) be controlled by standard operating procedures (SOPs); 4) use proper and adequate facilities;

5) use calibrated and well maintained equipment; and 6) provide fully retrievable raw data.

Satisfactory results for a method can only be obtained with properly performing equipment that is periodically inspected, cleaned, maintained, and calibrated according to SOPs. Records of those activities should be maintained.

A laboratory applying a specific method should have documentary evidence that the method has been appropriately validated; this holds for methods developed in-house as well as for standard methods, to demonstrate the validity of the method in the laboratory environment.

For routine use, relevant tests should be selected, depending on the use of the equipment, in order to verify that the instrument is performing in a regulated, controlled manner.

Instrument hardware should be validated prior to routine use, after repair, and at regular time intervals. Computer systems should be validated during, and at the end of, the development process and after software updates. Computer systems with complex software are frequently gradually developed over many years. It is critical to note that quality cannot be tested into a product or system at the final testing stages. To ensure quality during the development process, the life cycle concept has been developed.

Analytical methods should be validated prior to routine use and after changing method parameters.

Analytical systems should be tested for system suitability prior to, and during, routine use, practically on a day-to-day basis.

However, validation and verification of an HPLC equipment are not one-time events. They are on-going processes, covering the entire life of the instrument.

Human Exposure to Endocrine-Disrupting Chemicals: LC/MS for Risk Assessment

Hiroyuki Nakazawa
Rie Ito
Yusuke Iwasaki
Koichi Saito
Department of Analytical Chemistry, Faculty of Pharmaceutical Sciences, Hoshi University, Tokyo, Japan

Abstract
It has been emphasized that certain chemicals incorporated in daily life products, including plastic materials having wide industrial and consumer applications, may have endocrine-disrupting effects. There are in vitro and in vivo data showing that such chemicals are weak agonists of nuclear receptors and influence embryonic and/or fetal development of laboratory animals. The association between exposure to endocrine-disrupting chemicals (EDCs) and an increased incidence of endocrine disease in humans has underscored the need for accurate analytical techniques that would relate exposure to these compounds to an individual's risk of developing diseases. The development of highly sensitive and reliable analytical methods is required to assess human exposure to related chemicals. To acquire as much information as possible from limited amounts of samples, hyphenated analytical methods that use liquid chromatography–mass spectrometry (LC–MS) and LC–tandem mass spectrometry (MS/MS) for the determination of EDCs, such as bisphenol A (BPA), phthalate esters (PEs), and perfluorinated chemicals (PFCs), were developed. These simple, accurate, reliable, and high-sensitivity methods have been applied to the trace analysis of biological and environmental samples. By using LC–MS/MS, BPA, PEs, and PFCs were determined in human biological samples for the assessment of human exposure.

INTRODUCTION

Many reports of phenomena in humans and wildlife that were difficult to explain with existing biological, toxicological, and medical knowledge emerged in the 1960s and the 1970s. One report concerns the development of vaginal cancer in girls born to women who took diethylstilbestrol (DES) to prevent miscarriage during pregnancy. Abnormal reproductive function and behavior, demasculinization, and deleterious effects on the immune and nervous systems of fish, reptiles, birds, and other wildlife were reported as well. In 1962, Carson sent a reminder[1] concerning the biogeocenosis effect of agrichemicals, including dichlorophenyl trichloroethane (DDT), in her book entitled "Silent Spring." In 1996, Colborn, Dumanoski, and Peterson, analyzing the risks associated with chemicals that affect human health even at minute levels, published a warning[2] regarding chemicals existing in materials expelled into the environment. Those chemicals disrupt hormonal secretion by the endocrine system, which is important for the maintenance of homeostasis in living organisms. That finding sparked a series of local and international studies that focused on those chemicals as endocrine-disrupting chemicals (EDCs). In July 2007, the U.S. Environmental Protection Agency (EPA) published a final list.[3] The list included the chemicals that are the first to be considered for screening under the Federal Food, Drug, and Cosmetic Act. This final list was not to be construed as a list of known or likely endocrine disruptors. On the final list are 73 agrichemicals that humans are very likely exposed to. Our group has published several papers[4–8] as well as a review paper[9] on various residual agrichemicals, including those on that list. Modern society has created a large number of chemicals that we have come to depend on for a comfortable and convenient lifestyle. Many chemicals are used in daily commodities and materials, including toys, food container packing materials, cosmetic products, and building materials, as well as in specialized areas, such as laboratory equipment and medical devices. Plasticizers, monomers, and heavy metals eluted from such daily commodities have endocrine-disrupting effects. In fact, when human blood was analyzed, chemicals that may have been derived from high-molecular-weight molecules were detected.[10] However, the amounts of minute chemicals, such as EDCs, that destabilize complex body functions were not clarified. In addition, the extent of the endocrine-disrupting effects of chemicals on successive generations of living organisms ("low" dosage problem), which is a dose–behavior relationship, remains to be known.[11–14] For bisphenol A (BPA), the National Toxicology Program (NTP) reported in the draft NTP brief on BPA (April 14, 2008) that despite recognition of the lack

of data on the effects of BPA on humans and the limited evidence of the "low" dose effects on laboratory animals, as will be discussed in detail below, the possibility that BPA may alter human development cannot be dismissed. As mentioned above, we are living in times[15] where the danger has not yet been accurately exposed.

By citing cases demonstrated through various research projects, we will discuss the analysis and risk factors of minute amounts of EDCs, namely, BPA, phthalate esters (PEs), and perfluorinated chemicals (PFCs).

ANALYSIS OF BPA

BPA is widely used as an ingredient of polycarbonate and epoxide resins. BPA disposition[16] was examined in a cynomolgus monkey that was orally and intravenously (IV) administered radioisotope-labeled BPA (^{14}C-BPA). BPA half-life was approximately 10 hr (oral administration) and most of the BPA was converted into glucuronic acid conjugate that was excreted into the urine within 24 hr. It is assumed that BPA disposition in the human body is the same as that in cynomolgus monkey. Völkel et al. administered 5 mg of deuterium-labeled BPA (BPA-d_{16}) per os to healthy volunteers, monitored the pharmacokinetics and metabolism, and found that BPA half-life inside the human body was approximately 6 hr and that most of the BPA was excreted into the urine[17] as glucuronic acid conjugate, similar to the case of cynomolgus monkey. Glucuronic acid conjugation with BPA has been detected[18,19] in animal tests and it is assumed[20] that glucuronic acid conjugate is a useful biomarker. In BPA metabolism in humans, the discovery of sulfate conjugate[21] as well as the glucuronic acid conjugate indicated the need to consider various metabolic processes. When BPA metabolism was examined using rat or mouse liver S9, chemical species that exhibited higher estrogenic activity than BPA, dimers, and other chemical species were observed[22,23] although it was difficult to say if they were the major BPA metabolites in humans. Thus, the mono- or di-glucuronic acid conjugate may also exist.

BPA is widely incorporated in products used in our daily lives, such as canned beverages, etc.[24] The amount of BPA in the environment, food, and biological samples is still controversial and should be monitored. In this section, we will introduce examples of the analysis of BPA exposure that we conducted.

ANALYSIS OF BPA IN HUMAN BLOOD PLASMA SAMPLES

Since BPA exists in trace amounts in biological samples, highly sensitive methods are required for its analysis. In addition, the pretreatment process for the removal of other components is important for the analysis. Because of its chemical structure, liquid chromatography–electrochemical detection (LC–ECD) is applied[25] to the analysis of human blood plasma samples. However, it is essential to discuss the pretreatment method for the biological sample used in BPA analysis because the sample contains many other compounds. When human blood plasma is used for analysis, the plasma sample is initially purified with a solid-phase extraction (SPE) cartridge and then subjected to LC–ECD. In this case, the quantitative limit of 0.6 ng/ml(blood plasma) was established.[26] On the contrary, the quantitative limit of 0.5 ng/ml (seminal plasma) was established[27] for BPA in human seminal plasma pretreated with SPE cartridge. Watanabe et al. reported the utility of LC with fluorescence detection using 4-(4,5-diphenyl-1H-imidazol-2-yl) benzoyl chloride as labeling reagent for the determination of BPA in plasma samples.[28] Recently, mass spectrometry (MS) has become popular as it has increased the reliability of compound identification. Currently, LC–MS and LC–tandem mass spectrometry (MS/MS) are mainly used in the analysis of BPA in biological samples. LC–MS was developed for the determination of BPA in serum and plasma samples.[29] Gas chromatography (GC)–MS method was also developed.[30,31]

ANALYSIS OF BPA AND BADGE-4OH IN HUMAN URINE SAMPLES

Ionization was enhanced by adding an appropriate amount of acid to the mobile phase of LC–MS.[32] Therefore, we studied the influence of adding a small amount of acid to the mobile phase on the ionization efficiency. The standard product of BPA and the hydrolysis product of BPA diglycidyl ether (BADGE-4OH) to which ammonium acetate was added were measured, and their multiple reaction monitoring (MRM) response ratios were compared. When 0.5 m*M* ammonium acetate was added, chromatograms having sufficient sensitivity and selectivity were obtained. The method of analysis was validated to determine the reliability of the established analytical method. The limit of detection (LOD) was 1.0 ng/ml and the correlation coefficient was 0.999. In the recovery test using human urine samples, 95% or higher recovery was obtained. The method is useful for the determination of BPA and BADGE-4OH in urine samples.

Völkel, Kiranoglu, and Fromme monitored free and total BPA in human urine samples to assess daily uptake. Using LC–MS/MS, an LOD of 0.3 μg/L was determined.[33] Literature on the determination of urinary BPA using LC–MS or LC–MS/MS is available.[34–36] Moreover, the pretreatment method as well as the method to concentrate and/or purify BPA in urine samples were examined. For example, coacervative microextraction,[37] hollow fiber-assisted liquid-phase microextraction,[38] and

SPE based on molecularly imprinted polymers[39] were examined as the pretreatment method of BPA in urine samples.

ANALYSIS OF PEs

Polyvinyl chloride (PVC) resin is widely used in our daily lives and is essential for the production of plastics used in the manufacture of food gloves,[40,41] medical devices,[42,43] furniture, flooring, and so on. PEs, particularly di(2-ethylhexyl)phthalate (DEHP), are extensively used as plasticizers to increase the flexibility of PVC products; however, it has been reported that DEHP was easily eluted from PVC products into food, drugs, and body fluids. DEHP is considered to exhibit reproductive and developmental toxicity,[44,45] carcinogenicity, and testicular toxicity.[46–48] It was also found to affect the reproductive organs and fertility.[49]

As PEs are rapidly metabolized, measurement of the metabolites is generally accepted when the amount of exposure to humans is evaluated. PEs are mainly metabolized into phthalate monoesters and excreted into the urine (Fig. 1). Albro and Lavenhar reported[50] 30 or more metabolites of DEHP metabolism. The exposure amount[51,52] of mono(2-ethylhydroxyhexyl) phthalate (MEHHP) in which mono(2-ethylhexyl) phthalate (MEHP) is subjected to oxidation by ω-1 and mono(2-ethyl-5-oxohexyl) phthalate (MEOHP) that is an oxide of MEHHP, etc. has been reported. MEHP oxides such as MEHHP and MEOHP were excreted into the urine at a high ratio compared to MEHP, when they were measured after DEHP exposure.[53–55] It is known that PEs other than DEHP are metabolized into the mono form.[56] The rate of metabolism is 69% when dibutyl phthalate is metabolized into monobutyl phthalate and 73% when dibutyl benzyl phthalate is metabolized into monobutyl benzyl phthalate. Because it is considered that PE, the parent compound (di form), is a ubiquitous compound, its metabolites are frequently monitored during exposure evaluation. Various pretreatments have been discussed[57,58] to avoid contamination of PEs during analysis. Kato et al. developed[57] the method without DEHP contamination, using essential oil quantitative equipment for measurement of blood plasma samples. Ito et al. developed the column-switching method to avoid DEHP contamination.[43,58]

The U.S. Centers for Disease Control and Prevention (CDC) has continuously promoted studies on human exposure to PE. The National Health and Nutrition Examination Survey (NHANES) project of CDC conducted a large-scale investigation of human exposure to PEs.[59] This project reported the analysis[60] of 8 phthalate monoesters, which are the metabolites of PEs, and the simultaneous analysis[52] of 11 PE metabolites when another metabolite is added using LC–atmospheric pressure chemical ionization (APCI)–MS/MS. In addition, electrospray ionization (ESI) and the use of LC–MS/MS for the simultaneous analysis of 15–16 materials related to PEs, including phthalic acid (PA) and an isomer, were reported.[61,62] Fig. 2 shows the main chemicals used as biomarkers for the evaluation of the amount of exposure to PA. Epidemiologic analysis of exposure levels in healthy individuals and the effects on the human body was conducted[63–65] using such exposure reports as those published by CDC.[66] However, there are many unsolved problems, including the identification of exposure levels on a nationwide level and the evaluation of exposure in medical practice. Clearly, much work needs to be done.

With regard to the studies of PEs conducted to date, we will introduce: 1) the evaluation of exposure to DEHP using human urine samples; 2) the measurement of DEHP and related compounds in human blood samples; and 3) the measurement of exposure to DEHP eluted from medical devices made of PVC, in this section.

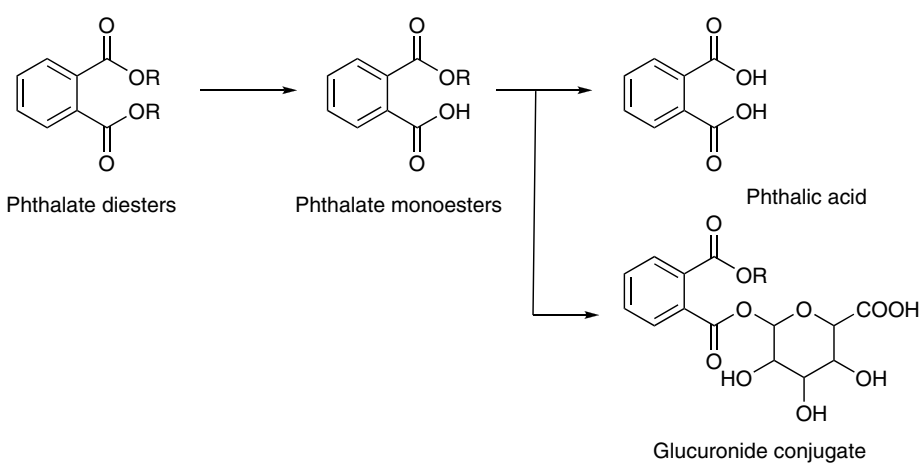

Fig. 1 Metabolic pathway of phthalate. Phthalates with R and R groups are metabolized into phthalate monoesters, which are found in urine as glucuronide conjugates or free acids.

Evaluation of Exposure to DEHP Using Human Urine Samples

As has been described earlier, evaluation of the amount of exposure to PEs using human urine samples is frequently performed by measuring the metabolites. In our monitoring study,[51] where we monitored MEHP, MEHHP, and MEOHP, the metabolites of DEHP, in urine, we performed SPE easily and rapidly by introducing online automation. In addition, we established a highly sensitive and accurate method[51] that uses LC–MS/MS and a deuterated surrogate standard. As a result of applying the above method to the determination of DEHP metabolites in the urine samples of 70 healthy volunteers, we found that the urinary concentration of MEHHP is 9.5–320.8 ng/ml, that of MEOHP is 13.9–187.5 ng/ml, and that of MEHP is not determined (ND) to 13.9 ng/ml. The urinary concentrations of MEHHP and MEOHP are higher than that of MEHP and their detection rates are 100%. Accordingly, MEHHP and MEOHP are as useful as MEHP as biomarkers for the measurement of the amount of exposure to DEHP using urine samples.

In addition to the evaluation of healthy individuals, studies on workers who were exposed to PEs in a plastic factory were carried out. We measured urinary MEHP and MBP concentrations of workers ($n = 246$) in a factory that manufactures PEs in China. MEHP was detected in all but three workers. The exposure levels after correction for creatinine was conducted were 12.4–22836.9 μg/g for MBP and 1.1–9753.2 μg/g for MEHP. The average values are 776 μg/g for MBP and 423 μg/g for MEHP. Compared to the exposure levels of previously described healthy individuals, it is clear that the workers are exposed to PEs at notably high levels.[67] This is a proof that urine samples are suitable for the assessment of DEHP exposure.[68–71]

Measurement of DEHP in Human Blood Samples

As DEHP metabolism in human blood is accelerated by blood enzymes, such as esterase, its metabolites are frequently measured. In the study[72] where the metabolites of deuterium-substituted DEHP in urine and in blood serum were compared after oral administration of DEHP, MEHP was found to be the main metabolite in blood serum, existing in greater quantities than MEHHP and MEOHP detected in urine. Therefore, we decided to measure DEHP and MEHP in blood serum. Four healthy volunteers were asked to consume food in containers that were made in part of plastic, and DEHP and MEHP concentrations in blood sera were measured. The concentration of DEHP was equal to or less than the quantitative lower limit (trace level) in all the volunteers. The concentration of MEHP was trace in three of the four volunteers and was lower than the quantitative lower limit in one volunteer.[73] In addition, we measured DEHP and MEHP in human blood plasma samples using LC–MC with the column-switching system as pretreatment. DEHP and MEHP concentrations in blood plasma sampled from six healthy volunteers were equal to or less than the quantitative limit (DEHP <25 ng/ml, MEHP <5 ng/ml).[74] The results prove that DEHP is rapidly metabolized so that the blood concentration is low and quantification is difficult at normal exposure levels. Urine samples are more suitable for the evaluation of the exposure index of PEs than blood samples.

Measurement of DEHP Eluted from Medical Devices Made of PVC

As medical practice with devices made of PVC has many advantages, the risk of exposure to DEHP tends to be ignored. Therefore, it is important that the amount of exposure be determined accurately. Studies that used PE exposure models in medical practice have been conducted.[75–77]

What should be considered in the elution of DEHP from PVC medical devices are fat-soluble agents and blood products into which DEHP may be eluted at high concentrations. The amount of DEHP that eluted into blood products stored in PVC bags was measured. When the amounts of DEHP in red blood cell products, whole blood products, blood platelet products, and blood plasma products were compared, a high concentration of DEHP was detected in whole blood products. This means that the sample matrix affects the elution of DEHP.[78] We also analyzed blood products stored in PVC bags and found that the amount of DEHP eluted increased with the storage period, and the exposure to DEHP in an amount that exceeded tolerable dairy intake (TDI) value was noted after only one blood transfusion even if the blood product had not reached the expiration date.[78] In addition, we established a method for the simultaneous analysis of DEHP and MEHP with high sensitivity and accuracy and

applied it to an elution test using drugs from medical containers. MEHP that is not used as plasticizer was detected and it was verified in a material test[43] that MEHP is indeed present. It is known that DEHP is metabolized into MEHP in the presence of blood enzymes; however, no blood enzymes existed in this case. We then decided to examine whether or not the sterilization process, which is essential for medical devices, affects the elution behavior of DEHP and MEHP. Using unsterilized products as control, we measured the elution of DEHP and MEHP from PVC products that were subjected to autoclave sterilization, gamma sterilization, and ethylene oxide gas sterilization (EOG) and found that high concentrations of MEHP were eluted from PVC products subjected to gamma sterilization. The material test also showed that MEHP was detected only from the samples subjected to gamma sterilization. The results suggest the possibility that DEHP is decomposed into MEHP during gamma sterilization.[79]

PERFLUORINATED CHEMICALS

Recently, PFCs have been focused on as new EDCs. Perfluorooctanesulfonic acid (PFOS), perfluorooctanoic acid (PFOA), perfluorooctane sulfonylamide (PFOSA), perfluorononanoic acid (PFNA), and perfluorohexanesulfonic acid (PFHxS) are examples of PFCs. They are widely used in daily commodities, such as water repellents for fabric, surfactants, leveling agents, fire-extinguishing agents, lubricants, and anticoagulants. PFCs are characterized by the attachment of several fluorine atoms to all the carbon atoms in a straight chain and a sulfonate group or a carboxylic group at the ends of the carbon atoms (Fig. 3). As the bonds between carbon atoms and fluorine atoms are extremely strong, PFCs are very stable. PFCs are relatively stable in the environment, such as in river water. On the contrary, endocrine-disrupting effects, including teratogenesis, influence on thyroid hormone,[80,81] and norepinephrine-enhancing action,[82] were found in experimental animals.[82–84] Therefore, PFCs are considered to have an adverse effect on future generations.

As an example of PFC contamination, Giesy and Kannan reported[85] the worldwide contamination by PFOS, PFHxS, and PFOSA, which are used in plastic materials and additives. PFCs remain intact in marine mammals, fishes, and birds for long periods as PFC metabolism and elimination occur very slowly. As PFCs[86] easily bond to human blood plasma protein, it is assumed that PFCs tend to remain in the blood, and therefore, PFC monitoring in blood is very useful for the evaluation of human exposure.[87–89] Methods for the analysis of PFOS, PFOA, PFOSA, and PFHxS in human blood samples have been reported.[90] PFOS was detected[90] at a rate of 100% (65 samples) in the concentration range of 6.7–81.5 ng/ml (blood serum). This indicates that human contamination with PFCs is widespread and their effects on the human body should be carefully studied. Our study suggested that PFOS and PFOA may be transported into the human fetus in the uterus through maternal blood.[91] Therefore, strict surveillance is necessary to evaluate the risk posed by PFCs to biogeocenosis and humans, especially children. Regarding chemicals related to PFOS, monitoring on a nationwide level remains to be accomplished and therefore, analytical methods with high sensitivity and reliability are required for human biological samples.

In this section, we will introduce our studies of PFCs, including: 1) the development of analytical methods to detect PFCs in blood; 2) the correlation between PFCs in maternal blood and cord blood to evaluate human exposure and their influence on future generations; and 3) the analysis of house dust and carpet dust as room environment media, to discover the source of exposure to PFCs.

Development of Analytical Methods to Detect PFCs in Human Blood Samples

The first analysis of PFOS and related chemicals in human blood serum involved the use of LC–MS/MS after liquid–liquid extraction with methyl *tert*-butyl ether (MTBE).[90]

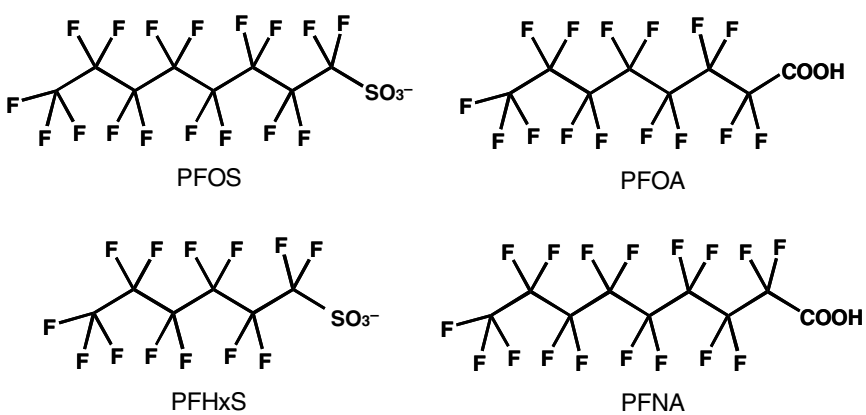

Fig. 3 Structures of PFCs: PFOS, perfluorooctanesulfonic acid; PFOA, perfluorooctanoic acid; PFNA, perfluorononanoic acid; PFHxS, perfluorohexanesulfonic acid.

This method is widely used[92] in the analysis of human blood samples in the United States. A screening analysis in which LC–MS with ESI is applied to human blood serum after the same pretreatment has been reported.[93] CDC has reported[94] the analysis of 13 PFCs in blood and maternal milk with automated SPE and LC–MS/MS. In Japan, environmental monitoring of PFCs has been performed.[95] However, investigation of human exposure has seldom been done. Currently, LC–MS or LC–MS/MS is used[91,94,96–99] to determine PFCs in biological samples. However, it is said that the use of LC–MS/MS that has high accuracy is favorable to correctly evaluate human exposure. As sample pretreatment methods, the liquid–liquid extraction method,[95–97] the SPE method,[94,98] and the column-switching method[91,99] have been reported. However, the liquid–liquid extraction method and the manual SPE method are tedious and time-consuming.

To develop a rapid, highly sensitive, and highly accurate method for the analysis of exposure in biological samples, we established the SPE LC–MS/MS method[99] in which the column-switching method and LC–MS/MS[100] that has superior selectivity are adopted. The column-switching method used in DEHP measurement (as mentioned in the preceding section) was applied to PFC measurement. As a result, pretreatment was easily achieved and contamination was reduced during measurement. This system concentrated and cleaned up analytes on the SPE cartridge after a sample from which protein was removed with acetonitrile was injected into the LC with an auto sampler and ammonium acetate buffer (pH = 4.7) and methanol (90/10, v/v) of 50 m*M* were infused for 5 min. The hexagonal valve was switched and gradient elution of a mixture of water/acetonitrile at 1 m*M* to which ammonium acetate was added was performed with the backflushing method. The analytes were eluted from the SPE cartridge and introduced into the analytical column. The ESI negative ion mode was adopted as MS/MS condition and the calibration curve and actual samples were measured in the MRM mode.

Using the online SPE pretreatment, PFCs in human blood plasma samples can be measured easily only by removing proteins. The background can be reduced by applying MS/MS. LOD is 0.08–0.14 ng/ml (S/N = 3) and the limit of quantitation (LOQ) is 0.50 ng/ml. Using an internal standard, a calibration curve was obtained with good linearity (correlation coefficient of 0.999 or higher) in the range of 0.5–100 ng/ml. In the spike recovery test of blood plasma samples, the average recovery was 93.3% or higher ($n = 6$). To validate the reliability of the proposed method, we conducted internal quality control and participated in an international accuracy control project. As internal quality control, we evaluated the reproducibility of the measured values of four samples for 20 days using PFOS standard solution at 10 ng/ml and drew control charts. As a result, the measured values were within the action lines for all 20 days. As regards external accuracy control, we participated in the international accuracy control project held in August 2005 and evaluated the validity of the values[101,102] measured using the proposed method. The measured values were all in the range of Z scores, proving the high reliability of this method.

Correlation between PFC Concentrations in Maternal Blood and Cord Blood

Blood sampled from 447 pregnant volunteers living in Hokkaido was analyzed. PFOS was detected in all samples, and PFOA and PFNA were detected at the rates of 93.1% and 43.9%, respectively. The detection range was 1.3–16.2 ng/ml for PFOS, ND (<0.5 μg/ml) to 5.2 ng/ml for PFOA, and ND (<0.5 ng/ml) to 1.6 ng/ml for PFNA. PFOS and PFOA concentrations were measured to determine the relationships between PFC concentration in blood and such parameters as the duration of pregnancy, fetal growth, and complications during pregnancy. It was verified that PFOS and PFOA concentrations were significantly higher in pregnant women suffering from fetal distress, weakness, or rigidity of the soft birth canal, than in healthy pregnant women. These new findings clarified the influence of PFOS and PFOA on the fetal growth stage. Meanwhile, PFOSA and PFDA were hardly detected.

Then, maternal blood and cord blood of 15 healthy pregnant volunteers were analyzed[91] to evaluate the transport of PFOA, PFOSA, and PFOS to the fetus in the uterus. PFOS was found in all maternal blood and cord blood samples whereas PFOA was detected in three maternal blood samples. PFOSA concentration in all maternal blood samples and PFOA and PFOSA concentrations in all cord blood samples are equal to or less than the LOQ levels. The detection range of PFOS in maternal blood and cord blood was 4.9–17.6 ng/ml and 1.6–5.3 ng/ml, respectively. A strong correlation was found between them, and the transport rate was assumed to be 30% from the obtained linear slope (Fig. 4). Accordingly, the possibility that PFCs are transported to the fetus in the uterus through cord blood was suggested.

We also analyzed blood and seminal plasma of 50 male volunteers (age: 18–24 years old). We investigated the

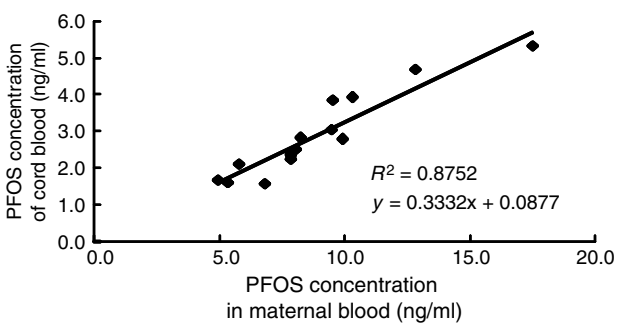

Fig. 4 Correlation between PFOS concentrations in maternal blood and cord blood.

influence of PFOS on sperm count and sperm physical properties. As PFOS was detected at low levels in seminal plasma, it is unlikely that PFOS affects the male reproductive organ.

Investigation of source of exposure to PFCs

Studies of the source of exposure to PFCs have rarely been conducted. Thus, studies of the source of contamination with PFC, the source of exposure, the diffusion path, the accumulated form, and toxicity are necessary. Currently, environmental contaminant of PFCs were mainly reported in polluted mud,[103] environmental water,[104] and atmosphere.[105] However, the concentrations of detected PFCs are extremely low, and it is not sufficient to evaluate them as an exposure source. Therefore, we focused on house and carpet dust,[106] which exists in our daily lives and contains many chemicals, to clarify the source of exposure to PFCs, and discussed[107] a highly sensitive and accurate method for the analysis of PFCs in house and carpet dust. The analytes were PFOS, PFOA, PFNA, and PFHxS, which are frequently detected in human blood, and surrogate standards were $^{13}C_4$-PFOS and $^{13}C_2$-PFOA. The supercritical fluid extraction (SFE) method was used for house and carpet dust. Effective extraction is expected when supercritical liquid is used as the extraction solvent, as the elution ability of supercritical liquid is similar to that of conventional liquid and supercritical fluid can permeate every corner of the sample, as air does.

Accurate analysis was achieved using optimum LC–MS/MS conditions: LOD was 0.58 ng/ml or higher and LOQ was 2.5 ng/ml in all the analytes. The spike recovery test was conducted with internal standards and the average recovery was 97.9% or higher [relative standard deviation (RSD) 5.8%, $n = 6$], thereby suggesting that this method is useful to quantitatively determine PFCs in house and carpet dust. This method revealed that PFC concentration in house dust was extremely high compared to that in environmental samples, including environmental water and air.

Then, PFC concentration in the blood of 20 healthy volunteers was measured and compared to that in house dust collected from each volunteer's house. PFOS and PFOA were detected from all human blood samples (plasma). PFNA and PFHxS were also detected at high frequencies. When PFC concentrations in blood plasma and house dust were compared, weak correlation was found for PFOA (Fig. 5). Accordingly, it is assumed that house dust is one of the sources of exposure to PFCs in humans.

RISK ASSESSMENT

One of the ultimate goals is to clarify how trace amounts of harmful chemicals affect human health. We need to know how much of the subject chemical humans take in through an intake medium, such as water, air, or food (evaluation of the amount of exposure), and to measure the concentration of the subject chemical in each medium. To calculate the amount of human exposure to EDCs, two exposure routes are considered. One is the calculation of the exposure amount from the intake medium, and the other is the estimation of exposure amount by analyzing human biological samples.

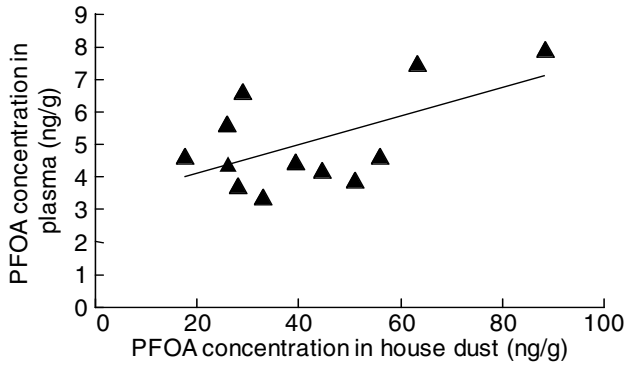

Fig. 5 Correlation between PFOA concentrations in human plasma and house dust.

PEs and PFCs detected in human urine and blood samples are chemicals that we may be constantly exposed to. Thus, evaluation of the amount of exposure and the toxicity using various assays including animal experiments is necessary to assess the risk. In the case of EDCs, many problems exist, such as "low" dosage and the multigeneration influence in the safety assessment (toxicity test), and no concrete conclusion has been reached so far. Therefore, it is necessary to evaluate the amount of human exposure to EDCs and to perform safety assessment based on the evaluation results.

This section focuses on the fact that there is irregular exposure to PEs eluted from medical devices and the exposure level is high compared to that of BPA and PFCs, to which humans are constantly exposed. Therefore, we evaluated the risk of exposure to PEs eluted from medical devices. We evaluated: 1) the exposure to DEHP when a PVC blood bag is used and 2) the exposure to DEHP from medical devices subjected to gamma sterilization.

DEHP EXPOSURE EVALUATION WHEN BLOOD BAG IS USED[78]

Evaluation of the elution of DEHP and MEHP into blood products revealed that DEHP was eluted at the highest concentration into human whole blood products. Accordingly, risk assessment was conducted with whole blood products that contained the highest concentration of DEHP. When 400 ml of whole blood was transfused at one time to a patient (50 kg), the total amount of DEHP exposure was 0.7 mg/kg/time. This value was compared to that[108] reported by the U.S. Food and Drug Administration (FDA). According to the U.S.

FDA, DEHP exposure through blood transfusions to a trauma patient is 8.5 mg/kg/day when the patient's weight is 70 kg. This confirmed that the exposure level in our study was very low. In addition, the combined amount of exposure of DEHP and MEHP was calculated. When 400 ml of whole blood was transfused at one time to a human patient, the amount of MEHP exposure was 10 μg/ml × 400 ml = 4 mg. If the patient's weight were 50 kg, the amount of exposure to MEHP would be 4 mg $(50\ \text{kg})^{-1}$/time = 0.08 mg/kg/time in one blood transfusion. Because MEHP is also eluted, we decided to conduct risk assessment of the joint exposure to DEHP and MEHP.

The U.S. FDA reported[108] the relative testicular toxicity of MEHP to DEHP as relative potency factor (RPF) = 10; that is, MEHP toxicity is 10 times higher than DEHP toxicity. The U.S. EPA performed risk assessment of a mixture using RPF, which is also known as the toxic equivalency factor (TEF), and the concentration of the mixture of MEHP and DEHP is calculated with the following formula:

$$C_{\text{mixture}} = C_{\text{index}} + \sum [\text{RPF}_i \times C_i]$$

where C is the concentration and RPF_i is the relative potency factor of the index compound.

To perform risk assessment of the combined amount of exposure of DEHP and MEHP, first, DEHP was adopted as the index compound (C_{index}: DEHP concentration) and RPF was multiplied by the amount of exposure to MEHP (C_i: MEHP concentration). Then, the value obtained was converted into the amount of exposure to DEHP, namely, 0.8 mg/kg/time. Similarly, when the amount of exposure to DEHP (when 400 ml of blood was transfused to a human weighing 50 kg) was calculated, the total amount of DEHP was 0.7 mg/kg/time (0.66 mg/kg/time); that is, the exposure amount in the combined exposure to DEHP and MEHP is 1.5 mg/kg/time with DEHP conversion. The TDI of DEHP via non-oral administration is 600 μg/kg/day, and it is suggested that patients are exposed to DEHP twice as much as TDI at one time during the blood transfusion.

DEHP EXPOSURE EVALUATION[79] FROM MEDICAL DEVICES WITH GAMMA STERILIZATION

The concentration of MEHP that was eluted from a PVC sheet subjected to gamma sterilization was approximately 600 ng/ml. In this analysis method, a piece of PVC sheet measuring 1 × 3 cm was soaked in 5 ml of polyoxyethylated hydrogenated castor oil, a pharmaceutical additive, and MEHP was extracted. The amount of MEHP that eluted into the 5 ml solution was 3 μg (=600 ng/ml × 5 ml). The surface area of the PVC sheet used in the extraction was 6 cm^2 for both sides, and the amount of MEHP eluted per unit area was 0.5 μg/cm^2. The surface area of gamma ray-sterilized infusion set (tube) having the largest surface area among commercially available PVC medical devices was 101.3 cm^2. The amount of MEHP that was eluted from the medical device is 50.7 μg (=0.5 μg/cm^2 × 101.3 cm^2).

When this medical device was used for two days, the amount of MEHP a patient weighing 50 kg was exposed to at one time was 0.51 μg/kg/day. The amount of DEHP exposure per day (approximately 35 ng/ml was eluted from samples subjected to gamma sterilization) was similarly calculated to be approximately 0.03 μg/kg/day (29.5 ng/kg/day). When this value was substituted into the formula for the exposure evaluation described before, risk evaluation of the concentration with combined exposure to DEHP and MEHP is calculated. DEHP concentration + [10 × MEHPconcentration] = 0.03 + [10 × 0.51] = 5.13 (μg/kg/day).

TDI of DEHP is 40 μg/kg/day in the case of oral administration, and it is 600 μg/kg/day in the case of non-oral administration. According to the risk evaluation of the joint exposure to DEHP and MEHP eluted from PVC with gamma sterilization, the exposure amount was 5.13 μg/kg/day as DEHP, which is below TDI.[79]

As "medical treatment" with blood products, etc. is not conducted on a daily basis and many advantages are gained from medical care, it is considered that the risk is underestimated. When medical devices are applied to pregnant women and newborn, both of whom are high-risk patients, it may be necessary to pay close attention to the DEHP exposure.

It is necessary to evaluate the amounts of human exposure to EDCs and to perform safety assessment based on those values.

CONCLUSION

EDCs have generated complex and wide-ranging issues. To this end, it is important to evaluate (risk assessment) risk as trace amounts of harmful chemicals affect our health from various perspectives. One of the issues that need to be discussed immediately is how accuracy control and analysis method validation should be performed to secure and guarantee the reliability of results.

It is necessary to not only depend on the latest analytical equipment, but to obtain reliable data, achieve reproducibility of the experiment, and analyze and disclose obtained data.

Hybrid Micellar Mobile Phases

Abstract
Micellar liquid chromatography (MLC) is a reversed-phase liquid chromatographic (RPLC) mode with mobile phases containing a surfactant with either ionic or non-ionic head groups above the critical micellar concentration. An organic solvent (usually a short-chain alcohol or acetonitrile) is also added to decrease the retention and improve peak shape. Surfactant monomers are adsorbed on the RPLC bonded stationary phase, giving rise to a stable modified surface, whereas the mobile phase contains micelles in addition to surfactant monomers. Solute interactions with the mobile and stationary phases are mainly governed by hydrophobic forces, but electrostatic attraction and repulsion between ionic groups may be important. The combination of the surfactant-modified stationary phase, micelles, and the hydro-organic medium determines the retention, efficiency, and selectivity of the separation, which are affected by a variety of experimental factors, such as the nature and concentration of surfactant and organic solvent, temperature, ionic strength, and pH. The retention behavior is highly stable and can be described through mechanistic models, taking into account the solute interactions with the mobile and stationary phases. In addition to the particular selectivity, the most relevant features of MLC are the elution of compounds in a wide range of polarities (neutral and ionic) using isocratic elution, and the feasibility of direct injection of physiological fluids.

INTRODUCTION

The first report on the use of an aqueous solution of a surfactant above its critical micellar concentration (CMC) as the mobile phase in reversed-phase liquid chromatography (RPLC) was published in 1980.[1] The technique named micellar liquid chromatography (MLC) is an interesting example of the modification of the chromatographic behavior taking advantage of a secondary equilibrium with the micelles in the mobile phase. Micelles alter solute partitioning between the bulk solvent (i.e., water or hydro–organic mixture) and the stationary phase that is coated with surfactant monomers (Fig. 1). This is translated into a major impact on both retention and selectivity.[2]

Solutes in the mobile phase can remain in the bulk water, be associated to the free surfactant monomers or micelle surface, be inserted into the micelle palisade layer, or penetrate into the micelle core. The surface of the surfactant-modified stationary phase is similar to an opened micelle and can give rise to similar interactions with the solutes. With non-ionic surfactants, the interactions are mainly hydrophobic in nature. Charged heads of ionic surfactants in both micelles and monomers adsorbed on the stationary phase are in contact with the polar solution, producing additional electrostatic interactions with charged solutes. Finally, the association of solutes with the non-modified bonded stationary phase and free silanol groups still exists.

The most serious limitations of pure micellar solutions are their poor efficiencies and weak elution strength. As early as 1983, the addition of a small percentage of 1-propanol was found to enhance both the efficiency and symmetry of chromatographic peaks, and decrease the retention.[3] Later, the term "hybrid micellar mobile phases" was given to the ternary eluents of water/organic solvent/micelles. Although 1-propanol is still the most frequent additive, other alcohols (methanol, ethanol, 1-butanol, and 1-pentanol) and organic solvents common in conventional RPLC (acetonitrile and tetrahydrofuran) have also been used. It should be noted that micellar solutions increase the solubility of butanol and pentanol in water to reach concentration levels useful in chromatography.

In the hybrid system, solute partition equilibria are significantly displaced away from the micelle and the stationary phase toward the bulk hydro–organic phase, which is more non-polar (Fig. 1). However, as long as the integrity of micelles is maintained, the addition of organic solvent to micellar mobile phases will not create a hydro–organic system. The chromatographic behavior of alkyl homologous series has been used to demonstrate that the separation mechanism in hybrid MLC is

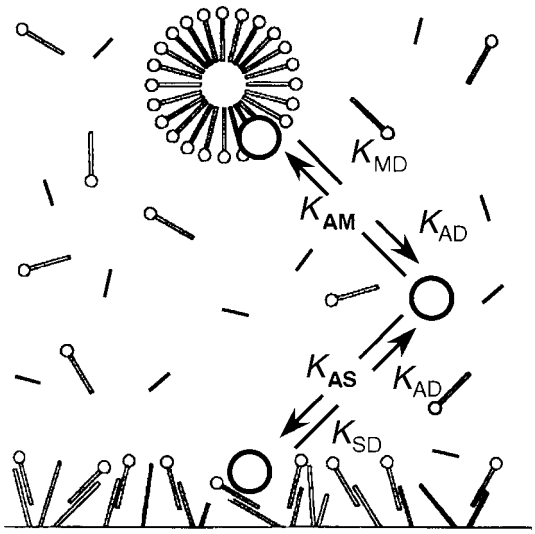

Fig. 1 Solute–micelle and solute–stationary phase interactions in hybrid micellar mobile phases (see text for meaning of equilibrium constants).

more similar to pure MLC than to conventional RPLC.[4] In hydro–organic systems, the retention of homologue compounds is described as follows:

$$\log k = \log \alpha(CH_2) n_C + \log \beta \quad (1)$$

where n_C is the number of carbon atoms in the homologue, $\alpha(CH_2)$ is the non-specific selectivity of a methylene group, and β is the contribution of the series functional group to the retention. In contrast to this behavior, a linear relationship between k and n_C is observed either with pure or hybrid micellar mobile phases.

NATURE OF THE MOBILE AND STATIONARY PHASES

Most MLC procedures use micelles of the anionic surfactant sodium dodecyl sulfate (SDS). Other useful surfactants include the cationic cetyltrimethylammonium bromide or chloride (CTAB or CTAC) and the non-ionic Brij-35.[2,5] The separations are usually carried out in C_{18} or C_8 columns.

The presence of a small amount of an organic solvent in the mobile phase produces changes in the micellization process which depend on the nature of the additive. A progressive increase in the CMC of SDS (8.2×10^{-3} *M* in water at 25°C) is observed by adding methanol and acetonitrile; the reverse is observed when ethanol, propanol, butanol, and pentanol are added. As an example, the CMC of SDS in the presence of 4% (v/v) organic solvent is 8.7×10^{-3} *M* (methanol), 9.2×10^{-3} *M* (acetonitrile), 7.4×10^{-3} *M* (ethanol), 5.9×10^{-3} *M* (propanol), 2.7×10^{-3} *M* (butanol), and 2.0×10^{-3} *M* (pentanol).[6]

Methanol, which has the shortest carbon chain, is more polar and soluble than other alcohols. SDS monomers are more easily solvated in an aqueous–methanol medium. This inhibits them from interacting and forming micelles. A similar behavior is expected for acetonitrile. Ethanol and propanol, which are also miscible with water, remain outside the micelles, dissolved in the bulk liquid, but interact with the micelle surface. Repulsion among the ionic heads of surfactant monomers is reduced in the presence of these two alcohols, thus aiding the formation of micelles.

As the length of the alcohol alkyl chain increases, its affinity for the SDS micelle is enhanced. Butanol and pentanol are inserted in the intermonomer spaces of the micelle palisade aligned with the surfactant molecules, the polar hydroxyl group oriented toward the Stern layer, and the alkyl chains located in the non-polar micelle core. A swollen mixed micelle is thus formed. Such micelles are geometrically hindered to allocate additional surfactant monomers, which is translated into a CMC reduction. However, above 4% butanol and 1.5% pentanol, the decay rate in the CMC values slows down. An explanation for this behavior is that above a given concentration, the amount of alcohol entering the palisade is not significant and the excess is solubilized in the core of the swollen micelle. Further additions of alcohol lead to a dramatic change in the mobile-phase microstructure, yielding a microemulsion.

Surfactant coating masks the stationary phase. In the case of C_8 and C_{18} columns, the hydrophobic tail of surfactants associates to the alkyl chain bonded to the silica stationary phase, with the polar head groups oriented away from the surface (Figs. 1, 2A and B). For SDS and CTAB, this creates negatively and positively charged layers, respectively, which affect the penetration depth of solutes into the bonded phases. For CTAB, surfactant adsorption leads to a more hydrophobic stationary phase, because the cationic trimethylammonium head group is partially incorporated into the bonded phase, associated to free silanols. In contrast, on cyano columns, both charged surfactants (SDS and CTAB) are adsorbed head down with their tails projected outward, thus creating pseudoalkyl-bonded phases (Fig. 2C and D).[7]

Organic solvents induce changes in the properties of surfactant-coated stationary phases, such as polarity, surface area, or pore volume. Several studies have demonstrated that *n*-alcohols interpenetrate the C_{18}-bonded alkyl chains to form a single monolayer, i.e., the hydroxyl group oriented toward the aqueous phase. The competition between organic solvent and surfactant molecules for the active sites on the column explains the reduction of adsorbed surfactant at increasing concentration of organic solvent in the mobile phase. For ionic surfactants, this reduction is linear with slopes that depend on the strength of the solvent (methanol<ethanol<propanol<butanol<pentanol).[2]

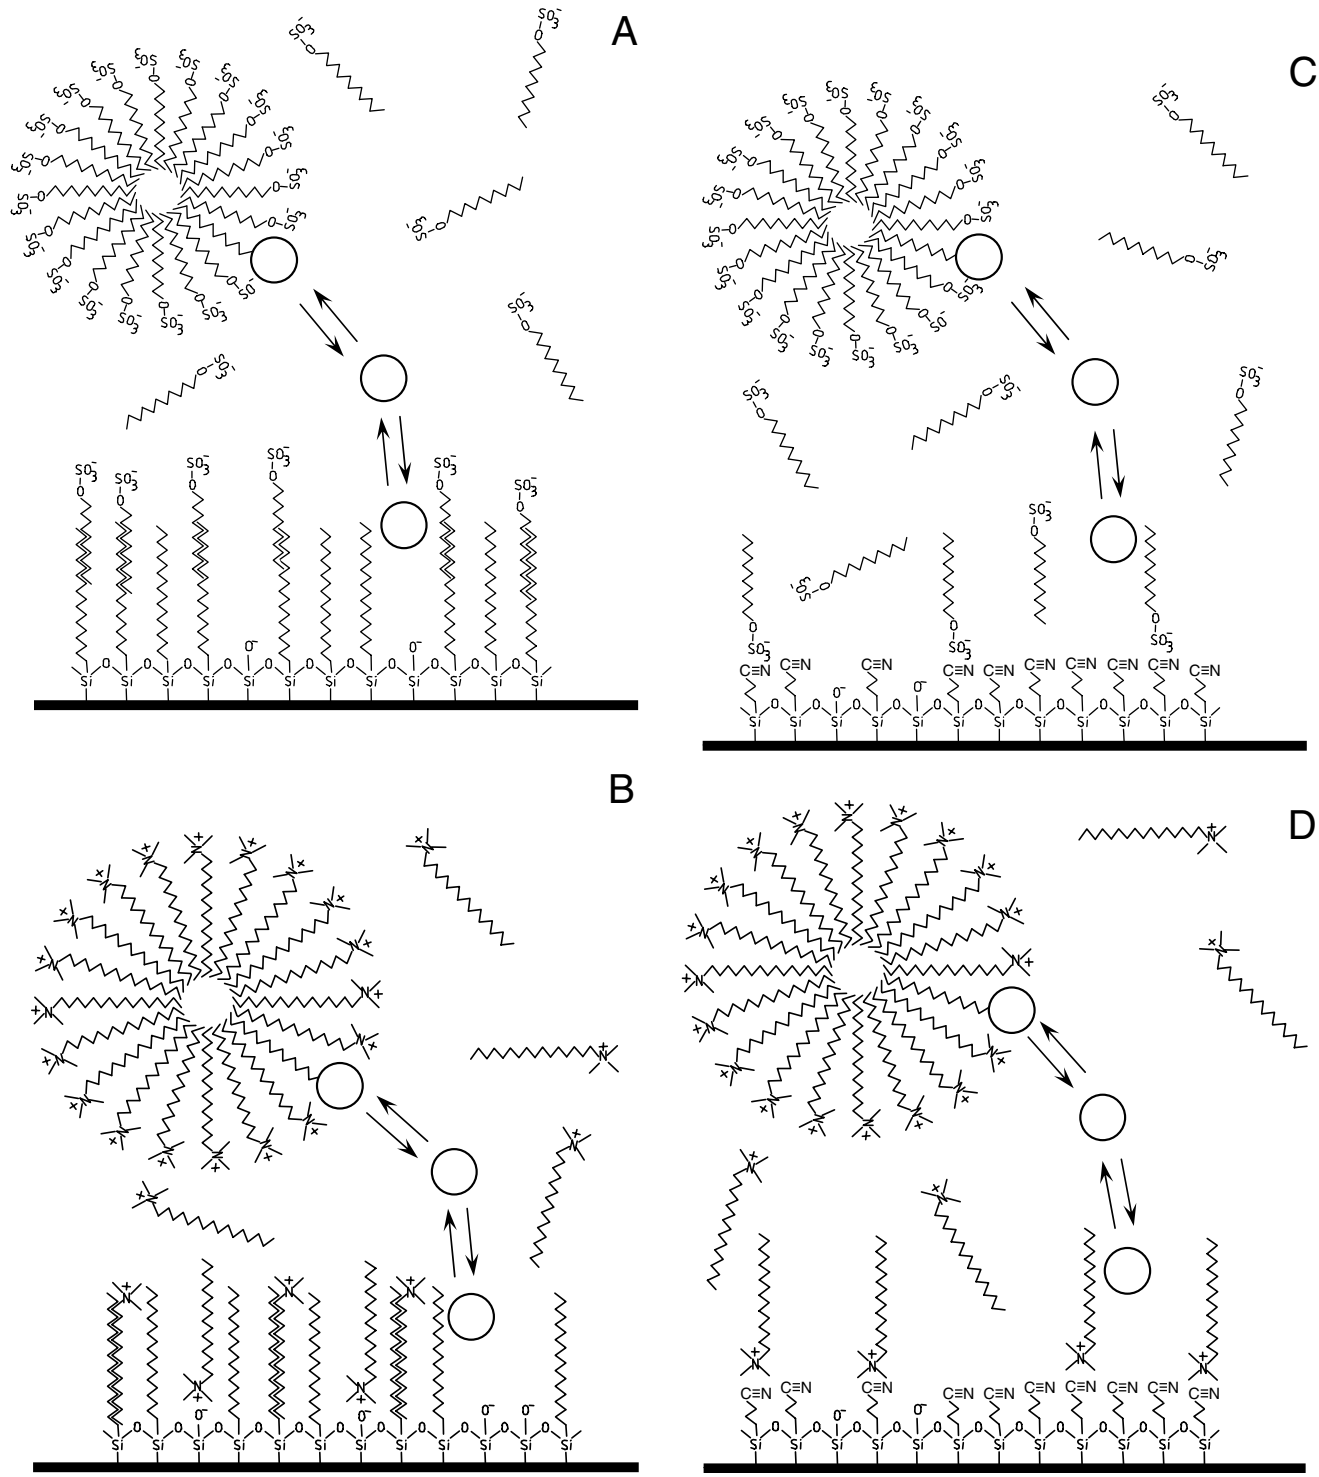

Fig. 2 Schematic representation of separation microenvironments in MLC using octadecyl- (A,B) and cyanopropyl-(C,D)-bonded phases, and mobile phases containing the anionic SDS (A,C) and the cationic CTAB (B,D).

Solute retention varies with the concentration of propanol, butanol, and pentanol in the mobile phase, in the same way as CMC does. This means that the collateral effects which change the CMC in an organic–micellar system are, at least partially, those that induce shorter retention with hybrid mobile phases: the modification of bulk water and micelle. As noted, another important issue that affects retention is the modification of the

structure of the stationary phase. The analogous effects on both microenvironments (micelle and stationary phase) are evidenced in the parallel variation of solute–micelle and solute–stationary phase association constants, as the concentration of organic solvent changes.[8]

RETENTION MECHANISMS

In MLC, solutes are separated on the basis of their differential partitioning between bulk solvent and micelles in the mobile phase or surfactant-coated stationary phase.[9] For water-insoluble species or for species strongly bound to micelles, partitioning can also occur via direct transfer between the micellar pseudophase and the modified stationary phase. Partition equilibria are affected by a variety of factors, such as the nature and concentration of surfactant and organic modifiers, temperature, ionic strength, and pH.

Neutral solutes eluted with all types of surfactants and charged solutes eluted with non-ionic surfactants will only be affected by non-polar, dipole–dipole, and proton donor–acceptor interactions. Besides these interactions, charged solutes interact electrostatically with ionic surfactants. In any case, the steric factors can be important, owing to the difficult access of micelles to the bonded-phase pores.

For charged solutes eluted with ionic surfactants, two situations are possible: repulsion or attraction, depending on the mutual charges of solutes and surfactant. In the case of electrostatic repulsion with the stationary phase, charged solutes cannot be retained and elute at the dead volume, unless significant hydrophobic interactions with the modified bonded layer exists. In contrast, combined electrostatic attraction and hydrophobic interactions with the modified stationary phase may give rise to strong retention.

According to their elution behavior, solutes can be classified into those binding to micelles, non-binding, and antibinding. Binding solutes show decreased retention when the concentration of micelles in the mobile phase is increased. For solutes that do not associate with micelles, the retention may remain unaltered upon changes in micelle contents (non-binding), or increase with the micelle concentration (antibinding). The most common behavior is binding to micelles, while antibinding is uncommon, and has only been observed with stationary phases that do not adsorb large quantities of surfactant (such as C_1), or with cyano-bonded phases, where the surfactant charge is buried close to the bonded phase. In both cases, charged solutes are strongly excluded or repelled from the micelle, which forces them to bind to the stationary phase, where they are retained due to hydrophobic forces. The change in the antibinding behavior to non-binding and further to binding upon the addition of salts reveals the electrostatic nature of the interactions.

Electrostatic interactions between solutes and charged stationary phase and micelles are also the main factors responsible for the shifts in the dissociation constants and retention of ionizable solutes. In alkyl-bonded stationary phases with SDS, both weak acids and bases show the largest retention in acidic solution (descending k vs. pH curves). Mirror curves (i.e., ascending) are found with CTAB: the largest retention is observed in basic solution. This behavior contrasts with that observed in conventional RPLC, where the k vs. pH curves are descending for weak acids and ascending for weak bases.

DESCRIPTION OF THE RETENTION BEHAVIOR

In pure micellar mobile phases, retention is described by a hyperbolic relationship.[10]

$$k = \frac{\phi P_{AS}}{1 + \upsilon(P_{AM} - 1)[M]} = \frac{K_{AS}}{1 + K_{AM}[M]} \quad (2)$$

where k is the retention factor, ϕ is the phase ratio, P_{AS} and P_{AM} are the solute–stationary phase and solute–micelle partition coefficients, υ is the specific volume of surfactant monomers, and $[M]$ is the concentration of surfactant forming micelles (total surfactant concentration minus the CMC). The right term with K_{AS} and K_{AM} is often used for simplicity.

The same model is valid for hybrid micellar mobile phases at fixed concentration of organic solvent, although both constants, K_{AS} and K_{AM}, decrease when the modifier concentration increases especially for non-polar solutes. An extended model, including the effect of changes in organic solvent concentration, has also been proposed:[11]

$$k = \frac{K_{AS}\frac{1 + K_{SD}\varphi}{1 + K_{AD}\varphi}}{1 + K_{AM}\frac{1 + K_{MD}\varphi}{1 + K_{AD}\varphi}[M]} \quad (3)$$

where φ is the volume fraction of organic solvent, K_{AS} and K_{AM} are the association constants in pure micellar eluents, and K_{AD}, K_{MD}, and K_{SD} measure the relative changes in solute concentration in bulk water, micelle, and stationary phase, respectively, in the presence of organic solvent, taking the pure micellar solution as reference (see also Fig. 1). The last three constants increase with the organic solvent strength. For polar and moderately polar solutes eluted with propanol, K_{SD} can be disregarded and Eq. 3 is simplified as follows:

$$\frac{1}{k} = c_0 + c_1[M] + c_2\varphi + c_{12}[M]\varphi \quad (4)$$

Chromatographic optimization is usually performed at a preselected pH. However, the simultaneous consideration of the three factors (i.e., surfactant, organic solvent, and pH) expands the separation capability for some problems. The retention can be predicted from (see below)

$$k = \frac{K_{AS}\frac{1+K_{SD}\varphi}{1+K_{AD}\varphi} + K_{HAS}\frac{1+K_{HSD}\varphi}{1+K_{HAD}\varphi}K_H[H]}{\left(1 + K_{AM}\frac{1+K_{MD}\varphi}{1+K_{AD}\varphi}[M]\right) + \left(1 + K_{HAM}\frac{1+K_{HMD}\varphi}{1+K_{HAD}\varphi}[M]K_H[H]\right)} \quad (5)$$

where K_{AS}, K_{AM}, K_{AD}, K_{MD}, and K_{SD} are the equilibrium constants associated to the basic species; and K_{HAS}, K_{HAM}, K_{HAD}, K_{HMD}, and K_{HSD} correspond to the acidic species. K_H is the protonation constant in the hydro–organic bulk solvent, and $[H]$ is the proton concentration.[12]

Eqs. 2–5 give accurate predictions of the retention with several types of surfactant (anionic, cationic, and nonionic) and organic solvents (alcohols and acetonitrile), and solutes of diverse charge and polarity, with errors usually below 3–5%.

ELUTION STRENGTH

One of the most serious problems of pure micellar eluents is their weak elution strength. Shorter retention times are obtained by increasing the surfactant concentration, but the chromatographic efficiency usually deteriorates. Ultrawide pore or shorter chain-length-bonded stationary phases constitute other alternatives, but the most practical solution seems to be the addition of a small amount of an organic solvent to the mobile phase. This strategy may result in adequate elution strengths, together with improved chromatographic efficiencies and selectivities, which will produce favorable effects on both the resolution and the analysis time. However, the addition of an organic solvent is unsuitable for low-retained solutes because the retention level may fall below the optimal retention range. In other instances, adequate retention times are achieved, but the efficiencies remain low.

The elution strength of the organic solvent in MLC has been described according to Eq. 3.[13] However, a simple logarithmic relationship (similar to that used in conventional RPLC) is customary:[14]

$$\log k = \log k_0 - S\varphi \quad (6)$$

where S is the sensitivity of solute retention to changes in the volume fraction of organic solvent and $\log k_0$ is the retention in a pure aqueous micellar solution. A similar equation has been used for the surfactant:

$$\log k = \log k'_0 - S'[M] \quad (7)$$

If Eq. 2 is rewritten in the logarithmic form:

$$\log k = \log K_{AS} - \log\left(1 + K_{AM}[M]\right) \quad (8)$$

and linear relationships are assumed between $\log K_{AS}$ and $\log (1+K_{AM}[M])$ with φ, the following results:

$$S = S_s - S_m \quad (9)$$

S_s and S_m represent the sensitivity of variations in solute partitioning from bulk solvent into the stationary phase and micelles, respectively, with changes in φ. The negative sign in Eq. 9 reflects the competing nature of the two partition equilibria. In the absence of micelles, $S_m = 0$ and $S = S_s$, which represents the solvent strength parameter in conventional hydro-organic RPLC. Eq. 9 also shows that the elution strength in hybrid micellar systems will generally be smaller. The magnitude of the reduction depends on the interaction degree of solutes and organic solvents with micelles.

Longer length alcohols, which are more hydrophobic, are able to shorten the retention to a larger extent. Retention times are smaller for micellar solutions containing greater amounts of modifier, but even relatively low amounts can produce dramatic effects. These are attenuated as the surfactant concentration is increased. Finally, the decrease in retention times is more intense for more hydrophobic solutes. Depending on the strength of the interactions, the surfactant or the organic solvent has a prevalent effect on the elution strength of the micellar systems. In the case of basic drugs eluted with SDS micellar mobile phases, changes in retention with the surfactant concentration are larger due to the high affinity of these compounds for the anionic micelles.

The elution strength of hybrid micellar mobile phases was measured for a number of organic additives (alcohols, alkane diols, alkanes, alkylnitriles, and dipolar aprotic solvents, such as dimethyl sulfoxide and dioxane) added to micellar SDS, CTAC, and Brij-35.[15] Benzene and 2-ethylanthraquinone were used as probe compounds. The presence of alcohols, alkane diols, alkylnitriles, and dipolar aprotic solvents produced a diminution of the retention times, reaching remarkable levels for the most hydrophobic compound (2-ethylanthraquinone). The observed elution strength order roughly correlated the octanol–water partition coefficients of the additives, $P^{a}_{o/w}$ (Fig. 3), or their ability to bind to micelles (not shown). In contrast, alkanes (pentane, hexane, and cyclohexane) had relatively little effect on the retention.

In MLC, highly hydrophobic solutes are removed from the column more effectively with regard to conventional RPLC, transported by micelles. Also, when compounds in a wide range of polarities are eluted with hybrid micellar mobile phases at increasing volume fraction of organic

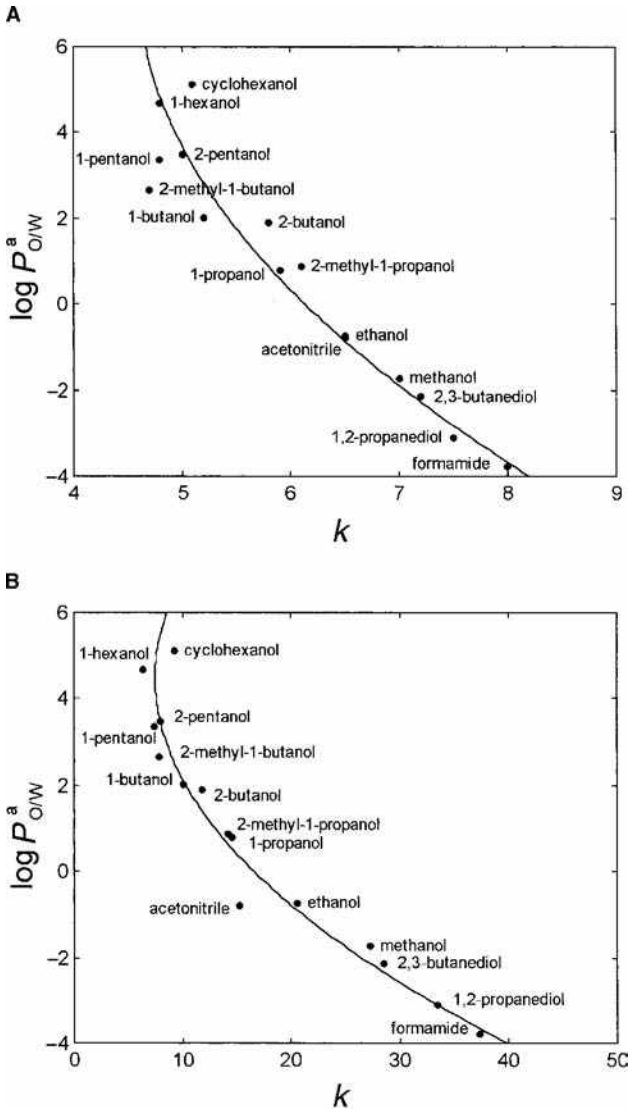

Fig. 3 Correlation between octanol–water partition coefficients of the organic solvents (log $P^a_{o/w}$), and the retention factors for: A, benzene and B, 2-ethylanthraquinone in hybrid SDS micellar mobile phases. The concentration of surfactant and organic solvent was 0.285 *M* and 5%(v/v), respectively.
Source: From Effect of a variety of organic additives on retention, and efficiency in micellar liquid chromatography, in Anal. Chem.[15]

solvent, the retention times of late-eluting compounds are reduced to a larger extent than earlier peaks.

EFFICIENCY

Low efficiencies are observed for highly hydrophobic solutes eluted with pure micellar mobile phases. This fact hindered the initial development of MLC. The addition of a small amount of organic solvent at least partially remedied this situation.[16] Efficiency enhancements—dramatic in some cases—have been reported for solutes eluted with SDS micellar mobile phases in the presence of alcohols, alkane diols, alkylnitriles, and dipolar aprotic solvents. In some instances, efficiencies are comparable or even superior in MLC with regard to conventional RPLC, using the same column and instrument. Concomitant with the enhanced efficiencies, improvements in peak symmetry have been observed. The reason for these effects is an increased solute mass transfer between micelles/stationary phase and aqueous phase due to the greater solute–micelle exchange rate constants, lower stationary phase viscosity, and smaller amount of adsorbed surfactant.

The case of basic drugs is particularly interesting, with large efficiency enhancements and peak-tailing suppression in SDS systems.[17] This makes the use of special columns less necessary. The surfactant layer adsorbed on the column prevents the interaction of basic compounds with free silanol groups, which accounts for the low efficiencies observed with conventional columns in hydro–organic RPLC. Cationic basic drugs interact with the negatively charged surfactant layer in a fast process, without penetrating too deep in the alkyl-bonded layer to interact with the buried silanols (slow process).

Plots of log $P^a_{o/w}$ vs. plate count for benzene and 2-ethylanthraquinone eluted with micellar SDS, in the presence of several alkanols and alkane diols, show an initial steep increase in efficiency, after which an approximately constant value is reached (Fig. 4). Among the alcohols, maximal efficiency for benzene and 2-ethylanthraquinone is obtained with butanols and pentanols, with enhancement factors of 2.5 and 25, respectively (compared to pure SDS). However, final efficiencies for 2-ethylanthraquinone are much lower compared to benzene. Dipolar aprotic modifiers (acetonitrile or dimethylsulfoxide) appear to be somewhat more effective in enhancing efficiencies than alcohols with comparable $P^a_{o/w}$. The advantage of using acetonitrile as additive in MLC for the analysis of sulfonamides, tetracyclines, and most polar steroids has been reported.[18]

Chromatographic efficiency seems to be linked to the additive-to-surfactant concentration ratio in the micellar mobile phase. The plate count increases with this ratio, and reaches a maximal level (e.g., at pentanol/SDS = 6 and acetonitrile/CTAC = 12).[16] The organic solvent/surfactant ratio affects the exchange rates of the solute between micelle/stationary phase and micelle/aqueous phase. It also controls the extent of the surfactant coverage and the fluidity of the organic layer on the stationary phase.

RESOLUTION PERFORMANCE

The rate of change in retention at varying surfactant and organic solvent concentration depends on the solute charge and polarity, and on the nature of both surfactant and

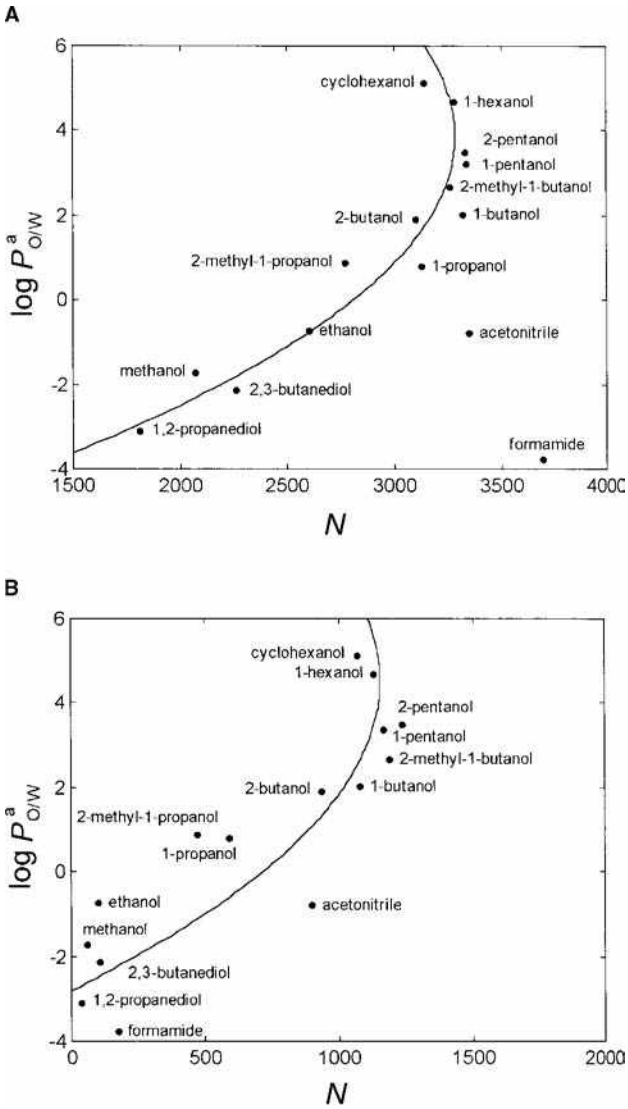

Fig. 4 Correlation between octanol–water partition coefficients of the organic solvents and the efficiencies (plate count) for A, benzene and B, 2-ethylanthraquinone in hybrid SDS micellar mobile phases.
Source: From Effect of a variety of organic additives on retention, and efficiency in micellar liquid chromatography, in Anal. Chem.[15]

organic solvent in the mobile phase. Although the elution strength increases with the concentration of the micelle and the organic solvent, their effect on peak resolution can be quite different, even opposite. The resolution behavior of solutes depends on the relative change of the apparent solute–micelle and solute–stationary phase association constants. These usually decrease with an increase in volume fraction of organic solvent. The magnitude of the diminution is, however, not equal for each solute.

Improving the resolution and simultaneously reducing the analysis time are the two most important goals in optimization strategies. Several examples have been published where a hybrid micellar mobile phase was able to achieve an acceptable separation—impossible with pure micellar eluents—within much shorter analysis times. The first decision in method development in MLC concerns the selection of a surfactant/organic solvent system. The second step consists of the optimization of the selectivity. The separation can be improved by varying only one factor (i.e., proton, surfactant, and/or organic solvent concentration), or by modifying one after optimizing the other. However, operating like this, the best separation conditions can be easily missed.

Typically, resolution diagrams in MLC are complex, with several local maxima, frequently denoting interaction between factors. For this reason, reliable optimal conditions require considering all factors simultaneously, by applying an interpretive optimization strategy (i.e., based on the description of the retention behavior and peak shape of solutes). In this task, the product of free peak areas or purities has proved to be the best optimization criterion.[19] An interactive computer program is available to obtain the best separation conditions in MLC.[20]

GUIDELINES AND SCOPE

The routine work with hybrid micellar mobile phases requires keeping some cautions usually not described in scientific reports or specialized manuals. The experimental procedure comprises two main stages: the mobile phase preparation and the column conditioning.[21]

The surfactant concentration range in the mobile phase is usually relatively narrow. The lowest concentration should be well above the CMC. Usual values are 0.05 *M* for SDS and 0.04 *M* for CTAB. Concentrations exceeding 0.20 *M* are not convenient due to the high viscosity of the mobile phase and degradation of the efficiencies. Most separations are performed in a buffered medium, phosphoric, and citric acid systems being the most appropriate. It should be taken into account that potassium salts are not compatible with SDS (which is used in more than 60% of the work involving MLC), since potassium dodecyl sulfate may precipitate from aqueous solution at room temperature.

The concentration of organic solvent must be low enough to guarantee the existence of micelles. Such maximal amount depends on the type of surfactant and organic solvent. For SDS, the maximal volume fractions of acetonitrile, propanol, butanol, and pentanol that seem to guarantee the presence of micelles are 30%, 15%, 10%, and 7% (v/v), respectively. However, analytical reports where authors claim the use of hybrid micellar mobile phases and these maximal values are exceeded—micelles do not exist—are not unusual.

Selection of the most suitable organic solvent should consider the polarity of analytes and the strength of their association with the surfactant. Solute log $P_{o/w}$ values can be used, in most cases, as a guide to make this decision.[18] Thus, with SDS as surfactant, a low concentration of propanol (1%v/v) is useful to separate compounds with log $P_{o/w} < 1$ as amino acids. A greater concentration of this solvent (5–7%) is needed for

compounds in the range $1 < \log P_{o/w} < 2$ as diuretics and sulfonamides. Pentanol (2–6%) is more convenient for low polar compounds with $\log P_{o/w} > 3$ as steroids. For basic compounds, such as phenethylamines with $0 < \log P_{o/w} < 2$ and β-blockers with $1 < \log P_{o/w} < 3$, propanol is however too weak, due to the strong electrostatic interaction between the cationic solutes and the anionic surfactant adsorbed on the stationary phase. In this case, a high concentration of propanol (15%), or preferably a moderate concentration of butanol (<10%) should be used. Methanol and ethanol are scarcely used in practice, owing to their weak elution strength.

Working in MLC involves coating the column with a layer of surfactant, and its further regeneration before stopping the system or removing it for storage. Before flushing the micellar mobile phase, removing any organic solvent contained in the column with water is recommended. Once the mobile phase is flushed, about 1 hr is required to assure complete surfactant coverage. In order to avoid any column damage, the micellar mobile phase should be continuously flushed through the system. To reduce the cost, it can be recycled even during the analysis, as long as a low number of injections are performed. Regeneration should be carried out by removing first the micellar mobile phase with pure water (10–20 volumes), and next replacing water by 100% methanol (at least 10 volumes). The complete cleaning procedure takes about half an hour.

Applications are mainly focused on the determination of drugs (e.g., anticonvulsant agents, barbiturates, β-blockers, diuretics, corticoids, stimulants) in formulations of physiological fluids, such as serum, plasma, or urine.[2,5,22] In this case, the direct injection capability of MLC is especially appreciated. Simple filtration of the sample permits the direct injection of the physiological fluids in the chromatographic system, with no noticeable damage after repetitive injections. MLC has also been extended to the analysis of samples of industrial, environmental, veterinarian, and nutritional interest.

MLC has revealed as an interesting way to simulate different systems. It has been demonstrated that RPLC with micellar mobile phases of Brij-35 can emulate in vitro partitioning processes in biomembranes, better than the conventional RPLC.[23] The therapeutic action of diuretics has been attributed to their hydrophobic character, among other properties. It has been shown that MLC with SDS mobile phases and C_{18} columns offers a scale for hydrophobicity that leads to a further correlation between the retention and the sites of action of diuretics within the nephron.[24] MLC has also served to model the behavior of environmental pollutants in ground water. In this case, the stationary phase and the micellar mobile phase simulate soil particles containing organic matter and groundwater carrying a surfactant, respectively.[25]

CONCLUSIONS

Pure micellar mobile phases are certainly attractive, considering the increasing restrictions in the use of organic solvents in laboratories. Hybrid micellar mobile phases were first belittled because some of MLC's appeal was considered to be lost. However, most reported analytical procedures in MLC utilize hybrid eluents. For most analytes, retention with pure micellar mobile phases is too high, which necessitates the addition of an organic solvent to achieve adequate retention times. This makes peak shape to improve as well.

Procedures that use the hybrid eluents still have the advantage of requiring significantly smaller amounts of organic solvent with respect to conventional RPLC. In MLC, the organic solvent is also highly retained in micellar solution, which reduces the risk of evaporation. The mobile phases can therefore be kept stable for a long time. The toxicity, flammability, environmental impact, and cost of RPLC are consequently reduced.

Micellar mobile phases are compatible with a wide range of solutes (ionic to water-insoluble). The decrease in the strength of acids in the SDS micellar system expands the pH range where the acidic species is dominant to more basic medium with regard to hydro–organic mixtures. This gives rise to three advantages: maximal retention is more often observed within the operable limits of silica-based columns, column life is extended as working at less stressing pH is possible, and measurements are more reproducible since these are made in a region of constant retention, where only one species dominates. Regarding basic compounds, their retention is increased by attraction to the stationary phase of the cationic species, which is dominant in acidic medium. This allows an improved control of selectivity. Peak tailing is also eliminated due to the effective masking of silanol groups.

Chromatographic peaks in MLC appear usually more evenly distributed with regard to those obtained with conventional hydro–organic mixtures. Owing to this compression effect, the use of gradients is less necessary. The above features have allowed the development of multiple applications that are competitive against conventional RPLC.

Hydrodynamic Equilibrium in CCC

Petr S. Fedotov
Boris Ya. Spivakov
Vernadsky Institute of Geochemistry and Analytical Chemistry, Russian Academy of Sciences, Moscow, Russia

INTRODUCTION

In all cases, countercurrent chromatography (CCC) utilizes a hydrodynamic behavior of two immiscible liquid phases through a tubular column space which is free of a solid support matrix. The most versatile form of CCC, called the hydrodynamic equilibrium system, applies a rotating coil in an acceleration field (either in the unit gravity or in the centrifuge force field). Two immiscible liquid phases confined in such a coil distribute themselves along the length of the coil to form various patterns of hydrodynamic equilibrium.[1]

DISCUSSION

According to the hypothesis proposed by Ito,[2] the multitude of hydrodynamic phenomena observed in the rotating coils can be attributed to the following types of liquid distribution.

1. The basic hydrodynamic equilibrium (the two liquid phases are evenly distributed from one end of the coil, called the head, and any excess of either phase is accumulated at the other end, called the tail). Here, the tail–head relationship of the rotating coil is defined by the direction of the Archimedean screw force which drives all objects toward the head of the coil.
2. The unilateral hydrodynamic equilibrium [the two solvent phases are unilaterally distributed along the length of the coil, one phase (head phase) entirely occupying the head side and the other phase (tail phase) the tail side of the coil]. The head phase can be the lighter or the heavier phase and also can be the aqueous or the non-aqueous phase, depending on the physical properties of the liquid system and the applied experimental conditions. This type of equilibrium may also be called bilateral, indicating the distribution of the one phase on the head side and the other phase on the tail side.[3]

To illustrate the process of establishing the hydrodynamic equilibrium, it is worthwhile to begin with the distribution of two immiscible solvent phases in the "closed" coil, simply rotated around the horizontal axis in the unit gravitational field. The coil is filled with equal volumes of the lighter and heavier phase and then sealed at both ends. At a slow rotation of 10–20 revolutions per minute (rpm), two liquid phases are evenly distributed in the coil (basic hydrodynamic equilibrium) due to the Archimedean screw force. As the rotational speed increases, the heavier phase quickly occupies more space on the head side of the coil and, at the critical speed range of 60–100 rpm, the two phases are completely separated along the length of the coil, with the heavier phase on the head side and the lighter phase on the tail side (unilateral hydrodynamic equilibrium).

After this critical speed range, the amount of the heavier phase on the head side decreases sharply, reaching substantially below the 50% level at about 160 rpm. Further increase of the rotational speed again distributes the two phases fairly evenly throughout the coil, apparently due to the strong radial centrifugal force field produced by the rotation of the coil. The phase distribution described can be observed in many solvent systems [chloroform-acetic acid-water (2/2/1), hexane-methanol, *n*-butanol-water, etc.], glass coils [10–20 mm inner diameter (I.D.)] with different helical diameters (5–20 cm) being applied.

As a first approximation, the complex hydrodynamic phenomenon taking place in the rotating coil may be explained by the interplay between two force components acting on the fluid. The tangential force component (F_t) generates the Archimedean screw effect to move two phases toward the head of the coil, and the radial force component (F_r) which acts against the Archimedean force. The critical speed range is the most interesting. An increase of the rotational speed up to 60–100 rpm alters the balance of the hydrodynamic equilibrium by an enhanced radial centrifugal force field that increases the net force field acting at the bottom of the coil and decreases that acting at the top. Under this asymmetrical force distribution, the movement of the heavier phase toward the head is accelerated, whereas the movement of the lighter phase toward the head is retarded. This results in a unilateral hydrodynamic phase distribution in the rotating coil.

The hydrodynamic equilibrium condition may be used for performing CCC as follows. First, the coil is completely filled with the stationary phase, either the lighter or the heavier phase, and the other phase is introduced from the

head end of the coil while the coil is rotated around its axis. Then, the two liquid phases establish equilibrium in each turn of the coil and the mobile phase finally emerges from the tail end of the coil, leaving some amount of the stationary phase permanently in the coil. Solutes locally introduced at the head of the coil are subjected to a partition process between two phases and eluted in order of their partition coefficients. In general, higher retention of the stationary phase significantly improves the peak resolution. Consequently, the unilateral hydrodynamic equilibrium condition provides a great advantage in performing CCC, because the system permits retention of a large amount of stationary phase in the coil if the lighter phase is eluted in a normal mode (head-to-tail direction) or the heavier phase in a reversed mode (tail-to-head direction).

In general, the retention of the stationary phase in the coil rotated in the unit gravity field entirely relies on relatively weak Archimedean screw force. In this situation, application of a high flow rate of the mobile phase would cause a depletion of the stationary phase from the column. This problem can be solved by the utilization of synchronous planetary centrifuges, free of rotary seals, which enable one to increase the rotational speed and, consequently, enhance the Archimedean screw force. The seal-free principle can be applied to various types of synchronous planetary motion. In all cases, the holder revolves around the centrifuge axis and simultaneously rotates about its own axis at the same angular velocity ω.

When the coil is mounted coaxially around the holder, which revolves around the central axis of the device and counterrotates about its own axis, two axis being parallel (Type I), two solvent phases are distributed along the length of the coil according to the basic hydrodynamic equilibrium. It does not favor the stationary-phase retention. Another, similar planetary motion, except that the holder revolves around the central axis of the centrifuge and rotates about its own axis in the same direction (Type J), produces, regardless of the rotational speed, a totally different phase-distribution pattern which is typical for the unilateral hydrodynamic equilibrium. The unilateral distribution can also be attained in the coaxially mounted coils in cross-axis planetary centrifuges.[4] It is important to note that all the planetary motions providing the unilateral distribution form an asymmetrical centrifuge force field that closely resembles that observed in the coil rotating at the critical speed in the unit gravity.

The unilateral hydrodynamic equilibrium conditions provide the basis for high-speed CCC (HSCCC, $\omega = 800$ rpm or more) which has mainly gained acceptance for CCC separations. The stroboscopic observation on two-phase flow through the running spiral column of a Type J system reveals the following pattern. When the lower phase (chloroform) is eluted through the stationary lighter phase (water) from the head toward the tail of the spiral column, a large volume of the stationary phase is retained in the column and the spiral column is divided into two distinct zones: the mixing zone in about one-fourth of the area near the center of the centrifuge and the settling zone showing a linear interface between the two phases in the rest of the area. The mixing zone is always fixed at the vicinity of the central axis of the centrifuge while the spiral column undergoes the planetary motion. In other words, the mixing zone in each loop is traveling through the spiral column toward the head at a rate equal to the column rotation. Consequently, at any portion of the column, the two liquid phases are subjected to a typical partition process of repetitive mixing and settling at a high frequency, over 13 times per second at 800 rpm of column revolution, while the mobile phase is being continuously pumped through the stationary phase.[3]

At a first approximation, the hydrodynamic phenomenon observed also may be explained by the interplay between two force components acting on the fluid. At the distal portion of the coil, both the strong radial force field and the reduced relative flow of the two phases establish a clear and stable interface between the two liquid phases. At the proximal portion of the spiral column, where the strength of the radial-force component is minimized, the effect of the Archimedean screw force becomes visualized as agitation at the interface caused by the relative movement of two liquid layers.[2]

It should be noted that the centrifuge force field acts on the fluid in the rotated coil in parallel with other forces of different nature[5]:

- F_A, buoyancy force due to the difference between the stationary and mobile phases
- F_i, inertial force caused by coil motion, comprises components of centrifugal force field
- F_η, viscosity force due to the overflow of the stationary phase along the coil tube walls
- F_γ, interfacial tension force
- F_W, adhesion force
- F_h, hydraulic resistance force caused by moving of two immiscible phases relative to each other

HYDRODYNAMIC EQUILIBRIUM IN CCC

The following balance of these forces of a different nature is considered:

$$F_i = F_A + F_\eta + F_\gamma + F_W + F_h$$

From this, the basic equation of the stationary-phase retention process can be derived, a number of assumptions and complex theoretical treatments being required. Taking as example the planetary centrifuge of Type J, the average cross-sectional area of a stationary-phase layer has been estimated for hydrophobic liquid systems, which are characterized by high values of interfacial tension γ, low values

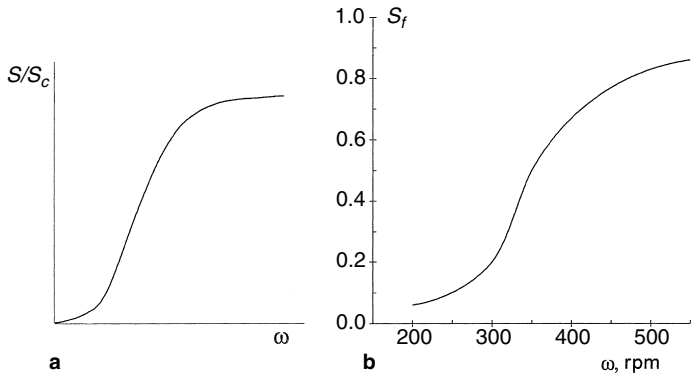

Fig. 1 a, Theoretical ω-dependence of S/S_c; and b, Experimental ω dependence of S_f for the *n*-decane–water system. Planetary centrifuge of Type J; $\beta = 0.37$; flow rate = 1 ml/min.

of viscosity η, and low hydrodynamic equilibrium settling times:

$$\left(\sqrt{\frac{S_c}{S}} - 1\right)(S_c - S) \approx \frac{v_m^{1/2} r^{1/2} \eta_s}{\rho_m \Delta\rho R \omega^{3/2}}$$

where S and S_c are the cross-sectional areas of the stationary-phase layer and the spiral column, respectively, v_m is the linear speed of the mobile phase flow, η_s is the viscosity of the stationary phase, and r and R are rotation and revolution radii, respectively; ρ_m is the density of the mobile phase and $\Delta\rho$ is the density difference between two phases. After a few assumptions, it can be rewritten as

$$\frac{S}{S_c} \approx 1 - k_1 \frac{\beta^{1/4}}{\omega^{3/4} R^{1/4}} \approx 1 - k_2 \frac{1}{\omega^{3/4}}$$

where $\beta = r/R$, is a proportional coefficient characterizing peculiarities of the liquid system (it is dependent on the interfacial tension, viscosity of the stationary phase, and density difference between two phases); $k_2 = k_1(r^{1/4}/R^{1/2})$.

The ratio of the cross-sectional area of the stationary-phase layer to that of the coil tube (S/S_c) governs the volume of the stationary phase retained in the column. The theoretical dependence of S/S_c on the rotation speed ω and the experimental dependencies of the S_f value (ratio of the volume of the stationary phase retained in the column to the total column volume) on ω for *n*-decane-water and chloroform-water liquid systems are in good agreement (Fig. 1).

Hence, an approach based on considering the balance of forces of a different nature acting on the fluid in the rotating coil may give some correlation among the peculiarities of the liquid system, operation conditions, design parameters of the planetary centrifuge, and the stationary-phase retention. However, any rigorous mathematical model describing the complex hydrodynamic equilibrium of two liquid phases in the rotating coiled column has not been yet elaborated. This issue remains open.

Hydrophilic Vitamins: TLC Analysis

Fumio Watanabe
Emi Miyamoto
Department of Health Science, Kochi Women's University, Kochi, Japan

INTRODUCTION

The benefit of using thin-layer chromatography (TLC) for the identification of unknown vitamins and related compounds by comparing R_f values of the unknown compounds with authentic vitamins is beyond doubt. The quantification of the separated vitamins can be performed by the use of modern densitometry. TLC [or high-performance thin-layer chromatography (HPTLC)], as a powerful separation and analytic tool, is used particularly with pharmaceutical preparations and food products. Because amounts of most hydrophilic vitamins are low, or very low, in tissues or body fluids, bioautography or derivatization is used before densitometry.

In this section, we summarize the recent advance of TLC analysis for hydrophilic vitamins.

THIAMINE (VITAMIN B_1)

To investigate thiamine metabolism in mammals, thiamine (R_f values: 0.16, 0.04, and 0.03), urinary excretion of thiamine metabolites [thiochirome (R_f values: 0.31, 0.28, and 0.33), thiazole (R_f values: 0.85, 0.79, and 0.81), and 2-methyl-4-amino-pyrimidinecarboxylic acid (R_f values: 0.42, 0.21, and 0.26)], and related compounds [pyrimidinesulfonic acid (R_f values: 0.48, 0.39, and 0.46), α-hydroxyethylthiamine (R_f values: 0.23, 0.09, and 0.06), N'-methylnicotinamide (R_f values: 0.31, 0.06, and 0.05)] were analyzed and identified by TLC on silica gel with acetonitrile–water (40:10 vol/vol) adjusted to a pH of 2.54, 4.03, and 7.85 with formic acid as solvents, respectively.[1] Although N'-methylnicotinamide and thiochrome could not be separated in single-phase chromatography at pH 2.54, a second phase at right angle, with a pH 4.03 solvent, separated these quite clearly without affecting the resolution of the other compounds.[1]

The quantitative analysis of thiamine hydrochloride (vitamin B_1), using HPTLC on silica gel plates with two different mobile phases, was elaborated.[2] After TLC separation, vitamin B_1 was derivatized by the use of *tert*-butyl hypochlorite or potassium hexacyanoferrate (III)–sodium hydroxide as reagents. The *tert*-butyl hypochlorite reagent formed yellow-fluorescing derivatives with a limit of detection of less than 3 ng per chromatogram zone. The potassium hexacyanoferrate (III)–sodium hydroxide reagent led to a bluish-fluorescing derivative with a limit of detection of 500 ng per chromatogram zone.

RIBOFLAVIN (VITAMIN B_2)

TLC on silica gel 60 plates was used in various TLC solvent systems for both determination and identification of flavin derivatives in baker's yeast[3] and foods (plain yogurt and bioyogurt, raw egg white, and egg powder).[4,5] The R_f values of two unknown compounds found in plain yogurt were identical to those of 7α-hydroxyriboflavin (R_f values: 0.32 and 0.21) and riboflavin-β-galactoside (R_f values: 0.14 and 0.10), but not to those of other flavin compounds [flavin adenine dinucleotide or FAD (R_f values: 0 and 0), flavine mononucleotide or FMN (R_f values: 0 and 0.05), 10-hydroxyethylflavin (R_f values: 0.71 and 0.40), riboflavin (R_f values: 0.55 and 0.32), and 10-formylmethylflavin (R_f values: 0.86 and 0.76)] by TLC on silica gel with chloroform–methanol–ethyl acetate (5:5:2) and 1-butanol–benzyl alcohol–glacial acetic acid (8:4:3) as solvents, respectively.[4]

7α-Hydroxyriboflavin was identified in blood plasma from humans, following oral administration of riboflavin supplements, by fluorescence after TLC [benzene–1-butanol–methanol–water (1:2:1:1 vol/vol)]and by its spectrum.[6]

PYRIDOXINE (VITAMIN B_6)

TLC of vitamin B_6 compounds, on various layers in different solvents, was studied.[7] The R_f values of pyridoxine, pyridoxal, pyridoxamine, pyridoxal ethyl acetate, 4-pyridoxic acid, 4-pyridoxic acid lactone, pyridoxine phosphate, pyridoxal phosphate, and pyridoxamine phosphate were 0.62, 0.68, 0.12, 0.54, 0.91, 0.91, 0.95, 0.95, and 0.86, respectively, by TLC on silica gel HF_{254} with 0.2% NH_4OH in water as solvent. When adsorbents containing fluorescent indicators are used, all forms and derivatives of vitamin B_6 can be detected

through fluorescence, or through quenching of indicator fluorescence in ultraviolet (UV) light (254 nm).

When radioactive pyridoxine hydrochloride was orally supplemented to evaluate vitamin B_6 metabolism in adult domestic cats, two unknown radioactive compounds (compounds X and Y) were excreted in the urine.[8] The R_f values of compound X (R_f values: 0.95, 0.83, 0.2, 0.5, and 0.62) and compound Y (R_f values: 0.35, 0.20, 0.22, 0.32, and 0.25) were identical to those of pyridoxine-3-sulfate and *N*-methylpyridoxine, respectively, but not to those of pyridoxine (R_f values: 0.73, 0.83, 0.78, 0.52, and 0.62) in various solvent systems [0.5% ammonium hydroxide, 95% ethanol, chloroform–methanol (3:1 vol/vol), isoamyl alcohol–acetone–triethylamine–water (24:18:8:6 vol/vol), and 2-butanol–1.5 N ammonium hydroxide (3:1 vol/vol), respectively] by TLC on silica gel plates.

COBALAMIN (VITAMIN B_{12})

Usual dietary sources of vitamin B_{12} are animal food products (meat, milk, eggs, and shellfish), but not plant food products. To evaluate whether foods contain true vitamin B_{12} or inactive corrinoids, vitamin B_{12} compounds were purified and characterized using TLC on silica gel.[9] The R_f values of the unknown vitamin B_{12} compound, purified from an algal health food (Spirulina tablets) were identical to those of pseudovitamin B_{12} (R_f values: 0.14 and 0.42), but not to those of vitamin B_{12} (or 5,6-dimethylbenzimidazolyl cyanocobamide) (R_f values: 0.23 and 0.56), benzimidazolyl cyanocobamide (R_f values: 0.18 and 0.52), 5-hydroxybenzimidazolyl cyanocobamide (R_f values: 0.20 and 0.47), and *p*-cresolyl cyanocobamide (R_f values: 0.38 and 0.62) by TLC on silica gel 60 with 1-butanol–2-propanol–water (10:7:10 vol/vol) and 2-propanol–NH_4OH (28%)–water (7:1:2 vol/vol) as solvents, respectively. The results indicate that an inactive vitamin B_{12} compound (pseudovitamin B_{12}) is predominant in Spirulina tablets.[10]

Because amounts of vitamin B_{12} are very low in foods, tissues, and body fluids, bioautography is used before densitometry. A selected strain of *Escherichia coli* is used as a micro-organism for the bioautography. Growth spots are enhanced by the addition of 2,3,5-triphenyltetrazolium chloride, which is converted to the red-colored formazan by *E. coli* growth. Determination of vitamin B_{12} in human plasma and erythrocytes was accomplished by one-dimensional bioautography.[11] A sensitive two-dimensional bioautography was also developed to investigate B_{12} metabolism in health and a wide range of diseases.[12]

NICOTINIC ACID AND NICOTINAMIDE

Nicotinic acid and nicotinamide and their derivatives were analyzed by TLC on MN 300G cellulose plates in various solvent systems (K. Shibata, personal communications, October 16, 2001). The R_f values of nicotinamide adenine dinucleotide phosphate or $NADP^+$ (R_f values: 0.03, 0.50, and 0.70), nicotinamide adenine dinucleotide or NAD^+ (R_f values: 0.13, 0.61, and 0.58), nicotinic acid adenine dinucleotide (R_f values: 0.15, 0.52, and 0.57), nicotinamide mononucleotide (R_f values: 0.11, 0.63, and 0.73), nicotinic acid mononucleotide (R_f values: 0.13, 0.47, and 0.75), nicotinamide (R_f values: 0.87, 0.88, and 0.45), and nicotinic acid (R_f values: 0.77, 0.82, and 0.55) are shown in various solvent systems [1 *M* ammonium acetate–95% ethanol (3:7), pH 5.0; 2-butyric acid–ammonia–water (66:1.7:33), and 600 g of ammonium sulfate in 0.1 *M* sodium phosphate–2% 1-propanol (pH 6.8), respectively]. The detection is performed by illumination under short-wavelength (257.3 nm) UV light. Urinary metabolites of the vitamin could be analyzed by TLC.[13]

PANTOTHENIC ACID

A rapid, simple, and specific TLC method has been developed for the estimation of panthenol and pantothenic acid in pharmaceutical preparations containing other vitamins, amino acids, syrups, enzymes, etc.[14] The vitamin was extracted with ethanol (from tablets and capsules) or benzyl alcohol (from liquid oral preparations) and isolated from other ingredients by TLC on silica gel 60 plates with 2-propanol–water (85:15 vol/vol) as a solvent. β-Alanine (panthothenate) or β-alanol (panthenol) was liberated by heating for 20 min at 160°C. The liberated amines were visualized with the ninhydrin reaction and estimated by spectrodensitometry at 490 nm. Recoveries for panthenol and pantothenic acid were 99.8 ± 2.25% and 100.2 ± 1.7%, respectively.

BIOTIN

Unidentified biotin metabolites were analyzed and identified in urine from healthy adults by TLC.[15,16] Three unknown biotin metabolites were identified as biotin sulfone (R_f values: 0.49 and 0.17), bisnorbiotin methyl ketone (R_f values: 0.78 and 0.29), and tetranorbiotin-*l*-sulfoxide (R_f values: 0.22 and 0.01) by derivatization with *p*-demethylaminocinnamaldehyde after TLC on microcellulose with 1-butanol–acetic acid–water (4:1:1) and 1-butanol as solvents, respectively.[15]

FOLIC ACID

Folates [pteroylmonoglutamates (PteGlu)] and related compounds were separated by TLC on cellulose powder (MN300 UV_{254}) with 3.0% (wt/vol) NH_4Cl and 0.5%

(vol/vol) 2-mercaptoethanol as solvents.[17] The R_f values of PteGlu (R_f value: 0.24), H_2-PteGlu (R_f value: 0.1), 5,10-CH=H_4-PteGlu (R_f value: 0.32), H_4-PteGlu (R_f value: 0.56), 5-CHO-H_2-PteGlu (R_f value: 0.72), 5-HCNH-H_4-PteGlu (R_f value: 0.72), 5,10-CH_2-H_4-PteGlu (R_f value: 0.75), 5-CH_3-H_4-PteGlu (R_f value: 0.8), 10-CHO-H_4-PteGlu (R_f value: 0.82), 5-CH_3-H_2-PteGlu (R_f value: 0.87), 10-CHO-PteGlu (R_f value: 0.7), and 10-CHO-H_2-PteGlu (R_f value: 0.73) were shown in this TLC system, which is applied to evaluate the transport and metabolism of reduced folates in blood.

A TLC densitometric method could be applied to evaluate the purity of folic acid preparations for the final purpose of determination of the *N*-(4-aminobenzol)-L-glutamic acid content as an impurity.[18] The separation was performed in 1-propanol–NH_4OH (25%)–ethanol (2:2:1) and toluene–methanol–glacial acetic acid–acetone (14:4:1:1) as solvents. The silica gel plates developed were scanned at 278 nm.

ASCORBIC ACID (VITAMIN C)

TLC has been widely used to determine ascorbic acid concentrations in foods,[19–21] pharmaceutical preparations,[21–23] and biological materials.[21,24,25] Isomers of ascorbic acid and their oxidation product, dehydroascorbic acid, were separated by TLC on sodium borate-impregnated silica gel and cellulose plates.[21] This TLC method has been adapted to separate and identify ascorbic acid and dehydroascorbic acid in fresh orange and lime juices, pharmaceutical preparations (ascorbic acid), and guinea pig tissues (liver, kidney, and eye lens) and fluids (plasma and urine).

The components of an analgesic mixture (paracetamol, ascorbic acid, caffeine, and phenylephrine hydrochloride) were separated by HPTLC on silica gel plates with methylene chloride–ethyacetate–ethanol–formic acid (3.5:2:4:0.5 vol/vol) as the mobile phase.[22] The plates were scanned at 264 nm for ascorbic acid (R_f value: 0.53), 254 nm for paracetamol (R_f value: 0.87), and 274 nm for phenylephrine hydrochloride (R_f value: 0.22) and caffeine (R_f value: 0.69).

Ascorbic acid and dipyrone (metamizole) are sometimes combined in pharmaceutical dosage forms to relive pain and fever. Simultaneous determination of ascorbic acid and dipyrone was done by TLC on silica gel using water–methanol (95:5 vol/vol) as the solvent.[23] The developed plates were directly scanned at 260 nm. The R_f values for ascorbic acid and dipyrone were 0.92 and 0.65, respectively.

MULTIVITAMIN COMPLEX

Vitamin B_1, vitamin B_2, and nicotinic acid, all of which frequently occur together in foods, were separated by TLC and fluorimetrically determined by using a commercially available fiber optic-based instrument.[26] A fluorescent tracer (fluoresceinamine, isomer II) was used to label the nicotinic acid. Vitamin B_1 was converted to fluorescent thiochrome by oxidizing with potassium ferricyanide solution in aqueous sodium hydroxide. These vitamins were separated by HPTLC on silica gel using methanol–water (70:30 vol/vol) as mobile phase. Under these conditions, the R_f values of the vitamin B_1, vitamin B_2, and nicotinic acid derivatives were 0.73, 0.86, and 0.91, respectively.

A vitamin B complex (vitamin B_1, vitamin B_2, vitamin B_6, vitamin B_{12}, and folic acid) was also separated into its components using TLC plates impregnated with different transition metal ions.[27] $CuSO_4$ at 0.4% impregnation in all the employed solvent systems resulted in the simultaneous resolution of constituents of the vitamin B complex with appreciable differences in R_f values.

Water-soluble vitamins (vitamin B_1, vitamin B_6, vitamin B_{12}, and vitamin C) in "Kombucha" drink (a curative liquor) were separated by TLC on silica gel plates with water as the solvent.[28] The plates were visually examined under UV light at 254- and 366-nm wavelengths. The four vitamins were identified and determined by comparing the R_f values with the reference values (vitamin B_1, 0.21; vitamin B_6, 0.73; vitamin B_{12}, 0.34; and vitamin C, 0.96).

An overpressured layer chromatographic procedure, with photodensitometric detection for the simultaneous determination of water-soluble vitamins in multivitamin pharmaceutical preparations, was developed and evaluated.[29] HPTLC on silica gel plates with 1-butanol–pyridine–water (50:35:15 vol/vol) as mobile phase was used. The quantitation was carried out without derivatization [vitamin B_2 (R_f value: 0.30), vitamin B_6 (R_f value: 0.64), folic acid (R_f value: 0.37), nicotinamide (R_f value: 0.80), and vitamin C (R_f value: 1.02)] or after spraying ninhydrin reagent [calcium panthothenate (R_f value: 0.72)] or 4-demethylaminocinnamaldehyde [vitamin B_{12} (R_f value: 1.84) and biotin (R_f value: 0)].

CONCLUSIONS

TLC is used as a powerful separation tool particularly for the analysis of pharmaceutical preparations and food products. The separated vitamins can be quantified by the use of densitometry. In biological materials (tissues and body fluids), which contain only trace amounts of vitamins, bioautography or derivatization is used before densitometry.

TLC offers great advantages (simplicity, flexibility, speed, and relative low expense) for the separation and analysis of hydrophilic vitamins.

Hydrophobic Interaction

Karen M. Gooding
Eli Lilly and Company, Indianapolis, Indiana, U.S.A.

INTRODUCTION

Hydrophobic-interaction chromatography (HIC) is a mode of separation in which molecules in a high-salt environment interact hydrophobically with a non-polar bonded phase. HIC has been predominantly used to analyze proteins, nucleic acids, and other biological macromolecules by a hydrophobic mechanism when maintenance of the three-dimensional structure is a primary concern.[1–4] The main applications of HIC have been in the area of protein purification because the recovery is frequently quantitative in terms of both mass and biological activity.

In HIC, a high-salt environment causes the association of hydrophobic patches on the surface of an analyte with the non-polar ligands of the bonded phase. Elution is generally effected by an "inverse" gradient to lower salt concentration. This is considered "inverse" because it is the opposite of gradients used for ion-exchange chromatography. Effective salts for HIC are those which are "antichaotropic"; that is, they promote the ordering of water molecules at interfaces. Because interaction is only with the surface of a macromolecule such as a protein, the number of amino acids involved in the chromatography is relatively small, and changes in surface structure can cause differential binding and, hence, separation.

Reversed-phase chromatography (RPC) and HIC are both based on interactions between hydrophobic moieties, but the operational aspects of the techniques render selectivities totally different. The physical properties and selectivities of the two methods are contrasted in Fig. 1. The bonded phase of HIC supports consists of a hydrophilic matrix into which hydrophobic chains are inserted, generally in low density. This can be contrasted with the higher-density organosilane chemistry used in RPC. The chromatograms illustrate that both the selectivity and the number of peaks obtained for a protein mixture vary between the two modes. Cytochrome c is not retained at all by HIC and myoglobin is split into two peaks by RPC. A primary reason for the vast difference is the mobile-phase environment for each method. The organic solvents and generally acidic conditions used in RPC cause denaturation of most proteins and even splitting into subunits, whereas the high-salt concentrations at neutral pH used in HIC result in stabilization of globular or three-dimensional structures for biological macromolecules. The hydrophobic amino acid residues of globular proteins are generally folded inside the structure or located in a few patches on the surface. As a protein is denatured, the buried amino acids are exposed, yielding more sites for hydrophobic binding. The hydrophobic interaction system thus encounters primarily surface amino acids—far fewer hydrophobic residues than the reversed phase.

SUPPORTS

Bonded phases for HIC consist of a hydrophilic polymeric layer into which hydrophobic ligands are inserted. The hydrophilic layer totally covers the silica or polymer matrix, providing a wettable and non-interactive surface which is neutral to the protein. In HIC, even short ligands cause substantial binding and there is a definite relationship between ligand chain length and retention, contrary to the minimal effect of chain length observed in the RPC of proteins and peptides. The ligand chains are postulated either to interact with hydrophobic surface patches on the proteins or to be inserted into their hydrophobic pockets; it is the latter interaction which is strengthened by and related to chain length. The strength of the binding causes some proteins to bind irreversibly if the ligand is too long; therefore, most ligands are either aromatic or 1–3 carbon alkyl chains.

Because HIC supports are designed for macromolecules, they either possess pore diameters of at least 300 Å to allow inclusion or are non-porous. Both silica and polymer matrices are used because the hydrophilic polymeric coating minimizes or eliminates most matrix—based effects. The absolute retention and selectivity of an HIC support may be affected by the specific composition of the bonded phase, as well as the ligand. For example, protein mixtures have shown distinct selectivity on different HIC columns which have propyl functional groups.[5]

OPERATION

Mobile Phase

In HIC, the concept of weak and strong solvents is different than in other modes because the weak solvent, or the one

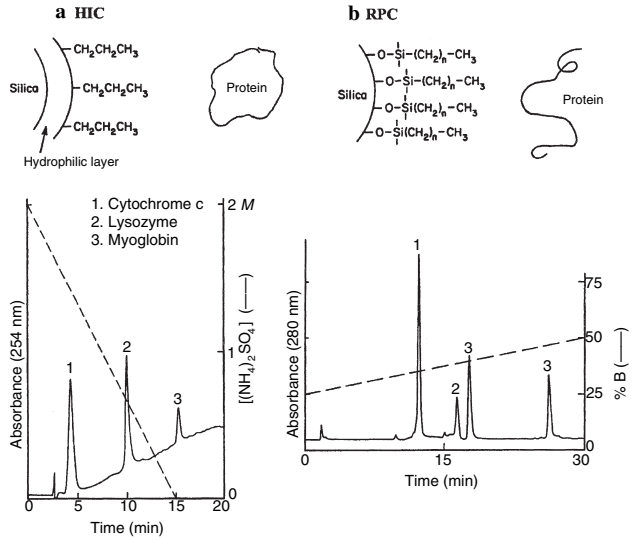

Fig. 1 (a) SynChropak Propyl; 15 min gradient from 2–0 *M* $(NH_4)_2SO_4$ in 0.1 *M* potassium phosphate, pH 6.8. (b) SynChropak RPP (C_{18}); 30 min gradient from 25% to 50% ACN with 0.1% TFA.
Source: Used with permission of Eichrom.

which promotes binding, is that containing high-salt concentration. The strong solvent, or one which causes elution, is that with low-salt concentration.

Salt

The most important variable in HIC retention, other than the ligand chain, is the composition of the salt used to promote binding. The effectiveness is based on the molal surface tension increment, which is parallel to the Hofmeister salting-out series for precipitation of proteins. The strength of HIC binding for some commonly used salts is K_3citrate > Na_2SO_4 > $(NH_4)_2SO_4$ > Na_2HPO_4 > NaCl.

Although potassium citrate and sodium sulfate cause stronger retention, ammonium sulfate is probably the most popular choice for HIC. Besides being effective for retention, it is highly soluble, stabilizing for enzymes, and resistant to microbial growth. Ammonium sulfate is available in high purity because of its use for salt fractionation. Sodium sulfate is less soluble and may precipitate under conditions of high concentration. The initial concentration of salt must be at a level high enough to cause binding of all the proteins to the bonded phase to avoid variable retention of early eluting peaks, which may also be broad.[6] Most proteins will bind when 2 *M* ammonium sulfate is used. In HIC, the concentration of antichaotropic salt is proportional to log *k*, as has been shown for conalbumin in four different salts.[7] The exact relationship varies for each salt, as well as for the specific protein.

pH

In HIC, the mobile phase should be buffered to provide control of ionization because amino acids which are not ionized are more hydrophobic than those which are charged. The effect of pH on hydrophobicity produces some variation of retention with pH; however, it is not directly related to the p*I* of the analyte because only surface amino acids interact with the ligands. In a study of the effect of pH on retention by HIC for a series of lysozymes from different bird species, those containing histidine residues in the hydrophobic contact region exhibited deviation for pH values of 6–8, which is near the p*K* of histidine (pK = 6).[7]

Additives

Because HIC is based on surface-tension phenomena, changing those characteristics by the addition of surfactants affects retention. In a study of the effects of surfactants on retention of proteins by HIC, the addition of CHAPS {3-[(3-cholamidopropyl) dimethylammonio]-1-propane sulfonate} to the mobile phase resulted in shortened retention, improvement of peak shape, and a change in peak order for enolase and bovine pancreatic trypsin inhibitor.[8] The effects were dependent on the concentration of the surfactant. Surfactants can usually be washed easily from hydrophobic interaction columns because the bonded phases are neither highly hydrophobic nor ionic.

The hydrophobic basis of HIC means that alcohols may reduce interaction with supports; however, disruption of protein conformation may also occur. Because of the high salt concentrations used in HIC, organic solvents should only be added after compatibility with the mobile phase has been tested to ensure that precipitation will not take place. Generally, no more 2 Hydrophobic Interaction Chromatography than 10% organic is added. Other additives that increase the stability of a given protein can often be included in the mobile phase for HIC without adversely changing the separation.

Flow Rate and Gradient

Almost all HIC separations are performed in the gradient mode because proteins bind with multipoint interactions. The flow rate and gradient have an effect on retention in HIC because HIC follows the linear solvent strength model.[9] The time of the gradient is another determinant in improving resolution in that longer gradients provide increased resolution. Generally, a 20–60 min gradient from 2–0 *M* ammonium sulfate in

0.02 *M* buffer at neutral pH, with a moderate flow rate (1 ml/min for a 4.6 mm I.D.), will provide a satisfactory starting point for an HIC analysis.[1]

Temperature

Hydrophobic interaction chromatography is different than other modes of chromatography in that it is an entropy-driven process, characterized by increased retention with increased temperature. This is a major benefit when subambient temperatures must be used to preserve the structure and biological activity of labile proteins. Retention is usually decreased rather than increased as temperatures are lowered. In one study, the retention of lysozyme was relatively unchanged throughout a temperature range 0–45°C, whereas bovine serum albumin exhibited two peaks which changed in proportion with temperature, as well as increased in retention.[10] Some of the increase in retention with elevated temperatures, in this or other studies, can be attributed to protein unfolding and the increased exposure of internal hydrophobic residues, especially when peak broadening also occurs.

Loading

Loading capacities for proteins on HIC columns are quite high because proteins retain their globular forms during the procedure.[1,4] High loading is generally accompanied by high recoveries of biological activity. Dynamic and absolute loading capacities of HIC supports are in the range of 10 mg/ml and 30 mg/ml, respectively. Loading is also related to the relative sizes of the pore diameter and the solute, with 300 Å giving maximum capacity for many proteins.

APPLICATIONS

The primary application for HIC has been in protein analysis and purification due to the good selectivity and preservation of biological activity.[1–4] Because of the major differences in selectivity, HIC can be used as an orthogonal technique to RPC, as well as to ionexchange and size-exclusion chromatography.

Although the best high-performance liquid chromatography (HPLC) method for peptide analysis is RPC, HIC offers a different selectivity for those peptides possessing three-dimensional conformations under high-salt conditions. When the separations of peptide mixtures by HIC and RPC have been compared, peaks were generally narrower on RPC due to the organic mobile phase. In a study of calcitonin variants, it was seen that peptides with certain amino acid substitutions could not be resolved by RPC, but were separated by HIC.[11] The main utility of HIC for peptide separations seems to lie in applications for extremely hydrophilic or hydrophobic peptides, or those with three-dimensional structures stable in high salt.

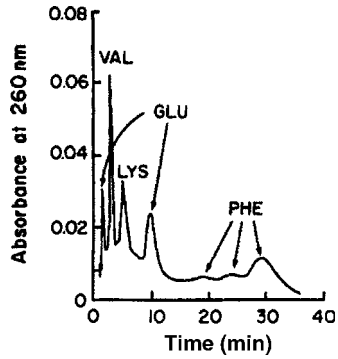

Fig. 2 Column: Polyol HIC, 100 nm; mobile phase: 0.7 *M* disodium hydrogen phosphate, pH 6.3.
Source: From High-performance liquid chromatography of tRNAs on novel stationary phases, in J. Chromatogr.[12]

The separation of nucleic acids, particularly t-RNA, has been another useful application of HIC for biological macromolecules. The tertiary structure of t-RNA has made analysis under the gentle conditions of HIC very feasible.[12] Fig. 2 shows an example of the purification of t-RNA molecules specific for different amino acids on a 100 nm polyol HIC column. Separation of t-RNA molecules has also been accomplished successfully by using HIC conditions on supports with alkylamino ligands, which are functionally similar to those traditionally used to separate nucleic acids.[1]

CONCLUSIONS

Hydrophobic interaction chromatography is a mode of chromatography particularly effective for the analysis of proteins and other macromolecules. The hydrophobic interactions are primarily with non-polar groups on the surface of the analytes due to maintenance of the tertiary structure. High loading and recovery of both mass and biological activity are achieved.

Hydroxy Compounds: Derivatization for GC Analysis

Igor G. Zenkevich
Chemical Research Institute, St. Petersburg State University, St. Petersburg, Russia

Abstract
The hydroxyl group is one of the most propagated functional groups in organic compounds, including numerous biogenic substances. The determination of OH compounds has been one of the important problems of gas chromatography (GC) analysis in more than half a century that this method has been in existence.

The main classes of hydroxy compounds are aliphatic alcohols with OH groups attached to sp^3 hybridized carbon atoms and phenols, in which the OH groups are attached to sp^2 carbon atoms located in the aromatic systems. Another group of hydroxy compounds—namely, the carboxylic acids, having the structural fragment COOH—is discussed separately.

Even the simplest bifunctional compounds of these classes being analyzed on non-polar phases show broad non-symmetrical peaks on chromatograms. This leads to low detection limits and bad reproducibility of RIs (the position of the peaks' maxima strongly depends on the quantities of analytes) as compared with non-polar compounds. The general method to avoid all of the above-mentioned problems is based on the conversion of hydroxy compounds to less polar and thermally stable volatile derivatives. The less polar products typically yield narrower chromatographic peaks, which provide better signal-to-noise ratio and, hence, lower detection limits. Non-polar derivatives have much better interlaboratory reproducibility of RIs compared with initially polar compounds.

Most important types of organic reactions used in derivatization of hydroxy compounds are silylation (a kind of etherification), acylation (esterification), and alkylation (preferably used for phenols).

INTRODUCTION

The hydroxyl group is one of the most propagated functional groups in organic compounds. Important biogenic substances (carbohydrates, phenolic acids, flavones, etc.) belong to the class of hydroxy compounds. One of the principal methods of metabolism of different ecotoxicants and drugs in vivo is their hydroxylation followed by the formation of conjugates with carbohydrates, sulfuric, or amino acids. For example, the bio-oxidation of the widespread environmental pollutants polychlorinated biphenyls (PCBs) leads to hydroxy-PCBs.[1] The determination of OH compounds has been one of the important challenges in gas chromatographic (GC) analysis for more than half a century that this method has been in existence.

The main classes of hydroxy compounds are aliphatic alcohols with OH groups attached to sp^3-hybridized carbon atoms, and phenols, in which the OH groups are located in the aromatic systems attached to sp^2 carbon atoms. Some carbonyl compounds (preferably having a few C═O groups, like 2,4-alkanediones, ketocarboxylic acids and their esters, 1,2- and 1,3-cycloalkanediones) exist in equilibrium with their corresponding enols in accordance with the general scheme $-CH_2-CO- \rightleftarrows -CH{=}C(OH)-$, which implies the presence of hydroxyl groups in these molecules as well. Another type of hydroxy compounds, namely, the carboxylic acids—having the structural fragment CO_2H—are discussed separately in another entry (see *Acids: Derivatization for GC Analysis*, p. 3).

A simple rule for predicting the possibility of GC analysis of organic compounds is based on the reference data on their boiling points. If any compound can be distilled without decomposition at pressures ranging from atmospheric to 0.01–0.1 Torr, it can be subjected to GC analysis at least on standard non-polar polydimethyl siloxane stationary phases. Thus, most of the monofunctional hydroxy compounds, as well as their *S*-analogues (thiols, thiophenols) can be analyzed directly. The confirmation of chromatographic properties of any analyte should not only be verbal (at the binary "yes/no" level) but also indicate its GC retention index (RI) as the most objective criteria, as illustrated in Table 1.

The chemical properties of hydroxy compounds depend on the presence of active hydrogen atoms in the molecule. The pK_a values of aliphatic alcohols are 70 comparable to that of water (≈16), but phenols having weak acidic properties are characterized by $pK_a \approx 9–10$. Enols of carbonyl compounds are also usually weak acids.

An increase in the number of polar functional groups in the molecules leads to an increase in the strength of intermolecular interactions. This is manifested as a rise in melting and boiling points of compounds. For example, some aliphatic diols and triols have boiling points at atmospheric pressure and, hence, are volatile enough for GC analysis. Similar compounds with four or more hydroxyl groups have

Table 1 Physicochemical (boiling point) and chromatographic (RI) characteristics of some compounds with single hydroxy group and their thio-analogs.

Compound	T_b, °C	$RI_{non\text{-}polar}$
1-Tetradecanol	290.8	1664 ± 12
4-Methyl-2,6-di-*tert*-butyl phenol	265	1491 ± 10
1-Decanethiol	239.2	1320
2-Methylbenzenethiol	194	1061 ± 11

no boiling points at atmospheric pressure, which means that their GC analysis is impossible. The same restrictions are valid for the series of polyfunctional phenols Table 2.

Even the simplest bifunctional compounds of these classes when analyzed on non-polar phases show broad non-symmetrical peaks on chromatograms. This leads to low detection limits and bad reproducibility of RIs, because the position of the peaks' maxima strongly depend on the quantity of the analyte relative to the quantity of the non-polar compound. A general method to avoid all of the above-mentioned problems is based on the conversion of hydroxy compounds to their thermally stable and less polar volatile derivatives. This task is one of the most important prerequisites to GC analysis. This chemical treatment may be used not only for non-volatile compounds, but also for the so-called semivolatile substances. The less polar products typically yield narrower chromatographic peaks, which provide better signal-to-noise ratios and, hence, lower detection limits. Non-polar derivatives have much better interlaboratory reproducibility of RIs compared with initially polar compounds.

METHODS OF DERIVATIZATION OF HYDROXY COMPOUNDS

The principal methods used for the derivatization of hydroxy compounds may be classified on the basis of the following types of chemical reactions:

Table 2 Physicochemical and chromatographic characteristics of some polyhydroxy compounds.

Compound	Number of OH groups	T_b, °C	$RI_{non\text{-}polar}$
Glycerol	3	290.5	1196 ± 28
meso-Erythrol	4	329–331	≈1320
Xylitol	5	None	None
Hydroquinone	2	287	1338 ± 14
Pyrogallol	3	309	1420–1550
1,2,4-Benzenetriol	3	None	None

$$\text{Sylilation}: R(OH)_n + XSi(CH_3)_3 \rightarrow R(OTMS)_3 + nXH[TMS = Si(CH_3)_3]$$
$$\text{Acylation}: R(OH)_n + nR'COX + nB \rightarrow R(OCOR')_n + nBH^+X^-$$
$$\text{Alkylation}: R(OH)_n + nR'X \rightarrow R(OR')_n + nXH$$

where the generally accepted codification of structural fragment *X* is as the carrier of the target silyl, acyl, or alkyl chemical functions.

The experimental details of these derivatization reactions are presented in some well-known specialized texts.[2–5] The first two reactions mentioned are sensitive to the presence of water in the samples (typical silylation and acylation reagents react with water more quickly than with the target organic compounds) and usually cannot proceed in aqueous media. The analysis in these conditions typically requires special sample preparation (drying before derivatization).

The large group of silylation reactions [trimethylsilyl (TMS) derivatives are the most widely used] involve the replacement of active hydrogen atoms in molecules of analytes by silyl groups donated by different *O*-, *N*-, or *C*-silylating reagents. The reaction order of the OH compound's reactivity in general is *prim*-OH > *sec*-OH > *tert*-OH ≈ Ar-OH > R-SH. The first part of Table 3 includes physicochemical and GC constants of different reagents in the approximate order of increasing silyl donor strength. The second part of this table presents compounds later introduced into analytical practice, with still unestimated relative silylation activity, as well as a few non-TMS reagents. Besides the individual chemicals, their different combinations are known as the so-called silylating mixtures, e.g., hexamethyldisilazane (HMDS) + trimethyl chlorosilane (TMCS) or HMDS + dimethyl formamide (DMFA). The triple mixture *bis*-TMS-acetamide (BSA)/TMS-imidazole (TMSI)/TMCS (1:1:1 v/v) seems to be the most active currently known silylating agent. It can be used for the derivatization of all types of substances with active hydrogen atoms, including enols of carbonyl compounds and even *aci*-forms of aliphatic nitro compounds. To illustrate the "popularity" of silylating mixtures, it should be mentioned that more than a dozen such mixtures are presented in Sigma-Aldrich catalogs at present.[6]

Some reagents in Table 3 are characterized not only by their own RI, but also by the RI values of the principal by-products of the reaction. This permits us to predict the possible overlapping of their chromatographic peaks with signals of derivatives of the target analytes.

The list of recommended silylating compounds is constantly changing. Some older reagents get replaced by more effective ones. Most of them, depending on the chemical nature of the carrier of TMS groups, are classified as *N*- or *O*-silylating agents. At the same time it is important to note the increasingly frequent application of different *C*-silylating agents, like ethyl(trimethylsilyl)acetate (ETSA) or allyl trimethyl silane (Allyl-TMS). The

Table 3 Physicochemical and gas chromatographic properties of some silylating derivatization reagents.

Reagent	Abbreviation	MW	T_b, °C (P)	$RI_{non\text{-}polar}$	By-products ($RI_{non\text{-}polar}$)[a]
Most widely used reagents (in order of increasing silyl donor strength)					
Hexamethyldisilazane	HMDS	161	126	817 ± 29	NH_3 (ND)[b]
Trimethylchlorosilane	TMCS	108	57.7	560 ± 8	HCl (ND)

last-mentioned reagent, in the silylation reaction, forms a single gaseous product: propene. Besides that, this reagent indicates highest chemical selectivity in relation to substrates of different chemical origin: it reacts only with alcohols and acids, but has no influence on phenols, thiols, and amines.

Keeping in mind the possible variety of substrates used for silylation, it is not so simple to reliably characterize the differing activity of various silylation reagents. So far the typical form of presentation of such information includes a semiquantitative description (e.g., "++"—good silylation; "+"—silylation is possible, "−"—no reaction

Table 4 Some examples of the recommendations on the use of some silylating reagents.

Reagent (abbreviation)	Special comments	Applicability for different classes of compounds				
		Alcohols	Phenols	Acids	Thiols	Amines
BSA	Reactive, universal	++	++	++	+	++

observed) supplemented by some verbal comments, as demonstrated by Table 4.[6]

Another way of simplifying the visual perception of information about derivatization reaction for users is to list recommended reagents for different classes of organic compounds, supplemented by short comments on important details of the processes. Some examples of this form, for selected hydroxy compounds, are presented in Table 5.[7]

Standard electron impact (EI) mass spectra of TMS derivatives of aliphatic hydroxy compounds register no peaks of molecular ions M^+, but in many cases, signals of ions $[M\text{-}CH_3]^+$ are reliably registered. The same derivatives of phenols and enols of carbonyl compounds with –p conjugated system C═C–O in the molecules register the signals of M^+ or higher intensities. Typical base peaks in the mass spectra of *O*-TMS derivatives are $[Si(CH_3)_3]^+$ (*m*/*z* 73) and, sometimes, $[Si(CH_3)_2OH]^+$ (*m*/*z* 75). For example, in Fig. 1, the mass spectrum of *tris*-TMS ether of glycerol (Fig. 1a) is compared with that of *bis*-TMS derivative of acetoacetic acid ($CH_3COCH_2CO_2H$, enol form, Fig. 1b). The signal of molecular ions with MW 308 is absent in the former, while signal with MW 246 is distinctly registered in the latter.

The principal disadvantage of TMS derivatives is their easy postreaction hydrolysis. Most of these compounds cannot exist in aqueous media. If stability is important, another type of derivatives, namely dimethyl-*tert*-butylsilyl, that has approximately 10^3 times lower hydrolysis constants owing to sterical hindrance of Si–O bonds by

Table 5 Some examples of the form of presentation of the recommendations on the selection of derivatization reagents for different classes of organic compounds.

Class of compounds or type of functional groups	Type of derivatization	Reagent(s) (abbreviation)	Additional notes
Hydroxyl groups in alcohols and phenols	Silylation	BSA, BSTFA, BSTFA + TMCS, HMDS, MSTFA, MSTFA + TMCS	Most often used derivatives; Good thermal stability
		TMCS	Usually used in combination with HMDS; can be used for salts
		TMSI	Can be used with some syrups
		MTBSTFA	More stable than TMS, good MS fragmentation patterns
	Acylation	MBTFA, TFAA, TFAI, PFAA, HFBI, HFAA	Good for trace analysis with ECD
	Alkylation	PFB-Br	With alkoxides only
Carbohydrates	Silylation	MSTFA, TMSI	Can be used with some syrups
	Acylation	MBTFA,TFAI	Applicable to *mono*-, *di*-, and *tri*-saccharides

tert-butyl groups, seems preferable.[8] Unfortunately, mass spectra of such derivatives are not very informative for the elucidation of structures of unknown analytes; the base peaks for most of them belong to non-characteristic ions $[C_4H_9]^+$ (*m/z* 57) and $[M\text{-}C_4H_9]^+$, but they are considered as "good MS fragmentation patterns" for identification of compounds with known mass spectra using MS library search techniques. Other trialkyl derivatives were

recommended for the derivatization of hydroxy compounds, but in practice, they are not easily available and are used rarely.[9]

Some halogenated silylating reagents are used in the synthesis of derivatives for GC analysis with selective (element-specific) detectors, e.g., $ClCH_2SiMe_2Cl$, $BrCH_2SiMe_2Cl$, and $C_6F_5SiMe_2Cl$ in electron capture detection. In nitrogen/phosphorus (NP)-selective flame photometric detectors, the conversion of hydroxy compounds into 2-cyanoethyldimethylsilyl derivatives using $(C_2H_5)_2N–Si(CH_3)_2–CH_2CH_2CN$ (2-cyanoethyldimethyl-silyl diethylamine) as reagent is recommended.[10]

Polyfunctional hydroxy compounds, according to the general principles of derivatization, require the modification of all functional groups in their molecules. For instance, within the important group of hydroxy carbonyl compounds, the steroids, all carbonyls prior to silylation should be converted to alkoxyimino fragments $C{=}O \rightarrow C{=}N–OR$ or hydroxylamino fragments with following silylation: $C{=}O \rightarrow C{=}N–OH \rightarrow C{=}N–O–SiMe_3$ (the same methods are used for carbohydrates). Besides, there is a single-step method for the derivatization of steroids in which treatment with the most active silylation reagents leads to the formation of *per*-TMS derivatives of enols. For selective derivatization of hydroxyl and carbonyl groups with varying reactivities in steroids, a great variety of reagents have been proposed.[2–5] These complex organic compounds with large retention parameters require fewer restrictions on the chemical origin of reagents. For example, one of them, namely *N*-methoxy-*N*,*O*-*bis*-TMS carbamate (BSMOC) [$CH_3O–N(TMS)CO_2TMS$], has an RI on standard non-polar phase of 1146 ± 9 and has been used for the derivatization of only carboxylic acids, selected sugars,[11] and steroids.[12]

The second group of hydroxy compound derivatization reactions includes acylation of OH groups with the formation of esters. The most important are listed in the Table 6.

It is recommended that these reactions be conducted in the presence of bases without active hydrogen atoms (pyridine, triethyl amine, etc.). These basic media are necessary for the conversion of acidic by-products into non-volatile salts to protect the acid-sensitive analytes from decomposition and to avoid the appearance of extra peaks of by-products on the chromatograms. Exceptions are indicated by "reagent/(H^+)." Phenols can be converted into Na salts before acylation. A large variety of anhydrides of perfluorinated carboxylic acids are recommended for derivatization because of the favorable chromatographic properties of perfluoroacyl derivatives.

The possible enolization of carbonyl compounds explains the significant discrepancies in the formation of different derivatives of polyfunctional compounds like hydroxy ketones (a typical combination of functional groups in steroids). For example, androsterone [androstan-3-ol-17-one (I)] after treatment by trifluoroacetylating reagents forms only *mono*-TFA derivatives, whereas after silylation it may form both *mono*- and *bis*-TMS derivatives (depending on the silylating strength of the reagent), as illustrated in Fig. 2.

The third group of derivatization reactions of hydroxy compounds for GC analysis involves the formation of their alkyl or substituted benzyl ethers (Table 7). A more comprehensive list of alkylating reagents is presented in *Acids: Derivatization for GC Analysis*.

Methylation by diazomethane is a simple method of derivatization of relatively acidic compounds like phenols (pK_a 9–10) or carboxylic acids (pK_a 4.4 ± 0.2). The

application of this reagent for methylation of aliphatic alcohols needs additional acid catalysis. Methyl iodide is the most suitable reagent for the synthesis of permethylated derivatives of polyols (including carbohydrates) and phenols. Dimethyl sulfate $(CH_3O)_2SO_2$ can be used in basic media for the methylation of phenols, but the yields of methyl ethers in this case are not sufficient for the quantitative determination of initial compounds by GC.

Some special derivatization methods that lead to the formation of cyclic products were recommended for alcohols with more than two hydroxyl groups in the molecule (polyols including carbohydrates), amino alcohols, and polyfunctional aromatic hydroxy compounds. An appropriate arrangement of two functional groups [$(OH)_2$, (OH) + (NH_2) or (OH) + (CO_2H)] in 1,2 (*vic*); 1,3; or *ortho* (in aromatic series) positions is necessary for their realization (Table 8).

The simplest reagent of this type, widely used for the derivatization of *vic*-polyols, is acetone in the presence of water-coupling additives. The resultant isopropylidene derivatives (2,2-dimethyl-1,3-dioxolanes), similar to TMS ethers, usually indicate no signals of molecular ions, but signals of $[M\text{-}CH_3]^+$ ions are informative. As an example, the standard mass spectrum of *tris*-1,2:3,4:5,6-isopropylidene derivative of mannitol (Fig. 3) (MW 302) is presented in Fig. 4.

The choice of chemical reactions available for the derivatization of hydroxy compounds in aqueous samples (when it is impossible to remove the large excess of water) is relatively limited compared with the whole range of derivatization reactions. For example, hydrophilic and polar compounds such as monoethanolamine (MEA), $HOCH_2CH_2NH_2$, require derivatization prior to GC analysis, but can be preconcentrated from the air of industrial areas only as a mixture with water (owing to air humidity). A suitable method for the derivatization of MEA is based on its interaction with benzaldehyde in water media. This reaction produces the corresponding Schiff base $HOCH_2CH_2N{=}CHC_6H_5$, which can exist in the tautomeric cyclic form, namely, 2-phenyloxazolidine.[16]

The number of proposed methods of derivatization for alcoholic and phenolic *S*-analogues in GC analysis is significantly smaller than that for alcohols, because, in actual practice, the former compounds are analyzed less frequently. As per general recommendations, thiols and thiophenols may be converted into TFA (PFP, HFB) esters, or PFB ethers (*S*-TMS derivatives seem not to be as stable as *O*-TMS ethers). Derivatization of these compounds is necessary not only for the optimization of their chromatographic parameters, but also to prevent their easy oxidation by atmospheric oxygen dissolved in the liquid samples before analysis.

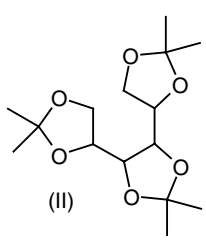

Fig. 3 Molecular structure of *tris*-1,2:3,4:5,6-isopropylidene derivative of mannitol (MW 302).

CONCLUSIONS

The simplest monofunctional hydroxy compounds are stable and volatile enough for direct GC analysis. However, the polyfunctional compounds of this class, owing to their high polarity and low volatility, usually cannot be analyzed in their native form. Hence their derivatization by various reagents is not only strongly recommended, but it is a generally accepted and routine procedure of sample preparation for GC analysis at present.

Besides the optimization of retention parameters and peak shaping, an additional function of derivatization is the protection of analytes from chemical transformation, which is most important for *S*-analogues of hydroxy compounds.

INTRODUCTION

Antibodies are serum proteins that are generated by the immune system which bind specifically to introduced antigens. The high degree of specificity of the antibody–antigen interaction plays a central role in an immune response, directing the removal of antigens in concert with complement lysis (humoral immunity). Importantly, this high degree of specific binding has been exploited as an analytical tool: Antigens can be detected, quantified, and purified from sources in which they are in low abundance with numerous contaminants. Examples include enzyme-linked immunosorbent assays (ELISAs), Ouchterlony assays, and Western blots. Antibodies that are specifically immobilized on high-performance chromatographic media offer a means of both detection and purification that is unparalleled in specificity, versatility, and speed.

We will focus, here, on the use of immobilized antibodies for analytical affinity chromatography, which offers a number of advantages over standard partition chromatography. The first advantage is the specificity imparted by the antibody itself, which allows an antigen to be completely separated from any contaminants. During a chromatographic run with an antibody affinity column, all of the contaminants wash through the column unbound, and the bound antigen is subsequently eluted, resulting in only two peaks generated in the chromatogram (contaminants in the flowthrough step and antigen in the elution step). With antibodies which are immobilized on high-speed media such as perfusive media,[1,2] typical analytical chromatograms can be generated in less than 5 min and columns can last for hundreds of analyses. In Fig. 1, an example of 5 consecutive analytical affinity chromatography assays are shown, followed by the results of the last 5 assays of a set of 5000. Note that, here, the cycle time for loading, washing out the unbound material, eluting the bound material, and reequilibration of the affinity column is only 0.1 min (6 sec). Also note that the calibration curve has changed little between the first analysis and after 5000 analyses, demonstrating both the durability and reproducibility of this analytical technique. Although many soft-gel media are also available for antibody immobilization, these media do not withstand high linear velocity and, therefore, are not suited for high-performance affinity chromatography.

Affinity chromatography using immobilized antibodies offers several advantages over conventional chromatographic assay development. First, assay development can be very rapid because specificity is an inherent property of antibody and solvent mobilephase selection is limited to a capture buffer and an elution buffer, which is often the same from one antibody to the next. Therefore, there is less "column scouting" for appropriate conditions. In addition, the assays are fast (see above) and chromatograms yield only two peaks instead of multiple peaks. Furthermore, the two peaks in the affinity chromatogram indicate both antigen concentration (from the eluted peak) and purity (from the ratio of the eluted peak to the total peak area). Thus, affinity chromatography with immobilized antibodies allows both fast assay development and rapid analysis times.

The limitations of immobilized antibody affinity chromatography are few. First, plentiful amounts of antibody, usually milligram quantities, are required to get reasonable ligand density on a useful amount of chromatographic media. Also, it is optimal if the antibody is antigen affinity purified, so that when it is immobilized, no other contaminating proteins with competing specificity dilute the antibody's concentration. Finally, the antibody must be amenable to affinity chromatography such that it is not irreversibly denatured by the immobilization process and can withstand many cycles of antigen capture and elution. Both monoclonal and polyclonal antibodies have been used successfully.

IMMOBILIZATION CHEMISTRIES

Many different chemistries can be used to immobilize antibodies onto chromatographic media and only a few will be discussed. In most cases, the chromatographic media is coated with the active chemistry, which will then react with the antibody. These include amine reactive chemistries such as epoxide-, aldehyde-, and cyanogen bromide (CNBr)-activated media, carboxyl reactive chemistries such as carbodiimides, aldehyde-reactive chemistries such as amino and hydrazide, and thiol-reactive chemistries such as iodoacetyl and reduce thiol media. Although there are several antibody isotypes (IgA, IgE, IgG, IgM), the most

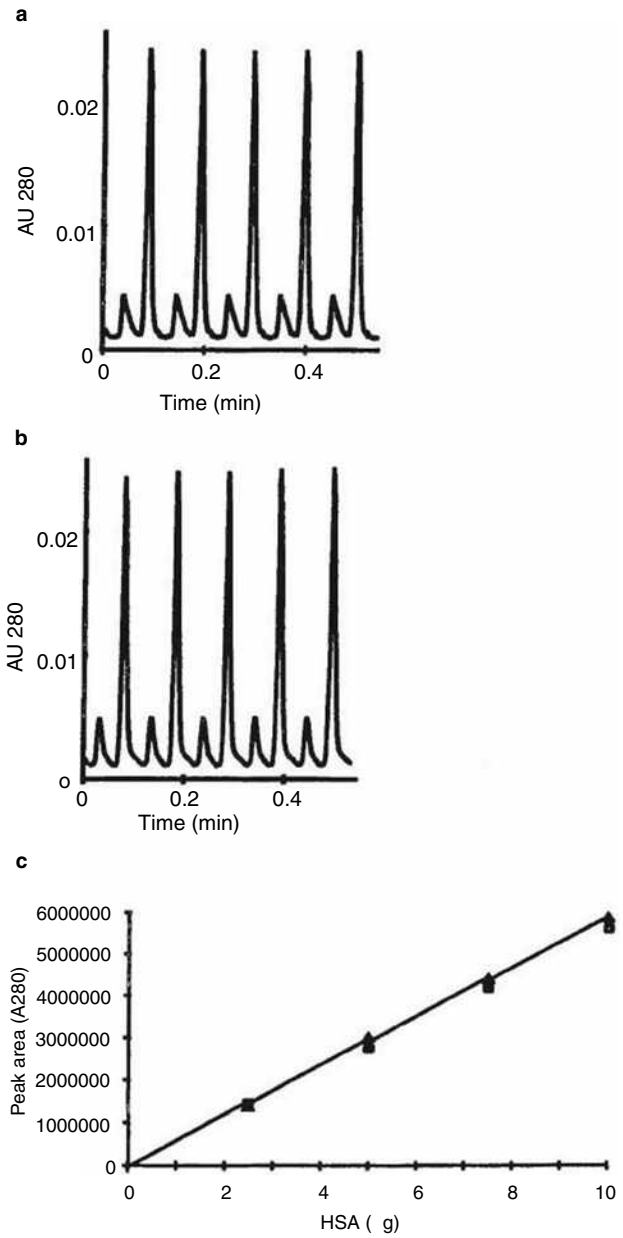

Fig. 1 Examples of affinity chromatography with an epoxyimmobilized polyclonal anti-human serum albumin (HSA) antibody in a 2.1 mm I.D. × 30 mm POROS CO column run at 5 ml/min (8000 cm/hr) using phosphate-buffered saline for loading and 12 m*M* HCl with 150 m*M* NaCl for elution. The sample was 10 μg HSA at 1 mg/ml. Part (a) shows the first five analyses of a relatively pure sample of HSA, where the first small peak is the unbound contaminant and the larger peak is the elution of the HSA from the affinity column; (b) shows the results of the last 5 analyses from a set of 5000; and (c) shows the calibration curve before (squares) the 5000 analyses and after (triangles).

common antibody immobilized for affinity chromatography is IgG, which is composed of four polypeptide chains (two heavy and two light) which are disulfide linked to form a Y-shaped structure capable of binding two antigens. For best results, it is also important to antigen affinity purify the antibody prior to immobilization to yield optimum binding capacity and a wider dynamic range for analytical work. Also note that the antibody may be digested with pepsin or papain to separate the constant region from the antigenbinding domains, which may then be immobilized.

Antibodies are very often immobilized through their amino groups either through the *N*-terminal amines or the epsilon amino groups of lysine. Reactions with epoxide-activated media are performed under alkaline conditions and lead to extremely stable linkages between the chromatographic support and the antibody. Similarly, immobilization using an aldehyde-activated media first proceeds through a Schiff base intermediate which must then be reduced (often by sodium cyanoborohydride) to yield a very stable carbon–nitrogen bond linking the antibody to the media. *N*-Hydroxy-succinimide-activated media also couples via primary amines and leads to a stable linkage in a single-step reaction. The major advantage of these chemistries is that they are extremely stable due to the formation of covalent bonds to the media. Although less stable but easy to use is CNBr-activated media, which also immobilizes antibodies through their primary amines.

Antibodies can also be immobilized through their carboxyl groups by first treating them with a carbodiimide such as EDC (1-ethyl-3-[3-dimethlaminopropyl]-carbodiimide) followed by immobilization on an amine-activated chromatographic resin. It is important to note that EDC does not add a linker chain between the antibody and the media, but simply facilitates the formation of an amide bond between the antibody's carboxyl and the amine on the media. Coupling through sulfhydryls on free cysteines can be accomplished with thiol-activated media by formation of disulfide bonds between the media and the antibody. However, this coupling is not stable to reducing conditions and a more stable iodoacetyl-activated media is often preferred because the resulting carbon–sulfur bond is more stable. Free cysteines can be generated in the antibody by use of mild reducing agents (e.g., 2-mercaptoethylamine), which can selectively reduce disulfide bonds in the hinge region of the antibody. Alternatively, antibodies may also be immobilized through their carbohydrate moieties. One method involves oxidation of the carbohydrate with sodium periodate to generate two aldehydes in the place of vicinyl hydroxyls. These aldehydes may then be coupled either directly to hydrazide-activated media or through amine-activated media with the addition of sodium cyanoborohydride to reduce the Schiff base. The primary advantages of these chemistries is to offer alternative linkages to the antibody beyond primary amines.

In addition, antibodies may also be coupled to other previously immobilized proteins. For example, the antibody may be first captured on protein A or protein G media and then cross-linked to the immobilized protein A or G with reagents such as glutaraldehyde or dimethyl pimelimidate. The advantage here is that the antibody need not be

pure prior to coupling because the protein A or protein G will selectively bind only antibody and none of the other serum proteins. The disadvantage is that free protein A or protein G will still be available to cross-react with any free antibody in samples to be analyzed, which will only be problematic with serum-based samples. Antibody coupling does not need to be covalent to be effective. For example, biotinylated antibodies can be coupled to immobilized streptavidin. The avidin–biotin interaction is extremely strong and will not break under normal antigen elution conditions. The advantage of this immobilization protocol is that many different biotinylation reagents are available in a wide range of chemistries and linker chain lengths. Once biotinylated and free biotin are removed, the antibody is simply injected onto the streptavidin column and it is ready for use. Immobilization can be accomplished through hydrophobic interaction by simply injecting the antibody onto a reversed-phase column and then blocking with an appropriate protein solution such as albumin, gelatin, or milk. This is analogous to techniques used to coat ELISA plates and perform Western blots, and although this noncovalent coupling is not stable to organic solvents and detergents, it can last for hundreds of analyses under the normal aqueous analysis conditions. The advantage of this immobilization is that it can be done very quickly (in several minutes) by simply injecting an antibody first and then a blocking agent.

OPERATION

A wide range of buffers can be used for loading the sample and eluting the bound antigen; however, for best analytical performance, a buffer system that has low a low ultraviolet (UV) cutoff and rapid reequilibration properties is desirable. One of the better examples is phosphate-buffered saline (PBS) for loading and 12 m*M* HCl with 150 m*M* NaCl. The NaCl is not required in the elution buffer but helps to minimize baseline disturbances due to the refractive index change between the PBS loading buffer and the elution buffer because both will contain about 150 m*M* NaCl. UV detection is well suited for these assays and wavelengths at 214 or 280 nm are commonly used.

For analytical work, large binding capacities are not required, but increased capacity does increase the dynamic range of the analysis. However, the dynamic range can be increased by injecting a smaller volume of sample onto the column at the expense of sensitivity at the low end of the

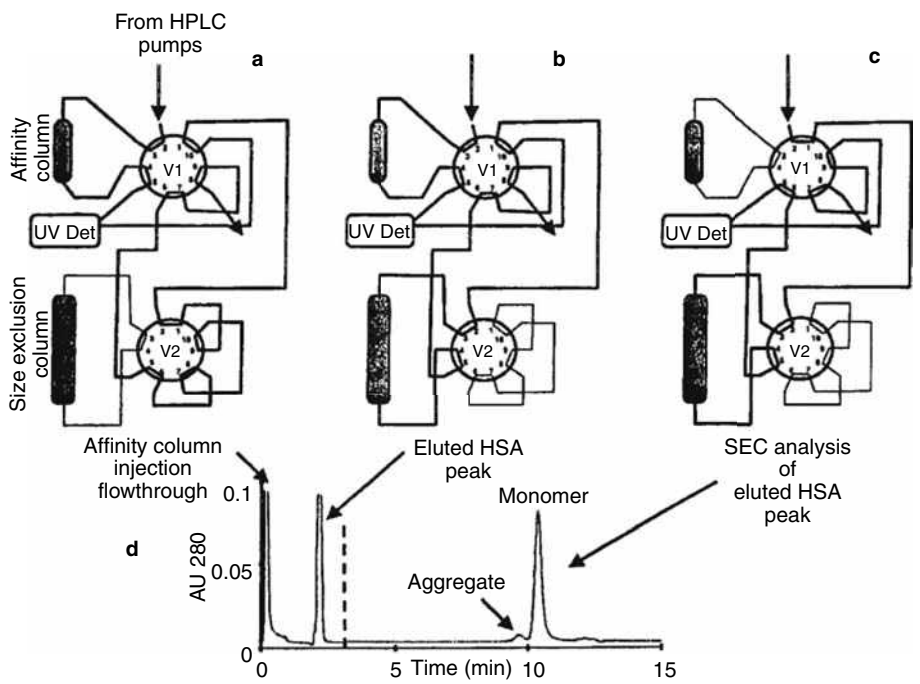

Fig. 2 Example of a multidimensional LC analysis for albumin aggregates using immobilized antibody affinity chromatography with SEC. Part (a) shows the flow path during the loading of the sample to capture the albumin monomer and aggregates while allowing all other proteins to elute to waste. Part (b) shows the transfer of the albumin and its aggregates to the size-exclusion column. Part (c) shows the flow path used to elute the size-exclusion column to separate the aggregate and monomer. Part (d) shows the UV trace from this analysis. Note that in this plumbing configuration, the albumin passes through the detector twice, once as it is transferred from the affinity to the size-exclusion column and again as the albumin elutes from the size exclusion column.The affinity column is a 2.1 mm I.D. × 30 mm POROS XL column to which anti-human serum albumin has been covalently cross-linked, run at 1 ml/min, loaded in PBS, and eluted with 12 m*M* HCl. The size-exclusion column is a 7.5 mm I.D. × 300 mm Ultrasphere OG run at 1 ml/min with 100 m*M* potassium phosphate with 100 m*M* sodium phosphate, pH 7.0. The sample was 100 μg heat-treated albumin.

calibration curve. Likewise, sensitivity can be increased by injecting more sample volume.

APPLICATION EXAMPLES

The most obvious way to use immobilized antibodies for analytical affinity chromatography is to simply use it in a traditional single-column method to determine an antigen's concentration and/or purity. However, there are a number of ways this technique can be advanced to more sophisticated analyses. For example, instead of immobilizing an antibody, the antigen may be immobilized to quantify the antibody as has been done with the Lewis Y antigen.[3] However, the analysis is still a single-column method.

Immobilized antibodies have also been used extensively in multidimensional liquid chromatography (MDLC) analyses. As shown in Fig. 2, an affinity column with immobilized anti-HSA is used to capture all of the human serum albumin in a sample, allowing all of the other components to flow through to waste. Then, the affinity chromatography column is eluted directly into a size-exclusion column where albumin monomers and aggregates are separated and quantified. In this example, neither mode of chromatography would be sufficient by itself. The affinity media does not distinguish between monomer and aggregate, and the size-exclusion column would not be able to discriminate between albumin and the other coeluting proteins in the sample. Other MDLC applications employing immobilized antibodies include an acetylcholine esterase assay utilizing SEC,[4] combinations of immobilized antibodies with reversed-phase analysis,[5–7] protein variant determination using immobilized antibodies to select hemoglobin from a biological sample followed by oncolumn proteolytic digestion, and LC/MS peptide mapping.[8]

There are many more examples of immobilized antibodies used for affinity chromatography which are not mentioned here, but it was the goal of this section to present some of the capabilities of this technique for analytical chromatographic applications.

Immobilized Metal Affinity Chromatography (IMAC)

Roy A. Musil
Althea Technologies, Inc., San Diego, California, U.S.A.

INTRODUCTION

The foundations for immobilized metal affinity chromatography (IMAC) were first laid in 1961 when Helferich introduced "ligand-exchange chromatography".[1] The modern-day usage of this technique and its practical applications as a purification tool did not emerge, however, until 1975 and the seminal work by Porath et al.[2]

Among the many new protein purification approaches introduced in recent years, IMAC stands out for its ease of use and widespread applicability. This highly versatile and efficient technique is based on the interaction between biological molecules and covalently bound chelating ligands immobilized on a chromatographic support. Indeed, because the popularization of the Qiagen Qiaexpress® bacterial expression and one-step purification system,[3] the use of IMAC has become nearly ubiquitous as tool for molecular biologists.

DISCUSSION

The principle behind IMAC lies in the fact that many transition metal ions [i.e., Ni(II) and Cu(II)] can coordinate to the amino acids histidine, cysteine, and tryptophan via electron-donor groups on the amino acid side chains.

An IMAC column may be loaded with a given metal–ion by perfusing the column with a metal–ion solution until equilibrium is reached between the metal chelated to the stationary phase and the metal ion in solution. The solid support (typically agarose, crosslinked dextran, or silica) is covalently linked to a metal-chelating ligand. The two most common ligands are iminodiacetic acid (IDA) and nitrilotriacetic acid (NTA).[4] All major chromatography suppliers now offer their own brands of IMAC supports, with IDA typically the ligand of choice. The IDA residue is very suitable as an immobilized chelating agent because a bidentate chelating moiety remains free after immobilization, to which a metal ion can be coordinated. The NTA ligand contains an additional chelating site for metal ions, which can minimize metal leakage on the column. Free coordination sites of the metal ion are then used to bind different proteins and peptides.

Pearson systematized metal ions into three categories according to their reactivity toward nucleophiles: hard, intermediate, and soft.[5] Hard metal ions, such as Fe(III), prefer oxygen, whereas soft metal ions prefer sulfur. Intermediate types of ions such as Cu(II), Zn(II), Ni(II), and Co(II) coordinate nitrogen but also oxygen and sulfur. All the metals mentioned have been successfully employed for use in IMAC.[6] The immobilized metal–ion adsorbents may be prepared by charging the chelating gels with a slightly acid solution of the metal salt (pH 3–5). Charging the gel under acidic conditions is essential in the case of Fe(III) to avoid the formation of ferric hydroxide particles in solution. The use of colored Ni(II) or Cu(II) ions facilitates checking of leakage and the possible presence of metal ions bound to the protein eluate.

In his pioneering contribution, Porath postulated that the histidine, cysteine, and tryptophan residues of a protein were most likely to form stable coordination bonds with chelated metal ions at near neutral pH.[2] To date, an analysis of several protein models[7] lend full to his original theory. Having said that, histidine, by far and away, plays the most prominent role in IMAC binding. In a very real sense, IMAC has subtly become synonymous as a histidine affinity technique. The absence of a histidine residue on a protein surface correlates with the lack of retention of that protein on any IDA–metal column. The presence of even a single histidine on a protein surface, available for coordination, results in retention of that protein on an IDA–Cu(II) column. Also, a protein needs to display at least two histidine residues on its surface to be retained on an IDA–Ni(II) column. Thus, beyond its role as a purification technique, IMAC has been used as a tool to probe the surface topography of proteins.[6]

The Qiaexpress® system is based on the selectivity of Ni–NTA for proteins with an affinity tag of six consecutive histidine residues: the 6x His tag. The 6x His tag is much smaller than such affinity tags as glutathione *S*-transferase, protein A, and maltose-binding protein and is uncharged at physiological pH. It has been shown to rarely contribute to a protein's immunogenicity, interfere with protein structure, function, or affect secretion from its expression system.[3]

As in any chromatography technique, one can break down the separation process to its two most fundamental aspects: adsorption and elution. On a more practical level, the execution of an IMAC experiment involves five discrete steps which can be readily automated: column equilibration (charging of the gel), sample loading, removal of unbound material (washing), elution, and regeneration.

Adsorption of a protein to an IMAC column has to be performed at a pH at which an electron-donor group(s) on the protein's surface is at least partially unprotonated. Because the pK_a value of histidine groups (which supply the strongest metal interactions) lies in the neutral range, the binding of protein samples to the column should normally occur at a pH value of approximately 7. However, the actual pK_a value of an individual amino acid varies strongly depending on the neighboring amino acid value. Various experiments show that depending on the protein structure, pK_a the value of an amino acid can deviate from the theoretical value up to one pH unit.[4] Therefore, an application buffer of pH 8 often achieves improved binding. In order to eliminate any non-specific electrostatic interactions, it is common to include salt in the equilibrating buffer. Typically, sodium chloride is used in concentrations between 0.1 *M* and 1.0 *M*.[8]

The buffer itself should not effectively compete with a protein for coordination to the metal ligand. Sodium phosphate or sodium acetate are recommended buffers (depending on the pH choice) and the presence of ethylenediaminetetraacetic acid (EDTA) or sodium citrate should be avoided. The presence of detergents (Triton X-100, Tween-20, urea, etc.) in the buffer does not normally affect the adsorption of proteins.[4]

Elution of proteins can be achieved by one of three methods: protonation, ligand exchange, or column stripping. Protonation is the most common method and probably the simplest. The pH is reduced by either a linear gradient or step-gradient in the range of pH 8 to 3 or 4, reflecting the titration of the histidyl residues. Most proteins elute between pH 6 and 4. Again, sodium phosphate or sodium acetate are the buffers of choice. Competitive elution with ammonium chloride (0–2.0 *M*), imidazole (0–0.5 *M*) or its analogs histidine (0–0.05 *M*) and histamine yield similar selectivity.[8] Competitive elution with a linear gradient or step-gradient is best run at a constant nearly neutral pH. The final method of elution is to use chelating agents such as EDTA or ethylene glycol tetraacetic acid (EGTA) (0.05 *M* solutions) which will strip the metal ions from the gel and cause the proteins to elute. Unless the protein of interest is the only one still bound on the column, this method will result only in recovery and not in purification or resolution.[3] Another undesirable feature of this protocol is that the eluate will contain a high concentration of free metal ion. Most resin manufacturers recommend that to maintain reproducibility and consistency, IMAC columns should be stripped of their metal ligands after each use and subsequently recharged with metal before the next run.[6] Recently, Fe(III)–IMAC has found specific application in the separation of phosphorylated macromolecules and other biological substances.[9] Unlike Cu(II)–IDA complexes which have no formal charge, the metal–ligand complex Fe(III)–IDA has a net positive charge. In terms of use, the highest protein capacity is reached at low pH (< 6) rather than at or above neutrality and at low ionic strength rather than at high salt concentrations. Electrostatic interactions for Fe(III) complexes play an important in protein binding.[2] However, Fe(III)–IMAC systems do not interact with phosphoproteins in the same way as ordinary ionexchange resins. Fe(III)–IMAC can be employed to resolve proteins with a wide range of isoelectric points (p*I* 4–11) something that is not generally possible in a simple, single ion-exchange chromatographic step.

Immobilized metal affinity chromatography has been shown to be effective for isolating proteins from crude mixtures, as well as for selective separations of closely related proteins.[2] With respect to separation efficiency, IMAC compares well with biospecific affinity chromatography and the immobilized metalion complexes are much more robust than antibodies or enzymes. These factors make IMAC particularly well suited for scale-up to process scale chromatography. The main scale-up points to be aware of are the degree to which the column is metal saturated, the chelating agent content of the sample, and the potential of leached metal (or its interactions) within the product eluate.

Leakage of metals from the column during elution can be the most significant problem due to their toxicity, but there are several ways to avoid this pitfall. Some references suggest the precaution of underloading IMAC columns (by as much as 20%) with the metal ion to begin with.[8] Another precaution is to add EDTA with imidazole, histidine, or histamine to the column fractions. EDTA competitively blocks formation of coordination complexes between protein carboxyl clusters and divalent metal cations, whereas the imidazolium groups block histidyl–metal complexation. For best reproducibility and general ease of use, a two-column format is preferred for process scale. A second scavenging column with 5% of the volume of the metal saturated purification column is simply placed in line.

Besides accommodating raw feedstreams, the relative independence of protein binding from salt concentration offers a great deal of flexibility for process sequencing. IMAC can follow virtually any other technique without the requirement for buffer exchange. The main exception is hydrophilic interaction chromatography (HIC) with ammonium sulfate. IMAC can also be used as the initial capture step enabling purification up to a 1000-fold[4] and subsequent preequilibration for downstream low-ionic-strength methods. Although high salt loading improves IMAC-binding specificity,[5] its concentration can be reduced after the major contaminants are washed through the column. Even with sodium chloride concentrations of up to 0.1 *M*, just a minor dilution can allow for the following charge-based chromatography method. This flexibility reveals IMAC as a valuable tool for streamlining the overall process design.

Immobilized Metal Ion Affinity Chromatography (IMAC): Chelating Sorbents

Radovan Hynek
Anna Kozak
Jirí Sajdok
Jan Kás
Department of Biochemistry and Microbiology, Institute of Chemical Technology, Prague, Czech Republic

INTRODUCTION

Immobilized metal ion affinity chromatography (IMAC) is a collective term that includes all kinds of affinity chromatography, where metal atoms or ions immobilized on polymer cause or dominate the interaction at the sorption site.

DISCUSSION

Metal-chelate affinity chromatography was introduced as a specific method for fractionation of proteins by Porath et al., in 1975.[1] The principle of this type of chromatographic method is that certain amino acid residues, such as histidine, cysteine, lysine, tryptophan, aspartic acid, glutamic acid, or phosphorylated amino acids, which are accessible on the protein surface, can interact through non-bonding lone-pair electron coordination with some metal ions. Metal cations Cu^{2+}, Ni^{2+}, Zn^{2+}, Co^{2+}, Fe^{3+}, Al^{3+}, and Cr^{3+}, and which have been chelated to ligands immobilized on support material, have already been used for such specific interactions.[2,3] The most widely used chelating ligands for the isolation of proteins are iminodiacetic acid (IDA) and its analogs, such as tricarboxyethylenediamine (TED). IDA is covalently coupled to an insoluble matrix (e.g., agarose or Sepharose) and forms stable coordinate compounds with a variety of divalent metal ions. These chelates create bases for the above-mentioned specific adsorption. Elution of adsorbed solutes from immobilized metal ion affinity adsorbents can be provided by changing the pH of the elution buffer or by a specific competing solute, such as histidine, imidazole, or sodium phosphate, depending on the interaction types involved.

Ligands coupled to agarose gels were commonly used at the beginning of IMAC application; however, these sorbents were not suitable for high-performance liquid chromatography (HPLC). Then, Small et al.,[4] used a silica-based matrix and demonstrated that such IMA sorbents can be used in HPLC techniques. The metal-chelate adsorbent "TSK gel chelate-5PW," suitable for HPLC, which was prepared by coupling IDA to a hydrophilic resin-based matrix (TSK gel G 5000 PW), later became commercially available (Fig. 1).

Since the introduction of metal ion affinity sorbents for the fractionation of proteins,[1] the method became popular for the purification of a wide variety of biomolecules. Metal ion affinity sorbents are also widely used for the immobilization of enzymes. At present, IMAC is a powerful method for separation of phosphorylated macromolecules, particularly proteins and peptides. The significance of techniques for separation and characterization of phosphorylated biomolecules is now increasing, because phosphorylation modulates enzyme activities and mediates cell membrane permeability, molecular transport, and secretion. Phosphorylated peptides can be separated from a peptide mixture on IDA–Sepharose with Fe^{3+} ions (Fig. 2). The majority of peptides pass freely through an IMAC column, whereas acidic peptides, including phosphorylated ones, are retained and can be released by a pH gradient.

Acidic peptides are released in the pH range 5.5–6.2 and phoshorylated peptides are eluted in the pH range 6.9–7.5.[5] Elution of retained peptides can also be performed with sodium phosphate. IMAC has been successfully used for the characterization of casein phosphopeptides in cheese extracts.[6] Phosphoproteins can be separated under very similar conditions as phosphopeptides. IMA sorbents were already used for fractionation of proteins

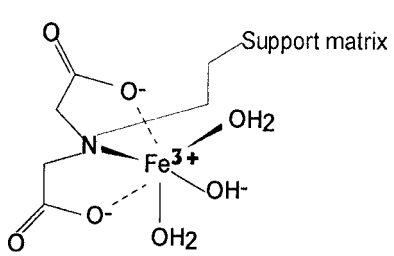

Fig. 1 Complex of water with IDA–$Fe3^{3+}$.

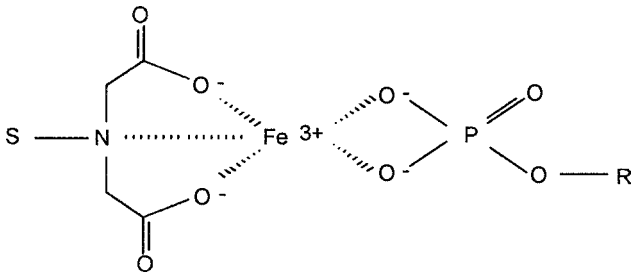

Fig. 2 Interaction of phosphate group with Fe^{3+} ion on IDA-Sepharose.

according to the number of phosphate groups contained in their molecules.

Separations of biomolecules on IMA sorbents achieved significant advances in the past few years, but detailed analyses of the mechanism of adsorption of molecules should be completed. Various factors, such as support matrix, chelating ligands, buffer composition, temperature, and so forth should be investigated in order to optimize analysis on metal-chelate ion affinity sorbents.

Immunoaffinity Chromatography

David S. Hage
Department of Chemistry, University of Nebraska-Lincoln, Lincoln, Nebraska, U.S.A.

Abstract
The general principles of immunoaffinity chromatography (IAC) are discussed in this entry. The term IAC refers to any chromatographic method in which the stationary phase consists of antibodies or antibody-related binding agents. The highly selective binding of antibodies has made IAC a popular purification tool for the isolation of many biological and non-biological substances, as well as a specific means for chemical measurement. In this entry, several formats of IAC are described, including the on-off elution mode for the purification or direct detection of chemicals and the indirect detection modes based on chromatographic immunoassays. The use of antibodies as a means for selective sample extraction or as part of a postcolumn detection scheme in combination with other chromatographic methods is also discussed.

INTRODUCTION

Immunoaffinity chromatography (IAC) refers to any chromatographic method in which the stationary phase consists of antibodies or antibody-related binding agents. Antibodies, or immunoglobulins, are a diverse class of glycoproteins that are produced by the body in response to a foreign agent, or antigen. Antibodies are highly selective in their interactions with other molecules and can be produced against a wide range of substances. These properties have made IAC popular as a purification tool for the isolation of targets that include hormones, peptides, enzymes, proteins, receptors, viruses, and subcellular components. The high selectivity of IAC has also made it appealing as a means for developing specific analytical methods. This entry will examine the basic principles of IAC and the various formats in which it can be used.

HISTORY OF IAC

The use of an immobilized ligand for the purification of antibodies was first reported in 1935, when antigens adsorbed on kaolin and charcoal were employed for the isolation of antibodies associated with syphilis and tuberculosis.[1] In 1936, Landsteiner and van der Scheer began to immobilize targets for antibodies by using a diazo coupling method and chicken erythrocyte stroma as the support material.[2] However, the first modern use of IAC is generally credited to Campbell et al., who in 1951 coupled serum albumin to *p*-aminobenzylcellulose for use in antibody purification.[3] There are now thousands of methods based on IAC that have been reported for the isolation of chemicals and biochemicals,[4–11] with a growing number of applications also using this method for chemical analysis.[5,8–19]

ANTIBODY STRUCTURE

The key component of any IAC method is the preparation of the antibody used as the stationary phase. The basic structure of a typical antibody (such as immunoglobulin G or an IgG-class antibody) consists of four polypeptides that are linked by disulfide bonds to form a Y- or T-shaped structure (see Fig. 1). The two upper arms of this structure are called the F_{ab} fragments and contain two identical antigen-binding regions. The lower stem region is known as the F_c fragment and has a structure that is highly conserved between antibodies that belong to the same class. Other classes of antibodies (e.g., IgA, IgM, IgD, and IgE) have the same basic structure as that of IgG but may contain multiple units that are cross-linked through the presence of additional peptide chains. The amino acid composition within the F_{ab} fragments is highly variable from one type of antibody to the next. It is this variability that allows the body to produce antibodies with a variety of affinities and binding specificities for foreign agents.

Typical antigens in nature include bacteria, viruses, and foreign proteins from animals or plants. All of these agents are fairly large in size compared to the binding sites on an antibody. As a result, these antigens usually have many different locations on their surfaces to which an antibody can bind; each of these locations is called an epitope. Smaller antigens (i.e., those with a molecular mass below several thousand daltons) are too small to produce an immune response by themselves. These substances can result in antibody production if they are first coupled to a larger species such as a carrier protein.

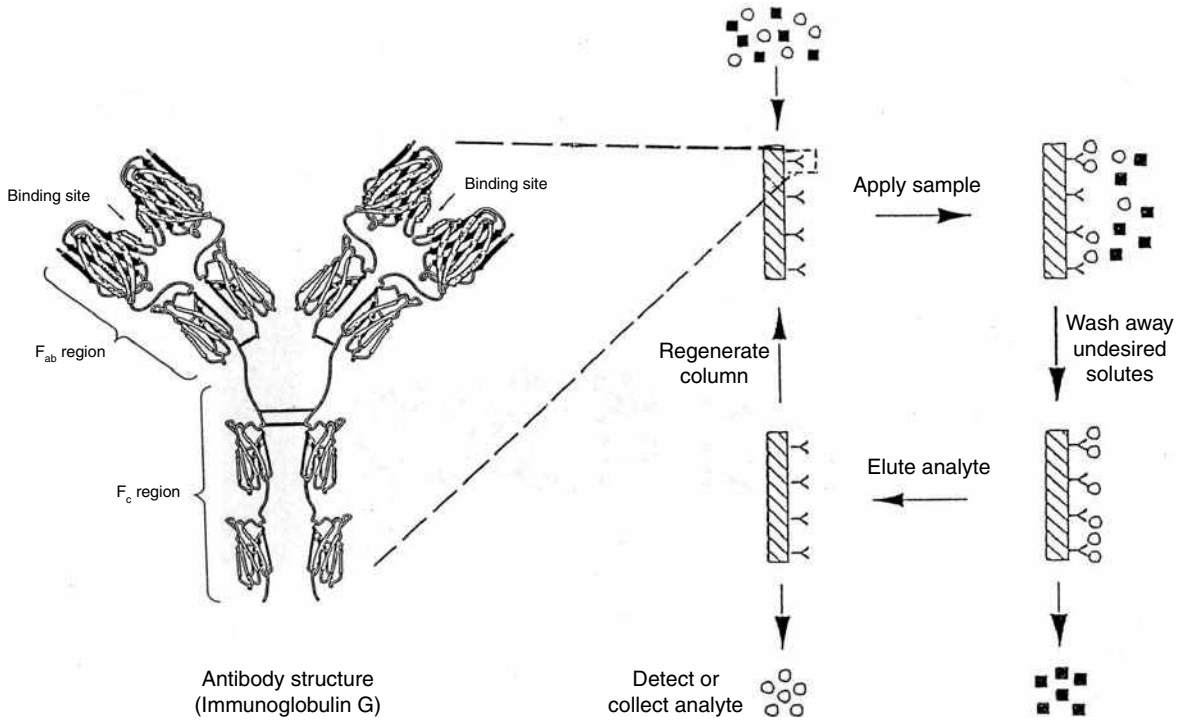

Fig. 1 Basic structure of an antibody and an example of the use of antibodies in the on-off mode of immunoaffinity chromatography.
Source: From Chromatographic immunoassays, in Anal. Chem.[14]

The agent that is coupled to the carrier protein in this situation is called a hapten.

ANTIBODY PRODUCTION

One way to produce antibodies that are directed against a given target is to inject the corresponding antigen or hapten–carrier conjugate into an animal such as a mouse or a rabbit. Samples of the animal's blood are then taken at specified intervals to collect any antibodies that are produced against the injected foreign agent. This method results in a heterogeneous mixture of antibodies that bind with a range of strengths and to various epitopes on the antigen or the hapten–carrier conjugate. These antibodies are called polyclonal antibodies because they are produced by several different immune system cell lines. Techniques have also been developed that allow for the isolation of single antibody-producing cells and their subsequent hybridization with cancer cells to produce combined cell lines that are stable and relatively easy to grow over long periods of time. These combinations of immune system/cancer cells are called hybridomas, and their product is a single type of well-defined antibody known as a monoclonal antibody. Both polyclonal and monoclonal antibodies have been used in IAC methods.[8,12]

IMMUNOAFFINITY SUPPORTS

The support material is an important factor to consider in the development of a successful IAC method. Originally, most IAC applications were based on low-performance supports that consisted of non-rigid media that could be operated under gravity flow or in the presence of peristaltic flow or a small applied vacuum. The supports were typically based on carbohydrate-related materials like agarose and cellulose, or synthetic organic supports, such as acrylamide-based polymers. However, IAC has also been used in high-performance liquid chromatography (HPLC), where more rigid and higher efficiency materials are employed. Some examples of HPLC supports that have been utilized for IAC include derivatized glass, silica, polystyrene-based perfusion media, azalactone beads, and monolithic supports.[8,12,18] When these types of supports are used in IAC, the resulting method is often referred to as high-performance immunoaffinity chromatography (HPIAC). Of these two approaches, low-performance IAC is the method most often employed for the purification of solutes or for use in sample pretreatment prior to analysis by other techniques. HPIAC can also be used for sample pretreatment or compound isolation, but it is more commonly employed as an analytical tool for measuring specific chemicals in complex mixtures.[5,8,12]

ANTIBODY IMMOBILIZATION

One common approach for antibody immobilization involves direct covalent attachment between the support and the free amine groups on the antibodies. Examples include reductive amination (i.e., the Schiff base method) or the reaction of antibodies with supports that have been activated with reagents such as 1,1′-carbonyldiimidazole or *N*-hydroxysuccinimide. Antibodies or antibody fragments can also be immobilized through more site-selective methods. For instance, free sulfhydryl groups that are generated during the production of F_{ab} fragments can be used to couple these fragments to thiol-activated supports. In addition, mild oxidation of the carbohydrate residues in the F_c region of antibodies can be used for coupling to a support by reacting these oxidized residues with amine- or hydrazide-activated materials. The main advantage of site-selective immobilization is that it produces immobilized antibodies or antibody fragments that have fairly well-defined points of attachment and greater accessibility of their binding regions to analytes, thus resulting in higher binding activities than are obtained by more general coupling methods.

Non-covalent immobilization can also be used for the site-selective coupling of antibodies to supports. This approach typically involves absorbing the antibody to a secondary ligand such as protein A or protein G, both of which bind to the F_c region of many antibody classes. This binding is quite strong under physiological conditions but can be disrupted by decreasing the pH of the surrounding solution. This method is useful when high antibody activity is needed or when it is desirable to have frequent replacement of antibodies in the IAC column. Other secondary ligands that can be used to adsorb antibodies in affinity columns are avidin or streptavidin, which bind to antibodies that have been labeled with biotin tags.[8]

APPLICATION AND ELUTION CONDITIONS

The mobile phase used in IAC is another factor to be considered in this method. The application buffer that is present during sample injection should facilitate quick and efficient binding of the analyte to the immobilized antibodies. This mobile phase is usually selected so that it mimics the natural environment of the antibody (e.g., a buffer with a physiological pH and ionic strength). The association equilibrium constants for antibody–antigen interactions under such conditions are often in the range of 10^6–10^{12} M^{-1}. This generally results in extremely strong binding between the analyte and the immunoaffinity column during sample application.

Although it is possible to use isocratic elution for IAC columns that contain low-affinity antibodies (i.e., those with association equilibrium constants below 10^6 M^{-1}), isocratic elution is not practical when working with high-affinity antibodies. The only way solutes can be quickly eluted from high-affinity antibodies is to change the column conditions to lower the effective strength of the antibody–analyte interaction. This change is effected by applying an elution buffer to the column. Usually an acidic buffer (pH 1–3) or a solution that contains a chaotropic agent (e.g., sodium thiocyanate) is used for analyte elution in such situations. Occasionally a competing agent, an organic modifier, a temperature change, or a denaturing agent is also employed. The elution buffer is typically applied in a step gradient, but more gradual linear or non-linear gradients have been reported as well.[5,8,12]

TRADITIONAL IAC

There are a variety of ways by which IAC can be carried out. The simplest format (shown in Fig. 1) is the on-off mode. In this technique, the sample is first injected onto the IAC column in the presence of an application buffer. As the analyte is being retained, other compounds in the sample pass through non-retained and are washed from the column. After these non-retained solutes have been removed, the elution buffer is applied. The analyte is then collected or detected as it elutes from the column. Later, the initial application buffer is reapplied and the antibodies are allowed to regenerate before the next sample is injected.

The on-off mode is the format most commonly used in IAC for the purification of compounds. This format has been used with a broad array of compounds, ranging from proteins and glycoproteins to carbohydrates, lipids, bacteria, viral particles, drugs, and environmental agents.[4–11] IAC has been especially popular in the isolation of specific antibodies or antigens, where an appropriate ligand (i.e., either an antibody or a purified antigen) is used to isolate its counterpart from a sample. This approach allows the isolation of an immunologically specific agent, regardless of its chemical or biochemical nature. The on-off mode is also used in analytical applications that involve analytes that are labeled or that occur at sufficiently high levels to allow their direct detection as they pass through an IAC column. In this type of application, the on-off mode of IAC is sometimes referred to as the direct detection mode.[12]

IMMUNOEXTRACTION METHODS

Another type of IAC is immunoextraction.[12–14] This term refers to the use of IAC for the removal of a specific solute or group of solutes from a sample prior to the determination of these targets by a second analytical method. Off-line immunoextraction is the easiest way for combining IAC with techniques such as gas chromatography (GC) or HPLC. In this method, antibodies are typically immobilized onto a low-performance support that is packed into a small disposable syringe or solid-phase extraction

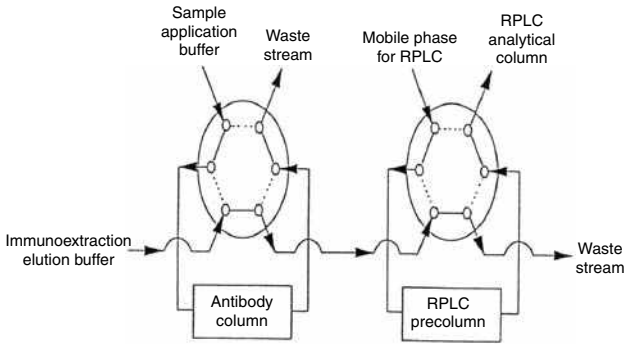

Fig. 2 Typical scheme for the online coupling of immunoextraction with reversed-phase liquid chromatography (RPLC).
Source: From Analysis of atrazine and its degradation products in water by tandem high-performance immunoaffinity chromatography and reversed-phase liquid chromatography, in *Immunochemical Technology for Environmental Applications*.[19]

cartridge. After the sample has been applied to the immunoaffinity column and undesired sample components have been washed away, an elution buffer is passed through the IAC support and the analyte is collected. In some situations, the collected fraction is dried and reconstituted in a solvent that is more suitable for later analysis, such as by adding a volatile solvent for compound analysis by GC. Off-line immunoextraction is quite common and has been used to analyze substances in samples that range from plasma and urine to food, water, and soil extracts. Immunoextraction has also gained popularity in recent years for the removal of high-abundance proteins from samples for proteomics studies; this approach is sometimes referred to as immunoaffinity depletion.[9]

The relative ease with which IAC can be directly coupled to an HPLC system makes online immunoextraction appealing as a means for automating and reducing the time required for sample pretreatment in HPLC. Direct coupling of IAC with size-exclusion and ion-exchange chromatography has also been accomplished, but the vast majority of online immunoextraction has involved coupling IAC with reversed-phase liquid chromatography (RPLC).[12–14] An example of an HPLC system that can be used for this purpose is shown in Fig. 2.[19] Part of the reason for the popularity of this combination is the widespread use of RPLC in chemical separations. Another reason is that the elution buffer for an IAC column is an aqueous solvent with little or no organic modifier, which makes this buffer act as a weak mobile phase for reversed-phase columns. Online immunoextraction coupled with RPLC has been used to measure compounds in food extracts, bodily fluids, enzyme digests, cell extracts, and environmental samples. Online IAC has also been coupled with capillary electrophoresis,[20–24] mass spectrometry,[25] and microfluidic devices.[16,26] In addition, coupling of immunoextraction with GC has also been investigated.[27]

CHROMATOGRAPHIC IMMUNOASSAYS

Another important technique in IAC is the use of immobilized antibody columns to create a chromatographic (or flow-injection) immunoassay.[12,14,28] One way this technique can be carried out is by employing a competitive binding format (see Fig. 3). The simplest competitive binding scheme is to mix the sample and a labeled analyte analogue (often called the "label"), which are then applied simultaneously to the IAC column; this method is known as a simultaneous injection competitive binding immunoassay. An alternative method is to first apply the sample to the IAC column and later make a separate injection of the label, a technique that is called a sequential injection competitive binding immunoassay. In both of these formats, an indirect measure of the analyte is obtained by examining the amount of label that elutes in either the non-retained or in the retained IAC fractions.

An alternative format for a chromatographic immunoassay is the displacement competitive binding immunoassay. In this format, the IAC column is first saturated with the labeled analogue, followed by application of sample to the column. As the analyte travels through the column, it is able to bind to any antibody sites that are momentarily unoccupied by the label as the analyte and antibodies undergo local dissociation and reassociation. This situation results in competition between the analyte and the label

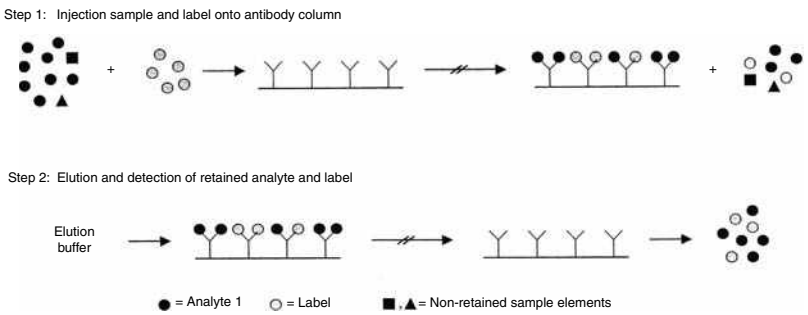

Fig. 3 Typical scheme for a chromatographic competitive binding immunoassay. This particular example is for the simultaneous format.
Source: From Chromatographic Immunoassays, in *Handbook of Affinity Chromatography*.[28]

and displacement of the label from the column, the degree of displacement being directly proportional to the amount of injected analyte.

A sandwich immunoassay in IAC uses two groups of antibodies that bind to different regions on the analyte of interest. The first group of antibodies is immobilized within the IAC column and is used for the extraction of an analyte from the sample. The second group of antibodies contains an easily measured label and is added in solution to bind the analyte either before or after sample extraction. This label allows the analyte to be measured by providing a final signal that is proportional to the amount of analyte that has been extracted by the IAC column.

In a one-site immunometric assay, the sample is first incubated with a known excess of labeled antibodies (or F_{ab} fragments) that are specific for the analyte of interest. After this binding has occurred, the resulting mixture is applied to a column that contains an immobilized analogue of the analyte; this column is used to extract any antibodies or antibody fragments that are not bound to the analyte. Those antibodies/antibody fragments that are bound to the analyte will pass through the column in the non-retained peak. Detection is accomplished either by examining the non-retained labeled antibodies or by monitoring the amount of excess antibodies that later dissociate from the column during the elution step.

A variety of detection schemes have been used with chromatographic immunoassays. The detection can be based on chemical tags that act as chromophores, fluorophores, chemiluminescent agents, or electrochemically active species. Enzymes like β-galactosidase, alkaline phosphatase, and horseradish peroxidase have also been employed as labels to generate products for detection by absorbance, fluorescence, chemiluminescence, electrochemical, or thermometric measurements. Liposomes, radiolabels, and bioassays have also been used for detection in chromatographic immunoassays.[14,28]

POSTCOLUMN IMMUNODETECTION

The technique of postcolumn immunodetection uses an IAC column that is attached to the exit of an analytical HPLC system. The IAC column in this approach serves to collect and retain a specific analyte from the HPLC column eluent for later detection.[12,29] The direct detection mode of IAC is the simplest approach for postcolumn immunodetection if the analyte of interest is capable of generating a sufficiently strong signal for detection. For instance, this approach has been used to measure the enzyme acetylcholinesterase by capturing it by IAC after elution from a size exclusion column, and later applying a chromogenic substrate to the IAC column for the detection of the enzyme.[30]

One factor that must be considered in postcolumn immunodetection is the need to adjust the eluent of the HPLC analytical column to a pH, ionic strength, and polarity that are appropriate for an IAC application buffer.[31] This factor is especially important when using immunodetection with RPLC because an appreciable amount of organic modifier may be present in the mobile phase leaving the reversed-phase analytical column, which may damage the IAC column. One way to avoid this problem is to combine the analytical column eluent with a dilution buffer prior to sample application onto the IAC column. Immunodetection by the on-off mode also requires that the eluting analyte be present in a conformation that is recognized by the antibodies in the IAC column.

Chromatographic sandwich immunoassays have been used for postcolumn immunodetection;[31] however, the one-site immunometric assay is a more common approach.[12,29,32] The use of a one-site immunometric assay in this application involves taking the analytical column eluent and combining it with a solution of labeled antibodies or antibody fragments that will bind to the analyte of interest. The column eluent and the antibody/antibody fragment mixture are then allowed to react in a mixing coil and are passed through an immunodetection column that contains an immobilized analogue of the analyte. The antibodies or antibody fragments that are bound to the analyte will pass through this column and on to the detector, where they will provide a signal that is proportional to the amount of bound analyte. If desired, the immunodetection column can later be washed with an eluting solvent to dissociate the retained antibodies or antibody fragments. However, a sufficiently high binding capacity is generally used in the immunodetection column so that a large amount of the analytical column eluent can be analyzed before the immunodetection column must be regenerated.

CONCLUSION

IAC is a powerful method for the selective binding of targets from samples. This method makes use of antibodies as specific binding agents within a column. There are several ways in which antibodies can be used in IAC. The first of these is the on-off mode, which can be employed for the purification of compounds by immunoaffinity columns or for the direct detection of such agents. It is also possible to use IAC for the indirect detection of chemicals, as is accomplished through the use of chromatographic immunoassays in which a labeled antibody or a labeled analogue of the target provides a signal that is related to the amount of a given chemical in the sample. In addition, IAC can be utilized for the postcolumn detection of analytes as they elute from other types of chromatographic columns. These formats have appeared in numerous applications and fields ranging from biotechnology, clinical analysis, and pharmaceutical testing to environmental work and food analysis.[4–17]

Immunodetection

E.S.M. Lutz
Bioanalytical Chemistry Department, AstraZeneca R&D Mölndal, Mölndal, Sweden

INTRODUCTION

Monitoring a liquid chromatography (LC) effluent by means of an immunoassay provides sensitive and selective detection in combination with the separation of cross-reactive compounds.[1,2] When implementing the immunoassay as a postcolumn reaction detection system after LC, it is frequently referred to as immunodetection.[3,4] Automation and assay speed are the main advantages of immunodetection over off-line coupling of immunoassays to LC by means of fraction collection.[5,6]

The typical setup of immunodetection is illustrated in Fig. 1.[5,6] The column effluent is mixed with labeled antibodies which will bind selectively to the analytes while passing through a reaction coil. This binding is based on the affinity between analyte and antibody and is characterized by the association and dissociation rate constants of the affinity reaction. Whereas the association rate constant (k_{+1}) is diffusion controlled, the dissociation rate constant (k_{-1}) depends on the interactions between the antibody and its antigen. Generally, k_{+1} lies in the range of 10^7–10^8 L/ml sec, whereas k_{-1} is comparably slow (10^3–10^5/sec). The volume of the reaction coil and the flow rates used determine the reaction time during which the labeled antibodies can bind to analyte molecules. Typical reaction times lie in the range of a few minutes and thus allow the fast association reaction to take place, whereas the dissociation reaction can practically be neglected. Quantification of the analyte concentration is then possible by distinguishing labeled antibody which has bound to analyte from free antibody. For that purpose, the free and the bound antibody needs to be separated (e.g., by means of an affinity column which traps free antibody), whereas the analyte–antibody complex passes the affinity column unretained for detection in a conventional flow through the detector. Using this setup, both analyte recognition and quantification occurs through the labeled antibody.

Alternatively, it is possible to use untreated antibodies in combination with a labeled antigen; see Fig. 2.[5,6] Under these circumstances, a two-step reaction is performed after the analytical separation. First, the column effluent is mixed with antibodies to allow the recognition of analyte(s). In the second step, the labeled antigen is added to saturate the fraction of free antibodies and allow quantification. When binding of labeled antigen to the antibody causes a change in detection properties, the reaction mixture can be monitored directly for quantification (homogeneous assay). However, generally the labeled antigen which has reacted with the antibody needs to be separated from the free labeled antigen to allow quantification. Again, affinity columns can be used for this purpose. Other forms of separating free and bound labeled antigens comprise restricted access columns, free-flow electrophoresis, and cross-flow filtration.

REAGENTS

So far, primarily antibodies and their Fab fragments have been implemented in immunodetection for analyte recognition. Antibodies can be raised against virtually any compound of interest; accordingly, their implementation into detection for LC provides a general approach. Antibody affinity and selectivity can be modulated by appropriate design of the hapten, by adequate screening of the antibodies, and by site-directed mutagenesis. Because the chemical structure and properties of antibodies against different antigens is comparatively homogenous, immobilization, stabilization, calibration, and storage procedures can be standardized.

The approach of implementing a biological assay as a postcolumn reaction detection system after LC can not only be applied to antibodybased assays (immunoassays) but also to assays employing other affinity interactions with high association and low dissociation rate constants, such as receptors. Information obtained from such a detection system not only provides quantitative results but also indicates the biological activity of the detected compound.

Requirements with respect to the label used to mark one of the immunoreagents are comparable to those in other postcolumn reaction detection systems.[4] The label should preferably allow sensitive and rapid detection and be non-toxic, stable, and commercially available. So far, mainly fluorescence labels have been employed (e.g., fluorescein), although, in principle, also liposomes, time-resolved fluorescence, and electrochemical or enzymatic labels are feasible. On the other hand, labels providing a slow response, including radioactive isotopes and glow-type chemiluminescence, are less suitable for immunodetection. When attaching the label to the immunoreagent, care has to be taken not to affect the affinity reaction between the antibody and its antigens and thus deteriorate assay performance.

A concern in recent research involving immunodetection has been availability, quality, and cost of reagents,

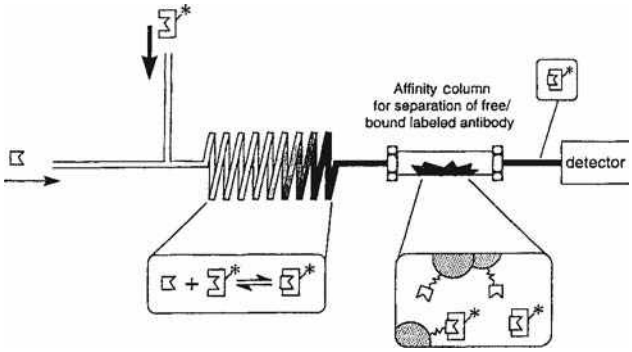

Fig. 1 Scheme of the immunodetection system employing labeled antibodies ( ) and an affinity column for separating labelled antibodies which have reacted with an analyte ( ) from free-labeled antibodies.

especially of antibody and receptor preparations. In the future, this concern may be overcome with novel cloning techniques providing possibilities to drastically reduce the cost of producing proteins as well as to develop proteins for specific applications.

INTERFACING LC/IMMUNODETECTION

The attractiveness of immunodetection consists in its on-line coupling to a separation step, such as liquid chromatography. Parameters to consider are band broadening caused by the postcolumn reaction and interference of the LC mobile phase with the immunoreaction.[4,7]

In conventional immunoassays with long incubation times, the environment in which the affinity reaction is taking place needs to be strictly controlled with respect to, for example, pH, salt, and organic modifier content. In contrast, immunodetection takes place within a few minutes, entailing less stringent requirements with respect to reaction conditions. Nevertheless, the mobile phase needs to be consistent with the affinity reaction; that is, the mobile phase should not denature the immunoreagents or compete with the analyte for the available binding sites. Mobile-phase compatibility has mainly been evaluated with reversed-phase LC, as it is a frequently used analytical separation technique and constitutes the greatest challenges in interfacing to biological assays. The crucial consideration is the organic-modifier content in the reversed- phase LC mobile phase. Investigations have shown that up to 15–25% (v/v) of organic modifier can be used in immunodetection without affecting the antibody–antigen interaction.[5] These results are in concurrence with immunodetection systems which have been coupled to reversedphase LC. At higher concentrations of organic modifier, the affinity reaction can be hampered seriously, which typically is overcome by dilution of the column effluent.[8,9]

However, many interesting analytes (e.g., peptides and proteins) are commonly separated by means of a gradient. The challenge of coupling immunodetection to gradient LC is twofold: On the one hand, the affinity interaction will be affected; on the other hand, the detection properties of the label will vary. For example, using a gradient of organic modifier affects the conformation of the antibody and, thus, its affinity characteristics, as well as the detection properties of a fluorescence label. When acceptance of an increasing baseline[10,11] is out of the question, additional interfacing between the separation step and the immunodetection is required. One approach is to introduce a buffer-exchange step after the separation (e.g., with on-line dialysis[12] or an ion-exchange column[7]). However, this will introduce extra band broadening as well as affect robustness with yet another part in the system.

APPLICATIONS

Feasibility of LC/immunodetection has been shown for quantitative analysis and for screening for biological activity, as summarized in Table 1. For analytical purposes, immunodetection in combination with LC is most promising in those cases when conventional immunoassays or conventional LC methods by themselves do not suffice for accurate analytical determinations. Being an approach offering high selectivity and sensitivity, applications are directed toward measurement of trace levels of compounds which lack appropriate detection properties in complex matrices. This is illustrated, for example, by measuring endogenous levels of the protein granulocyte colony-stimulating factor (GCSF) in biological matrices.[10] Affinity chromatography for sample preparation introduces high selectivity into the system but does not provide

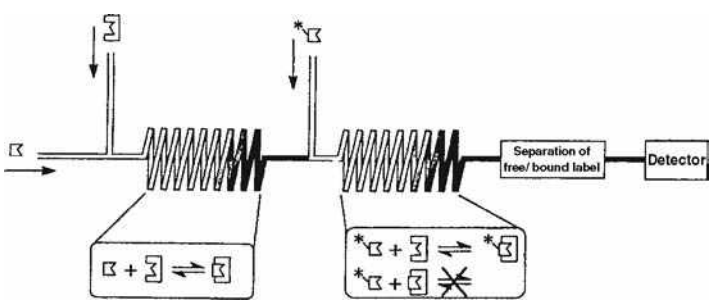

Fig. 2 Scheme of the immunodetection system employing untreated antibodies ( ) and a labeled antigen ( ).

Table 1 Review of immunodetection applications.

Application area	Compound	Matrix	Immunodetection type	Detection limit	Refs.
Protein bioanalysis	Granulocyte colony-stimulating factor (GCSF)	Plasma	Fluorescence-labeled antibodies, affinity chromatography	0.6 nmol/L	[10]
	Growth-hormone-releasing factor (GHRF)	Plasma	Fluorescence and enzyme-labeled antibodies, affinity chromatography, interface for dilution between LC and immunodetection for compatibility	0.2 ng/ml	[9]
	Urokinase	Plasma	Fluorescence-labeled receptor, affinity column	40 nmol/L	[11]
	Interleukine 4	?	Fluorescence-labeled antibodies, affinity chromatography	2 fmol	[16]
Drug bioanalysis	Diogoxin	Plasma	Fluorescence-labeled antibodies, affinity chromatography	0.2 nmol/L	[8]
Biomarker analysis	Sulfodipeptide Leukotrienes	Urine, human cell culture extract	Untreated antibodies and fluorescence-labeled ligand, reversed-phase restricted-access chromatography	0.4 nmol/L	[15]

a means to improve detection properties of the protein. By combining the affinity chromatography for sample preparation with an analytical separation by means of reversed-phase LC and immunodetection, levels of GCSF were determined in plasma.

In other bioanalytical applications, the emphasis lies more on overcoming cross-reactivity. For example, the heart glycoside digoxin is cross-reactive with several of its metabolites as well as with plasma constituents, thus hampering approaches solely based on immunoassays. By treating plasma samples with solid-phase extraction on a restricted access column, coupled online to reversed-phase LC/immunodetection, digoxin and two of its cross-reactive metabolites were analyzed in patients treated with the heart glycoside.[8]

A key to successful drug development is the identification of new lead compounds. Lead compounds can be identified through receptor assays, where the receptor–ligand interaction reflects the biomolecular mechanism associated with a disorder. By implementing the receptor interactions into postcolumn reaction detection systems, biologically active compounds can be separated and detected with high sensitivity and selectivity. This concept has been described for the analysis of estrogens using a recombinant steroid-binding domain of the human estrogen receptor for analyte recognition and coumestrol, a fluorescent estrogen, as reporter molecule.[13] Prior to detection samples were treated online and automated by reversed-phase solid-phase extraction and reversed-phase LC. Selectivity of this system is demonstrated for analysis in urine samples, which shows the feasibility of using this method in the determination of the abuse of steroid hormones in performance doping or cattle breeding. When performing both LC/immunodetection and mass spectrometry, information on biological activity is combined with structure elucidation.[11]

Recently, also direct recognition of active ligands attached to bead surfaces has been achieved with immunodetection.[14] This provides a rapid and automated screening tool which is compatible with solidphase bound compounds originating from solid-phase chemistry in combinatorial chemistry. However, this approach has so far only been published for a model system.

CONCLUSIONS

Immunodetection coupled online to LC as a tool for quantitative analysis has been developed for model compounds as well as been applied in relevant applications. The approach is particularly appealing for trace analysis in complicated matrices and for identifying ligands for certain receptors in drug discovery. However, each application still requires a fair amount of method development and optimization, and obtaining the desired, pure immunoreagents still is a concern, although advances in recombinant protein production are providing us with an increased choice and availability of affinity reagents at reduced cost.

In parallel with miniaturization of LC, immunodetection will be downscaled, thus lowering reagent consumption and, consequently, cost. However, increased challenges with respect to band broadening in a postcolumn reaction detection system and non-specific binding to capillary walls will need to be addressed. The trend toward miniaturization will simultaneously give the opportunity to couple immunodetection to other analytical separation methods, such as capillary electrophoresis. Combination of immunodetection with mass spectrometry enables the combination of information of biological activity with structure elucidation. Other developments in immunodetection concern the separation of free and bound labels, enabling the implementation of suspended materials in detection LC, including, for example, suspended membrane receptors, whole cells, and molecularly imprinted polymers serving as artificial receptors. Consequently, immunodetection potentially conquer new

application areas, such as the evaluation of absorption profiles of drugs and the investigation of drug metabolism on a cellular level.

Industrial Applications of CCC

Alain Berthod

Abstract
Countercurrent chromatography (CCC) is a separation technique using a biphasic liquid system. Since the stationary phase is liquid, the injected solutes have access to its volume rather than only its surface like with a solid stationary phase in classical liquid chromatography (LC). Column overload is much less of a problem in CCC than in LC. It is shown that 24 g of 98% pure glucoraphanin could be produced from a methanolic broccoli seed extract in 4 hr using about 10 L of solvent. The simple liquid–liquid partitioning of the injected material offers an original and unique new approach to any difficult separation. Therefore, CCC should deserve a try in the industrial environment. The modern reliable CCC columns are presented.

INTRODUCTION

For human consumption, industry has to produce material products and goods. The chemical industry produces millions of metric tons of basic chemicals such as soda, ethylene, sulfuric acid, and urea, as well as a few kilograms or less of fine and/or complicated chemicals such as chiral drugs, catalysts, antibiotics, and delicate perfumes.

Countercurrent chromatography (CCC) is useful in the production of the latter class of chemicals. This entry explains the role that CCC can play in industrial processes, revealing concepts and ideas and giving some examples of real large-scale purification performed by the CCC technique. In recent years, significant developments occurred in the preparative side of CCC and modern, large-volume, reliable CCC instruments appeared. At the moment, only a handful of chemical companies are using CCC in commercial processes. Often, they are apparently very successful with the technique, because they purchase more CCC systems and CCC becomes part of the production process. The word is slowly spreading: CCC works.

THE LIQUID STATIONARY PHASE

Defining CCC in few words is easy: CCC is a chromatographic separation technique that uses a support-free liquid stationary phase.[1] The mobile phase must be a solvent or a mixture of solvents immiscible with the liquid stationary phase.

It is the liquid nature of the stationary phase in CCC that renders it useful for three reasons:

1. The solutes can access the whole volume of the stationary phase, not only the surface of a solid stationary phase as in most other chromatographic techniques. Column overload is much more difficult with a CCC column than with a classical preparative liquid chromatography (LC) column of similar volume. Large amounts of a substance can be processed in a single run. Countercurrent chromatography is truly a preparative technique.
2. The retention mechanism is very simple. The only physicochemical parameter responsible for solute retention is the liquid–liquid distribution coefficient, K_D, also called partition coefficient. The retention volume of a given solute is

$$V_R = V_M + K_D V_S = V_C + (K_{D-1})V_S \qquad (1)$$

   where V_M and V_S are the volumes of the mobile and stationary phases respectively, inside the CCC system. The sum of these two volumes always corresponds to the CCC system volume, V_C, because there is absolutely no solid support inside the column.
3. It is possible to use the liquid nature of the stationary phase to gain advantages that have no equivalent in classical LC. For example, the roles of the phases can be switched during a run: the mobile phase becomes the stationary phase, and vice versa. This way of working with a CCC column is called the dual mode method (see *Octanol–Water Distribution Constants Measured by CCC*, p.1616). It is also possible to flush the content of a CCC column, ensuring a complete recovery of all parts of the injected sample.

A combination of these three points produces the following advantages.

A study and optimization of a separation of a complex mixture can be accomplished with a low-volume CCC column by injecting small amounts of the sample and using reduced solvent volumes. The biphasic liquid system composition is *optimized rapidly and efficiently*.

If the retention volumes of some constituents of the sample are too large, different methods using the liquid stationary phase can be employed to speed up the separation. For example, the dual mode method can be used. The retained constituents are eluted in the reversed mode. It is absolutely certain that *no part of the sample can stay trapped* inside the CCC column.

Once the separation is optimized, the distribution coefficient of each constituent is then calculated using Eq. 1. The very same liquid system must be used in a large-volume CCC column so that the distribution coefficients remain identical. So, the *retention volumes of each component can be predicted* because the distribution coefficients depend only and entirely on the liquid–liquid system. The scaling-up is straightforward.[2]

LARGE-SCALE SEPARATION OR PURIFICATION

Industrial CCC Equipment

In the twentieth century, only the Japanese company Sanki Engineering Ltd. marketed industrial CCC columns based on the hydrostatic CCC scheme (interconnected channels). Recently, new large-scale CCC columns based on the hydrodynamic scheme (open tubes coiled in rotating spools) were developed in the United Kingdom and China, and modern and reliable hydrostatic preparative CCC columns were developed in France (Fig. 1 and Table 1). These twenty-first-century machines are much more efficient, well designed, and reliable than previously proposed large-volume CCC columns. On industrial determination, they could definitively prove the CCC capability in terms of purity of the produced compounds, solvent saving, and throughput.

Classical Use of the CCC Column

In a recent work, 1 kg of glucoraphanin was isolated from raw broccoli seed using a 5 L Midi column (Dynamic Extraction, Berkshire, U.K.) (Table 1).[3] Glucoraphanin is a promising cancer preventive and antioxidant drug of the glucosinolate family. This potassium salt of β-thioglucoside-*N*-hydroxysulfate is highly polar and is always present in the seed along with its glucosinolate homologue, glucoiberin, differing from glucoraphanin shorter by a methylene group. Eight kilograms of broccoli seed were extracted by boiling methanol to produce about 4.8 kg of crude extract that was processed in 42 CCC runs done in 7 days. The biphasic liquid system used was a mixture of 1-propanol/acetonitrile/31% ammonium sulfate solution in the 1/2/4 v/v ratio. The lower aqueous phase was selected to be the stationary phase. The upper organic phase was the mobile phase flown in the tail-to-head direction at 40 ml/min. A total of 115 g of methanolic crude extract was dissolved in 240 ml of a 1/1 upper/lower phase mixture. The injection volume corresponded to about 5% of the whole column volume. The full CCC run needed about 10 L of mobile phase eluted in 4 hr, producing about 24 g of 98% pure glucoraphanin. The production of 1 kg of 98% pure glucoraphanin needed 420 L of solvents and 170 working hours. The average throughput of this purification was an impressive 6 g of glucoraphanin per hour meaning that 0.42 L of solvent was used to purify one gram of glucoraphanin.

The production of 1 kg of 98% pure glucoraphanin is the largest published CCC purification procedure to date. The high loading capability of large-volume CCC systems is commonly used in industry. Large amounts (in the scale of several grams) of natural products with high added values are separated by CCC. Alkaloids, antibiotics, enzymes, macrolides, peptides, rare fatty acids, saponins, tannins, taxoids and/or precursors of Taxol®, and other fine chemicals have been isolated, separated, and/or purified by preparative CCC.[1,2]

The specificities of CCC that could promote its use rather than the use of classical preparative liquid chromatography purification are as follows:

- An original or unique selectivity obtained with a subtle polarity difference between the two liquid phases.
- The possibility of injecting heavily concentrated, viscous, or even polyphasic samples (e.g., fermentation broths).
- The gentle interactions during the separation process that preserve delicate molecules (e.g., proteins) from denaturation.

Displacement Chromatography

In displacement chromatography, the sample to be purified is injected in a large volume, or even continuously, into the CCC machine. The sample components have different affinities for the stationary phase in an exclusive way: The component with a higher affinity for the stationary phase displaces another one with a lower affinity. Bands of pure components form. This method of using CCC offers the maximum throughput capability.[1,2] Displacement CCC can be done using the solute ionization capability (pH zone refining) or complexation capability (ion-exchange CCC).

The inset shows the small Elite CPC250 (0.25 L column) (http://www.armen-instrument.com and Table 1); b, The hydrodynamic Maxi 5 L column. Pr. Ian Sutherland (Brunel University, Uxbridge, U.K.) poses inside the rotor to give the scale. The inset shows the Spectrum 20 ml column (http://www.dynamicextractions.com and Table 1).

pH Zone Refining

pH zone refining is a form of displacement chromatography for ionizable compounds. It sorts compounds by their ionization constants, K_a, using a stationary phase with a different pH from the mobile phase.[4] For example, the stationary phase is an acidic organic phase [e.g., methyl *tert*-butyl ether (MTBE) with 1% acetic acid] and the

[b]The Armen CPC2X500 has two 0.5 L columns that could perform the TMB continuous separation way (see text).

mobile phase is an aqueous basic buffer (e.g., 0.015 *M* NH_3 solution, pH 10). The acid in the stationary phase is considered as the retainer and the base in the mobile phase is the displacer.

Up to 60% of the CCC system volume of a mixture of organic acids can be introduced into the apparatus (in their ammonium salt form at pH 10).[4] As the mixture contacts the acidic stationary MTBE phase, the injected organic salts are protonated: these ions take their molecular form. A very large polarity difference exists between the ionic form and the molecular form of these solutes. The protonated molecular forms stay in the organic phase, and the ionized basic forms prefer the aqueous phase. The weaker acid is protonated first, and so it is the most retained. Bands of pure and concentrated organic acids form in the order of decreasing pK_a values.[4]

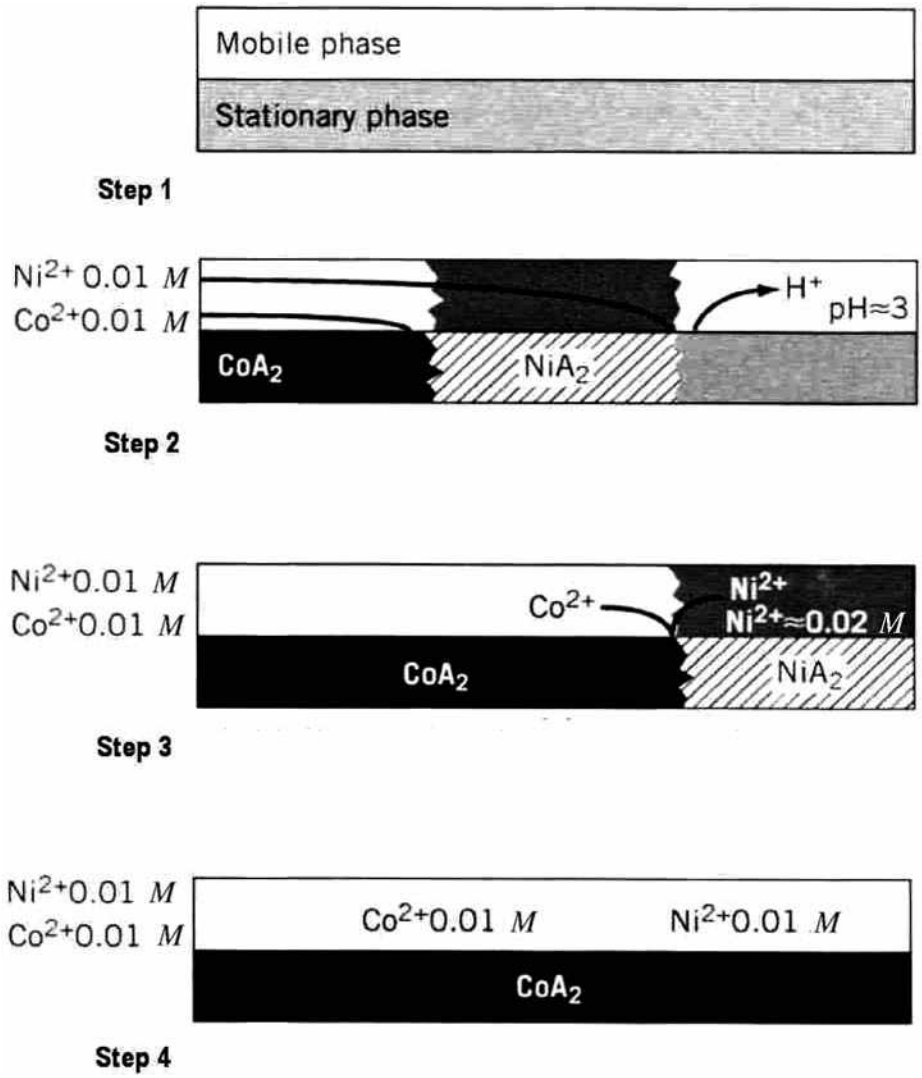

Fig. 2 Removal and separation of cobalt and nickel ions by CCC. Stationary phase: heptane + diethyl hexyl phosphoric acid (noted HA, concentration 0.5 *M*); mobile phase: aqueous solution of cobalt and nickel acetate (0.01 *M* each). Step 1: The CCC machine is equilibrated with water. Step 2: The ionic solution is introduced into the machine; the ions are extracted into the stationary phase; and the cobalt complex displaces the nickel one, which is less stable. Deionized water at pH 3 exits the column because all ions are replaced by protons. Step 3: The stationary phase is saturated in nickel ions. The greenish effluent leaving the machine contains only nickel ions, which is 2 times more concentrated than the entering solution. Cobalt ions are still extracted, displacing nickel ions. Step 4: End of the process—the stationary phase is saturated in cobalt ions. The machine is stopped; the dark blue stationary phase is collected; and cobalt ions are recovered by an acid wash.
Source: From Chromatographie a contre courant et micelles inverses pour la separation et l'extraction de cations metalliques, in Can. J. Chem.[5]

Ion-Exchange CCC

Complexation can be used to separate metallic ions on an industrial scale. Fig. 2 illustrates the process in the case of the separation of nickel and cobalt ions.[5] A chelating agent (e.g., diethyl hexyl phosphoric acid) is added to a heptane stationary phase. A large volume (up to 20 times the CCC machine volume V_C) of the ionic solution is introduced into the CCC column. The nickel ions are displaced in the aqueous phase, and the cobalt ions can be collected in the stationary phase. More than two ions can be separated in bands of increasing complexation constants order.[5] Because no ions can stay trapped inside the CCC machine, it could be a very potent tool in the separation of radionuclides in the processing of nuclear wastes.

Extraction

Countercurrent chromatography can be used to extract and to concentrate, in a low volume of the stationary phase, a component present in large volumes of the mobile phase. It was shown that a 60 ml CCC instrument was able to extract 285 mg of a non-ionic surfactant contained in 20 L of water (at 16.5 ppm or mg/L) and was able to concentrate it into 30 ml of ethyl acetate (at 9500 ppm or 9.5 g/L).[6]

CONCLUSION

At the moment, CCC is scarcely used in industry, the reason being that the technique is not well known because only a few small companies market good and reliable CCC systems. However, the capabilities of a

liquid stationary phase in industrial environment are very large. The CCC technique could be of great help in many industrial processes such as classical ones, extraction, purification, and separation of fragile compounds, as well as in novel ones such as the use of a CCC system as a powerful liquid–liquid reactor.

Injection Techniques for CE

Robert Weinberger
CE Technologies, Inc., Chappaqua, New York, U.S.A.

INTRODUCTION

In liquid chromatography (LC), a loop containing a defined volume is used to introduce the sample into the flowing mobile phase. Injection in high-performance capillary electrophoresis (HPCE) differs in two ways: (a) the injection volume is not as well defined and (b) injection is performed with the electric field turned off. Both of these features can contribute to quantitative errors of analysis. In addition, the length of the injection plug must be kept quite small to maintain the efficiency of the electrophoretic process.[1] The use of stacking electrolytes permits large injections to be made.[2] This is necessary to achieve acceptable limits of detection.

There are two modes of injection in capillary electrophoresis (CE): hydrodynamic injection and electrokinetic injection. In hydrodynamic injection, pressure or vacuum are placed on the inlet sample vial or the outlet waste vial, respectively. For electrokinetic injection, the voltage is activated for a short time with the capillary and electrode immersed in the sample.

The general process of performing an injection and run is as follows:

1. The capillary is rinsed with 0.1 N sodium hydroxide or 0.1 N phosphoric acid for 1–2 min.
2. A second rinse with background electrolyte (BGE) is performed for 2–3 min.
3. The inlet side of the capillary is immersed in the sample.
4. Injection is performed for 1–30 sec.
5. The voltage is ramped up (15 sec) to the designated value and the separation is performed.
6. The process repeats for the next sample.

VOLUMETRIC CONSTRAINTS ON INJECTION SIZE

Because the entire internal volume of a 50 cm × 50 μm-inner diameter (I.D.) capillary is only 981 nl, the injection volume must be kept quite small. The contribution to band broadening (variance) from a plug injection is given by

$$\sigma_{\text{inj}}{}^2 = \frac{l_{\text{inj}}{}^2}{12} \tag{1}$$

where l is the length of the injection plug. To calculate the band broadening from the injection process, the diffusion-limiting case can be considered using the Einstein equation:

$$\sigma_{\text{diff}}{}^2 = 2D_m t \tag{2}$$

Because the squares of the variances are additive, the contributions to band broadening from injection and diffusion can be inserted into the theoretical plate equation:

$$N = \left(\frac{L_d}{\sigma_{\text{tot}}}\right)^2 \tag{3}$$

For a 50 cm capillary and a solute migration time of 600 sec, the impact of the injection size for a small molecule ($D_m = 10^{-5}$ cm^2/sec) and large molecule ($D_m = 10^{-6}$ cm^2/sec) is shown in Fig. 1.

As illustrated in Fig. 1, injection of 1% (0.5 cm) of the capillary volume with sample produces a 92% loss of efficiency for a large molecule and an 8% loss of efficiency for a small molecule. Because diffusion is a limiting cause of efficiency, the large molecule provides a higher number of theoretical plates. The more efficient the separation process, the more difficult it is to maintain that inherent efficiency.

This model assumes that the sample is dissolved in BGE. Through the use of a low-ionic-strength solution as the sample diluent, sample stacking permits large-volume injections to be made.

In a well-controlled separation, injection can be the greatest source of band broadening.[1] This is one of the reasons that micromachined systems may become important for high-resolution DNA separations. In this case, it is possible to inject minute amounts of sample and use shortened separation channels.[3] Sensitivity does not suffer because laser-induced detection is employed.

HYDRODYNAMIC INJECTION

The volume of material injected per unit time (V_t, nl/sec) is determined by the Poiseuille equation.

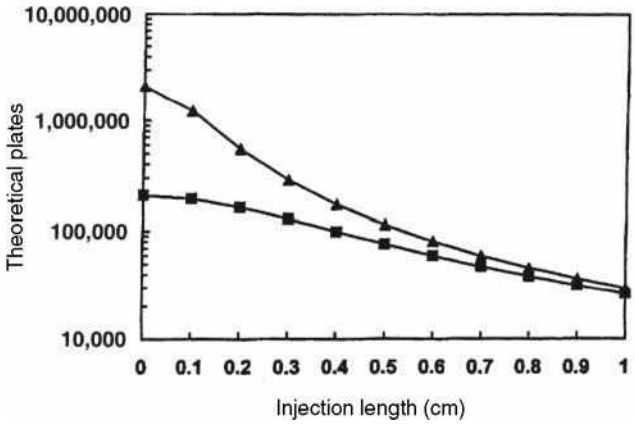

Fig. 1 Effect of the injection zone length on the number of theoretical plates for a small molecule and large molecule (■, $D_m = 10^{-5}$ cm^2/sec) and large molecule (▲, $D_m = 10^{-6}$ cm^2/sec) as solved by Eq. 3. Conditions: capillary length = 50 cm to detector; migration time = 600 sec.

$$V_t = \frac{PD^4\pi}{128\eta L} \tag{4}$$

where ΔP equals the pressure drop, D is the capillary internal diameter, η is the viscosity, and L is the length of the capillary. On some instruments, the pressure is generated by raising the capillary inlet side (siphoning).

The problems generated using an open-ended injection system as shown by the Poiselle equation dictate that changes in the experimental conditions will result in variations of the amount of material injected. Internal standards are best used to compensate for some of the experimental variables.

Pressure-driven systems are preferred compared to vacuum-driven systems for two reasons: (a) Generation of pressures over 1 atm is important when viscous polymer networks are used for size separations and (b) interface to the mass spectrometer is simpler.

ELECTROKINETIC INJECTION

The quantity (Q) of a solute injected is given by

$$Q = (\mu_{ep} + \mu_{eo})\pi r^2 ECt \tag{5}$$

where μ_{ep} and μ_{eo} are the electrophoretic and electro-osmotic mobilities, respectively, r is the capillary radius, E is the field strength, t is the time of injection, and C is the concentration of each solute.

As illustrated in Fig. 2, solutes with high mobility are preferably injected compared to those with low mobility.[4] Note the smaller peak heights for lithium and arginine compared to rubidium when electrokinetic injection is employed. Solutes that have identical mobility in free solution show no such bias (e.g., oligonucleotides and DNA fragments). This is fortunate because it is often necessary to use electrokinetic injection with gel-filled capillaries or when high-viscosity polymer networks are employed.

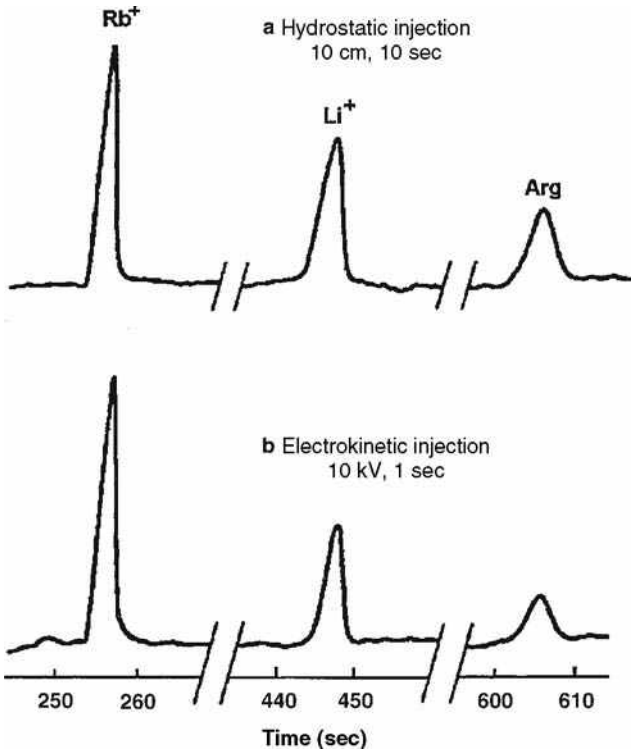

Fig. 2 Hydrostatic vs. electrokinetic injection. Buffer: 20 mM MES adjusted with histidine to pH 6.0; solutes: Rb^+, Li^+, and arginine, 5×10^{-5} M injection: (top) hydrostatic, $\Delta h = 10$ cm, $t = 10$ sec; (bottom) electrokinetic, 1 sec at 10 kV; detection: conductivity.
Source: Reprinted with permission from Bias in quantitative capillary zone electrophoresis caused by electrokinetic sample injection, in Anal. Chem.[4]

The problem with electrokinetic injection is that the field strength at the point of injection is inversely proportional to the sample conductivity. Calibration curves for ionic solutes show negative deviations from linearity because of this. Internal standards are necessary unless it is certain that the sample conductivities are identical. Low-conductivity samples are preferable because they stack.

The advantage of electrokinetic injection is that extreme trace enrichment is possible.[5] If the electro-osmotic flow approaches zero, it is possible to inject only solute ions, omitting the sample diluent.

"SHORT-END" INJECTION

The section of capillary between the outlet vial and the detector can be used for high-speed separations if sufficient selectivity is designed into the separation.[6] The process is

as follows. (1) Equilibrate the capillary in BGE as usual. (2) Place the sample at the capillary outlet. (3) Inject by pressuring the outlet vial or with electrokinetic injection using negative polarity (inlet-side negative). (4) Set the power supply to negative polarity and perform the usual voltage ramp. Because the capillary length is short, the injection should also be kept small and stacking buffers should be used. Be sure to set the detector time constant to 10–20% of the peak width to minimize that form of band broadening. Depending on the instrument, the short-end of the capillary usually ranges from 6 to 10 cm.

INJECTION ARTIFACTS, PROBLEMS, AND SOLUTIONS

No Injection

A plugged capillary is the usual culprit. Cut a few millimeters of the inlet or pressurize the outlet with a syringe to unplug it. When plugged, the observed current is usually zero. No injection can also occur if an empty or incorrect sample vial is used, if an incorrect vial is called for in the method, if the vial cap is missing or badly leaking, or if the external pressure source (if required) is not activated. It is possible that the capillary is broken. Breaks usually occur at the detection window. Check that the voltage polarity is correctly set.

Peak Tailing

Peak tailing can result from a poorly cut capillary inlet. If the capillary is not cut squarely, a concentration gradient can occur upon injection.[7]

Peak Splitting

Artifactual-injection-related peak splitting can occur under certain conditions. When the sample diluent contains organic solvents and micellar electrokinetic capillary electrophoresis or cyclodextrin containing electrolytes are employed, splitting can occur due to the distribution of the solute between two phases moving at different speeds at the point of injection.[8] The problem is solved by dissolving the solute in aqueous media. If the sample is insoluble in totally aqueous solvents, 6 *M* urea can be added both to the BGE and the sample diluent.

A fracture near the capillary inlet can also cause peak splitting. The break can occur if the capillary hits a vial wall or seal. The polyimide coating keeps the cracked portion intact. During injection, the sample moves into the capillary from both the open end of the tube and through the crack. The split peak is usually smaller than the main component and always has a migration time that is a little shorter. This is confirmed by examining the capillary inlet. If fractured, a small piece often detaches and the peak splitting is resolved.

Inorganic and Organic Cations: Ion Chromatographic Determination

Rajmund Michalski
Institute of Environmental Engineering, Polish Academy of Science, Zabrze, Poland

Abstract
Ion chromatography is an analytical technique that has changed the analysis of inorganic and organic ions, and has revolutionized analytical chemistry. Recently, there is a significant number of ion chromatography methods developed for the determination of cations in a wide variety of sample matrices. A short review of application of ion chromatography for the determination of inorganic and organic cations of alkali, alkaline earth, ammonia, heavy and transition metals as well as lanthanides and actinides is described.

INTRODUCTION

A variety of methods have been used for the analysis of inorganic and organic cations: traditional spectroscopic techniques such as colorimetry, wet chemical methods such as gravimetric analysis, turbidimetry, and titrimetry, and electrochemical techniques such as use of an ion-selective electrode and amperometric titrations. Some of these methods suffer from interferences and limited sensitivity; they can be labor-intensive and are often difficult to automate.

The most popular instrumental methods available for cation analysis are rapid and sensitive spectroscopic methods like AAS (Atomic Absorption Spectroscopy), ICP–AES (Inductively Coupled Plasma–Atomic Emission Spectroscopy), and ICP–MS (Inductively Coupled Plasma–Mass Spectrometry), as well as electrochemical methods such as polarography and anodic stripping voltammetry.[1]

In some cases they are unsuitable for direct trace analysis in complex matrix samples, because of spectral and chemical interferences, or for studies on metal speciation. Due to strong environmental impact, metal ion determination and speciation have been given significant attention in the last few years.[2,3]

An alternative to spectroscopic methods in the analysis of cations are liquid chromatography methods, which can be divided into:

1. Ion chromatography (ion exchange: cation, anion, and ion exclusion).[4]
2. Reversed-phase ion interaction chromatography.[5]
3. Chelation chromatography.[6]
4. Multidimensional and multimode chromatography (e.g., ion exchange coupled with ion exclusion).

Acceptance of ion chromatography for anion analysis was very rapid mainly due to the lack of alternative methods that could quickly and accurately determine several anions in a single analysis. However, the situation regarding analysis of cations was quite different because of many alternative rapid and sensitive methods available. Nevertheless, ion chromatography has advantages over spectroscopic techniques for cation analysis because it allows metal speciation and simultaneous determination of many ions, thus the total ionic composition is known using a single analytical technique.[7]

Division of ion chromatography methods regarding separation mechanism and detection mode used is given in Table 1. Taking into consideration analytical conditions and equipment necessary for the determination of inorganic and organic cations (separation column, eluent, detection mode), analytes determined by means of ion chromatography methods can be divided into three groups:

- alkali and alkaline earth metals, and ammonium[8]
- heavy and transition metals; lanthanides and actinides[9,10]
- organic cations.[11]

Determination of alkali metals, alkaline earth metals, and ammonia is the most often used application of ion chromatography in the range of cation analysis. The key advantage of this method is the ability to determine ammonia in complex samples that contain both inorganic cations and organic amines, as the latter compounds can interfere with the conventional colorimetric or ion selective electrode methods used for ammonia analysis.

Cation exchangers are usually made of organic polymers (styrene-divinylbenzene, ethylvinylbenzene-diviniylbenzene, polymethacrylate, and polyvinyl), however, a variety of other substrate materials are also available (e.g., latexed cation exchangers, silica-based exchangers).

Table 1 Cations determined by ion chromatography methods.

Analyte groups		Examples of analytes	Separation mechanism	Detection mode
Inorganic	Alkali, alkaline earth metals and ammonia	Li^+, Na^+, K^+, NH_4^+, Rb^+, Cs^+, Mg^{2+}, Ca^{2+}, Sr^{2+}, Ba^{2+}	Cation exchange	Suppressed and non-suppressed conductivity
	Heavy and transition metals	Cu^{2+}, Ni^{2+}, Zn^{2+}, Co^{2+}, Cd^{2+}, Pb^{2+}, Mn^{2+} Fe^{2+}, Fe^{3+}, Sn^{2+}, Sn^{4+}, Cr^{3+}, V^{4+}, V^{5+}, UO_2^{2+}	Anion exchange ion exclusion,	Ultraviolet and visible spectrometry (UV/Vis), AAS, ICP, ICP–MS, ICP–AES
	Lanthanides, actinides	La^{3+}, Ce^{3+}, Pr^{3+}, Nd^{3+}, Sm^{3+}, Eu^{3+}, Gd^{3+}, Tb^{3+}, Dy^{3+}, Ho^{3+}, Er^{3+}, Tm^{3+}, Yb^{3+}, Lu^{3+}, Am^{3+}, Cm^{3+}, Pu^{3+}	Anion exchange, cation exchange	UV/Vis, AAS, ICP, ICP–MS, ICP–AES
Organic	Low-molecular-weight amines, alkylamines, mono-, di-, tri-, tetramethylamine, alkanolamines, monoethanolamine, diethanolamine		Cation exchange, ion pair	Suppressed and non-suppressed conductivity
	High-molecular-weight amines alkylamines, aromatic amines, cyclohexamines, quaternary ammonium ions, polyamines		Cation exchange, ion pair	Suppressed and non-suppressed conductivity, UV/Vis

Elution order of alkali and alkaline earth metals and ammonia cations depends on many factors (e.g., column selectivity, eluent type) but is usually as follows: Li^+, Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}, and Ba^{2+}.

Type of eluent for cation-exchange chromatography depends on the detection method being used.[12] In suppressed and non-suppressed ion chromatography for the separation of alkali metals, ammonium and small aliphatic amines on strong cation exchangers, and mineral acids (e.g., HCl, H_2SO_4, HNO_3) are typically used as eluents.

Divalent cations such as alkaline earth metals exhibit a much higher affinity with stationary phase of strong acid cation exchangers and thus cannot be eluted with diluted mineral acids. Therefore, application of another eluent is necessary.

Simultaneous analysis of alkali and alkaline earth metals can only be performed with weak acid cation exchangers, using carboxylic groups as ion-exchange functionality group and usually with methanesulfonic acid as the eluent.

In non-suppressed ion chromatography, mixtures of ethylenediamine and aliphatic carboxylic acids (such as tartaric acid or oxalic acid) are typically employed. In suppressed ion chromatography, the required reduction of background conductivity would only be possible by using high-capacity membrane-based suppressor systems.

In spite of strong competition from atomic spectrometric techniques, ion chromatography of heavy and transition metal cations is now well established as the relative cheapness, ease of automation, and online capability is particularly attractive in a wide variety of routine trace analysis.

Unlike spectroscopic methods, ion chromatography can distinguish different metal oxidation states such as Cr(III)/Cr(VI), Fe(II)/Fe(III), or As(III)/As(V).[13,14] Moreover, ion chromatography has also been used to determine stable metal complexes. A further advantage of ion chromatography over spectroscopic methods is its relatively wide dynamic range, which means that it is possible to determine low analyte concentrations in the presence of high levels of other species, which would tend to cause problems in nebulizers used in atomic spectrometry.

There is a significant number of ion chromatography methods developed for the determination of metal pollutants in a wide variety of environmental samples.[15] Review of current state of research and progress in ion chromatography as an analytical tool for trace metal analysis in environmental samples is described by Shaw and Haddad.[16]

Separation of heavy and transition metals with ion exchangers requires complexation of metal ions in the mobile phase to reduce their effective charge density. Because selectivity coefficients for heavy and transition metals of the same valency are so similar, a selectivity change is obtained only by the introduction of a secondary equilibrium such as a complexation equilibrium established by adding appropriate complexing agents to the mobile phase.

When selecting a ligand for the separation and elution of heavy and transition metal ions from cation exchangers, the following guidelines should be taken into account:

- Metal ions and ligands must form neutral or anionic complexes.
- Different complex formation constants for the various metals increase the selectivity.
- Transition metal complexes being formed should be thermodynamically stable and kinetically labile.

Table 2 Examples of ion chromatography methods for inorganic and organic cations analysis established by ISO, US EPA, and ASTM.

Method number	Method name	Analytes	Matrices
	ISO methods		
ISO 14911 (1998)	Water quality—determination of dissolved Li^+, Na^+, NH_4^+, K^+, Mn^{2+}, Ca^{2+}, Mg^{2+}, Sr^{2+}, and Ba^{2+} using ion chromatography method	Li^+, Na^+, NH_4^+, K^+, Mn^{2+}, Ca^{2+}, Mg^{2+}, Sr^{2+}, Ba^{2+}	Drinking water, wastewater, ground water
	US EPA methods		
US EPA method 200.10 (1997)	Determination of trace elements in marine waters by online chelation preconcentration and inductively coupled plasma–mass spectrometry	Cd^{2+}, Co^{2+}, Cu^{2+}, Pb^{2+}, Ni^{2+}, VO^{2+}, VO_2^{2+}, UO_2^{2+}	Brines, seawater, marine water, estuarial water
US EPA method 200.13 (1997)	Determination of trace elements in marine waters by off-line chelation preconcentration with graphite furnace atomic absorption	Cd^{2+}, Co^{2+}, Cu^{2+}, Pb^{2+}, Ni^{2+}	Brines, seawater, marine water, estuarial water
US EPA method 300.7 (1995)	Dissolved sodium, ammonium, potassium, magnesium, and calcium in wet deposition by chemically suppressed ion chromatography	Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}	Wet deposition, rain water, snow, dew, sleet, hail
	ASTM methods		
D 6504–00	Standard practice for on line determination of cation conductivity in high purity water	Li^+, Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}	High purity water
D 6919–03	Standard test method for determination of dissolved alkali and alkaline earth cations and ammonium in water and wastewater by ion chromatography	Li^+, Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}	Reagent water, surface water, ground water, wastewater
UOP 959–98	Ammonium determination in aqueous solutions by ion chromatography	NH_4^+	Drinking water, wastewater
WK653	New determination of dissolved alkali and alkaline earth cations and ammonium in water and wastewater by ion chromatography	Li^+, Na^+, NH_4^+, K^+, Mg^{2+}, Ca^{2+}	Reagent water, surface water, ground water, wastewater

Among many ligands used for simultaneous ion chromatography of metals, the most common eluents used are oxalic acid, tartaric acid, citric acid, 4-(2-pirydylazo)resorcinol (PAR), pyridine-2,6-dicarboxylic acid (PDCA), α-hydroxyisobutyric acid (HIBA), 1,2-diaminocyclohexanetetraacetic acid (DCTA), diethylenetriaminepentaacetic acid (DTPA), and ethylenediaminetetraacetic acid (EDTA).

While non-suppressed and suppressed conductivity detection modes are suitable for detection of alkali and alkaline earth metals, for detection of other metal ions only non-suppressed conductivity detection can be used, because these metals would mostly be transferred by the suppressor reaction into insoluble hydroxides. Thus, spectrometric detection after suitable post- or precolumn derivatization is usually carried out.[17]

Transition metal ions may also be separated via ion-pair chromatography on macroporous polystyrenedivinylbenzene (PS/DVB) resins or chemically bonded silica. Elution of cations is achieved by their complexation with the eluent ligand and ion-pairing of negatively charged complex formed with ion-pair chromatography or their cation exchange with counterion.

Ion chromatography is increasingly used for the separation of lanthanides and actinides. Cation exchange of lanthanides has been performed in peculiar, latex-agglomerated columns in the presence of appropriate chelating agents. Usually it is α-hydroxyisobutyric acid (HIBA) that forms complexes with lanthanides whose order of elution is correspondent to their stability.

In case of anion-exchange separation mechanism, lanthanides have been predominantly separated using a mixed bed column containing both anion and cation-exchange sites.

Analysis of certain sample matrices can be difficult because of coelution problems occurring when some transition metals are present in much higher concentrations. Luckily, while transition metals form stable monovalent and divalent complexes with PDCA, lanthanides complexes with PDCA are trivalent.

Review concerning the determination of lanthanides in metallurgical, environmental, and geological samples is presented by Rao, Metilda, and Gladis.[18]

Analysis of organic cations such as amines is an application of ion chromatography of great significance. Short-chain aliphatic amines such as methylamines or ethanoloamines are used as organic neutralization agents or buffer substances. They are also used as corrosion inhibitors. Higher amines such as selected biogenic amines play a decisive role in the food analysis.

Another significant application of ion chromatography is the determination of organic amines in the petrochemical industry. Wastewaters from oil refineries, for example, contain these amines and their concentration levels may significantly vary.

The latest development in carboxylic-based weak acid cation exchangers are columns designed for the determination of hydrophobic and polyvalent amines, including biogenic amines, alkylamines, and diamines, using simple aqueous eluent and elevated column temperature.[19]

Because many amines elute under chromatographic conditions that are suitable for the separation of alkali and alkaline earth metals, direct conductivity detection is possible. However, amperometric and UV/Vis detection modes are much more selective and sensitive.

While addition of organic solvents to the mobile phase is of great importance for the analysis of organic amines, retention behavior of inorganic cations is not significantly affected by organic solvents.

Application of ion chromatography for the determination of inorganic and organic cations mostly concerns the following areas: environmental analysis, power plant chemistry, semiconductor industry, metal processing, pharmaceutics, biotechnology, mining, agriculture, food and beverages, electroplating, and pulp and paper industry.

In the middle of 1980s, the United States Environmental Protection Agency (US EPA) approved ion chromatography for the analysis of alkali and alkaline earth cations and ammonium in rain water and wet precipitation. In 1998, International Standard Organization (ISO) published Method 14911[20] for the simultaneous determination of dissolved alkali and alkaline earth cations, ammonia and manganese in water and wastewater using suppressed ion chromatography.

Recently, ion chromatography has become well established as a regulatory method for the analysis of inorganic ions in water and wastewater.[21] Regulatory ion chromatographic methods for environmental samples of both inorganic and organic cations recommended by ISO, US EPA, and American Society for Testing and Materials (ASTM) are listed in Table 2.

CONCLUSION

Currently, there is a significant number of ion chromatography methods developed for the determination of inorganic and organic cations in wide variety of sample matrices. Moreover, it has become one of the most widely applied analytical tools for the analysis of complex matrices and for the speciation studies in the field of metal analysis.

Ion chromatography gained general acceptance as fast and sensitive multielement detection method for the determination of alkali and alkaline earth metals, heavy and transition metals, actinides and lanthanides, as well as selected organic cations, allowing detection limits in the range of microgram per liter and analysis time of less than 20 min.

Inorganic Elements: CCC Analysis

Eiichi Kitazume
Faculty of Humanities and Social Sciences, Iwate University, Iwate, Japan

Abstract
The unique feature of countercurrent chromatography (CCC) applied to the separation and enrichment of inorganic elements is described. A highly efficient enrichment of metal ions was achieved by pH-peak-focusing high-speed countercurrent chromatography (HSCCC) that is developed by the variation of the pH-zone-refining high-speed CCC. In this method, Ca, Cd, Cu, Mg, Mn, and Zn are chromatographically extracted in a basic organic stationary phase containing ammonia and a complex-forming reagent such as di(2-ethylhexyl) phosphoric acid, by introducing the sample solution into the column rotated at 800–1200 rpm. When the column is eluted with the acidified mobile phase containing hydrochloric acid, metal ions are trapped and concentrated around the sharp pH border formed in between the acidic and the basic zones, moving toward the outlet of the column. Enriched metal ions are finally eluted with the sharp pH border as a highly concentrated peak into a small amount of eluate. The pH of the border is determined by the kinds of base and acid, and it shows the neutralization point. At this pH, trapped solute is moved toward the outlet of the column, based on its distribution ratio in each phase. The movement of this pH border through the column is determined by the molar ratio between the base in the stationary phase and the acid in the mobile phase. By selecting appropriate experimental conditions, such as acidity of the sample, bore of the column, and volume of the sample, each metal separation was achieved due to a longitudinal pH gradient on both sides of the pH border. Metal ions were concentrated at different positions in the moving pH border. When the pH border was sufficiently wide in the final stage of the elution, each concentrated metal could be separated mutually. The present method can be successfully applied to trace determination of cadmium in tap water, with coexisting relatively large amounts of magnesium. Also, the process of metal enrichment and separation is described.

INTRODUCTION

Countercurrent chromatography (CCC) was being applied to preconcentration and separation of inorganic elements since the end of the 1980s. During the early 1990s, certain inorganic elements, including rare earths, have been separated using high-speed countercurrent chromatography (HSCCC). In addition, preconcentration and separation of inorganics from geological samples have been studied. Many of the features of HSCCC have convinced us that this method can be successfully used in the separation of inorganic elements and in inorganic analytical chemistry. However, the liquid systems for inorganics are somewhat complicated as compared with those for the separation of organics because they usually contain significant amounts of an extracting reagent, which influences the kinetic properties and viscosity of the two-phase system.

To achieve high sensitivity when analyzing trace inorganic elements in a sample solution using an atomic absorption spectrometry (AAS) or Inductively coupled plasma (ICP) atomic-emission spectrometry (ICP–AES), conventional preconcentration methods such as evaporation, ion exchange, and solvent extraction techniques have been used. However, there are several problems in their methodologies for the determination of ultra-trace elements; e.g., peak broadening in the ion exchange technique and low enrichment factor in the solvent extraction techniques are encountered. It is difficult to directly work with under 0.5 ml concentrated sample solution by conventional methods. If there were effective methods for concentrating traces into 0.1 ml or lower solution volume, absolute detection limits for trace analysis using techniques such as AAS, ICP/AES, and ICP–mass spectrometry (ICP/MS) would be considerably lowered, as well as matrix effects would be eliminated.

pH PEAK FOCUSING

pH-peak-focusing countercurrent chromatography (pH-PFCCC) is a unique technique, based on neutralization between mobile and stationary phases.[1,2] It has been applied to the separation and enrichment of organic compounds such as indole auxins, bromoacetyl thyroxine and its analogs, dinitrophenyl amino acids, transretinoic acid, and diazepam. Neutralization is initiated at the mobile-phase front, but

advances through the column at a slow pace, forming a sharp border between basic and acidic zones. Trace impurities in the sample solution are concentrated at this narrow pH boundary in the column. This effect offers great potential for online enrichment and subsequent analysis of trace inorganic elements by interfacing HSCCC with analytical instruments such as non-flame atomic absorption spectrometry (NFAAS), ICP/AES, and ICP/MS.

Recently, the feasibility of an HSCCC centrifuge in enriching several metallic elements was demonstrated using pH-PFCCC. Under optimum conditions, an excellent enrichment factor of over 100 was achieved with good recovery of Ca, Cd, Mg, Mn, Pb, and Zn at a concentration of several parts per billion by online detection using a direct-current plasma atomic emission spectrometer (DCP-AES) as the detector.[3] In addition, many metal ions were efficiently enriched into an eluent volume of 100 μl or lower by HSCCC, resulting in a greater than 100-fold increase in peak intensities for a 10 ml sample solution. Preconcentrating the sample solution by substantially improving detection limits facilitates conventional trace determination of inorganic elements by instrumental analysis; however, more often the metals could not be separated from each other. If the pH border is sufficiently broad, and the order of the elements in the column is maintained until the final stage of the elution, each concentrated metal ion may be separated individually, as in displacement chromatography.

Under appropriate experimental conditions in pH-PFCCC, major matrix elements such as Ca and Mg in enriched tap water were found to be separated from trace elements.[4] Trace Cd, which appears between the chromatographic bands of Mg and Ca when using di(2-ethylhexyl) phosphoric acid (DEHPA) as an extracting reagent, was well determined without interference from alkali metals that are main components of biological and environmental samples.

EXTRACTION REAGENT FOR THE SEPARATION OF INORGANIC ELEMENTS

The existence of an extracting reagent in the mobile phase is an essential factor to be considered in the separation and enrichment of inorganic elements. It complicates the determination of several important parameters, e.g., distribution coefficients, peak resolution, and separation efficiency. Some basic researches revealed that kinetic properties of specific systems used in HSCCC affect the separation efficiency. Moreover, mass transfer rates into organic stationary phases are significantly responsible for the separating mode, i.e., stepwise or isocratic elution. In addition, the values of the distribution coefficients, determined by the batch extraction measurements in the systems, are sometimes considerably different from those of the dynamic distribution coefficients calculated from elution curves plotted from experimental data. Further theoretical and basic investigations are necessarily concerned with extraction kinetics as well as hydrodynamic behavior of the two phases in the HSCCC column.

In Table 1, typical extracting reagents used for separation and enrichment of inorganic elements are summarized. Organophosphorus extractants are often used because of their solubility properties. Di(2-ethylhexyl) phosphoric acid is commonly applied to industrial separations because of its high extractability and high separation factors between many inorganic elements, especially rare earth elements. Other metal ions are extracted as well as the trivalent metal ions.

ENRICHMENT ANALYSIS IN THE EFFLUENT

Large-Scale Enrichment Followed by Conventional Eluent

Enrichment of the desired trace elements prior to their determination cannot simply overcome problems such as interference and toxic or radioactive samples, but can facilitate highly sensitive determination of trace elements.

The parts-per-billion level of metal ions in 500 ml of the mobile phase was continuously concentrated into small volumes of the stationary phase retained in the column. Concentrated metal ions were simultaneously eluted with nitric acid and determined by the emission intensity with a DCP–AES. The recoveries of Ca, Cd, Mg, Mn, Pb, and Zn

Table 1 Typical extracting reagent for separation and enrichment of inorganic elements using HSCCC.

Extracting reagent	Two-phase system	Inorganic element
Di(2-ethylhexyl) phosphoric acid (DEHPA)	HCl, organic acid–heptane	Rare earth, heavy metals
2-Ethylhexylphosphonic acid mono-2-ethylhexyl ester (EHPA)	Carboxylic acid–toluene	Rare earth
Dinonyltin dichloride	HCl, HNO_3–Methylisobutylketone (MIBK)	Orthophosphate and pyrophosphate
Cobalt dicarbolide	HNO_3–nitrobenzene	Cs and Sr
Tetraoctylethylenediamine (TOEDA)	HCl, HNO_3, organic acid–chloroform	Alkali, alkaline earth, rare earth, heavy metals, Hf, Zr, Nb, Ta

ranged over 88% at the concentration, of each, of 10 ppb in 500 ml of the sample solution. Versatility of this method was further demonstrated in the determination of trace metals in tap water and deionized water.

Rare earth elements have been enriched into a stationary phase composed of toluene including 2-ethylhexylphosphonic acid mono-2-ethylhexyl ester (EHPA) from 1 L of aqueous solution and eluted with a stepwise pH gradient. As many elements remained in the column head because of their high partition coefficients to the stationary phase, they could be eluted with a mobile phase and also separated from each other.

A large-scale enrichment technique is very useful for determining extremely low level concentrations of metals in solution when a large amount of sample such as natural water is available.

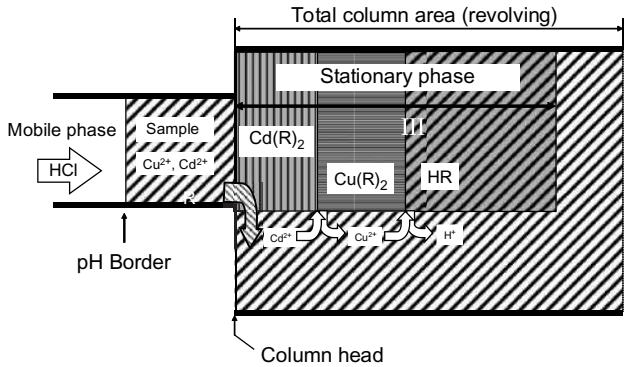

Fig. 2 Metal displacement process in stationary phase.

Enrichment Using pH-Zone-Refining Technique as Preconcentration Method of Inorganic Analysis for Subsequent Determination

Even if sufficient sample size, in volume, may not be available, enrichment techniques that concentrate trace metals in microliter samples are sometimes quite useful because modern instrumental detection systems such as AAS, ICP–AES, and ICP–MS do not need a large sample size. Moreover, if trace metals that have been separated from other major substances can be concentrated in an extremely small area of the polytetrafluoroethylene (PTFE) tube in HSCCC, this would be an ideal flow injection analysis system for the determination of inorganics. From this point of view, the recently developed pH-zone refining technique has great potential for enrichment, especially for instrumental inorganic trace analysis.

In the pH-zone refining technique, a basic organic solution containing a complex-forming reagent, such as DEHPA, is used as the stationary phase. After the sample solution is introduced into the column, metal ions stay close to the sharp pH-border region in the small-bore PTFE tube. Then, the trace inorganic ions in the sample are moved by the acid eluent (diluted hydrochloric, nitric acid, etc.) to the tail of the column while concentrating at the sharp moving pH "interface," and finally eluted as small fractions containing concentrated inorganic ions. This enrichment method for trace organic impurities is called "pH-peak-focusing countercurrent chromatography (pH-PFCCC)."

The concentration procedure is modeled in Figs. 1–3. In Fig. 1, the sample ion is concentrated into the column head immediately after the concentration procedure is started. (After the stationary phase has been introduced into the system, the HSCCC is started at an appropriate rotational rate, followed by the sample and the mobile-phase pumps.) For example, monovalent metal or inorganic ions (M^+) are concentrated into the stationary phase as MR in Fig. 1. The dark-shaded zone shows an organic stationary phase, which includes organophosphorus extractants (HR) and an alkali such as ammonia. The bright-shaded zone shows the sample phase with its pH adjusted by ammonia. When the column rotation is started, as the organic stationary phase is lighter than the mobile phase (diluted acid solution, HCl in Fig. 1), it

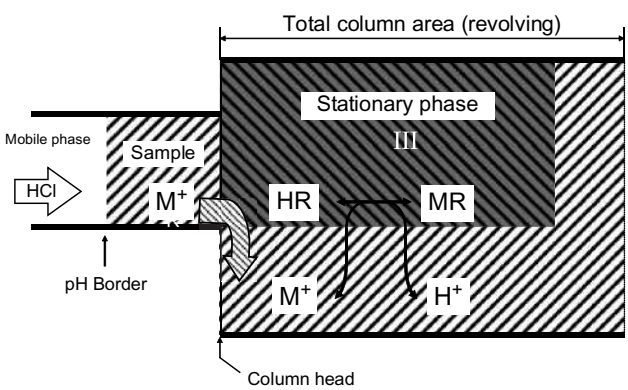

Fig. 1 Metal extraction into stationary phase.

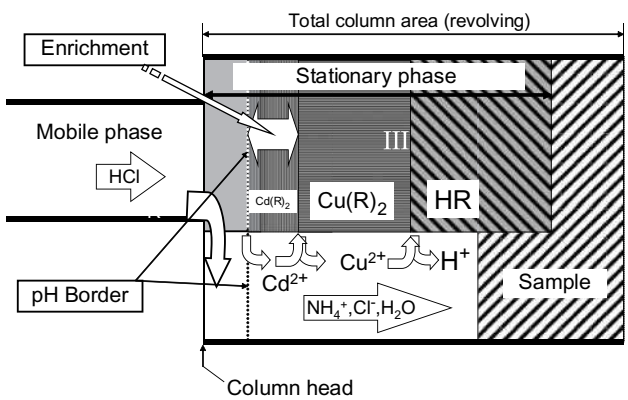

Fig. 3 Metal enrichment process after sample injection.

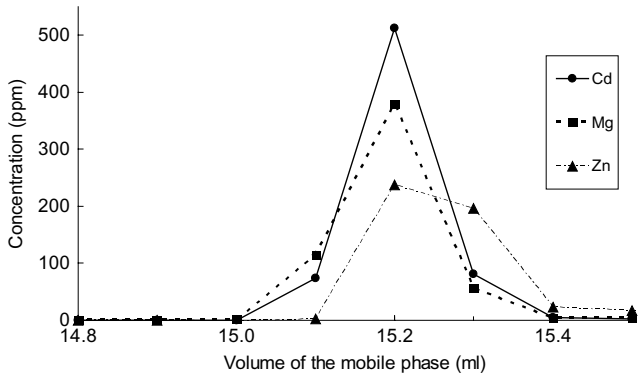

Fig. 4 Typical concentration results for a 10 ppm solution of Cd, Mn, and Zn. Experimental conditions: Apparatus: HSCCC centrifuge with 10.0 cm revolution radius; column: one multilayer coil, 0.5 mm I.D. × 32 m; sample: 5 ml of each 10 ppm solution (pH 9.25) in 0.1 *M* tartaric acid; mobile phase: 0.1 *M* HCl saturated with ether; stationary phase: 6 ml of 0.2 *M* DEHPA and 0.18 *M* ammonia in ether; flow rate: 0.05 ml/min; rotational speed: 950 rpm.

moves to the head of the column by Archimedean screw effect (ASE). The driving force, based on ASE, increases with the rotational speed of the column. Therefore the stationary phase can be retained in the column by selecting an appropriate rotational rate and pump rate, even if the mobile phase is introduced from the head direction (left side in Fig. 1) into the column. The retention ratio of the stationary phase to the whole column varies from 20% to 70%, but is stable when all conditions including pump speed and rotational speed are constant. So the position of the mobile phase is stable in a column while in operation. Inorganic ions (M^+) form complexes with ligand ions (R^-) and are mainly concentrated on the column head, shown as MR in Fig. 1. A proton is transferred into the mobile phase when the inorganicion is extracted into the stationary phase.

Fig. 2 shows the displacement procedure as well as the concentration procedure in the HSCCC column after most of the ions in the sample are extracted onto the stationary phase. If the sample contains two kinds of divalent metalions (Cu and Cd) in a large amount of solution, each metal might be arranged by the difference of its affinity or partition rate to the stationary phase. As Cd ion is usually more extractable than Cu ion, Cd can displace Cu at the end (left) of the Cu band in the stationary phase. However, the bandwidth of Cd increases until the entire sample is introduced into the column.

Metal-focusing process after the sample injection is shown in Fig. 3. After all the ions in the sample are extracted onto the stationary phase, mobile phase is introduced in to the column. Ammonia in the stationary phase begins to be neutralized with hydrochloric acid in the mobile phase. The neutralization area, where reaction between the acid and the base has just finished, is shown as pH border in Fig. 3. The pH border moves from left to right (the same direction as the mobile phase); however, its flow rate is lower than that of the mobile phase because of the delay caused by the neutralization of the acid in the mobile phase by the base in the stationary phase. Therefore the flow rate of the pH border may be controlled by adjusting the concentration of base and acid in the respective phase.

As a result, the Cd zone will be enriched despite an increase in its retention time of chromatogram. On the other hand, as the border between Cd and Cu also move as a result of proceeding elution of Cd, Cu zone also moves to the tail with enrichment.

If the concentration of hydrochloric acid just adjacent to the sample is very low or in case of using gradient elution mode, pH border shown as dotted line in Fig. 3 will move more slowly.

If the speed of the pH border is relatively high as compared with the movement of the Cu zone, its moving rate is as shown in the concentration stage in Fig. 2; pH border will catch up with the border between Cu zone and

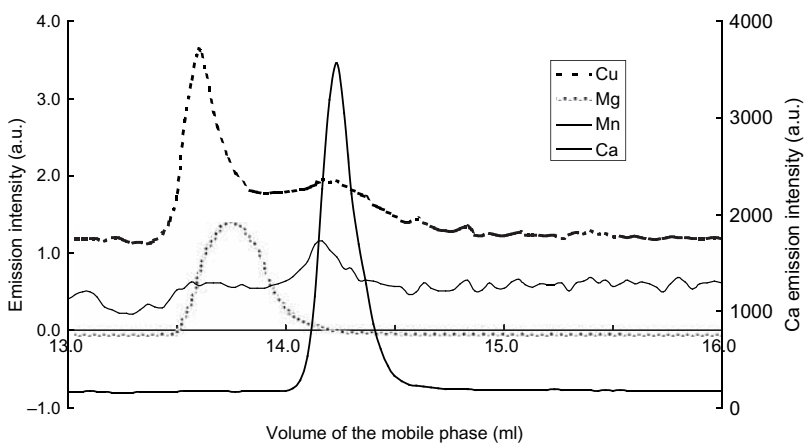

Fig. 5 Enrichment profiles of Mg, Cu, Mn, and Ca in 10 ml of tap water. Experimental conditions: column: one monolayer coil, 0.5 mm I.D. × 10 m (2 ml); sample: 10 ml of tap water (pH 8.0) in 0.1 *M* tartaric acid; mobile phase: 0.1 *M* HCl including 0.1 *M* tartaric acid; stationary phase: 0.22 *M* DEHPA and 0.20 *M* ammonia in heptane; flow rate: 0.1 ml/min at enrichment stage and 1.0 ml/min at detection stage; rotational speed: 1200 rpm; Sf: 7.5%.

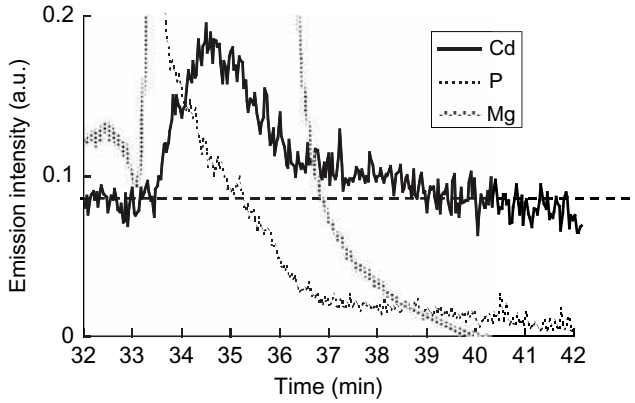

Fig. 6 Enrichment profiles of Cd and Mg in 30 ml of tap water. Experimental conditions: column: one monolayer coil, 1.6 mm I.D. × 0.86 m (2 ml); sample: 30 ml of tap water (pH 7.1) in 0.1 *M* tartaric acid; mobile phase: 0.1 *M* HCl including 0.1 *M* tartaric acid; stationary phase: 2 ml of 0.22 *M* DEHPA and 0.20 *M* ammonia in heptane; flow rate: 1.0 ml/min; rotational speed: 800 rpm; Sf: 20%.

reagent zone shown as HR in Fig. 3. Then the two peaks cannot be separated well in such relatively quick movement of the pH border. However, the peak height of each element will be increased by enrichment in small volume. In that case, both peaks will appear simultaneously.

In concentration mechanisms described above, there is little diffusion process observed as in usual elution procedures with ion exchange or other chromatographic separation methods, such as conventional HSCCC and HPLC. If there is no basic compound such as ammonia in the stationary phase, ions move to the tail with a different flow rate which is a function of the distribution ratio between the stationary phase and the mobile phase. Many ions can be separated from each other in that case, but as there is no pH border in the column, concentration is not affected, but the separation is affected by diffusion.

Fig. 4 shows the typical concentration results for a 10 ppm solution of Cd, Mg, and Zn. The injected sample solution contained 50 μg of each in 5 ml of 0.1 *M* tartaric acid solution, adjusted to a pH of 9.25. The mobile phase was pumped at a flow rate of 0.05 ml/min. Rotational speed was 950 rpm. The eluate was collected every 2 min (0.1 ml fractions). The fractions were diluted with water (1:10), and the emission intensity of each element was measured by plasma atomic emission spectrometer. The emission intensity of each element was found increased 20-fold as compared with the original sample solution. The results of this study demonstrated the high-performance capabilities of the pH-zone refining technique. Trace elements in the sample solution could be successfully concentrated into a small volume, almost under 0.1 ml with an enormous level of enrichment.

On the other hand, if the speed of the pH border is relatively low as in Fig. 3, so that the pH border cannot catch up with the border between the Cu zone and the reagent zone until the border passes through the stationary phase, both peaks would be separated. This phenomenon would be observed when the length of the stationary phase would be too small to allow the pH border to catch up with the Cu zone. Therefore, the Cu zone will be eluted before the enriched Cd zone comes close to it. In that case, the order of the elements will be maintained until the final stage of elution at the tail of the stationary phase in the column. Whereas the use of a large-bore column may accelerate the appearance of the peak owing to the short longitudinal distance of the stationary phase, each metal may be separated well as compared with the case of using a small-bore column. As well as enrichment, good chromatographic separation would be essential for exact measurement. The unilateral speed of the pH border can be controlled by choosing appropriate experimental conditions, such as bore size of the column and the molar ratio between acid and base.

When a small-bore column, e.g., 0.5 mm I.D., was used, all peaks appeared simultaneously if the volume of the retained stationary phase was over 15%.[3] However, if the retention volume of the stationary phase was less than 10% in a small-bore column, peak separation was observed as shown in Fig. 5.[4] Each peak was detected by plasma atomic emission spectrometry. This peak profile shows enrichment profiles with separation of Mg, Cu, Mn, and Ca in tap water. The intensity of Ca is shown on the right axis, 3 orders higher than that of the other elements, while the intensity of Mn is amplified 10 times. The spectral interference of Ca to the signal of Cu is observed. This separation phenomenon is considered to be quite useful for the exact determination of trace metals.

On the other hand, with a large-bore column, e.g., 1.6 mm I.D., for the same volume of stationary phase, peak separation was observed even if there was sufficient retention volume (more than 15%). This phenomenon may be explained by the shorter longitude of the stationary phase in a large-bore column, as compared with a small-bore column. Fig. 6 shows the signals of Mg, P, and Cd for 30 ml of tap water. The large peak of the Cd emission line may be the result of spectral interference caused by the scaled-out peak of Mg. On the shoulder of the Cd peak, a small peak was observed. This may be the real emission signal of Cd. When the large peak was used in the determination of Cd, the result was 3 ppb. On the other hand, the result determined using the small peak was about 1 ppb. Using the pH-PFCCC system, precision results for the determination of Cd or other elements that are influenced by matrix elements could be obtained.

CONCLUSIONS

In contrast to HPLC, the unique feature of CCC is that there is no solid support in the column. As the distribution abilities, including the capacity of the stationary phase, are easy to control, CCC can be applied to the separation, enrichment, and purification of inorganics over a wide range of concentration. In particular, enrichment of trace elements using pH-PFCCC will be an ideal preconcentration method[5,6] for subsequent determination of inorganics using modern instrumental analytical methods. Countercurrent chromatography can be combined directly with the flow injection technique, and it shows great potential for preconcentration of selected desired trace inorganic elements prior to their final detection and quantitation. Online enrichment and subsequent analysis, based on a simple and high-performance enrichment system for inorganics, may take the place of conventional sample preparation using a beaker and a separatory funnel in future investigations in this field.

Inorganic Oxyhalide By-Products in Drinking Water: Ion Chromatographic Methods

Rajmund Michalski
Institute of Environmental Engineering, Polish Academy of Science, Zabrze, Poland

Abstract
In an effort to protect the public from potentially hazardous microorganisms, drinking water supplies are routinely disinfected with a variety of treatment regimes. This entry describes some ion chromatography (IC) methods for the determination of inorganic disinfection by-products such as bromate, chlorite, and chlorate.

INTRODUCTION

The first documentation of drinking water treatment, describing procedures used for purifying water, can be found in Egyptian hieroglyphics. The basic methods were the same as they are today, i.e., boiling, chemical treatment, and filtration. The importance of drinking water quality and its influence on human health were known, but the specific contaminants would not be identified for centuries to come.

This situation changed in the nineteenth century when chlorine was introduced as a chemical disinfectant for water treatment. The introduction of chlorination to drinking water was followed by a remarkable reduction of cholera, dysentery, and typhoid worldwide.

Water treatment by disinfection processes is considered a major public health achievement of the twentieth century. Consequently, there has been a shift in the identification methods of water contaminants from microbiological to chemical. The number of chemicals determined in drinking water has grown exponentially; however, out of hundreds of them, only very few have been studied or have documented proof of their health effects.

In the 1970s, it was discovered that chlorination of drinking water produced carcinogens, such as trihalomethanes and haloacetic acids.[1] Since 1974, the presence of more than 500 disinfection by-products has been determined in drinking water.[2] Since that time, environmental regulatory agencies as well as drinking water treatment technologists have been carrying out extensive research for alternative disinfection methods that minimize the generation of by-products with significant health risks.

FORMATION, TOXICITY, AND REGULATION OF INORGANIC DISINFECTION BY-PRODUCTS IN DRINKING WATER

Many drinking water utilities are replacing chlorine, as their primary disinfectant, with alternative disinfectants, such as ozone, chlorine dioxide, and chloramines, which reduce regulated trihalomethane and some organochlorine compound levels but, at the same time, often increase the level of other potentially toxic compounds.

Ozonization has emerged as one of the most promising alternatives to chlorination. In the last decade, the use of ozone in the treatment of drinking water to improve taste and odor and to remove organic and inorganic micropollutants has been visibly spreading. In the early 1980s, it became obvious that the application of ozonization in drinking water treatment resulted not only in the formation of oxygenated compounds but also in bromide-containing water; brominated organic compounds and bromate were formed as well.

Recently, bromate has become the most important inorganic oxyhalide by-product, and its concentration in drinking water has to be controlled. Furthermore, the subjects of interest and advanced research are chlorite and chlorate. Bromates are formed when water containing bromide is ozonated. The concentration of bromide in natural waters varies, typically, between 10 and 1000 μg/L. From the theoretical and practical point of view, it can be seen that bromate formation can be influenced by many parameters, such as ozone dose, water pH, temperature, and indigenous concentration of bromide.[3]

Bromate formation can be restricted by careful adaptation of the ozone dosage to disinfectant demand. Other options include lowering of the pH, the use of ozone and hydrogen peroxide, addition of ammonia, removal of bromide before ozonization, and the use of membrane filtration or anaerobic processes.[4]

Chlorite (ClO_2^-) is a disinfection by-product that is formed when chlorine dioxide (ClO_2) is used for disinfecting drinking water, while chlorate (ClO_3^-) is formed when chlorine dioxide or chloramine is used.[5] Chlorination using hypochlorite acid solutions, which contain some ClO_3^- as a product of HClO disproportionation, may also contribute to ClO_3^- contamination in disinfected water. Even at low levels, chlorite may lead to hemolytic anemia

and can have dangerous effects on the nervous system in infants and young children.

Bromate has been identified as an animal, and possibly human, carcinogen. The International Agency for Research on Cancer (IARC) has classified bromate in group B-2 (the agent is possibly carcinogenic for humans).[6] In 1993, bromate was judged, by the World Health Organization (WHO), as a potential carcinogen, initially at a 25 μg/L level, which was associated with an excessive lifetime cancer risk of 7×10^{-5} on account of the limitations in the available analytical and treatment methods. Soon, health effects research indicated that it can be a human carcinogen that poses a potential 10^{-4} risk of cancer after a lifetime exposure in drinking water at a 5.0 μg/L level and a potential 10^{-5} risk at a 0.5 μg/L level.

The U.S. Environmental Protection Agency (U.S. EPA),[7] as well as the Commission of the European Communities,[8] has recently issued new rules that require public water suppliers to control some of the previously unregulated microorganisms and cancer-causing disinfection by-products in drinking water. According to these regulations, the maximum admissible level (MAL) is 10 μg/L for bromate and 1000 μg/L for chlorite.

No limit has been specified for chlorate, on account of the limited knowledge about its toxicity; however, the WHO recommends minimizing the level of chlorate as much as possible for as long as there is no reliable toxicological data. The MAL for bromate is primarily based on current analytical capability (not on toxicological considerations—the target concentration for bromate in drinking water is zero); thus, there is a need for ongoing development and refinement of analytical technologies to allow rapid and reliable determinations at the submicrogram-per-liter level.

Global and national agencies are continually striving to monitor bromate, chlorite, and chlorate levels in drinking water to establish appropriate regulatory limits. Based on the results of further research, a risk model could indicate a better-defined guideline value for oxyhalides in drinking water. Higher limits are set mainly on account of the non-availability of sensitive analytical methods in routine laboratories. Thus, there is a need for improving existing methods in terms of sensitivity, cost, and reliability.

The problem of bromate also concerns bottled water, which has become a healthier choice than tap water for many people, because they believe that bottled water contains fewer contaminants or they dislike the taste of chlorinated tap water. Therefore, the annual consumption of bottled drinking water in the world is substantial. Nevertheless, it is well known that significant amounts of bottled drinking water pass through treatment processes such as filtration, deionization, reverse osmosis, or ozonization to ensure its quality.[9]

APPLICATION OF ION CHROMATOGRAPHY IN THE DETERMINATION OF BROMATE, CHLORATE, AND CHLORITE IN DRINKING WATER ANALYSIS

Numerous techniques including colorimetry, wet chemical methods (e.g., titrimetry), electrochemical techniques (e.g., amperometry, polarography, ion-selective electrodes), UV spectrophotometry, capillary electrophoresis, and gas chromatography are used to determine inorganic oxyhalide compounds. Many of these methods suffer from interferences and limited sensitivity; they can be labor-intensive and are often difficult to automate. A very useful analytical technique for the determination of inorganic anions and cations is ion chromatography (IC). Since its introduction, IC has seen phenomenal growth in most areas of analytical chemistry; it has become a versatile and powerful technique for the analysis of a vast number of ions present in the environment and in biological tissues and fluids.

Modern IC is faster, more convenient, and has a greater separating ability than classical wet methods. The IC methods for determination of inorganic disinfection by-products can be divided into three groups. All of them are based on IC separation, but their detection methods are different. The first one, which is the most popular, uses conductivity detection; the second is based on UV/Vis detection after post-column derivatization; and the third is based on mass spectrometric detection.

Initially, application of IC for the analysis of inorganic disinfection by-products using conductivity detection was based on low-capacity ion exchangers. Therefore, injection volume and ionic strength of the sample were strictly limited to avoid column overloading. Also, the removal of interfering ions, such as chloride and sulfate, was necessary. Unfortunately, these methods are not well suited for routine analysis at levels below 1 μg/L because of the high cost of sample pretreatment, as well as the time spent on preconcentration and cleanup steps.

In the mid-1990s, ISO was working on Method 15061 for bromate[10] and Method 10304-4[11] for chlorite, chloride, and chlorate determination. The ISO 15061 standard specifies a method for the determination of dissolved bromate in drinking water, raw water, surface water, partially ozonated water, and swimming-pool water. Measurement of bromate is done in the range from 0.5 to 1000 μg/L, with or without sample preconcentration. If preconcentration is necessary, 6 ml of the sample is passed through three cation-exchange cartridges, in the Ba, Ag, and H forms, to reduce the total ionic strength.

The ISO 10304-4 standard specifies a method for the determination of dissolved chlorite, chloride, and chlorate anions in water at low levels of contamination (e.g., drinking water, raw water, swimming-pool water). An appropriate sample pretreatment and detection using conductivity, UV, or amperometric method ensures working ranges from 0.03–10 μg/L (chlorate) to 0.01–1000 μg/L (chlorite).

In 1987, the U.S. EPA presented a draft of Method 300.0, which was recommended for the determination of common anions (fluoride, chloride, nitrate, and sulfate) at milligram-per-liter levels using standard, low-capacity anion-exchange columns and conductivity detection.

Soon, this method was updated to include Part B for the determination of bromate and other inorganic disinfection by-products using modern high-capacity anion-exchange columns with a carbonate/bicarbonate eluent. The limit of detection using this column was still at a less-than-adequate level. In 1997, the U.S. EPA Method 300.1 was published as an update to Method 300.0, which was developed as a more sensitive method by identifying specific parameters (columns, eluent, and injection volume) that could be utilized to provide quantification of lower concentrations of bromate in drinking water, even in the presence of up to 50 mg/L of chloride ions. This method incorporated a new high-capacity anion-exchange column with higher efficiency for resolving trace bromate from the common anions.

By using a high-capacity anion-exchange column, it is possible to determine bromate at levels lower than 1 μg/L by directly injecting a very large volume (up to 1 ml) without any sample preconcentration or pretreatment.[12]

The interferences of chlorite create a significant problem during bromate determination. A number of procedures have been investigated for removing chlorite without adversely affecting bromate levels. Of these, the procedure that employs Fe(II) in acidic solution was found to be the most effective. The elimination of these interfering compounds was the final step toward the development of EPA Method 317.0.[13]

Considering these drawbacks, methods based on postcolumn derivatization and UV/Vis detection are found to be very attractive alternatives. The use of UV/Vis detection with a variety of postcolumn reagents, including chlorpromazine, *O*-dianisidine, fuchsine, or excess bromide (or iodide) under acidic conditions, has been shown to allow submicrogram per liter detection limits for bromate.

However, it is not easy to select one postcolumn derivatization method for bromate analysis from the various options, because each option has its own advantages and disadvantages. For example, the method that uses a mixture of nitric acid, potassium bromide, and *o*-dianisidine is the simplest one among the postcolumn derivatization techniques currently proposed. Nevertheless, the *o*-dianisidine used in this method is a possible carcinogen that requires special handling of waste from the system.

Chiu and Eubanks[14] reported a simple and rapid method based on the strong absorption of the tribromide generated from bromide under an excess of hydrobromic acid. This procedure was used for the determination of bromate by using IC with postcolumn derivatization.[15] Stable tribromide compounds were formed and detected by UV at 267 nm. The commonly occurring anions in typical drinking water are invisible to the detector and, therefore, do not interfere with analyzed bromate ions.[16]

Sensitivity for bromate determination has been improved by more than a factor of 10 through the use of a postcolumn derivatization reaction in which HI is generated in situ from KI and reacts with bromate to form the triiodide anions (I_3^-). In 2000, the U.S. EPA published Method 317.0, which uses postcolumn derivatization with *o*-dianisidine; this reacts with the eluting bromate to form a chromophore, which is then measured with a UV/Vis detector. This method offers excellent limits of detection, below 1 μg/L, for bromate, as well as for chlorite and chlorate.

The U.S. EPA Method 321.8 specifies the use of an anion-exchange column and detection of bromate using inductively coupled plasma–mass spectrometry (ICP–MS) in the atmospheric pressure mode. The U.S. EPA Method 326.0 has been developed for the analysis of ultra trace bromate concentrations in drinking water using a postcolumn derivatization reaction with Mo(VI). A review of the methods of IC determination of inorganic disinfection by-products published by U.S. EPA has been conducted by Hautman et al.[17] The ISO standards for the determination of inorganic oxyhalides in water are summarized in Table 1, and U.S. EPA methods recommended are listed in Table 2.

Table 1 ISO standards for the determination of inorganic oxyhalides in water.

Standard number	Standard name	Inorganic oxyhalide ion determined	Detection mode	Range (μg/L)
ISO 15061 (2001)	Water quality. Determination of dissolved bromate—method by liquid chromatography of ions	BrO_3^-	Conductivity. A UV detector (λ = 190–205 nm) is suitable for confirming the conductivity results only	0.5–1000
ISO 10304-4 (1997)	Water quality. Determination of dissolved anions by liquid chromatography of ions—Part 4: determination of chlorate, chloride, and chlorite in water with low contamination	ClO_3^-	Conductivity	0.03–10
		ClO_2^-	Conductivity	0.05–1
			UV (λ = 207–220 nm)	0.1–1
			Amperometry (0.4–1.0 V)	0.01–1

Table 2 U.S. EPA methods recommended for the determination of inorganic oxyhalides in water.

Method number	Method name	Oxyhalide ions determined	Columns	Eluent	Injection volume (μl)	Detection mode	Limit of detection (μg/L)
300.0—Part B (1993)	Determination of inorganic anions in water by ion chromatography	$BrO_3^-ClO_2^-ClO_3^-$	Dionex IonPac AG9 + AS9 (or equivalent)	1.7 m*M* $NaHCO_3$ + 1.8 m*M* Na_2CO_3	50	Suppressed conductivity

Besides the methods recommended by ISO and U.S. EPA, there exist many methods developed by manufacturers of chromatography equipment, such as Metrohm, Dionex, and Shimadzu. Much lower detection limits are obtained using hyphenated techniques such as IC coupled with MS detection.[18] ICP–MS coupled with IC offers the capability of speciation with multielemental detection, excellent sensitivity and detection limits, and a wide dynamic range. Other combinations are IC combined with negative thermal ionization isotope dilution mass spectrometric (IC–NTI-IDMS) analysis[19] and electrospray IC coupled with tandem MS (IC–MS/MS).[20] The application of atmospheric pressure ionization–mass spectrometry (API–MS), coupled with IC, showed a performance comparable to that of IC–MS/MS and IC–ICP–MS.[21] In contrast to IC–API–MS, IC–ICP–MS can tolerate a higher salt concentration in the eluent, which allows the use of high-capacity columns and larger sample volumes. This lowers the detection limits by one order of magnitude for the ICP–MS detection mode, as compared to API–MS. The obvious disadvantages of MS-based detection techniques are that all of them add considerable complexity and significant cost to the analysis and that, to date, no international IC method-based ion MS or ICP–MS detection has been promulgated for the regulatory monitoring of bromate or any other disinfection by-product anions. Hyphenated techniques are very sensitive and the operating cost of a single analysis is low, but they are highly sophisticated, and the instrumentation is very expensive. Hence, these methods are not used for routine analysis.

In 2000, an interlaboratory trial was organized, involving 26 laboratories using the draft standard ISO 15061 IC method with conductivity detection and/or alternative methods. Three alternative laboratory methods based on IC coupled with different detection systems were developed: ICP–MS, colorimetry, and fluorimetry. The performance data of these three methods are comparable to the respective data of standard IC with conductivity detection.[21]

The comparison of three postcolumn methods for the analysis of bromate in drinking water (potassium iodide–ammonium heptamolybdate; *o*-dianisidine; and sodium bromide–sodium nitrate methods) shows that all of them are compatible with conductivity detection; detection limits for bromate were 0.17, 0.24, and 0.19 μg/L, respectively.[22]

All IC methods used for bromate, chlorite, and chlorate analyses have some advantages and disadvantages. Nevertheless, at present IC is the only accepted standard method for the analysis of inorganic oxyhalide disinfection by-products. The choice of the most convenient and the best method for the determination of specific oxyhalides depends on many factors, such as expected concentration of analyte, sample matrix, limit of determination obtainable by the method used, and its availability.[23]

CONCLUSION

All the three groups of IC methods recently developed (based on conductivity, UV/Vis, and MS detection modes, respectively) yield comparable results and comply with the requirements of the international directives concerning inorganic oxyhalide by-products in drinking water.[24,25] The future application and choice of a method will depend on the equipment available in the laboratories, as well as the number and kinds of samples to be analyzed.

Abstract
Inverse gas chromatography (IGC) has been characterized as a method for determining the physicochemical magnitudes characterizing properties of solids and low-volatile liquids. The methods of determination of isotherms and specific surface areas of adsorbents and catalyzers are presented. The dependencies used to estimate the thermodynamic parameters characterizing surface energy and acceptor–donor properties of solids have been precisely presented. Rudimentary information about testing polymeric materials, volatile substances, and diffusion in gases is given.

THE ESSENCE OF INVERSE GAS CHROMATOGRAPHY

Gas chromatography is commonly known as a method for the separation of components of homogeneous mixtures. The chromatographic method is based on the differences in the drift rates of the concentration zones of mixture components, which are in dynamic equilibrium in mobile and stationary phases. The separation of mixture components results from different types of interactions of the chromatographed substances mainly with the stationary phase. These interactions depend on the physicochemical properties of the stationary phase and of the components of the mixture, and have a decisive influence on the retention values. Conversely, chromatographic effects can be used for investigating the intensity of interactions and the type and properties of the stationary phases in a chromatographic system. This type of chromatography is known as inverse gas chromatography (IGC) (Fig. 1). It is a dynamic method of testing, as opposed to the majority of methods for physicochemical investigations, which are static. Static methods yield plausible results, but they are time-consuming. On the other hand, IGC is less time-consuming, and the results obtained are also plausible. During one IGC run it is possible to determine many physicochemical quantities. Also, a commercial chromatograph can easily be adapted for physicochemical investigations.

Attempts for employing gas chromatography for testing the properties of liquids and solids were made in the 1950s. Smidsrød and Guillet[1] and Kiselev (working independently)[2] are thought to be the creators of the aforesaid separation method. The properties of high-boiling liquids, solids, volatile substances, and systems comprising a volatile substance and a high-boiling liquid or a volatile substance and a solid can be easily tested by the IGC method. A chromatographed substance with precisely defined physicochemical properties may be employed as a reference *probe* for testing the properties of the column filling material. The shape of the chromatographic peak and the retention time of the reference probe are dependent on its dispersive, polar, and ionic interactions with atoms (or their groups) in the outermost layer as well as in the bulk of the column filling.

Depending on the type of components in the chromatographic system, the following phenomena can occur in the column: dissolution, adsorption, phase transitions, diffusion, and non-specific or specific intermolecular interactions (including chemical reactions). The analysis of these effects, appearing in the form of an elution peak of the chromatographed substance with a defined shape and retention time, enables the determination of the properties of the stationary phase in a chromatographic system. In practice, the properties of adsorbents, catalyzers, polymers, and asphaltenes are often tested using IGC. Neutral and polar substances are employed for testing acidity, basicity, acceptor and donor properties, polarity, and dissolution and diffusion parameters of the column filling.

All physicochemical parameters derived from chromatographic measurements are related to the concentration profile of the eluted substance. To make measurements plausible, it is important to know the determinants of the substance's concentration profile. The elution peak always has a finite width, and, although often approximately Gaussian in shape, it is actually asymmetrical to a greater or lesser degree. In such cases, the theory of statistical moments has to be employed for characterizing the peaks of any shape, whether Gaussian or non-

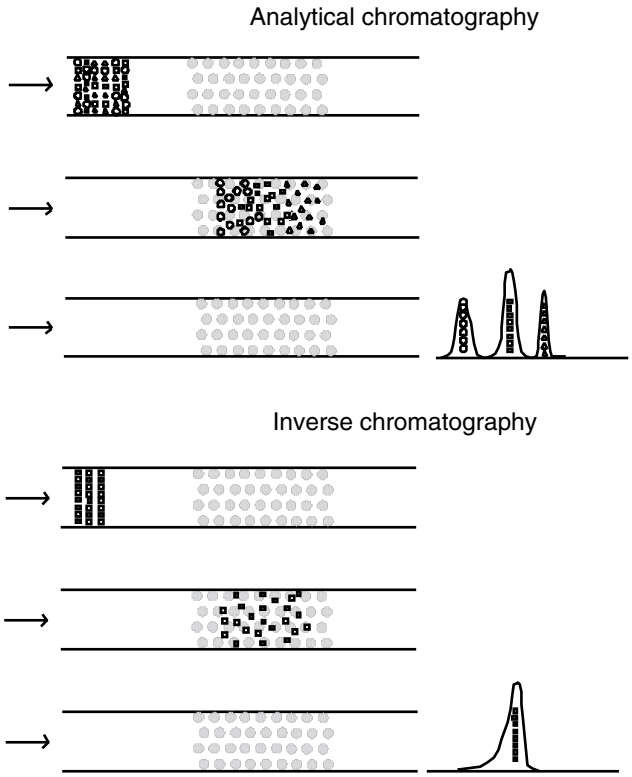

Fig. 1 Schematic representation of the principle of analytical chromatography and inverse chromatography.

Gaussian. The statistical moments approach directly gives the expressions for retention and plate height.

In linear chromatography, the equilibrium concentrations of admolecules in the stationary phase and in the mobile phase are proportional, so the equilibrium isotherms are straight lines beginning at the origin. In contrast, in non-linear chromatography, the equilibrium concentrations of admolecules in the stationary phase and in the mobile phase are not proportional, so the equilibrium isotherms are non-linear.

In ideal chromatography, it is assumed that the axial dispersion is negligibly small and the rate of the mass transfer kinetics is infinite; in other words the column efficiency is infinite. In non-ideal chromatography the column efficiency is a defined and measurable value.

The specific, $V_{g(T)}$, and the net, V_N, retention volumes are the chromatographic values most frequently employed in the calculation of thermodynamic quantities:

$$V_{g(T)} = \frac{V_N}{m} \tag{1a}$$

$$V_N = (t_R - t_M) j \frac{(p_o - p_{H_2O})T}{p_o T_{fm}} F_{fm} \tag{1b}$$

where m is the mass of the tested adsorbent or the mass of the liquid stationary phase deposited on the inert support; t_R is the total retention time of the chromatographed substance; t_M is the holdup time; j is the James–Martin compressibility factor; p_o is the gas pressure at the column outlet; p_{H_2O} is the pressure of water vapor; T is the column temperature; T_{fm} is the temperature of the flow meter; F_{fm} is the uncorrected flow rate of carrier gas through the bed.

DETERMINATION OF ISOTHERMS AND SPECIFIC AREAS OF ADSORBENTS AND CATALYZERS

One of the most important applications of IGC is in the testing of adsorbents and catalyzers. It is possible to determine the adsorption isotherms of volatile substances, the specific surface areas, the different potential functions for adsorbate–adsorbent interaction, and the diffusion coefficients of gases in porous solids.

There is a dependency between the shape of the chromatographic peak and the profile of the adsorption isotherm on the stationary phase. Symmetric peaks for which retention time does not depend on the volume of probe injected onto the column, which imply a linear adsorption (partition) isotherm, are usually obtained in the case of non-specific (dispersive) adsorbate–adsorbate and adsorbate–adsorbent interactions. The convex isotherm is usually obtained when the diffusive parts of the dependent peaks overlap and the adsorbate–adsorbent interactions are relatively stronger in comparison with the adsorbate–adsorbate interactions. The concave isotherm is usually obtained when the self-sharpening parts of the dependent peaks superimpose and the adsorbate–adsorbate interactions are relatively stronger in comparison with the adsorbate–adsorbent interactions.

Elution and frontal methods are commonly employed for the determination of adsorption isotherms of different probes on ground solids. The application of the elution techniques is more widespread. The use of one of these methods involves several injections for different amounts of the probe and overlapping of the obtained peaks to check whether the diffusive parts of them superimpose, which is a characteristic feature of the equilibrium conditions of ideal, non-linear models. It is mandatory to select an inert gas with a relatively small kinetic diameter, which is not adsorbed under the chromatographic conditions applied.

The areas of the peaks, S_{peak}, with the superimposed diffusive parts, are inversely proportional to the amount of admolecules, a:

$$a = \frac{n_a S_{ads}}{m S_{peak}} \tag{2}$$

where n_a is the amount of adsorbate injected onto the column; S_{ads} is the area on a chromatogram bounded by the peak height h between the outflow of the non-adsorbing substance and the extended profile of the chromatogram, cm^2; m is the mass of adsorbent in the column; S_{peak} is the peak area, cm^2.

The equilibrium pressure, p, corresponding to the determined adsorption, is calculated from the following equation:

$$p = \frac{n_a whRT}{F_c S_{peak}} \tag{3}$$

where w is the recording speed of the chromatogram, cm/min; h is the height of the peak, cm; R is the universal gas constant, J/mol·K; T is the column temperature, K; F_c is the carrier gas flow rate, cm^3/min.

The elution by characteristic point method (named also as peak profile method) enables the determination of an adsorption isotherm from a single chromatogram. The method gives good results for ideal, linear, and non-linear chromatographic conditions, for example, if the front or rear profiles of the elution peaks for various sample sizes superimpose.

Adsorption isotherms can be determined by the heat desorption method. This method was worked out by Nelsen and Eggertsen,[3] and it is widely employed because of the simplicity of its measurement apparatus and its great sensitivity. The principle of the method is based on the adsorption of nitrogen by a solid in the column from a stream of a gas mixture (usually H_2–N_2 or N_2–He) at the temperature of liquid nitrogen and then on its desorption after the removal of the liquid nitrogen. The quantity of adsorbed nitrogen, a, at an appropriate relative pressure, is estimated from the desorption peak, because it is more symmetrical. Each experiment performed for a given concentration of the adsorbate in the mixture gives one point on the adsorption isotherm. The most important characteristic of solids is their specific surface area. There are a few methods for the determination of specific surface area of solids based on chromatographic measurements.[4]

In one method adsorption isotherms are determined first and the specific surface areas are calculated from these isotherms by means of the BET method. The specific surface area of the solid, S, can be determined at ideal, non-linear chromatographic conditions, if the magnitude of monolayer adsorption, a_m, and the area occupied by a molecule of the adsorbate in the monolayer, ω, are known:

$$S = a_m N_A \omega \tag{4}$$

where N_A is the Avogadro number.

Methods in which the specific surface areas are calculated directly from the retention volume are based on the ideal, linear chromatographic conditions. The principle of these methods are derived from the theory of ideal, linear chromatography, which states that the specific retention volume, $V_{g(T)}$, of a substance is proportional to the magnitude of the surface area, S, of the adsorbent in the column:

$$S = V_{g(T)} \frac{S^{st}}{V^{st}_{g(T)}} \tag{5}$$

where $V_{g(T)}$ is the specific retention volume of an adsorbate on the investigated adsorbent; S^{st} is the specific surface area of the standard adsorbent; $V^{st}_{g(T)}$ is the specific retention volume of the adsorbate on the standard adsorbent.

Methods in which the specific surface area is calculated from the second (B_{2s}) and third (B_{3s}) gas–solid virial coefficients are valid if the values of B_{2s} [$=V_{g(T)}$] and B_{3s} are known. In such cases, the specific surface area can be calculated from the following equation:

$$S = -\pi D^2 \frac{B_{2s}^2}{B_{3s}} \tag{6}$$

where D is the diameter of the collision area of the adsorbate with the tested adsorbent, calculated on the basis of the density and dimensions of the adsorbate molecule.

DETERMINATION OF THERMODYNAMIC PARAMETERS

Thermodynamic parameters, excluding the highly precise parameters, of a chromatographic process may be determined if helium, whose properties are those of a perfect gas, is employed as the carrier gas.

The isosteric enthalpy of adsorption, ΔH_{ads}, can be determined by IGC, based on the changes in retention times or retention volumes with column temperature, employing the Clausius–Clapeyron equation for calculations, or, alternatively, using the second adsorption virial coefficient B_{2s}:[5]

$$\Delta H_{ads} = -RT^2 \frac{d \ln\left(\frac{V_{g(T)}}{T}\right)}{dT} \text{ or } \Delta H_{ads} = -RT^2 \frac{d \ln\left(\frac{B_{2s}}{T}\right)}{dT} \tag{7}$$

It is reasonable to use the Clausius–Clapeyron equation for calculating the isosteric enthalpy of adsorption as long as the equilibrium pressures are low (within Henry's law region) and the measurement temperatures are fairly close. Isothermal chromatographic measurements must be undertaken with changes of column temperature of 10 K at most.

Retention volumes are commonly used for the determination of enthalpy and entropy of adsorption, but Kováts retention indices can also be successfully used for such

calculations. Grajek[6] and Grajek, Witkiewicz and Jankowska[7] have suggested that if the number of carbon atoms of the adsorbate, $n \geq 5$, the following equation can be derived:

$$\frac{b(I_x - 100n)}{100} = \frac{-\Delta H^{I}_{ads(x)} + \Delta H^{V}_{ads(n)}}{2.303RT} + \frac{\Delta S^{I}_{ads(x)} - \Delta S^{V}_{ads(n)}}{2.303R} \quad (8)$$

where the differences $\left(\Delta H^{V}_{ads(n)} - \Delta H^{I}_{ads(x)}\right)$ and $\left(\Delta S^{I}_{ads(x)} - \Delta S^{V}_{ads(n)}\right)$ in Eq. 8 were directly proportional to the slope of the straight line and the intercept on the ordinate at $(1/T) = 0$, respectively. The $\Delta H_{ads(n)}$ and $\Delta S_{ads(n)}$ values were calculated from the specific retention volumes for *n*-alkanes employed as the reference "molecular probes" for adsorbates other than *n*-alkanes.[7]

The IGC at infinite dilution can also be employed for the determination of dispersive properties of solids. In the case where the tested solid adsorbent is covered with liquid, it is necessary to consider the interaction of the adsorbate with both the solid and the deposited liquid. The free energy of adsorption of one mole of adsorbate for a reference state of adsorption, ΔG_{ads}, is given by:[8]

$$\Delta G_{ads} = -RT \ln\left(V_{g(T)} \cdot \frac{P_o}{S\pi_o}\right) \quad (9)$$

where S is the specific area of the solid; π_o is the spreading pressure defined at the standard pressure P_o.

The reference states proposed by de Boer[8] are the most commonly employed ones for defining π_o and P_o.[9] Belgacem and Gandini[10] assumed the free energy of adsorption to be related to the work of adhesion, W_{adh}, mainly between the adsorbate molecules and the outermost layer of solid atoms and the atoms in bulk as well, and to the surface area of the adsorbate molecule, ω, in contact with the column filling:

$$\Delta G_{ads} = N_A \cdot \omega \cdot W_{adh} \quad (10)$$

According to Fowkes, the work of adhesion between an adsorbent surface (S) and a liquid (L), considering only dispersive interactions (D), can be described by the geometric mean of the surface free energy:[10]

$$W_{adh} = 2\sqrt{\left(\gamma^{D}_{S} \cdot \gamma^{D}_{L}\right)} \quad (11)$$

where γ^{D}_{S} and γ^{D}_{L} are the dispersive components of the surface energy of the solid and the liquid, respectively. From Eqs. 9–11 Schultz and Lavielle derived the equation:[11]

$$RT \ln V_{g(T)} = 2N_A\sqrt{\gamma^{D}_{S}} \cdot \omega\sqrt{\gamma^{D}_{L}} + K_3 \quad (12)$$

where K_3 is a constant term. Eq. 12 is usually plotted as $RT \ln V_{g(T)}$ vs. $\omega\sqrt{\gamma^{D}_{L}}$ and the values of the γ^{D}_{S} parameter are calculated.

Eq. 12 is developed for liquid adsorption on solid, although the molecules adsorbed at infinite dilution do not form an adsorbed liquid film. Schultz et al.[12] demonstrated the validity of this equation, and of the assumptions made, under certain conditions, by comparing the surface energy measured by contact angle method with that determined by gas–solid adsorption on solid surfaces; the dispersive component of the surface energy of the liquid equals the surface tension of the alkane probe at the same temperature, i.e., $\gamma^{D}_{L} = \gamma_H$, and ω represents the surface area that the probe covers when adsorbed onto the solid surface.

The values of these interactions appear as a deviation from the straight line of the reference alkane and can be quantified by the free energy, ΔG_{ads}, of adsorption–desorption of the specific polar adsorbate:[13]

$$\Delta G_{ads} = \Delta G^{D}_{ads} + \Delta G^{SP}_{ads} = N_A\omega W^{D}_{adh} + N_A\omega W^{SP}_{adh} \quad (13)$$

W^{D}_{adh} and W^{SP}_{adh} are the dispersive and the specific (non-dispersive) contributions in the work of adhesion.

The dispersive free energy of adsorption can be estimated by employing the following dependency:

$$\Delta G^{D}_{ads} = N_A\omega W^{D}_{A} = RT \ln V^{ref}_{N} \quad (14a)$$

And the specific free energy of adsorption can be estimated by employing the following dependency:

$$\Delta G^{SP}_{ads} = N_A\omega W^{SP}_{A} = RT \ln V_N \quad (14b)$$

In a plot of $RT \ln V^{ref}_{N}$ vs. $\omega\sqrt{\gamma^{D}_{L}}$, i.e., the product of the molecular surface area of the molecular probes, ω, and the *dispersive* component of the surface tension of the molecular probes, γ^{D}_{L}, the coordinates for a series of *n*-alkanes define a reference line (see Fig. 2).

All other polar probes exhibit higher net retention volumes, V_N, and the difference between their net retention volume and that of the *n*-alkanes for the same value of the dispersive component of surface energy leads to the value of the free energy of desorption, ΔG_{sp}, corresponding to the specific acid–base interaction, expressed as:

$$\Delta G_{SP} = RT \ln\left(\frac{V_N}{V^{ref}_{N}}\right) \quad (15)$$

Different approaches have been suggested for estimating the acidic/basic characteristics of the surfaces studied by IGC. In the simplest one the specific interactions between

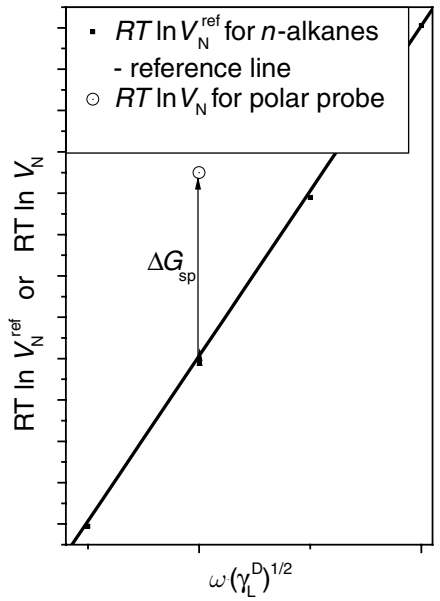

Fig. 2 Schematic representation of $RT \ln V_N$ vs. $\omega\left(\gamma_L^D\right)^{\frac{1}{2}}$ for an unknown probe.

the surface tested and two chromatographed reference polar adsorbates, i.e., a donor adsorbate and an acceptor one, are studied. The ΔG_{ads} values determined for the donor and the acceptor are related to the corresponding values of acceptor number, AN_S, and donor number, DN_S, for the solid:[14]

$$\Delta G^{SP}_{donor} \equiv AN_S \tag{16}$$

$$\Delta G^{SP}_{acceptor} \equiv DN_S \tag{17}$$

Lara and Schreiber[14] assumed that Eqs. 16 and 17 describe the acidic and the basic character of the surface, respectively. The donor number, DN_S, is a measure of the electron-donor (basicity) ability of the "molecular probe", while the acceptor number, AN_S, is a measure of the electron-acceptor (acidity) ability of "molecular probe": Based on the values of AN_S and DN_S, surfaces are characterized as follows:

$$\frac{AN_S}{DN_S} \geq 1.1 \quad \text{acidic surface}$$

$$\frac{AN_S}{DN_S} \leq 0.9 \quad \text{basic surface}$$

$$0.9 < \frac{AN_S}{DN_S} < 1.1 \quad \text{amphoteric surface}$$

$$AN_S \approx DN_S \approx 0 \quad \text{neutral(non-polar)surface}$$

The second approach, was proposed by Schultz and Lavielle.[11] It is based on the Gutmann's acid–base theory. The authors elaborated a semiquantitative approach to characterize the acidic/basic properties of solid surfaces based on the correlation of the enthalpy of desorption corresponding to specific interactions, ΔH_{SP}, with the acidic/basic properties of chromatographed polar adsorbates (acceptor number, AN_S, and donor number, DN_S, for the adsorbate):

$$\Delta H_{SP} = K_A DN_S + K_B AN_S \tag{18}$$

where K_A and K_B describe the acidic and basic characteristics of the solid surface, respectively, and are the slope and the intercept of the linear dependency $\frac{\Delta H_{SP}}{AN_S} = f\left(\frac{DN_S}{AN_S}\right)$, which enables the determination of the acidic and basic characteristics of the solid surface tested.

The third approach was developed by Boluk and Schreiber on the basis of Drago's acid–base concept.[15] In this case a homologous series of alcohols and amines were employed as the acidic and the basic probes, respectively. The interaction parameter, Ω, reflects the acidic/basic properties of the solid surface and is defined as follows: for acidic surfaces, the specific retention volume, $\left[V^o_{g(T)}\right]_b$, of basic adsorbate exceeds the $\left[V^o_{g(T)}\right]_a$ value for the acidic alcohol. In this case *n*-butylamine and *n*-butyl alcohol are commonly employed to calculate the interaction parameter, Ω:

$$\Omega = 1 - \frac{\left[V^o_{g(T)}\right]_b}{\left[V^o_{g(T)}\right]_a} < 0 \tag{19}$$

$$\Omega = 1 - \frac{\left[V^o_{g(T)}\right]_a}{\left[V^o_{g(T)}\right]_b} > 0 \tag{20}$$

where $\left[V^o_{g(T)}\right]_a$ and $\left[V^o_{g(T)}\right]_b$ are the specific retention volumes for the acidic and basic adsorbate, respectively.

DETERMINATION OF PROPERTIES OF LIQUIDS

The partition coefficient at infinite dilution of the solute, K^∞, between the carrier gas and the stationary phase can be defined as[9]

$$K^\infty = \lim_{x_i \to 0} \frac{c_S}{c_G} = \frac{V_N}{V_{Lm}} \tag{21}$$

where x_i is the mole fraction of chromatographed substance; c_S is the concentration of adsorbate in the stationary phase; c_G is the concentration of adsorbate in the gas phase; V_{Lm} is the molar volume of the stationary phase.

The partition coefficient, K, of the solute between a mobile (gas) phase and a stationary phase is the concentration ratio:

$$K = \frac{c_S}{c_G} = \frac{RT}{p_{ia}\gamma_s V_{Lm}} \tag{22}$$

p_{ia} is the pressure of saturated vapor of the adsorbate at the column temperature, T; γ_s is the activity coefficient of adsorbate in stationary phase.

If volume partition of the test substance is the only retention mechanism between the liquid deposited on the solid carrier and a gas phase, then the K value can be calculated using the specific retention value, $V_{g(T)}$:

$$K = V_{g(T)}\frac{T}{273.15}\frac{m}{V_L} = V_{g(T)}\frac{T\cdot\rho_L}{273.15} \tag{23}$$

The thermodynamic partition constant, K_i, has to be employed for calculating the free energy of adsorption of any adsorbate, which differs in nature from the chromatographic partition constant, K. Actually, the thermodynamic partition coefficient, K_i, is the ratio of the partial pressure of the chromatographed solute p_i to its molar fraction in the stationary phase, x_i. For designing chemical processes the thermodynamic K_i values are usually expressed as:

$$K_i = \frac{p_i}{x_i} \tag{24}$$

By the aforesaid reasoning, K_i can be expressed as $K_i = \gamma_i p_{i(o)}$. The K_i and activity coefficient values are used for calculating other magnitudes and thermodynamic quantities.

The partition coefficient K_i can be correlated to the thermodynamic parameters of the stationary phase via the following equations:

$$\Delta G_{ads} = RT\ln V_N + C_1 \tag{25}$$

$$\frac{-\Delta G_{ads}}{RT} = \ln K_i + C_2 \tag{26}$$

$$\frac{d\ln(K_i)}{d\left(\frac{1}{T}\right)} = \frac{-\Delta H_{ads}}{R} \tag{27}$$

$$\Delta S_{ads} = -\left(\frac{\Delta H_{ads} + \Delta G_{ads}}{T}\right) \tag{28}$$

where ΔG_{ads} is the standard free energy of adsorption; C_1 and C_2 are the constants on the reference state of the probe; ΔH_{ads} is the standard enthalpy of adsorption; ΔS_{ads} is the standard entropy of adsorption.

The partition and activity coefficients are used for determining the excess thermodynamic functions of the mixing of chromatographed substances on stationary phase: free energy, ΔG_E, enthalpy, ΔH_E, and entropy, ΔS_E. The values of these thermodynamic functions characterize the intermolecular interactions in the dissolution process. They can be calculated by using the following dependencies:

$$\Delta G_E = RT\ln K_i \tag{29}$$

$$\Delta H_E = R\frac{d\ \lg\ \gamma_i}{d\left(\frac{1}{T}\right)} \tag{30}$$

$$\Delta S_E = \frac{(\Delta H_E - \Delta G_E)}{T} \tag{31}$$

The IGC technique can be employed for the identification of asphaltenes. In this case the relative coefficients of interaction of standard substances with the stationary phase, I_g, are used:

$$I_g = 100\ \lg\frac{V_R^o}{V_{RP}^o} \tag{32}$$

where V_R^o and V_{RP}^o are the retention volumes of a standard substance and an n-alkane with molecular weight equal to that of the test substance. This parameter hardly depends on chromatographic conditions and therefore can be used in comparing properties of different asphaltenes.

The IGC technique is also useful for characterizing the properties of liquid crystals.[16] The melting and clearing temperatures of liquid crystals and their ability to overcool can be determined based on the dependency $t_R = f(T_c)$. Retention values differ in different physical states of the liquid crystal substance. The retention of chromatographed substance usually decreases with increasing column temperature within a temperature range for the solid state of the liquid crystal stationary phase. After achieving a minimum, and on further increase in temperature, retention significantly increases and achieves the maximum at the melting point, and a mesophase structure appears. In the mesophase the retention times decrease and they may increase again before the transition point to isotropic liquid, but to a small extent. Sometimes this cycle is visible during transition from one to another kind of mesophase. After finishing the transition to isotropic liquid, retention decreases.

The IGC technique can be employed for investigating the phenomenon of complex formation, especially for the following applications:

- Determination of the stability constants for complexing reactions.
- Testing the energy-related effects for the complexing reactions.[9]

By employing IGC, it is possible to test donor–acceptor molecular complexes and the stability of hydrogen bonds.

The main advantages of using IGC in the study of equilibrium constants of complexes are the following:

- There is the possibility of determining the equilibrium constants directly from retention data, without the necessity of the estimation of equilibrium concentrations.
- The method is relatively rapid and technically simple.
- Very small amounts of rare or even impure compounds can be used.
- By employing mixtures of solutes, measurement of many parameters can be made in a single experiment.
- Hydroxylable or water-insoluble complexes may be studied in non-aqueous media.

CHROMATOGRAPHIC TESTING OF POLYMERIC MATERIALS

Polymers can be tested by means of IGC technique. The following parameters and phenomena can be determined or investigated: molecular masses of polymers, phase transitions, glass transition temperatures, kinetics of reaction with polymers, values of thermodynamic functions of dissolution of different substances in polymers, and acidic/basic properties of polymers.

The determination of the crystallinity of polymer stationary phases is based on the differential solubility of the "molecular probe" in crystalline and amorphous domains. In effect the adsorbate "senses" only the amorphous regions, leading to an increase in retention volume with decreasing crystallinity.

The retention diagrams through the melting transitions of semicrystalline polymers (see Fig. 3) could be analyzed quantitatively to yield the crystallinity and the melting curve of a polymer. It was found that both above and below the melting point, T_m, retention proceeded by bulk sorption, thus allowing for a comparison of the specific retention volumes. Above T_m the polymer is completely amorphous and a linear retention diagram is obtained. By extrapolating this straight line to lower temperatures the specific retention volume for the amorphous polymer can be computed theoretically. A comparison with the experimentally determined specific retention volume yields the amorphous fraction of the stationary phase, x:

$$x = \frac{V_{g(T)}}{V_{g(T)}'} \tag{33}$$

where $V_{g(T)}$ is the specific retention volume of the chromatographed substance; $V_{g(T)}'$ is the specific retention volume of the chromatographed substance extrapolated to the dashed line.

The studies on polymer stationary phases revealed that retention diagrams exhibited certain singularities, such as those depicted in Fig. 3, corresponding to the transitions of the polymer stationary phase. Both glass (B) and melting (F) transitions were thus detected. These transitions of the stationary phase are of paramount importance in IGC for determining the nature of the information that can be derived from any one experiment.

In the region corresponding to segment AB of Fig. 3, the polymer is below its glass transition temperature, T_g, and penetration of the "molecular probe" molecules into the bulk of the polymer phase is precluded. Retention proceeds exclusively by surface adsorption, and the corresponding retention diagram is linear. At point B, corresponding to the glass transition, penetration of the "molecular probe" into the bulk of the polymer begins, causing an increase of specific retention volume with temperature. Owing to the initially slow rate of diffusion of the "molecular probe" into and out of the stationary phase, non-equilibrium conditions prevail. As the temperature increases in region BC, the diffusion coefficient rises sharply, leading to equilibrium conditions at point C.

At temperatures below the melting point of the polymer, in region CD, retention proceeds by bulk sorption, but the tested polymer–"molecular probe" interaction is restricted to the amorphous domains of the stationary phase. Upon melting, in region DF, the fraction of amorphous material increases, leading to an increase in retention volume. At temperatures above the melting point, segment FG, a linear retention diagram corresponding to bulk sorption into the completely amorphous polymer, is obtained. By extrapolation of this line to lower temperatures (i.e., dashed line FE), the crystalline content of the stationary phase can be determined by comparing the

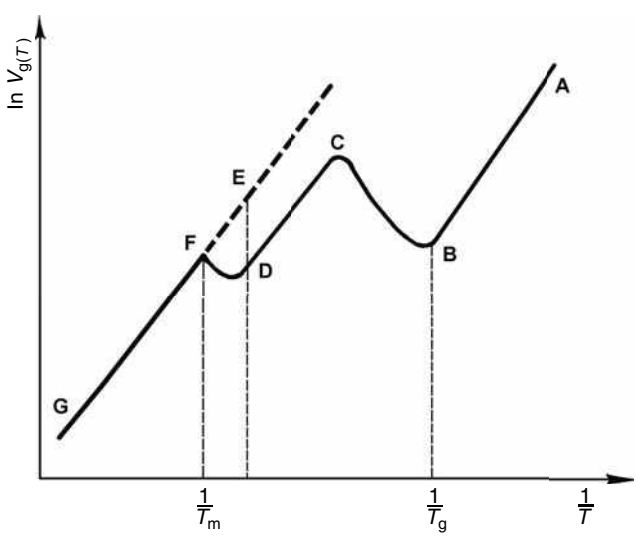

Fig. 3 The variation of the $\ln V_{g(T)}$ vs. $\frac{1}{T}$ for a semicrystalline polymer.

experimentally determined specific retention volume with the extrapolated value.

In region FG the polymer is completely amorphous and the properties of the tested polymer–"molecular probe" solution can be investigated. Care must be taken to ensure that any contribution from surface adsorption is taken into account. For non-crystalline polymers, liquid-like behavior is observed from point C onward. The location of point C on the temperature axis depends both on the tested polymer–"molecular probe" system considered and on chromatographic conditions, film thickness, and flow rate.

INVESTIGATION OF VOLATILE SUBSTANCES AND DIFFUSION IN GASES

The dependencies in plate theory, describing the efficiency of chromatographic columns, can be used in diffusion tests. It is possible to determine the diffusion coefficient of any volatile solute in the carrier gas by means of gas chromatograph apparatus. In this case a capillary column without any stationary phase, of length L and internal diameter d, with u being the flow rate of the carrier gas, is employed. Vapors of a volatile substance are injected into the column, and a peak of the substance is registered. The retention time, t_R, and the base width of Gaussian peak in units of chart distance,w_b, are measured. The plate height can be calculated from the following dependency:

$$H = \frac{L}{16}\left(\frac{w_b}{t_R}\right)^2 \tag{34}$$

The H values can be inserted into the Van Deemter equation for capillary columns, and the diffusion coefficient, D_f, can be estimated:

$$H = \frac{2D_f}{u} + \frac{d^2 u}{24D_f} \tag{35}$$

where d is the diameter of the column; D_f is the coefficient of molecular diffusion of the solute in carrier gas; u is the linear velocity of carrier gas.

The D_f values can be calculated from the linear relationship between Hu and u^2. If the method is to be successful, laminar flow must be maintained throughout the experiment.

Iodine-Azide Reaction as a Detection System in TLC

Robert Zakrzewski
Witold Ciesielski
Department of Instrumental Analysis, University of Łódź, Łódź, Poland

Abstract
The possibilities of application of iodine-azide reaction as a detection system has been presented. In this method, the developed plates are sprayed with a mixture of sodium azide and iodine solution. A modified procedure includes spraying the developed plate with sodium azide and starch solution and afterward exposing it to iodine vapor. In reversed-phase high-performance thin-layer chromatography (RP-HPTLC) mode, sodium azide becomes a constituent of the mobile phase. The catalytic effect of C–S, C=S, P–S, and P=S bonds results in white spots emerging on the violet–gray background. It has been found that the detection limits are as low as a picomol per dot, and the factors leading to such low values have been explored. The method has been used to distinguish different thiols in biological samples, such as urine or blood serum, pesticides, and drugs. The outcome of the derivatization process with phenyl isothiocyanate or butyl isothiocyanate is the transformation of the amino acids, biogenic amines, and amphetamines into inductors [phenylthiocarbamyl (PTC), butylthiocarbamyl (BTC), or phenyl thiohydantoin (PTH) derivatives] of the iodine-azide reaction.

INTRODUCTION

There are numerous methods for sulfur(II) detection in thin-layer chromatography (TLC). Most of them are based on general, rather than specific, techniques. The iodine-azide reaction takes place only in the presence of a sulfur(II) compound (selective induction), and only these compounds are visible on the thin-layer plate after treating with an iodine-azide reagent. The detection limits are as low as a picomol per spot. The factors that have an impact on the detection limits are discussed in this entry. The developed method has been applied to detect various thiols in biological samples (urine and blood serum), pesticides, and drugs.

IODINE-AZIDE REACTION

The iodine-azide reaction, $2N_3^- + I_2 \xrightarrow{\text{sulfur(II) compound}} 3N_2 + 2I^-$ introduced by Rashing,[1] has been explored extensively for decades in analytical chemistry. Sulfur(II) compounds act rather as inductors than as catalysts. Compounds such as sulfide, thiosulfate, thiocyanate, and polythionates and elemental sulfur (after cleavage of S_8 ring) are inductors of the iodine-azide reaction. Among the organic compounds, thiols, thionates, disulfides, organophosphorus compounds containing a P=S, or a P–S bond, and compounds with sulfur in the ring (after cleavage with iodide azide) have induction properties. Nitrogen evolved during the reaction, heat changes generated, and iodine consumed in the reaction are proportional to the amount of sulfur(II) compound present in a sample, and the quantity of the sulfur(II) compound is determined based on these changes.

The iodine-azide reaction has been widely applied for the determination of sulfur(II) compounds using various techniques, e.g., titration, spectrophotometry, coulometry, flow injection analysis, TLC, and high-performance liquid chromatography.

The iodine-azide reaction mechanism was introduced by Strickland, Mack, and Childs[2] and modified by Kurzawa and Kurzawa.[3] The reaction of iodine with azide ion, induced by the sulfur(II) compound, takes place in solution, as shown in Fig. 1. Azide ion reacts neither with iodine nor with a sulfur(II) compound directly, or these reactions are very slow (reaction 1). The equilibrium of reaction 1 shifts strongly to the left. If it were possible to remove iodide ions I^-, the reaction between $I_2N_3^-$ complex and the azide ion would take place (reaction 2).[4] In the presence of a sulfur(II) compound, the intermediate compound RSI is formed (reaction 3). The induction cycle starts with the reaction of intermediate compound RSI with an azide ion or a sulfur(II) compound involved in the induction cycle (reaction 4). The reaction ends when the entire amount of sulfur(II) compound is deactivated in the iodimetric reaction (reaction 5). Induced and iodimetric reactions are competitive. In the iodimetric reaction, the inductor is oxidized by iodine and removed from the induction cycle.

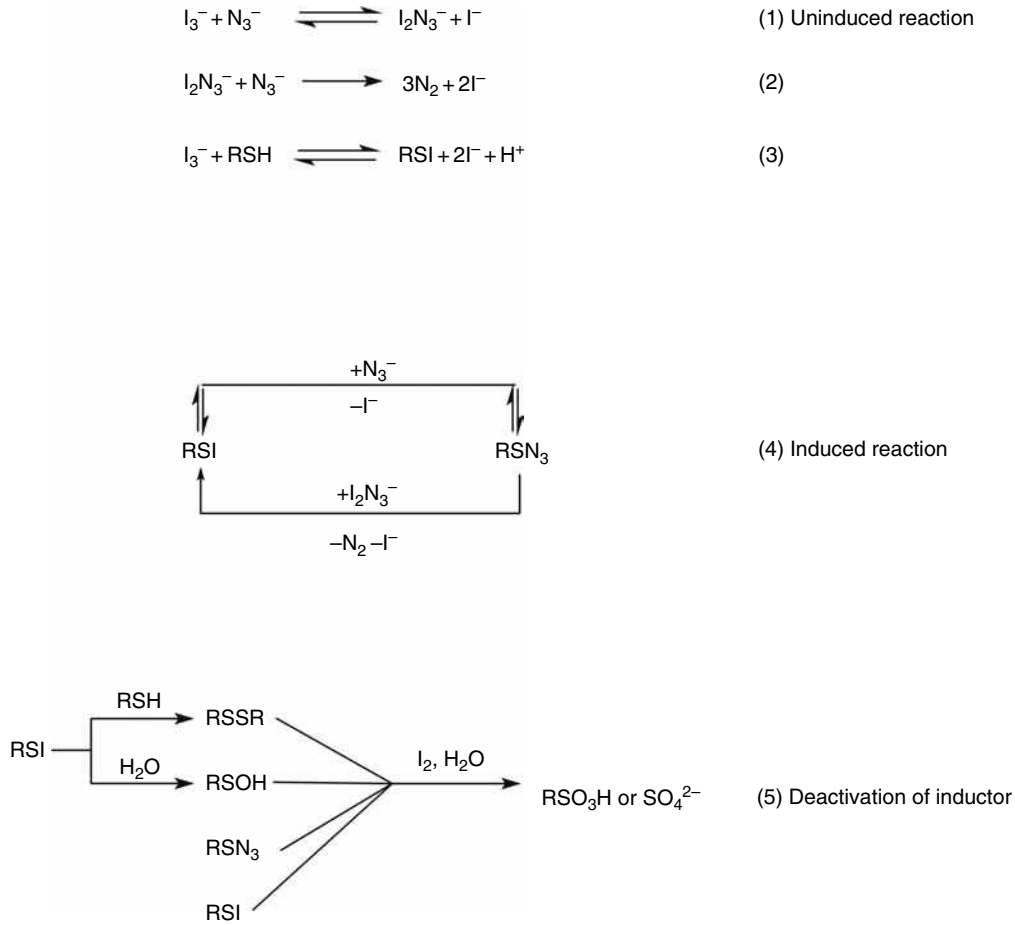

Fig. 1 Mechanism of iodine-azide reaction.

DETECTION OF SULFUR COMPOUNDS

The developed TLC plates were sprayed with different iodine-azide solutions as shown in Table 1. Generally, it can be stated that the sprayed reagents were prepared by mixing the two solutions: sodium azide and iodine (in potassium iodide to dissolve iodine in water)[5–20] (procedure 1). Sometimes starch solution was applied[21–27] (procedure 2), and in another procedure the developed TLC plates were sprayed with sodium azide and starch solution and then exposed to iodine vapor[28–40] (procedure 3). In the reversed-phase (RP) mode, sodium azide was incorporated into the mobile phase (procedure 4).[31,32,34]

In all the procedures, the chromatographic bands became visible as white spots on a yellow background or as white spots on a violet–gray background when starch was used. The spots appear because of the induction effect of the C–S, C=S, P–S, or P=S bonds. However, after some time, the background starts to disappear owing to iodine sublimation.

The method was applied to detect the various sulfur(II) compounds listed in Table 1. As can be seen, the lowest detection limits are obtained when the TLC plates are sprayed with azide/starch solution and exposed to iodine vapor (procedures 3 and 4). In procedures 1 and 2 (spraying TLC plates with azide and iodine and/or starch solution), the detection limits are in nanomol per spot levels.

Influence of Varied Factors on Detection Limit

Several parameters have to be determined for achieving the optimum conditions when using iodine-azide reaction as the detection system in TLC: pH (Fig. 2), the concentration of spray solution, and the influence of iodine and iodide ions on the course of iodine-azide reaction.

To optimize the postchromatographic reaction, the conditions should lead to the highest consumption of iodine in the induced reaction. This consumption of iodine is reflected in the induction coefficient, defined by the equation:

$$F_i = \frac{n_I}{n_S}$$

where n_I is the moles of iodine consumed in the inducted reaction and n_S is the moles of the inductor. From the

analytical point of view, the value of the induction coefficient is a measure of the determination sensitivity of a given sulfur(II) compound in volumetric, coulometric, spectrophotometric, and flow injection analysis determination. The induction coefficient can be applied for predicting detection limits in various methods. This implies a direct relationship: the higher the induction coefficient, the more sensitive the determination of a given inductor is. There is a good correlation between the induction potency of thiouracils and their detectability in TLC methods using the iodine-azide reaction as a visualization step.[37]

Iodine and Iodide Ions

Procedure 3 (spraying with sodium azide and starch solution and exposing to iodine vapor)[28–40] yields lower detection limits as compared with spraying using the mixture of the solutions sodium azide, iodine, and/or iodide ions (procedures 1 and 2).[5–20] Excess of iodine, which is difficult to avoid in procedure 1, raises the detection limits because it makes the white spots vanish (see Table 4 of Ref. 37 or Table 6 of Ref. 29). The phenomenon does not generally occur with other visualization techniques in planar chromatography: an excess of visualization solution does not raise the detection

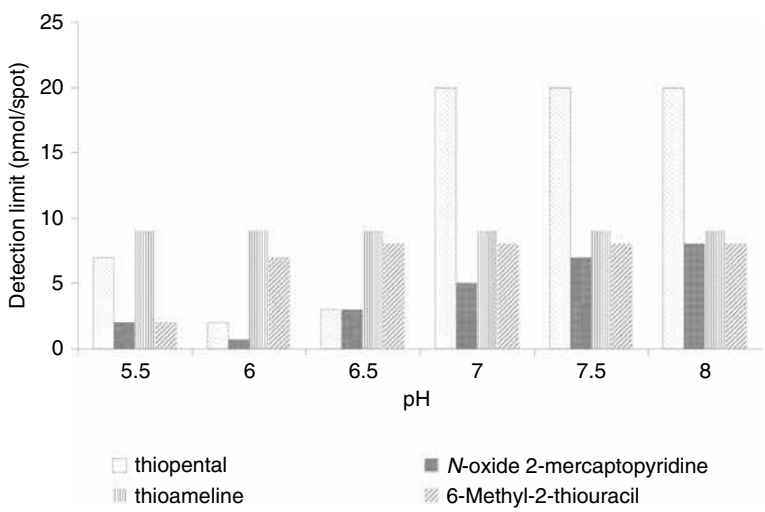

Fig. 2 The dependence of detection limits in TLC on pH of the spray solution.

limit. The use of iodine vapor, however, lowers the detection limits considerably by avoiding the excess of iodine, and it enables iodine to be dispersed evenly onto TLC plates.

The hampering effect of the iodide ions on the iodine-azide reaction induced with some organothiophosphorus compounds increases with increasing iodide-ion concentration.[29,41] Presence of high concentration of potassium iodide (0.5 mol/L) in the spray solution totally prevents the course of the iodine-azide reaction (for details see table 1 in Ref. 16 and Table 1 in Ref. 17). In this case, the rate of iodimetric reaction is higher than that of the induced reaction. This is the reason for the appearance of brown spots (these dots are similar to the ones obtained with iodine vapor) instead of white dots corresponding to a particular organothiophosphorus compound.

The presence of iodide ions raises the detection limits for many thiols (e.g., thiouracils[37]) when sprayed with iodine in potassium iodide solution; however, the detection limits are not raised to the same extent for some PTC derivatives of amino acids[30] for the same concentration of iodide ions. The iodine-azide reaction takes place at a lower rate in the presence of iodide ions, and white spots take longer to appear, particularly for higher concentrations of iodide ions.

Sometimes a small amount of iodide ions in the spray solution in the improved iodine-azide procedure had a positive impact on the detection limits (e.g., 2,4-dimercaptopyrimidine, 2-thioorotic acid, 2-mercapto-3,4,5,6-tetrahydropyrimidine).[38] For ethyl 4-amino-2-mercaptopyrimidine 5-carboxylate, increasing the concentration of iodide ions in the spray solution in the improved iodine-azide procedure enhanced the detection limits.[39] Fig. 3 shows instances of the reliance of the detection limits in TLC on iodide ions solution concentration.

pH of Spray Solution

For many compounds, the detection limit was found to be dependent on the pH of the reagent (sodium azide solution). A solution with pH lower than 5.5 is not recommended because of the emission of the poisonous, volatile hydrazoic acid HN_3. On the contrary, when the pH is over 8.0, the catalytic reaction does not proceed, as iodine forms hypoiodite (IO^-), which is not a reagent in the iodine-azide reaction. Therefore, a suitable pH should be chosen within the range 5.5–8. The pH chosen for spray solutions in TLC corresponds to the pH of the reaction medium in other techniques using iodine where the iodine-azide reaction is applied as a measurement method.

Concentration of Azide Ions

Increasing the sodium azide concentration in the spray reagent, up to 4% (procedure 3), causes a slight decrease in detection limits.[28–40] Beyond the 4% limit, further increase in the concentration of sodium azide solution does not influence the detection limits.

Induction Time

The spots become visible after a time lag on account of the induction time (i.e., time required for the induction reaction to complete) conditioned by induction properties of the particular compound. The induction time should not be too long because it may cause disappearance of the background owing to iodine sublimation.

QUANTITATIVE ANALYSIS

Densitometric analysis coupled with iodine-azide reaction as a detection system is relatively difficult to conduct owing to background disappearance. There are two processes behind this: iodine sublimation from a plate area and uninduced iodine-azide reaction proceeding outside a spot. Addition of potassium iodide to the spray solution lowers

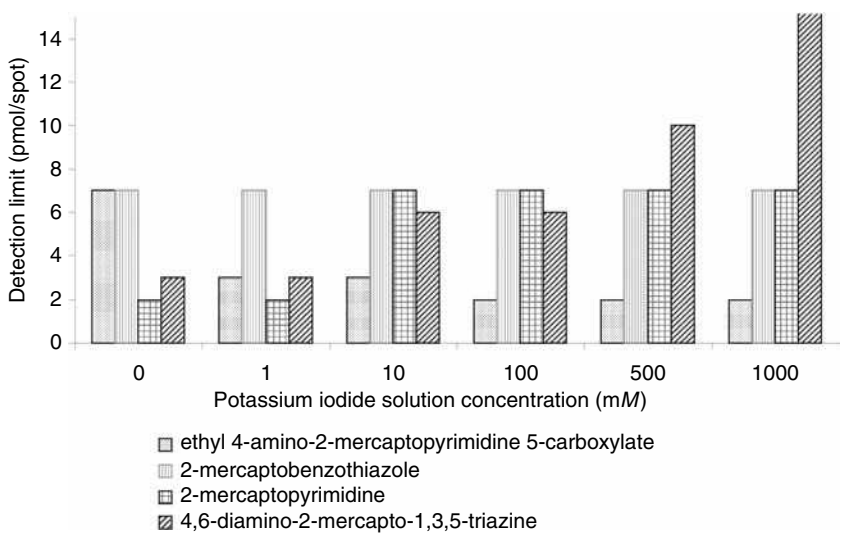

Fig. 3 The dependence of detection limits in TLC on potassium iodide concentration in the spray solution.

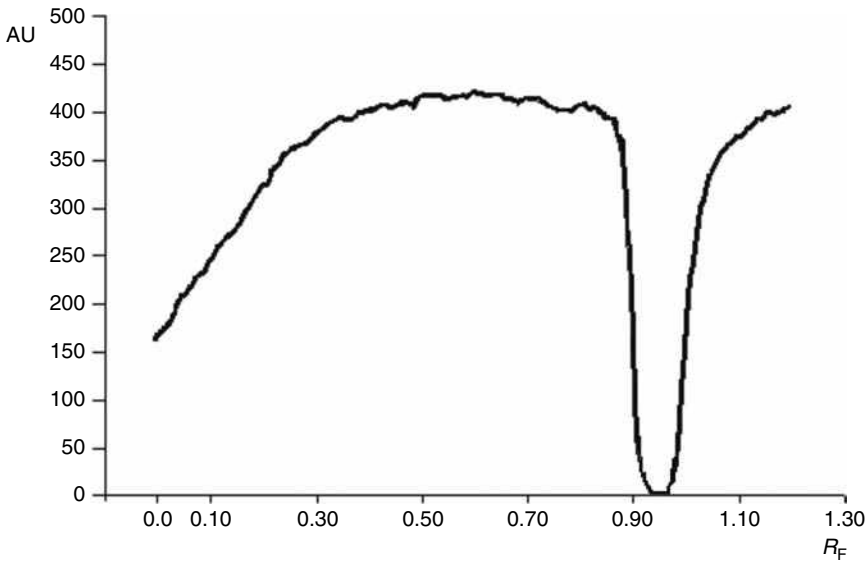

Fig. 4 Scan of TLC plate for the dot corresponding to 5 pmol/dot with TLC densitometer at 483 nm.

iodine volatility. At higher concentration of iodide ions, the background is stable because the concentration of the nonvolatile triiodide ions increases as a result of a further shift in the equilibrium of iodine–iodide ions ($I_2 + I^- \rightleftarrows I_3^-$) to the right. High concentration of potassium iodide in the spray solution also results in hampering the uninduced iodine-azide reaction;[4] moreover, the amount of iodine is constant on a specific area of the plate. The higher the concentration of iodide ions, the more stable the background obtained.

The background color changes from violet–gray (corresponding to iodine–starch complex) to brown (iodine–iodide–starch complex) as the iodide ion concentration increases. This color transformation is the consequence of the hypsochromic shift of background maximum absorption wavelength from 550 to 483 nm. Plates were covered with sodium azide (in the spray solution) and iodine (plates were placed in an iodine chamber). Thanks to the presence of starch and iodide ions plates change color from violet–gray to brown. In the case of TLC plate where thiuram is present, iodine-azide reaction induced by thiuram takes place, and a white spot appears, which makes densitometric analysis possible.[40]

In procedure 3, the plate is scanned at 483 nm, which corresponds to the maximum absorption of iodine–iodide–starch complex (Fig. 4). As the plate is covered with iodine, a constant absorbance is maintained and recorded as a background from iodine–iodide–starch complex. When the light passes a white dot, the signal decreases owing to the consumption of iodine in the iodine-azide reaction induced by thiuram within this spot. Outside the thiuram spot, the absorbance signal gets restored to its initial value and a negative peak is recorded. Calibration plots were constructed by plotting spot area (calculated from end and start R_F value) against the corresponding amount (in picomols) of thiuram. In an alternate method, a PC scanner was also applied as an analytical instrument. The chromatograms were stored in the form of 24-bit true-color images (Fig. 5). The pixels of white chromatographic bands were counted and calibration plots were constructed by plotting the number of pixels against the corresponding amount (in picomols) of thiuram. Results obtained with the PC scanner are similar to those obtained with TLC densitometry coupled with iodine-azide detection procedure.

APPLICATION OF THE METHOD

The evaluated methods were applied to detect thiols in blood serum, urine,[28,37,38,39] and food samples;[40] aspartic acid in drugs;[29] free sulfur traces in chemical reagents that include sulfur in their structure;[14] ores and products of their flotation;[13] tire treads;[13] and rubber vulcanizates[11] (Table 2).

β-Lactam antibiotic drugs,[27] amino acids,[31,32] and biogenic amine[34] as a PTC derivative, BTC amino acids,[33] thiouracils,[37] pyrimidines, and pyridines[38] were separated in HPTLC and detected with the suggested method.

Free sulfur traces	Tire treads	—	[13]
Free sulfur traces	Rubber vulcanizates		[11]

Dash indicates not stated.

CONCLUSION

The discussed results confirm the potential and beneficial effects of iodine-azide reaction as a detection system in planar chromatography. The proposed detection system allows selective and sensitive detection for thiol or thione at picomol per spot level (procedures 3 and 4). The other detection methods routinely used in TLC—iodine vapor, UV—gave a positive but less sensitive test. Iodine-azide detection system is inexpensive; the reagents are readily available chemicals; and the analysis times are short. The non-improved iodine-azide method (procedures 1 and 2) has not been widely applied on account of the relatively high detection limits obtained with the procedure.

It was found that the results obtained using a PC scanner were as good as those recorded by the more conventional measurements using TLC densitometer.

Iodine–Azide Reaction: HPLC Analysis

Robert Zakrzewski
Witold Ciesielski
Department of Instrumental Analysis, University of Łódź, Łódź, Poland

Abstract
A postcolumn detection system based on the reaction between azide ions and iodine, induced by sulfur(II) compounds, is presented. The method involves separation of sulfur(II) compounds using varied chromatographic systems, followed by spectrophotometric measurement of the residual iodine from the postcolumn reaction after mixing with the iodine–azide reagent. The obtained chromatograms show a negative peak as a result of the decrease in background absorbance. Various factors that have an impact on the determination of sulfur(II) compounds are discussed.

INTRODUCTION

High-performance liquid chromatography (HPLC) is a powerful tool for the separation of different classes of compounds. However, detection sensitivity remains an important issue, particularly when dealing with minor components in complex mixtures. Both the selectivity and the sensitivity of these detectors can be further enhanced by using suitable derivatization techniques. This has led to the use of procedures that render the substances more readily detectable by chemical reaction either before (precolumn) or after chromatography (postcolumn). The main advantages of the postcolumn approach include separation of analytes in their original form. So far postcolumn reactions are not so widely used in HPLC, although such reaction detectors have been available for several years. The reason for this may be caused by the problem in adjusting this continuous detection system to the chromatographic apparatus without destroying the achieved chromatographic separation. One requirement for postcolumn reaction is to store the column effluent and the added reagent after thorough mixing during the reaction time and to transport both into detectors without destroying the once-achieved separation.

Postcolumn detection by reaction uses a chemical or photochemical reaction to generate a detectable product species (P) from the analyte (A) by addition of a reagent or photons:

$$A + R \rightarrow P$$

Iodine–azide detection system is very selective because the reaction between iodine and azide ions takes place only in the presence of sulfur(II) compounds:

$$2N_3^- + I_2 \xrightarrow{\text{sulfur(II) compound}} 3N_2 + 2I^-$$

Sulfur(II) compounds act as inductors rather than as catalysts. Both inorganic (sulfide, thiosulfate, thiocyanate, polythionates, and elemental sulfur after cleavage of the S_8 ring) and organic (thiols, thionates, disulfides, organophosphorus derivatives with a P═S or P═S bond, and compounds containing a sulfur element in a ring) sulfur(II) compounds have induction properties. The mechanism of the iodine–azide reaction is discussed elsewhere in the literature.[1,2]

Under predetermined conditions, the amount of iodine consumed in the induced reaction, the heat changes generated, [3] and the amount of evolved nitrogen[4] are proportional to the amount of the sulfur(II) compound present. The most widely used method for sulfur(II) compound determination is the evaluation of iodine consumption in the induced reaction. These parameters are monitored by volumetric,[5] coulometric,[6] or spectrophotometric[7] analysis; slow titration with biamperometric detection of the end point;[8] a stopped-flow technique;[9] or detection by HPLC[10–12] and thin-layer liquid chromatography (TLC).[13,14]

DETECTION OF SULFUR(II) COMPOUNDS

Currently, three modes of separation (ion,[11] ion-pair,[12] and reversed-phase[15–19] chromatography) for the detection of sulfur(II) compounds using the iodine–azide detection system are available.

In ion-pair[11] and ion[12] chromatography, a proper mobile phase is pumped through the chromatographic column at an optimal flow rate. A sulfur(II) compound sample is injected into the HPLC system. The effluent from the column containing separated analytes is allowed to flow

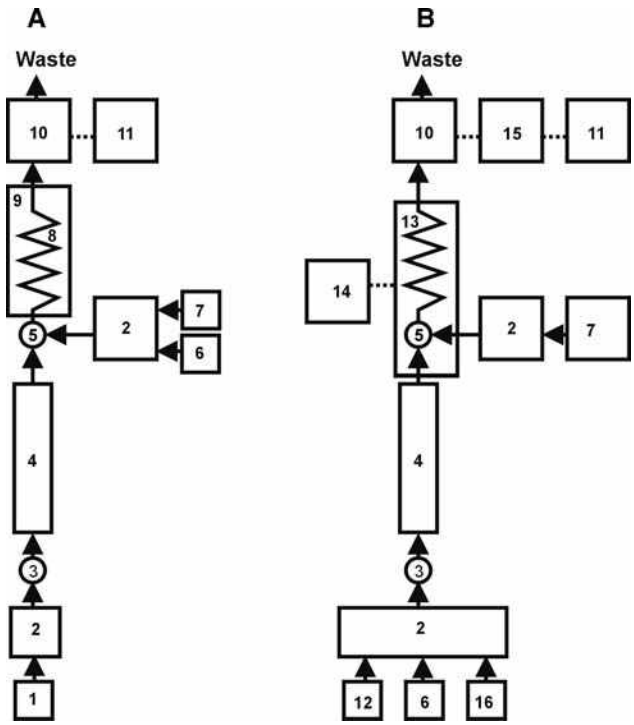

Fig. 1 Flow diagram of an HPLC system with postcolumn iodine–azide reaction detection. A, Ion and ion-pair chromatography, and B, reversed-phase chromatography 1, mobile phase; 2, pump; 3, injection valve; 4, HPLC column; 5, mixing tee; 6, sodium azide solution; 7, iodine solution; 8, reaction tube; 9, thermostat; 10, LC spectrophotometer; 11, recorder or computer as a recorder; 12, acetonitrile; 13, postcolumn reaction module; 14, temperature control system; 15, bus Sat/In module; 16, water.

through a T-union where the iodine in potassium iodide ions and acetic acid solution as well as sodium azide are delivered at a suitable flow rate. The resultant stream is passed through a mixing tee. The iodine–azide reaction induced by a single analyte takes place in the postcolumn reaction tube (Fig. 1A). For the reversed-phase mode,[15–19] sodium azide is a constituent of the mobile phase and the effluent is mixed with iodine in potassium iodide solution; the iodine–azide reaction takes place in the postcolumn reaction module maintained at an appropriate temperature (Fig. 1B). A UV/Vis detector at $\lambda = 350$ nm is applied in all separation modes.

Thus, in the absence of sulfur(II) compounds, a constant absorbance of iodine is recorded when the HPLC system is supplied with azide ions from the mobile phase and iodine solution from postcolumn reagents. Moreover, a decrease in the signal is observed when a sulfur(II) compound is present in the chromatographic band. This is attributed to iodine consumption in the iodine–azide reaction and is detected as a negative peak at 350 nm. The peak is quantitatively dependent on the amount of the sulfur(II) compound present. Fig. 2 shows the chromatogram obtained for 2-thiobarbituric acid.

INFLUENCE OF VARIOUS FACTORS ON DETECTION WITH A POSTCOLUMN IODINE–AZIDE REACTION

To establish optimal conditions for HPLC determination with a postcolumn iodine–azide reaction, a wide range of parameters that can lead to high iodine consumption should

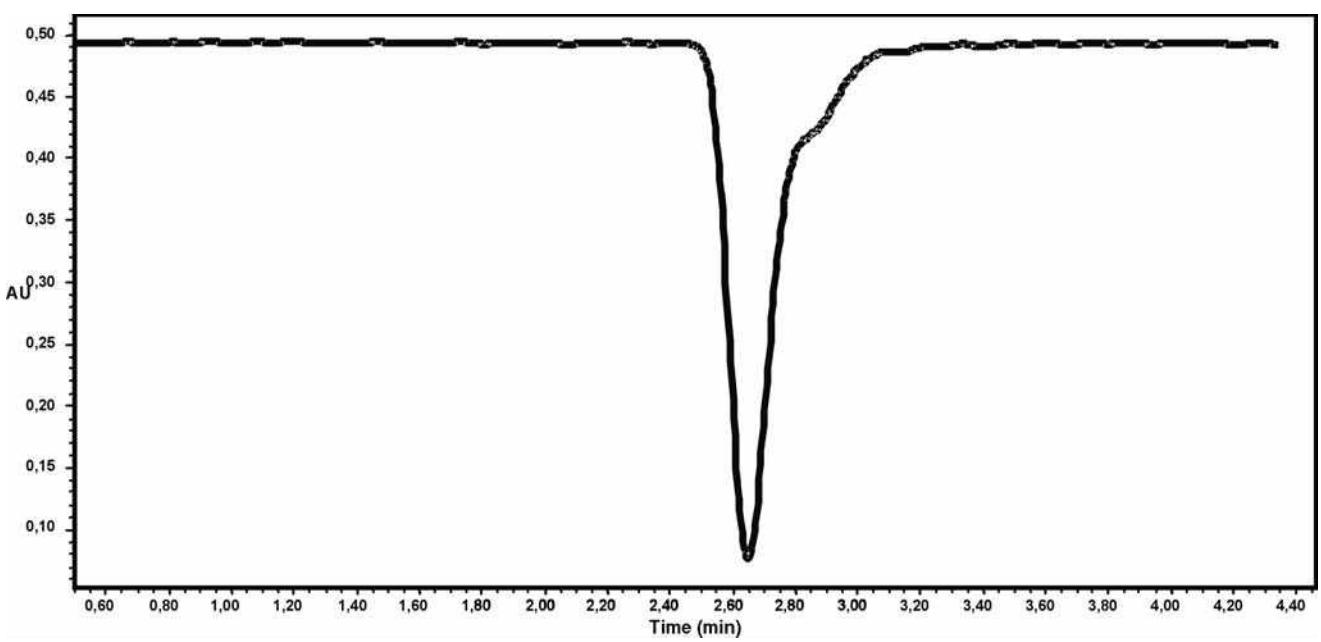

Fig. 2 Chromatogram of 2-thiobarbituric acid 10 n*M* (for chromatographic conditions, see Tables 1–3).

be taken into consideration. Among them are those with an effect upon the separation process alone (i.e., stationary phase) and those that influence the iodine–azide detection process (i.e., concentration of iodine and potassium iodide solution, and its flow rate, as well as postcolumn reaction module temperature). However, there are also a great number of factors that have an impact on both the processes mentioned above. Successful HPLC determination means a separate evaluation procedure for each parameter. The highest consumption of iodine in the induced reaction is the critical indicator when it comes to optimal conditions for postcolumn reaction. The optimal determination conditions of detection, chromatographic separation, and postcolumn reaction, and the results of sulfur(II) compound determination are listed in Tables 1–4, respectively.

Organic Modifier of the Mobile Phase

The main goal of applying an organic solvent into the mobile phase is to acquire the proper resolution of separated sulfur(II) compounds. However, the type and concentration of the organic solvent have an impact on the course of the iodine–azide reaction. Generally, it has been observed that the addition of an organic solvent lowers the consumption of iodine in the induced reaction, with some exceptions (e.g., thiopental, vitamin B1).

Sodium Azide Concentration

Buffer sodium azide of neutral pH is an inhibitor of bacterial growth. In addition, it neither modifies the chromatographic performance of proteins nor exhibits any affinity for them. On account of its activity toward anion exchangers and binding sites, buffer sodium azide is usually excluded from ion-exchange chromatography; also, it finds no application in the determination of sulfur anions forming part of a mobile phase.[11,12] However, in reversed-phase HPLC (RP-HPLC), sodium azide is incorporated into the mobile phase as one of the reagents in the iodine–azide reaction, which substantially simplifies the determination procedure. To complete the postcolumn reaction, sodium azide solution at higher concentrations is introduced into the ion chromatographic technique. On account of the poisoning properties of sodium azide, it is recommended that it should be used in small quantities. In an RP-HPLC study, sodium azide was used as a buffer for pumping the separation column. Its use was based on two main facts: first, it was important to stop the dilution of sodium azide, which could lead to a decrease in iodine consumption in the induced reaction; second, the same buffer solution could be used for the separation process and the postcolumn detection system.

pH of the Postcolumn Reaction Medium

Both the separation process and the iodine–azide reaction are influenced by the pH of the sodium azide solution. The effect of pH is mainly found in the level of iodine consumption. Some restrictions on pH need to be imposed when it comes to sodium azide solution. In solutions of pH lower than 5.5, the emission of poisonous, volatile hydrazoic acid is detectable, and at pH values over 8.0 the formation of iodate(I) obstructs the iodine–azide reaction.

In ion and ion-pair chromatography, pH of the postcolumn reaction solution is adjusted by the acetic acid solution in the postcolumn reaction module because the separation pH is different from the pH of the iodine–azide reaction course (for details see Table 3). In reversed-phase chromatography, sodium azide solution plays two roles: as a constituent of the mobile phase and as the reaction medium for the iodine–azide reaction. Therefore, pH adjustment for thiol determination is performed only once in the mobile phase without any additional pH correction of the postcolumn reaction solutions. Consequently, the procedure is simplified and no extra operations concerning the introduction of other solutions are required.

Influence of the Mobile Phase and Iodine Solution Flow Rates on Induction Properties

Induction properties depend not only on the reaction solution (concentration of acetonitrile and sodium azide, pH) but also on the reaction time, which is called the induction time. This is the time required for the iodine–azide reaction induced by a sulfur(II) compound to get completed.

Table 1 Detection conditions of sulfur(II) compound determination.

Compound	Column	Injection value (μl)	Wavelength of detection (nm)
Sulfur anion	TSK-gel IC-Anion-PW 50 × 4.6 mm	50	350

In chromatography using the iodine–azide detection system, the induction time is the contact time between the eluate [containing sulfur(II) compounds and optional azide ions] and the postcolumn reaction solution (containing the iodine and optional azide ions). The induction time can be increased either by lengthening the postcolumn reaction tube or by increasing the flow rates of the mobile phase and the iodine solution. An excessive increase in the reaction time leads to peak broadening. Hence, it is necessary to optimize the reaction time by exploiting its dependence on the flow rate of the mobile phase and postcolumn reaction solutions as well as on the distance from the column tip to the detector cell.

It has been observed that the peak height of most sulfur(II) compounds decreased with increasing flow rate of the iodine solution, as the inductor does not get enough time for inducing the iodine–azide reaction. To slow down the iodimetric reaction in the postcolumn module, application of small amounts of iodine is recommended. Under such conditions, the iodine consumption in the iodine–azide reaction as well as the peak height increase.[1,5] Too low a flow rate of the iodine solution may lead to significant band broadening and lower peak heights. The influence of flow rate of the iodine solution on the ratio of sulfur(II) compound peak height to noise peak height for 2-thiobarbituric acid and thiopental is illustrated in Fig. 3.

Table 3 Postcolumn conditions of sulfur(II) compound determination.

Compound	Postcolumn reaction solution flow rate (ml/min)	Iodine solution concentration (μ*M*)	Iodide solution concentration (m*M*)	Sodium azide solution concentration	Acetic acid concentration (*M*)	Postcolumn reaction module temperature (°C)

6-Propyl-2-thiouracil	0.4–1.0 nmol/ml urine	0.3 nmol/ml urine	0.4 nmol/ml urine	0.9% (quantification limit)

The concentration of iodine and iodide ions influences the course of the iodine–azide reaction. The iodine in iodide ion solutions or a mixture of iodine, iodide ions, and acetic acid solutions is delivered to the HPLC system after the separation step.

In an RP-HPLC determination, the concentration of iodine solution within the range 0.1–0.4 m*M* did not influence the course of postcolumn reaction for a constant potassium iodide solution concentration and a constant flow rate.

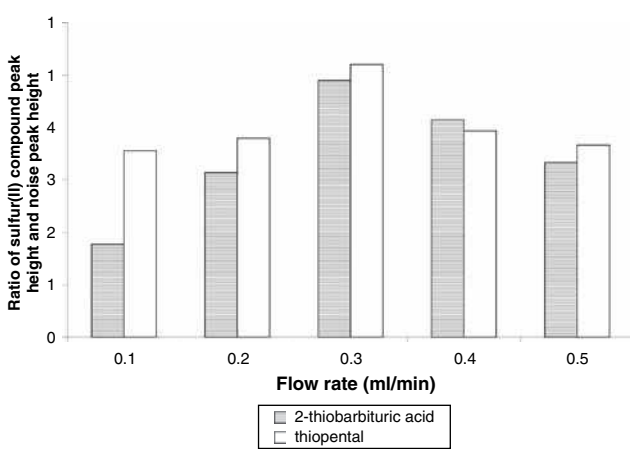

Fig. 3 The influence of iodine solution flow rate on the ratio of peak height to noise peak height for 2-thiobarbituric acid and thiopental (for chromatographic conditions, see Tables 1–3; 2 pmol on-column for 2-thiobarbituric acid and thiopental).

In the case of thiosulfate determination, the peak height increased with the iodine solution concentration within the range of 1–3 μ*M*; then the peak height stayed constant within the range of 3–6 μ*M*. The peak height decreased with increase in the iodine solution concentration above 6 μ*M*. The decrease in peak height is caused by the iodimetric reaction that competes with the induced postcolumn reaction for thiosulfate. The optimal iodide concentration was chosen to obtain an absorbance level at ~0.5 AU.

Addition of potassium iodide is necessary for dissolving iodine in water. Then the following equilibrium condition is attained

$$I_2 + I^- \rightleftarrows I_3^-$$

and the triiodide ion concentration is monitored. The degree to which the iodide ions may influence the course of the iodine–azide reaction depends on the inductor's properties. In the case of many sulfur compounds, it can be stated that an excess of iodide ions increases the consumption of iodine in the iodine–azide reaction with consequent lengthening of induction time. The influence of iodide ions on the course of the iodine–azide reaction applied as a postcolumn detection system in HPLC can be divided into three steps (Fig. 4):

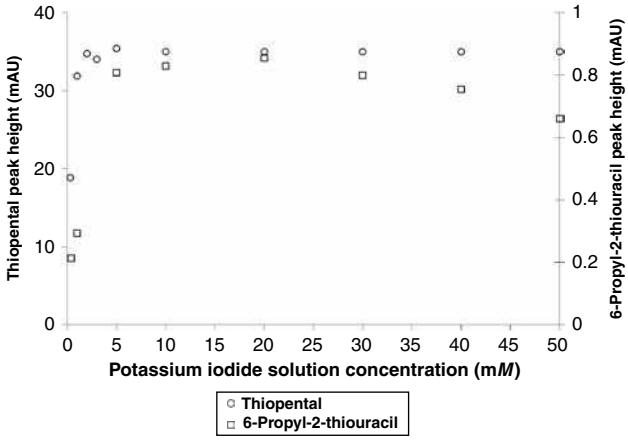

Fig. 4 The influence of potassium iodide solution concentration on peak height of thiopental and 6-propyl-2-thiouracil (2 pmol on-column for thiopental 0.2 pmol on-column for 6-propyl-2-thiouracil; for chromatographic conditions, see Tables 1–3).

1. The sulfur(II) compound peak height increases with the rise in the iodide ion concentration owing to the shift in the iodine–triiodide equilibrium that results in the growing concentration of triiodide ions.
2. The peak height is at its maximum value.
3. The peak height remains constant with the increase of the iodide ion concentration when the iodide ions do not have any impact on the course of the iodine–azide reaction induced by a particular sulfur(II) compound; or the peak height decreases with the increase of iodide ion concentration when the iodide ions hampered the course of iodine–azide reaction induced by a particular sulfur(II) compound (e.g., 6-propyl-2-thiouracil).

Postcolumn Reaction Module Temperature

An increase in postcolumn reaction temperature accelerates the oxidation reaction rate of a sulfur(II) compound to a non-inducing level. It has been found that a temperature maintained at 30–40°C level gives the highest sensitivity of determination.

Interferences

It is possible to eliminate matrix interferences by shifting the detection wavelength from the UV region (corresponding to sulfur(II) compound absorption) to the region corresponding iodine adsorption ($\lambda = 350$ nm). In general, the iodine–azide detection system allows only sulfur(II) compounds to be visible on chromatograms. However, four groups of additional peaks may be found on account of certain other compounds:

1. Iodine–azide reaction inductors (e.g., cysteine or cystine), which generate negative peaks.
2. Compounds that react with iodine under experimental conditions (e.g., ascorbic acid), which generate negative peaks.
3. Compounds that react with iodide ion [e.g., bromate(V), iodate(V), nitrate(III)], which generate positive peaks.
4. Compounds that absorb at 350 nm (e.g., sulfasalazine).

ANALYTICAL APPLICATION OF THE METHOD

The evaluated technique has been applied for the determination of sulfur ions (S^{2-}, $S_2O_3^{2-}$, SCN^-) and polithionates in hot-spring water and river water (at nanomolar level for thiosulfate, micromolar level for polithionates, and parts per billion level for sulfide ions).

Application of the elaborate HPLC method for the determination of thiopental, methimazole, thioguanine, and 6-propyl-2-thiouracil using the iodine–azide reaction detection system has been extended to include patient urine samples at the nanomol per milliliter level (Table 5). The chromatogram of a patient urine sample is shown in Fig. 5.

CONCLUSION

The discussed results confirm the potential and the beneficial effects of iodine–azide reaction as a detection reaction in HPLC. The proposed detection system allows

Table 5 Application of the method.

selective determination of various sulfur(II) compounds with high sensitivity. A postcolumn detection system using the iodine–azide reaction in HPLC is a fast, reliable, and inexpensive method; the required reagents are readily available chemicals and the analysis time is short.

The sensitivity of this method is comparable to, or better than, those of LC separation techniques for urine. The technique overcomes the limitations of and obstacles in conventional methods such as the use of expensive and frequently contaminated organic solvents and of tedious and time-consuming sample preparation [e.g., derivatization procedure, solid-phase extraction (SPE)] with satisfactory levels of sensitivity.

Moreover, the postcolumn reaction is compatible with the mobile phase of HPLC. The results from this study indicate that the proposed HPLC with the iodine–azide postcolumn reaction can potentially be used for routine clinical monitoring and in pharmacokinetic studies of thiols.

Ion Chromatography: Modern Stationary Phases

Rajmund Michalski
Institute of Environmental Engineering, Polish Academy of Science, Zabrze, Poland

Abstract
Because of the better understanding of the processes taking place at the surface of stationary phases, the number of ion-exchange materials for ion chromatography has increased significantly over recent years. As a result, the multitude of commercially available columns with their different selectivities for anion and cation separations and their determination is almost confusing. This entry is a review of stationary phases used in modern ion chromatography.

INTRODUCTION

Ion chromatography is based on an ion-exchange process taking place between the mobile phase and the ion-exchange groups bonded with the support material. The stationary phase used in ion chromatography consists of polystyrene (PS), ethylvinylbenzene (EVB), or methacrylate resins copolymerized with divinylbenzene (DVB) and modified with ion-exchange groups. Furthermore polyvinyl, silica-based, and many other materials are used. Stationary phases used in ion chromatography differ, not only in the type of support material, but also according to their different pore sizes and ion-exchange capacities. Improvements in eluent methodologies, novel detection modes, and particularly new highly selective and efficient stationary phases make ion chromatography a significant and competitive technique for solving analytical problems in many fields of interest. A review of modern stationary phases used for ion chromatography is given by Weiss and Jensen.[1] A comparison and critical appraisal of particle-packed columns and monolithic columns in high-performance liquid chromatography (HPLC) is described by Unger, Skudas, and Schulte.[2] In general there are three major criteria in characterizing an HPLC (including IC) column: hydrodynamic, kinetic, and thermodynamic properties. There are several major variables that distinguish ion-exchange stationary phases, such as structure of the bonded phase, including the chemistry of the functional group, charge density and related nominal capacity, and properties of the support matrix, including composition and pore diameter.

COLUMNS FOR ANION DETERMINATION

The application of ion-exchange phenomena in analytical chemistry is described by Walton and Rocklin.[3] Throughout many years in the past, a large variety of stationary phases with various selectivities and capacities have been developed for both anion- and cation-exchange chromatography.[4]

The major differences between classical ion-exchange chromatography and modern high-performance ion chromatography are the methods of sample introduction and the types of separation and detection systems used. In classical ion-exchange chromatography, columns are filled with anion- or cation-exchange resins having particle sizes between 75 and 250 μm. Earlier suppressed and non-suppressed ion chromatography required low column capacities. These columns were easily overloaded by high sample concentrations. Increasing suppression capacity has enabled ever-increasing eluent concentrations and, in turn, increasing column capacities.

At the beginning, with ion chromatography, column materials utilized particles greater than 40 μm and generated only about 120 and 300 theoretical plates efficiency. In the first commercial column used for IC (Dionex AS-1), the particle size was reduced to 25 μm and efficiencies increased to ~700 theoretical plates. Modern high-capacity columns have efficiencies over 5000 plates (for 4 × 250 mm column dimensions) and 5 μm particle size.[5]

Anion exchangers contain alkanol or alkyl quaternary amine functional groups, and their selectivity variation has been obtained by modifying the structures of the ion-exchange sites. Anion exchangers are divided into polymer-based anion exchangers [styrene–divinylbenzene (PS–DVB), ethylvinylbenzene-divinylbenzene EVB–DVB, polymethacrylate and polyvinyl copolymers], latex-agglomerated anion exchangers, silica-based, and others.[6]

Polymer-Based Anion Exchangers

In contrast to silica-based column packings usually used in classical high-performance liquid chromatography, in ion chromatography, organic polymers are often employed as the predominant support material. These resins show a

much higher stability over an extreme pH range, between 0 and 14, compared to silica-based materials (pH 2–8). Common carbonate eluents used with ion chromatography have a pH around 10, whereas hydroxide eluents have pH close to 12.

PS–DVB Copolymers

These copolymers are the most widely used packing materials for ion chromatography. In general, these kinds of columns can be divided into two groups, i.e., surface-aminated PS–DVB, and surface-aminated EVB–DVB copolymers.

A surface-functionalized polymer-based EVB–DVB is produced by grafting technology, which was first used for the preparation of stationary phases by Schomburg.[7] Various monomers are attached to the support material via cografting, and each of these monomers contributes its specific properties to the selectivity of the stationary phase, which can be modulated by varying the percentages of the comonomers. Surface-functionalized polymer-based EVB–DVB columns are produced by Dionex (Sunnyvale, U.S.A.).

The percentage of DVB in the resin is indicated as "percent cross-linking," which determines the porosity of the resin. The distinction is made between microporous and macroporous resins. Examples of commercially available PS–DVB and EVB–DVB columns used in anion-exchange chromatography are given in Tables 1 and 2, respectively.

Polymethacrylate and Polyvinyl Anion Exchangers

Methacrylate-based resins with quaternary amine functional groups are stable at pH 1–12. Anions can be separated using weak organic and inorganic acids. Macroporous polyvinyl resins are stable at pH 0–14, thus allowing the use of a large number of eluents. When compared with methacrylate materials, they exhibit lower chromatographic efficiency; however, these phases are suitable for separating analytes from complex samples. Examples of anion-exchange columns with polymethacrylate and polyvinyl phases are given in Tables 3 and 4, respectively.

Latex-Agglomerated Resins

A special type of peculiar anion exchanger was first introduced in 1975. These stationary phases, which are called latex-based anion exchangers, have been further developed by Dionex.[8] They comprise a surface-sulfonated PS–DVB substrate with particle diameters between 5 and 25 μm and are fully aminated, high-capacity, porous polymer beads made of poly(vinylbenzyl chloride) or polymethacrylate, which are called latex

particles. The latex particles have a diameter of about 0.1 μm and are agglomerated to the surface by electrostatic and van der Waals interactions.

By changing the degree of cross-linking and by varying the functional groups bonded to the latex it is possible to moderate the properties of final materials. Since the introduction of gradient elution in ion chromatography, in 1987, hydroxide-selective latex-based anion exchangers have also been developed.[9] Example of latex-agglomerated anion-exchange columns produced by Dionex are given in Table 5.

Silica-Based Anion Exchangers

The application of inorganic ion exchangers in chemical analysis is given by Quereshi and Varshney.[10] Contrary to organic polymers, silica-based substrates have the advantage of high mechanical stability. Moreover, chromatographic efficiencies of silica-based phases are very high (up to 20,000 theoretical plates), but they can only be used with eluents in the pH range between 2 and 8. Nevertheless, newer silica-based stationary phases have been developed.[11] The characteristics of some commercially available silica-based columns are given in Table 6.

Other Materials for Anion Separations

Inorganic and organic anions can also be separated on cross-linked polymers modified with cyclic ethers. Pioneering work in the field of adsorbing crown ethers onto chemically bonded reversed phases and PS–DVB polymers has been carried out by Kimura et al.[12] The number of applicable crown ethers is limited because of their limited solubility and high price. Moreover, crown ether resins are mechanically unstable and are therefore operated with low flow rates, thus resulting in long analysis times.

In 1994, Lamb et al.[13] developed a series of cryptand-based anion separators. The biggest advantage of cryptand columns, used in gradient elution mode, is the ability to elute non-polarizable and polarizable anions in the same run, which is very difficult (or even impossible) with latex-agglomerated anion exchangers and aminated grafted polymers.[14]

Although Al_2O_3 is one of the most common adsorbents used in liquid chromatography, it has seldom been used in the past for ion chromatography, because of the low ion-exchange capacity and the inadequate stability against strong acids and bases. Anion-exchange properties of aluminia can occur at pH values below the isocratic point, which depends on the type of eluent.

COLUMNS FOR CATION DETERMINATION

Like anion exchangers, cation exchangers are divided into polymer-based cation exchangers (PS–DVB, EVB–DVB, polymethacrylate, and polyvinyl copolymers), latex-agglomerated cation exchangers, silica-based, and other (e.g., crown ether, aluminia materials).[15] Modern cation exchangers contain sulfonic, carboxylic, carboxylic–phosphonic, and carboxylic–phosphonic–crown ether functional groups.

Polymer-Based Cation Exchangers

Styrene–divinylbenzene copolymers

These types of polymer resins are widely used as substrate materials for the manufacture of cation exchangers. Simultaneous analysis of mono- and divalent cations is not possible with surface-sulfonated cation exchangers; thus, they are used for sequential analysis of alkali and alkaline earth metals. The ion-exchange capacity is determined by the degree of PS–DVB sulfonation. The characteristic structural and technical properties of selected surface-sulfonated PS–DVB columns are summarized in Table 7.

EVB–DVB Copolymers

Because of various affinities toward strong acid cation exchangers, alkali and alkaline earth metals can only be analyzed sequentially on sulfonated PS–DVB. Simultaneous analysis of alkali and alkaline earth metals, as well as aliphatic amines, can be realized with acid cation exchangers using carboxyl groups as the ion-exchange functionality. Examples of cation-exchange columns produced by Dionex are given in Table 8.

Latex Cation Exchangers

Latex cation exchangers were introduced by Dionex Corp. 10 years later than latex-agglomerated anion exchangers. These types of cation exchangers consist of a weakly sulfonated PS–DVB substrate with latex beads with a very small diameter agglomerated on its surface by both electrostatic and van der Waals interactions.

In contrast to surface-sulfonated phases, latex cation exchangers exhibit a significantly higher chromatographic efficiency. Examples of Dionex latex cation-exchange columns are given in Table 9.

Other Cation-Exchange Resins

Although organic polymers are predominantly used for cation-exchange chromatography, silica-based exchangers are also used. These cation exchangers are only of minor importance, despite their comparatively high chromatographic efficiencies. Cross-linked polymers, modified with cyclic ethers, are also used in cation-exchange columns.[16]

NEW PERSPECTIVES AND CHALLENGES

The following general trends in the development of new stationary phases for ion chromatography can be identified: new stationary phases matrices and bonding chemistries; improvement of column efficiency, trend toward reduction in the diameter of separation column, and new chemistry of the bonded functional groups/layers.[17,18]

New directions in the development of stationary phases for various modes of ion chromatography are, among other things, zwitterionic ion exchangers. The combination of positively and negatively charged sites in a single particle, or within the functional groups of a single molecule attached to the surface of an absorbent, provides unique opportunities to vary the selectivity of separation.[19] This results in reduced shrinking and swelling, and improved mechanical stability of zwitterionic ion exchangers, in comparison to traditional ion exchangers. Moreover, these types of ion exchangers demonstrate unique separation selectivities and, often, simultaneous separation of anions and cations with a single column is possible.

In recent years, the interest in using porous silica and polymer-based monolithic stationary-phase media for ion chromatographic separations of inorganic and organic ions has increased.[20,21] As compared to particle bed columns, monolithic columns represent a single piece of porous cross-linked polymer or porous silica. Monoliths are made in different formats as porous rods, generated in thin capillaries or made as thin membrane or disks.

Ion exchangers based on polymeric monoliths have made an appearance, mainly for biomolecule separations; it will be of interest to see if such columns will be useful for the separation of smaller molecules. Monoliths, compared with packed columns, have recently decreased pressure drop requirements, allowing the use of longer columns.

The interest in monoliths appears to be the greatest in preparative and analytical chromatography, where high-throughput (short and fast columns) and/or high-efficiency (long columns) separations are required.[22]

Monolithic columns are applied in low- and medium-pressure ion chromatography, ultrafast ion chromatography, capillary chromatography, flow gradients, and double-gradient ion chromatography, and, also, multi-column/multidimensional ion chromatography.[23] Monolithic columns are considered, by many, to be a

more practical alternative to packed columns because they offer many advantages like packed columns, but without problems typical of packed columns.[24] The further expansion of monolithic columns is expected, both in classical ion chromatography and in microchip and capillary ion chromatography.[25]

CONCLUSION

The central and most essential part of an IC system is the separation column, and its stationary phase. The number of commercially available ion-exchange columns that have been developed for ion chromatography has increased impressively. The diversity of anion- and cation-exchange columns available today allows the ion chromatography user selection of stationary phase that is best suited for the required application. Nevertheless, the potential of packing and stationary phase design and development has not been explored to the full extent.

Ion Chromatography: Suppressed and Non-suppressed

Ioannis N. Papadoyannis
Victoria F. Samanidou
Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece

INTRODUCTION

Ion chromatography (IC) is a mode of high-performance liquid chromatography (HPLC) in which ionic analyte species are separated on cationic or anionic sites of the stationary phase. The separation mechanisms can be broadly compared to ion exchange, using fixed-site exchange resins of various composition and ion-interaction methods, using a variety of columns as substrates to support dynamically exchanged or permanently bonded ionic groups. Alternative approaches of minor significance also exist. The mobile phase is an aqueous buffer solution. The rate of migration of the ion (inorganic ions and organic acids and bases) through the column is directly dependent on the type and concentration of eluent ions. Retention is based on the affinity of different ions for the ion-exchange sites and on the competition between eluent buffer ions and analyte ions, which is dependent on the ionic strength of the buffer and can be adjusted by altering the pH of the mobile phase or the concentration of any organic modifier in it.

DISCUSSION

Ion chromatography operates at pressures ranging from several hundred to several thousand pounds per square inch. In most cases, the same chromatographic components (pumps, injectors, etc.) can be employed in both HPLC and IC. Most of the chromatographic principles developed in HPLC stand for IC also, with possible minor modifications. Injection volumes in ion chromatography are generally somewhat larger than those normally in HPLC, typically in the range 50–100 μl, in contrast to HPLC, where 5–20 μl are injected.

It was in 1975 when Small and his co-workers introduced the high-pressure operation mode of ion chromatography. In their original paper, they described a novel system for the chromatographic determination of inorganic ions, in which a resin was used for the separation and a second ion-exchange column was combined to chemically suppress the background conductance of the eluent, thus improving detection limits for eluted ions. Since 1975, IC has grown rapidly and ion chromatographic methods for ions are currently among the best available and have been applied to a wide range of inorganic species. This can be attributed to concurrent advances in separation technology and detection methods.

Detection techniques can be subdivided into three broad categories:

1. Electrochemical detection (using conductivity, amperometry, or potentiometry).
2. Spectroscopic detection (using ultraviolet/visible (UV/Vis) absorbance, refractive index, fluorescence, atomic absorption or atomic emission).
3. Techniques based on postcolumn reactions.

Conductivity detectors provide the advantage of universal detection, as all ions are electrochemically conducting. Thus, the majority of ion chromatography detectors rely upon conductivity measurements.

The principle of conductivity-detector operation is the differential measurement of conductance of the eluent, prior to and during elution of the analyte ion. The detector response depends on analyte concentration, the degree of ionization of both eluent and analyte (governed by the eluent pH), and limiting equivalent conductances of the eluent cation and of the eluent and analyte anions (where an anion-exchange system is considered). If the eluent and analyte are fully ionized, the signal is proportional to the analyte concentration and to the difference (positive or negative) in limiting equivalent conductances which determines sensitivity.

Conductivity detection provides a sensitive measure of ion concentrations in solution, but its measurement is hampered by high conductivity of the eluent, as ion exchange requires a competing electrolyte to displace the analytes from the column. In order to eliminate background conductivity and thus to improve the analyte signal, *H*, Smith et al., proposed the use of a second ion-exchange column. In this way, two different ion chromatography techniques are distinguished: eluent suppressed and non-suppressed (also called single-column ion chromatography) using different packing

materials and different eluents, leading to specific advantages and disadvantages for each technique.

ELUENT SUPPRESSED ION CHROMATOGRAPHY

Various schemes have been devised to improve the signal-to-noise ratio (S/N) by decreasing the background signal of the eluent/displacer or increasing the conductance of the analyte, or both.

The principle of conductivity suppression is the reduction of background conductivity by converting the eluent to a less conductive medium (H_2O) through acid–base neutralization while the analyte ions' conductivity is increased, by converting them to a more conductive medium: Anions are converted to their acid forms and cations to their hydroxide forms. These reactions lead to higher S/N ratios, thus significantly improving baseline stability and detection limits.

Suppressor devices include packed column suppressors, hollow-fiber membrane suppressors, micromembrane suppressors, suspension postcolumn reaction suppressors, autoregenerated electrochemical suppressors, and so forth.

The packed column suppressor, originally introduced by Small et al., suffers from a number of drawbacks, such as time shifts due to Donnan exclusion effects, band broadening (due to a large dead volume and high dispersion), and oxidation of nitrite, which is easily oxidized to nityrate, due to the formation of nitrous acid in the suppressor. Because of these limitations, they were only practical for isocratic elution. However, the main disadvantage of the method is the necessity for periodical regeneration of the suppressor (also called stripper) to restore its ion-exchange capacity.

For anion analysis, the regenerant must supply a source of hydrogen ions to convert the eluent anions to a less conductive form. The most common regenerant is dilute sulfuric acid, whereas for cation analysis, the most common regenerant is hydroxide (sodium, potassium, or tetramethylammonium hydroxide).

The preferred eluents for anions are dilute carbonate–bicarbonate mixture, sodium hydroxide and, for common alkali metals and simple amines, dilute mineral acids (HCl, HNO_3, $BaCl_2$, $AgNO_3$, amino acids, alkyl and aryl sulfonic acids). The most common choice is HCl, but in the case of divalent ions, an eluent of much higher affinity for the ion-exchange resin, such as $AgNO_3$, must be used.

Typical neutralization reactions for chemical suppressors are as follows:

Anion-exchange chromatography:

Eluent reaction: $NaOH + resin\text{–}SO_3^-H^+ \rightarrow Resin\text{–}SO_3^-Na^+ + H_2O$

Analyte reaction: $NaX + resin\text{–}SO_3^-H^+ \rightarrow Resin\text{–}SO_3^-Na^+ + HX$, where X = anions ($Cl^-$, Br^-, NO_2^-, etc.).

Cation-exchange chromatography:

Eluent reaction: $HCl + resin\text{–}NR_3^+OH^- \rightarrow Resin\text{–}NR_3^+Cl^- + H_2O$

Analyte reaction: $MCl + resin\text{–}NR_3^+OH^- \rightarrow Resin\text{–}NR_3^+Cl^- + MOH$, where M = cations ($Na^+$, K^+, etc.).

The reaction, in the case of bicarbonate, yields the largely undissociated carbonic acid that does not contribute significantly to the conductivity.

Without chemical suppression, the contribution to the total measured conductivity from the eluent is many orders of magnitude higher than that from the analyte, leading to low sensitivity (Fig. 1).

Some of the drawbacks that packed column suppressors have were eliminated when hollow-fiber membrane suppressors were introduced in 1981. These were found to be even more convenient and efficient, with low dead volume and high capacity, and they are dynamically regenerated. Eluent passes through the core of the fiber and regenerant washes the outside. However, they have also limited suppression capacity and are restricted only to isocratic operation.

Micromembrane suppressors introduced in 1985 use thin, flat ion-exchange membranes to enhance ion transport while maintaining a very low dead volume, providing a high suppression capacity, with low dispersion.

Later, electrochemically regenerated suppression modules were introduced, where an electrochemical process is used to regenerate a solid-phase chemical suppressor for continuous reagent-free operation. Self-regenerating suppressors are similar to micromembrane suppressors, except that regenerant hydronium and hydroxide ions are produced, *in situ*, by electrolysis of water supplied by recycle or an external source.

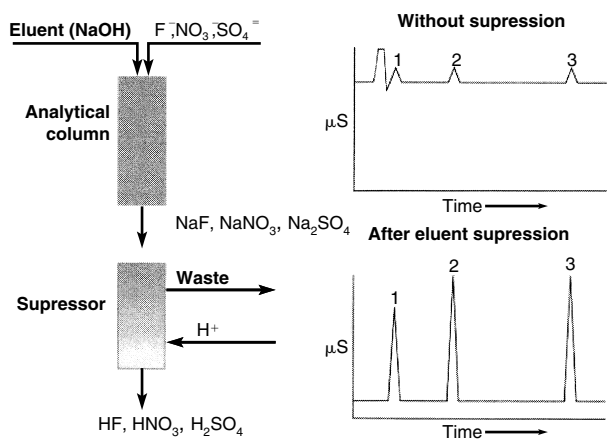

Fig. 1 The effect of the background conductivity suppression on the monitored signal of the analyte anions, after separation by means of ion chromatography. Peaks: 1 = fluoride, 2 = nitrate, 3 = sulfate.

This is achieved by incorporating electrodes inside the regenerant chambers; thus, external acid or base supply are unnecessary. The two electrolysis reactions taking place are

Anode: $2H_2O \rightarrow 4H^+ + O_2 + 4e$

Cathode: $2H_2O + 2e \rightarrow H_2 + 2OH^-$

Another technique of improving the S/N ratio is the one that uses postcolumn addition of a solid-phase reagent (SPR), which is a colloidal suspension of ultrafine ion-exchange particles. The SPR reacts with the analyte to increase its conductivity. Additionally, the SPR has a low electrophoretic mobility and, hence, conductance. This technique avoids the dead time due to suppressor column and also eliminates the regeneration cycle.

NON-SUPPRESSED SINGLE-COLUMN ION CHROMATOGRAPHY

Another approach of ion chromatography is the non-suppressed single column, in which no suppressor device is used. In this case, the only method for improving the sensitivity is to maximize the difference between mobile-phase conductivity and analyte conductivity.

Non-suppressed single-column ion chromatography (SCIC) was introduced in 1979 by Gierde and coworkers, based on a two-principal innovation:

1. The use of a special anion-exchange resin of very low capacity (0.007–0.007 mEq/g).
2. The adoption of an eluent having a very low conductivity, which can be passed directly through the conductometric detector. Typical eluents used are benzoate, phthalate, or other aromatic acid salts, with low limiting equivalent conductances (leading to direct detection) or potassium hydroxide eluent, with high conductivity for anions or dilute nitric acid for cations, leading to indirect detection mode (decrease of conductivity as the analyte is eluting).

The major limitation of non-suppressed conductivity detection is that gradient systems cannot be used; thus, the background conductivity remains constant.

Virtually every type of HPLC detector can be combined with SCIC: refractive index, UV absorbance (direct and indirect), electrochemical, and so forth.

A typical non-suppressed SCIC separation obtained with a low-capacity resin-based strong anion exchanger (PRP-X100 Hamilton) used as the analytical column is illustrated in Fig. 2 for the simultaneous determination of eight inorganic anions (F^-, Br^-, NO_2^-, Cl^-, NO_3^-, PO_4^{3-}, SO_4^{2-}, CO_3^{2-}), with conductometric detection, using a mixture of 2.0 m*M* sodium benzoate and 2.5 m*M* *p*-hydroxybenzoic acid (pH 9.0 adjusted with 1*N* NaOH) as eluent, with the organic modifier methanol 8% v/v, at a flow rate of 0.7 ml/min. The detection limits (S/N = 3) were 100 μg/L for carbonate and 50 μg/L for the rest of the cited anions, when 50 μl of the samples were injected onto the analytical column.

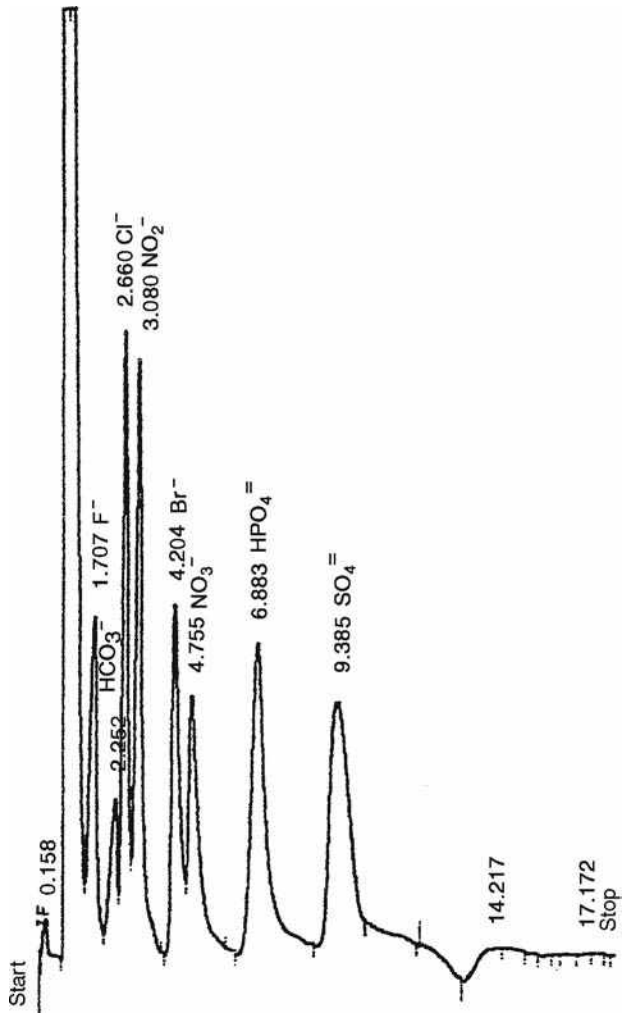

Fig. 2 Non-suppressed SCIC determination of eight inorganic anions.

COLUMNS

Two types of packing materials are commonly used for ion chromatography: silica-based and polymer-based ion exchangers. The polymer-based ion exchangers typically contain a PSDVB (polystyrenedivinylbenzene) backbone, lightly sulfonated (cation exchanger) or lightly aminated (anion exchanger), whereas the silica-based ion exchangers use a porous silica bead, chemically prepared to form

the anion or cation exchanger. The resins have the advantage that they can be used over the entire pH range, whereas silica based materials can be used in a narrow working pH range (2–6.5).

Detection limits for ions vary with the sensitivity of the detector, with the volume of sample injected, and with the identity, concentration, and pH of the eluent, as well as with chromatographic factors, such as column efficiency and so forth.

COMPARISON OF ESIC AND SCIC

The main advantages of eluent suppressed ion chromatography (ESIC) are that a wide range of eluents and columns can be used, the wide dynamic range, and the higher sensitivity; the main disadvantage is the periodical necessity for suppressor-column regeneration.

On the other hand, SCIC is rapid, sensitive, with easy sample preparation, and simple instrumentation; however, it requires a significant difference in conductance between eluent and analyte ions and the temperature stability is crucial. The answer to the question of which IC technique is most efficient is dependent on several considerations, such as the nature of sample analytes, the concentration of the solute ions, the sensitivity required, the equipment available, and so forth.

APPLICATIONS

Ion chromatography, suppressed and non-suppressed, can be applied both to anion and cation analysis. The current situation is that the methods for anion determination have far outnumbered those for cation analysis, for the reason that there are available methods for the latter, which are rapid and sensitive (e.g., AAS, ICP, ASV). It is difficult to mention all the ionic species detectable by this analytical technique. Practically, any compound that can be converted to an ionic form is amenable to analysis by IC. Among the inorganic ions determined are (F^-, Br^-, NO_2^-, Cl^-, NO_3^-, PO_4^{3-}, SO_4^{2-}, CO_3^{2-}, CrO_4^{2-}, I^-, IO_3^-, $C_2O_4^{2-}$, BrO_3^-, SCN^-, Na^+, K^+, Mg^{2+}, Ca^{2+}, NH_4^+, at the ppm or ppb levels, in drinking water, food samples, food additives, beverages, environmental samples (soil extracts, rain water, surface water or groundwater), cosmetics, pharmaceuticals, biomedical, plating bath analysis, biological fluids, industrial process products, wastewater, and so forth. IC is also capable of speciation analysis of polyvalent anions or transition metal ions with multiple oxidation states, at levels lower than those possible with ICP or AAS. Organic species of biological and biochemical interest can also be determined.

Ion Chromatography: Water and Waste Water Analysis

Rajmund Michalski
Institute of Environmental Engineering, Polish Academy of Science, Zabrze, Poland

INTRODUCTION

Water and waste water are important areas of chemical analysis. The development of new methods and improvement of existing ones are major tasks for analytical chemists. There is a need for strict control and monitoring of many substances present in water and waste water to prevent contamination and to protect our natural resources.

Substances present in various types of water may be classified as biological, chemical (both inorganic and organic), physical, and radiological impurities. In many laboratories within the confines of routine analysis, the most frequently determined species are inorganic anions and cations.

Until 1975, only a small range of analytical parameters could be measured automatically; therefore, it was necessary to develop and validate new methods to extend the scope of such parameters. An alternative, introduced in 1975, that has almost replaced most of the wet chemical methods used in water analysis is ion chromatography.

Ion chromatography is an attractive technique, especially for laboratories that need to determine numerous anions and cations in several thousand samples but do not have the throughput to justify the purchase of large automatic analyzers that are usually based on colorimetric procedures. Ion chromatography eliminates the need to use the hazardous reagents that are often integral to wet chemical methods.

Regulator demands for justifiable analytical results and laboratories' needs for validated methods have led to the necessity for standardized ion chromatography methods. This entry reviews standard ion chromatography methods for determination of inorganic anions (F^-, Cl^-, NO_2^-, NO_3^-, BrO_3^-, ClO_2^-, ClO_3^-, PO_4^{3-}, SO_3^{2-}, SO_4^{2-}, CrO_4^{2-}, I^-, SCN^-, and $S_2O_3^{2-}$) and cations (Li^+, Na^+, NH_4^+, K^+, Mn^{2+}, Ca^{2+}, Mg^{2+}, Sr^{2+}, and Ba^{2+}) in water and waste water.

ION CHROMATOGRAPHY AS A REFERENCE METHOD

Water is considered to be one of the basic substances supporting life and the natural environment, a primary component for industry, a consumer item for both humans and animals, and a vector for domestic and industrial pollution. Various directives provide a framework for the control of aquatic substances, the quality of bathing, surface, and drinking water and effluents.

The number of species determined in water has grown exponentially during the past 50 years. However, very few have been studied or have led to documented proof of their health effects.

Nearly half of the monitored parameters are being measured for operational reasons (e.g., iron, ammonium, pH, chloride, dissolved organic carbon) and for reasons of customer satisfaction (e.g., color, taste, total hardness).[1] Of the health-related substances, a number of metals and small groups of organic compounds and pesticides, in most countries, are being measured on a regular basis. They include such metals as antimony, arsenic aluminum, chromium, magnesium, magnum, cadmium, copper, nickel, lead, mercury, and iron, as well as inorganic ions (ammonium, fluoride, nitrite, nitrate, and cyanide) and organic compounds (e.g., benzo(a)pyrene, trihalomethanes, chlorobenzenes, pesticides). Recently, inorganic oxyhalide disinfection by-products such as bromate, chlorite, and chlorate have also begun to be measured.

The United States Environmental Protection Agency (USEPA) has established regulations and methodology for inorganic contaminants under the Safe Drinking Water Act. Fluoride, nitrate, and nitrite are limited as primary pollutants because they can cause adverse health effects. For instance, high levels of fluoride cause skeletal and dental fluorosis and nitrite and nitrate overexposure can cause methemoglobulinemia that can be fatal to infants. Other common inorganic anions, e.g., chloride and sulfate, are considered as secondary contaminants and are responsible for water taste, odor, color, and certain other aesthetic effects.

The determination of common inorganic anions (fluoride, chloride, nitrite, bromide, nitrate, phosphate, and sulfate) and cations (sodium, potassium, magnesium, and calcium) was traditionally carried out using wet chemical methods such as gravimetry, titration, photometry, turbidimetry, and colorimetry.

Many of these methods suffer from interferences and limited sensitivity and they can be labor intensive and difficult to automate. Although performance criteria (accuracy, precision, and limit of detection) can be specified for analytical methods, it is still difficult to obtain similar results in different laboratories. For example, there are over 200 available methods to assay for

sulfate and nitrate. Unfortunately, most of those methods are characterized by a lack of sensitivity or selectivity and they are difficult and cumbersome to use.

One of the prime analytical chemists of the twentieth century, Professor Harvey Diehl of Iowa State University, proposed that the Nobel Price should be given to the scientist that develops a better method for sulfur analysis than gravimetry or nephelometry. Today, we can say that ion chromatography has met this challenge.[2]

In 1975, Small et al.[3] described a novel ion-exchange chromatographic method for the separation and conductometric detection of ionic species. They employed a low-capacity ion-exchange stationary phase for the separation of analyte ions, in conjunction with a second ion-exchange column and conductivity detector that allowed for continuous monitoring of eluent.

In September 1975 ion chromatography was publicly presented at a meeting of the American Chemical Society where the Dionex Corporation exhibited the first commercially available instrument for performing ion chromatography.[4] Several years later, Gjerde et al.[5] developed a variety of ion chromatography, a non-suppressed ion chromatography techniques.

Ion-exchange is the primary separation mode used with modern ion chromatography, although other approaches used for separation of inorganic anions and cations include ion interaction, ion exclusion, and chelation chromatography. Ion chromatography, with suppressed conductivity detection, is the most widely used and generally offers the best performance.

Analyzed ions are separated on the ion-exchange column and these ions, together with the eluent, are moved to the suppressor. In the suppressor, the conductance of the eluent is lowered, or suppressed, and the conductance of the sample ions is increased, leading to a large increase in the signal-to-noise ratio of the detection signal.[6] The conceptualization of suppressed conductivity by Small et al.[3] was the seminal idea in the development of ion chromatography. The development and use of suppression devices for the conductometric detection of inorganic ions by ion chromatography was described by Haddad et al.[7]

In recent years, a large variety of stationary phases, with different selectivities and capacities, have been developed for both anion-, and cation-exchange chromatography. The stationary phases used in ion chromatography have usually been polystyrene–divinylbenzene (PS–DVB), polymethacrylate, and polyvinyl resins. Recently, there has been an increasing interest in using porous monolithic stationary phases for high-performance separation of inorganic and organic ions.[8]

A variety of eluents can be used in the separation of anions; although bicarbonate eluents have been used as the mainstay eluent in suppressed ion chromatography. The ideal eluent seems to be hydroxide since, after suppression, it forms water that has virtually zero conductance and, therefore, provides the perfect conductivity baseline. However, hydroxide eluent is difficult to use because it readily absorbs carbon dioxide and forms carbonate.[9] The most popular eluents used in cation analysis are low concentration mineral acids such as HCl, HNO_3, and H_2SO_4, also containing organic modifiers (e.g., ethylenediamine, 2,3-diaminopropionic acid).[10]

Through the choice of stationary phase and eluent composition, the selectivity can be modulated, but the eluent must meet the requirements of the detection system. Although the conductivity detector is still the most popular, other types of detection can be applied for different analytes. These include electrochemical (amperometric, pulsed and integrated amperometric, potentiometric), photometric (UV–Vis, indirect photometric following post column derivatisation, chemiluminescence, refractive index), and fluorescence.

Ion chromatography plays a very important role in hyphenated techniques used in species analysis.[11] Coupling techniques represent the link of ion chromatography systems with an independent analytical detection method, usually spectroscopic (AAS-Atomic Absorption Spectroscopy, ICP-AES-Inductively Coupled Plasma Atomic Emission Spectroscopy, ICP-MS-Inductively Coupled Plasma-Mass Spectrometry[12]).

Ion chromatography can be used for the determination of ionic solutes such as inorganic anions, inorganic cations (including alkali metals, alkaline earth metals, transition metals, and rare earth metals), carboxylic, phosphonic and sulfonic acids, detergents, carbohydrates, low molecular weight organic bases, and ionic metal complexes.

It is applicable for the determination of ions in many sample matrices although the determination of inorganic ions in water continues to be the most widely used application. Ion chromatography offers several advantages over conventional methods for determination of inorganics:

- short time of analysis;
- sensitivity at the μg/L level;[13]
- high selectivity in samples with complex matrices;[14]
- simple water sample pretreatment;[15]
- small sample volume;
- simultaneous determination of anions and cations, or inorganic and organic ions;[16]
- species analysis (e.g., $NO_2^-/NO_3^-/NH_4^+$; $SO_3^{2-}/SO_4^{2-}/S^{2-}$; $H_2PO_4^-/HPO_4^{2-}/PO_4^{3-}$; Br^-/BrO_3^-; $Cl^-/ClO_2^-/ClO_3^-/ClO_4^-$;Cr(III)/Cr(VI); Fe(II)/Fe(III));[17]
- use of cheap, safe, and environment friendly chemicals.

Acceptance of ion chromatography for anion analysis was very rapid, primarily due to the lack of alternative methods that could determine multiple anions in a single analysis. However, the situation regarding the analysis

of cations was quite different because of many rapid and sensitive spectroscopic methods such as AAS, ICP-AES, ICP-MS, as well as polarography and stripping voltammetry.

Ion chromatography provides a straightforward method for the simultaneous determination of alkali and alkaline earth cations and ammonia. A key benefit of this approach is the ability to detect ammonia in complex samples that contain both inorganic cations and organic amines, as the latter compounds can interfere with the conventional colorimetric or ion selective electrode methods used for ammonia analysis.

More than 15 years ago, capillary electrophoresis appeared as a promising substitute for ion chromatography, mainly because of its higher speed of separation. Comparison of ion chromatography and capillary electrophoresis has shown that these techniques can be considered as being complementary rather than competitive.[18] Nevertheless, until now there were no international standards applied for capillary electrophoretic methods.

Standardization of Ion Chromatographic Methods

Regulators and clients expect to receive accurate and comparable results from a laboratory. Legislators generally define which of various validated methods should be applied to analyze environmental water samples. In general, standard methods can be chosen to serve as reference methods, but the laboratory serving a public client should apply official reference methods.

The best methods for inorganic anion and cation determinations should meet the following criteria:

- determination of target ions with limit of determination of 25% of maximum acceptable concentration;
- simple sample treatment;
- short analysis time;
- low cost of single analysis;
- method availability.

Ion chromatography methods meet these requirements and can be used for routine applications in environmental laboratories. Considering that several individual wet chemistry methods for common inorganic anions or cations could be replaced by one fast and reliable chromatographic separation, it is not surprising that ion chromatography has quickly become accepted worldwide by regulatory bodies to be used for the analysis of anions and cations in water and waste water. However, there are relatively few regulatory methods for cations analysis that use ion chromatography.

Standardization on the international level is the responsibility of International Standardization Organization (ISO). ISO Technical Committee 147, founded in 1971, is responsible for the standardization in the field of water quality. Ion chromatography methods have been developed, especially for drinking and waste water analyses; however, other applications (e.g., rain water, swimming pool water) are acceptable as well. During the standardization process, the draft standard methods have to go through a validation procedure, including checks for accuracy, precision, recovery, and, finally, an interlaboratory trial before they are published as standard methods.

The normative part of an analytical standard method in ISO includes at least the following clauses: scope, normative references, interferences, principle, essential minimum requirements, reagents, apparatus, quality requirements for the separator column, sampling and sample pretreatment, procedure, calculation, expression of results, and test report.

Methods can be deleted from the standards system if they do not pass the approval stage successfully, a confirmation after 5 years is refused, or there is a replacement of an existing standard by a new one.[19] The philosophy of setting standards in ISO and the US EPA is different. ISO prefers documents that do not specify trademarks or equipment produced by a single manufacturer.

In 1993, the USEPA published Method 300.0—the first USEPA method widely accepted as the standard for common inorganic anions.[20] Soon, this method was updated to include part B for the determination of bromate and other inorganic disinfection by-products using a modern high-capacity anion exchange column with carbonate/bicarbonate eluent.

Many different regulatory agencies use the same methodology as USEPA Method 300.0; however, each agency has a unique method format and style. Also, differences exist in the methods of quality control.[21]

Standard methods can be adopted as recommended on a voluntary basis by any laboratory around the world. Governments can decide to incorporate existing standards into their national standards.

After the publication of USEPA and, particularly, ISO ion chromatography standards concerning ion chromatography, the number of laboratories applying this technique has increased dramatically. For those laboratories, ion chromatography is a reliable and economical supplement to existing wet chemical methods.

Ion chromatography can be considered to be a well-established, mature technique for the analysis of anions and cations and many organizations, such as ISO, US EPA, ASTM (American Society for Testing and Materials), and AOAC (Association of Official Analytical Chemists) base their standards or regulatory methods of analysis upon it.

From 1992 to 2005, five ion chromatography standards concerning ion determination in water and waste water have been published. Only one standard concerns cation determination. All ISO ion chromatography standards are

based on suppressed conductivity detection, although two of them (ISO 10304 part 3, and part 4) allow the use of UV–Vis and amperometry detection modes.

The USEPA published seven ion chromatography methods, three of which (Methods: 317.0, 321.8, and 326.0) concern determination of oxyhalide disinfection by-products (bromate, chlorite, and chlorate). It is noteworthy that two USEPA Methods (314.1, and 332.0) published the analysis of perchlorate, which is a new challenge for analytical chemistry.

CONCLUSIONS

Ion chromatography is an innovative analytical technique that has significantly improved analysis of ions in water and waste water. The most routine ion chromatography methods have been standardized over the last 20 years.

The most important advantages of ion chromatography are: a broad range of applications, well-developed hardware, many detection options, reliability (good accuracy and precision), high selectivity, high speed, high separation efficiency, good tolerance to sample matrices, and low cost of consumables. With this included, ion

chromatography is widely accepted as the standard reference methodology for water and waste water analysis. Ion chromatography separation will continue to be developed as more and more inorganic contaminants (e.g., perchlorate, chromate, cyanide) become regulated at lower and lower levels in the future.

Ion Exchange: Mechanism and Factors Affecting Separation

Karen M. Gooding
Eli Lilly and Company, Indianapolis, Indiana, U.S.A.

INTRODUCTION

Ion-exchange chromatography (IEC) is a technique in which ionic solutes bind to charged functional groups on the bonded phase. The power and versatility of IEC as an analytical and preparative technique is due in large part to the ability to drastically change the selectivity through manipulation of the mobile phase. Although it is obvious that the pH determines the charge on the support and the analytes, the nature of the salt is an equally important parameter. The constituent ions of the salt associate with the support functional groups and/or those of the solute, yielding distinct ionic interactions. Mobile-phase additives, temperature, and gradient conditions also contribute to the separation in IEC.

MOBILE PHASE

pH

Adjustment of the pH is a critical factor in IEC because the pH dictates the charge of both the solutes and the ion exchanger, thus controlling their affinity for one another or their ability to release from a bound state. The essential nature of pH in the process necessitates its exact control; therefore, any mobile phase used for IEC should contain an effective buffer (0.02–0.1 *M*) within its optimum pH range. Some common buffers which cover much of the range of pH used in IEC are phosphate, citrate, acetate, and tris(hydroxymethyl) aminomethane (Tris).[1,2] The pH should be selected to yield ionization of the functional groups on the support as well as those on the analytes. For molecules with a single charge, the pH should be at least two units from the p*K* in the direction of ionization. The guideline for zwitterions is that the pH be at least two units from the isoelectric point (p*I*). A pH near neutrality is often effective for complex mixtures of diverse substances. Even carbohydrates, whose hydroxyl groups do not ionize until the pH is greater than 12, can be separated by IEC when the pH is adjusted to a high enough value with low concentrations of base as the mobile phase.[3]

The choice of pH for IEC of proteins or other macromolecules is not as simplistic as it is for small molecules. Although using the p*I* as a guide frequently yields an adequate separation, the p*I* encompasses all the charged groups in the molecule, whereas, because of their defined tertiary structures, only the surface amino acids of proteins are actually involved in the binding. Under denaturing conditions, more amino acids are likely to be exposed to the bonded phase.

Salt Concentration

IEC is a very predictable technique because the mechanism is well defined. The capacity factor (k) for the binding of an ionic solute to an ion-exchange functional group in IEC is directly related to the concentration (c) of salt in the mobile phase:

$$\log k = \log K_0 + Z_c \log\left(\frac{1}{c}\right)$$

where K_0 is the distribution coefficient and Z_c is an experimentally determined parameter that reflects the apparent number of ionic charges associated with the process of a specific solute with a specific surface.[4] For isocratic separations of simple molecules with up to several charges, the analysis time can be optimized along with resolution by adjustment of the salt concentration. For more complex analytes or mixtures, salt gradients are often necessary to achieve acceptable separations. Generally, a gradient from 0 to 1 *M* salt in a buffer at a suitable pH will yield a preliminary separation.

An opposite mechanism to ion exchange occurs when the ionic strength is too low. Ion exclusion is a phenomenon in which a charged analyte is repelled by the like charges within a pore. This is very likely to occur if water is used alone as the mobile phase with ion-exchange supports or with other modes of silica-based columns. Adding buffer and salt usually eliminates the problem.

Salt Composition

Elution with increased concentrations of salt is the most common and readily controlled method of achieving displacement of molecules which are strongly bound by an ion exchanger. The salt counterions competitively displace solute ions from the charged sites on the stationary phase. Smaller, more highly charged ions are most effective at this displacement. Specifically, the strength of displacement for cations

$$Mg^{2+} > Ca^{2+} > NH_4^+ > Na^+ > K^+$$

is and for anions, it is

$$SO_4^{2-} > HPO_4^{2-} > Cl > CH_3COO^-$$

The strength of the ions for displacement is not necessarily related to optimum selectivity or resolution. Selectivity is dictated by the effect of the salt on both the solute and the bonded phase. Besides displacing the solute from the support, either of the ions of the salt can complex with the ion-exchange functional group or the solute, alter the tertiary structure of the solute, or enhance hydrophobic properties. It is this combination of effects which results in selectivity. For example, when a mixture of proteins was run on a polyethyleneimine (PEI) weak anion-exchange column with gradients formed with 1.0 *N* salt, substitution of sodium acetate for sodium phosphate produced not only longer retention but also much better resolution of the proteins.[5] Sodium phosphate produced narrower peaks with less tailing, but the peaks had only slight differences in retention. In this case, the short retention was proven to be due to a special affinity of phosphate for PEI, which did not occur with anion-exchange supports having quaternary (*Q*) or diethylaminoethanol (DEAE) functional groups. The salt effects on selectivity encompass anions and cations in both anion-exchange and cation-exchange chromatography, as illustrated in Fig. 1, implying that the selectivity occurs because of ionic interactions with the functional groups of both the support and the solute. In the case of adenosine 5-diphosphate (ADP), divalent ions like calcium can bridge between the oxygens in the phosphate and thus reduce the ionic properties. Phosphate salts reduce the retention of ADP on PEI supports due to the phosphate–PEI affinity discussed earlier. Another example of ion-based selectivity is the excellent resolution obtained for sugars when a calcium salt is used with a cation-exchange resin. This ability to change selectivity so dramatically by varying the salt significantly broadens the utility of IEC.

The only restrictions on the choice of salt are those involving analyte solubility or stability. Volatile salts such as ammonium acetate even allow IEC to be interfaced with

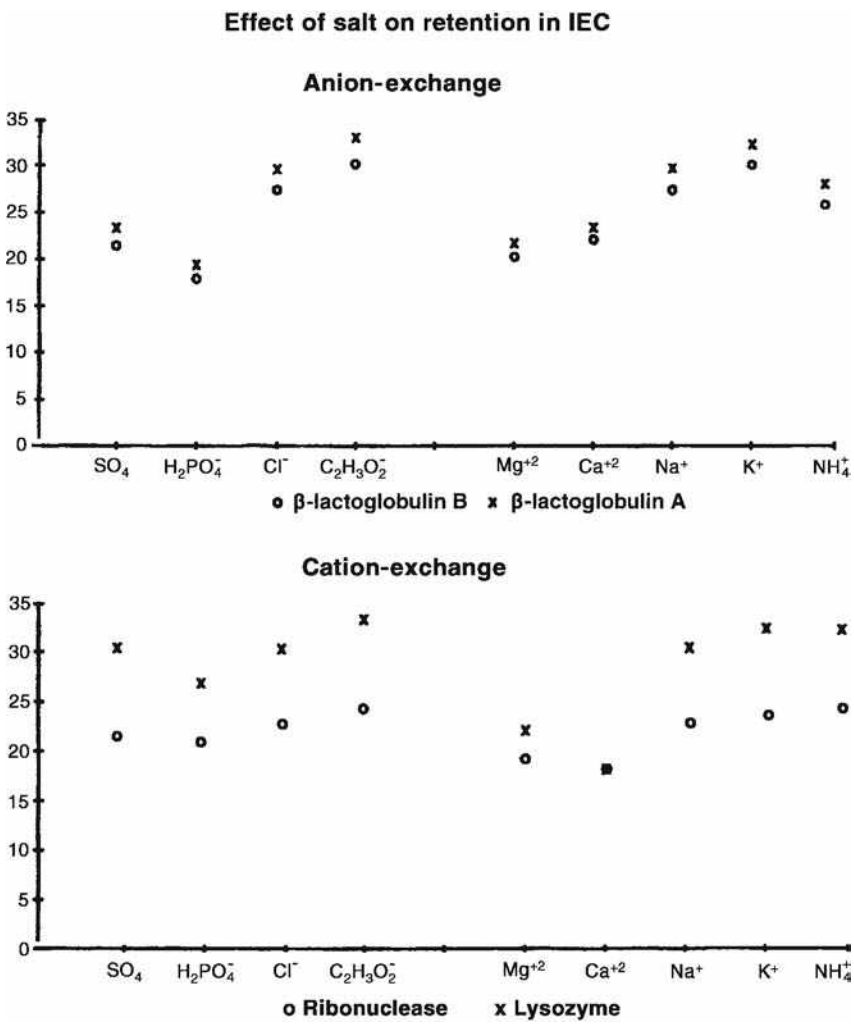

Fig. 1 Anion-exchange chromatography (AEX): SynChropak AX300 (polyethyleneimine, 300 Å, 6 μm); cation-exchange chromatography (CEX): SynChropak CM300 (carboxymethyl, 300 Å, 6 μm); 30 min gradient (0–1*N*) of sodium or chloride salts in 0.02 *M* Tris, pH 7.

mass spectrometry or evaporative lightscattering detection. It is very important that a given salt be totally stripped from a support before changing to other ions to avoid mixed ion effects. An acid such as trifluoroacetic acid is often effective as a bridge/washing solvent for this purpose.

SURFACTANTS AND ORGANIC SOLVENTS

Secondary separation which may be present in IEC is generally size exclusion or hydrophobicity. Size exclusion will occur if macromolecules are larger than the pores in a support. Hydrophobic interactions are most often observed under conditions of high salt for solutes with significant non-polar characteristics, such as certain peptides. The hydrophobicity of an ion-exchange support is due to either the matrix or the cross-linking agents which were employed in the synthesis of the bonded phase. Any hydrophobic interactions are fundamentally undesirable and can be minimized by the addition of 1–10% of an organic solvent, such as methanol, ethanol, or acetonitrile, to the running buffer. The solubility of the salt in the organic mobile phase should always be verified to avoid precipitation.

Non-ionic detergents may also reduce hydrophobic interactions with a column. These detergents, such as CHAPS or urea, can also be added to ion-exchange mobile phases to aid in the solubilization of membrane or other insoluble proteins. Such detergents are easy to equilibrate and remove from ion-exchange columns; however, ionic detergents should be avoided because of their very strong binding to the column or the solutes.

FLOW RATE AND GRADIENT

Small molecules can often be effectively separated isocratically by IEC; however, due to multipoint interactions, isocratic IEC of proteins and most biological macromolecules is not usually feasible, yielding no resolution and extreme tailing. Such complex molecules are generally separated by gradient elution.

As a salt gradient proceeds to higher levels in IEC, molecules elute at a specific salt concentration, generally without binding from secondary effects. The relationship of gradient conditions to elution (k^*) can be described by

$$k^* = 0.87 t_G \frac{F}{V_M} \left(\log \frac{C_2}{C_1} \right) Z$$

where C_1 and C_2 are the total salt concentrations (salt plus buffer) at the beginning and the end of the gradient, respectively, Z is the effective charge on the solute molecule, F is the flow rate; V_M is the total mobile-phase volume, and t_G is the gradient time.[6] The Z number will vary with solute and pH. An initial ion-exchange protocol of a 20–30 min linear gradient from 0–1 M salt in a buffer at a suitable pH will usually yield a separation which can be later optimized, if necessary. For shortest analysis times, a gradient should begin at the highest salt concentration where the analytes are bound and it should end at the lowest ionic strength that causes elution. The pH gradients may also be used to elicit elution during IEC, although this has been a less popular strategy than salt gradients. Ion-exchange columns can be effectively washed with a mobile phase of higher ionic strength than the upper gradient limit or with low pH. For gradients, intermediate flow rates of 1 ml/min for a 4.6 mm inner diameter column are usually satisfactory.

TEMPERATURE

The use of elevated temperature in IEC reduces the mobile-phase diffusion coefficient and concomitantly

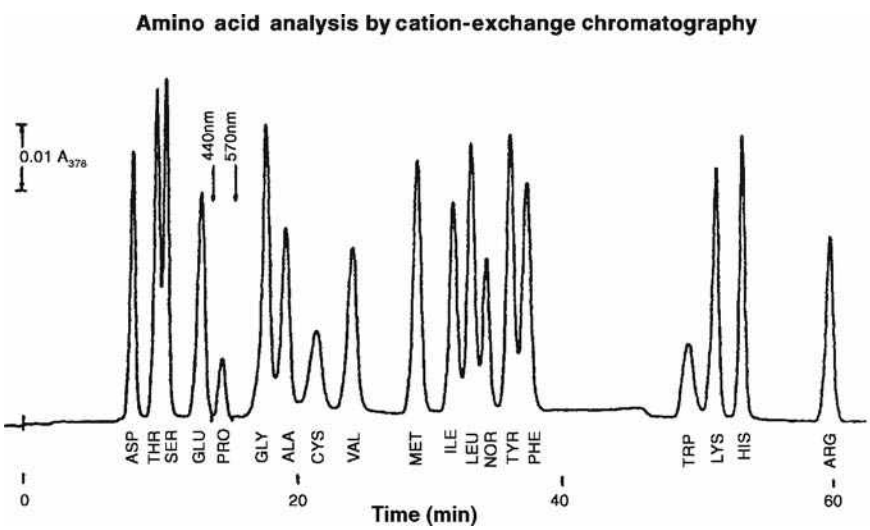

Fig. 2 Column: Micropak AA (sulfonated polystyrene); solvent A: 0.2 M sodium citrate, pH 3.25; solvent B: 1 M sodium citrate, pH 7.40. Gradient: 5 min 100% A; 100–75% A in 20 min; 75–70% A in 5 min; 70–35% A in 5 min; 10 min 35%; 35–0% A in 1 min. $T = 50°C$ for 25 min, then 90°C. Detection after ninhydrin postcolumn reaction.
Source: Reprinted from Amino acid analysis with ninhydrin postcolumn derivatization, *LC at Work*, Varian Associates, with permission.

decreases band spreading. Most mobile phases in IEC are composed of water with salts and thus produce efficiencies which are less than those obtained in modes using organic solvents. Because increased temperatures decrease retention, they may permit the use of lower salt concentrations. Elevated temperatures have been especially effective in amino acid analyses by cation-exchange chromatography, as illustrated in Fig. 2.

CONCLUSIONS

The effectiveness of IEC as a method for separating charged species is enhanced by the ability of many operational factors to change the selectivity and resolution. Salt concentration, salt composition, and pH are the most important operational parameters which strengthen the versatility of the technique.

Ion-Exchange Buffers

J.E. Haky
H. Seegulum
Department of Chemistry and Biochemistry, Florida Atlantic University, Boca Raton, Florida, U.S.A.

INTRODUCTION

Ion-exchange chromatography is a separation method based on the exchanging of ions in a solution with ions of the same charge present in a porous insoluble solid. The method is used for the deionization of water.[1,2] It is often employed for the separation and identification of the rare earth and transuranium elements.[2] Additionally, ion-exchange chromatography is also used in clinical laboratories for the automated separation and analysis of amino acids and other physiologically important amines used for pharmaceutical purposes.[3]

DISCUSSION

In ion-exchange chromatography, ions are separated on the basis of their differences in relative affinity for ionic functional groups on the stationary phase. Anionic and cationic functional groups are covalently attached to the stationary phase, usually resins, which are amorphous particles of organic material.[1–3] Sulfonated styrene-based polymers are the most widely used cation-exchange resin, and similar polymers containing quaternary ammonium groups are the most widely used anion exchangers.[4] Oppositely charged solute ions are attracted to ionic functional groups on the stationary phase by electrostatic forces. Retention is based on the attraction between solute ions and charged sites bound to the stationary phase.[4,5]

Due to the desirable solvent and ionizing properties of water, most ion-exchange chromatographic separations are carried out in aqueous media. Once the selection of the column type has been made, the resolution of components in the sample can be optimized by adjusting ionic strength, temperature, flow rate, and, most importantly, the pH and concentration of buffer or organic modifier in the mobile phase.

Solvent strength, which is defined as the ability of the solvent to elute a given solute from the stationary phase, increases with increased ionic strength of the mobile phase. Selectivity is generally not affected by changes in ionic strength, except for samples containing solutes with different valence charges. With increased temperature, the rate of solute exchange between the stationary phases and mobile phases increases, and the viscosity of the mobile phase decreases, resulting in increased solvent strength. Solvent strength also increases with the volume percent of organic modifier for hydrophobic solutes. However, most ion-exchange chromatography is performed in totally aqueous mobile phases, due to the hydrophilic nature of most ionic solutes. Flow rates of the mobile phase can change resolution in ion-exchange chromatography, but the effects are often minimal.[5]

Increases in mobile-phase pH cause decreases in solute retention in cation-exchange chromatography and increases in retention in anion-exchange chromatography. Separation selectivity can also be greatly influenced by small changes in pH. In ion-exchange chromatography with aqueous mobile phases, buffers are used to maintain the pH in the mobile phase. A buffered solution can resist the changes in pH when an acid or base is added or when dilution is occurring. The pH of a buffer is given by the Henderson–Hasselbalch equation:

$$\mathrm{pH} = \mathrm{p}K_a + 109\,\frac{[\mathrm{A}^-]}{[\mathrm{HA}]} \tag{1}$$

where $\mathrm{p}K_a$ refers to the acid dissociation constant of the species in the denominator, HA, and A refers to the conjugate base of the acid HA. Buffer capacity, the measure of how well a solution resists changes in pH when a strong acid or base is added, increases as the concentration of the buffer increases. However, the pH of a buffer solution is virtually independent of dilution. When the $\mathrm{pH} = \mathrm{p}K_a$ the maximum buffer capacity is met and a good working range of the buffer is approximately when the $\mathrm{pH} = \mathrm{p}K_a = 1 \pm 1$.[1] A buffer is very easy to make. For example, to prepare 1.00 L of buffer containing 0.100 M tris(hydroxymethyl)aminomethane hydrochloride at pH of 7.4, simply weigh out 0.100 mol of its hydrochloride salt and dissolve it in a beaker containing about 900 ml of water. Then, add a base (e.g., NaOH), until the pH is exactly 7.4. Then, quantitatively transfer the solution to a volumetric flask. Finally, dilute to the volumetric mark and mix.[1]

By increasing the buffer concentration, the concentration of the counterions are increased in the mobile phase and stronger competition is provided between the sample components and the counterions for the exchangeable ionic centers, resulting in reduced solute retention.[5] As stated

Table 1 Typical buffers for ion-exchange chromatography.

Buffer salt	pH Range
Ammonia	8.2–10.2
Ammonium acetate	8.6–9.8

Triethanolamine	6.7–8.7

earlier, selectivity and retention can also be adjusted by changing the pH of the mobile phase. This occurs because such a change in pH modifies the character of both the ionexchange medium and the acid–base equilibrium as well as the degree of ionization of the sample.[3] A pH gradient in which the pH of the mobile phase is changed during the chromatographic analysis can also be used to control the solvent strength and retention of ionic solutes. Such gradients can also be used to control selectivity.[6]

The working pH range for a separation can be estimated from the pK_a values of the sample components. If such pK_a values are not available, they can often be estimated by considering the number and types of functional groups present and the molecular structures of the components in the sample.[1] In order to ensure that solutes are ionized and retained by the ion exchanger, the optimum buffer pH of the mobile phase should be 1 or 2 pH units above the pK_a of acids and 1 or 2 pH units below the pK_a of bases.[3]

Two criteria should be met when choosing the components of the buffer. First, the buffer must be able to maintain the operating pH for the separation to be performed. Second, the exchangeable buffer counterion must yield the desired eluent strength.[3] Some common buffer salts used in ion-exchange chromatography and their usable pH ranges are summarized in Table 1. Examples of their use includes the chromatography of amino acids, polymeric, cation exchanger using various combinations of citrate and borate buffer.[3] Additionally, carbohydrates can be separated by anion-exchange chromatography using an aqueous solution of sodium hydroxide–sodium acetate as the eluent.[3] Being weak acids, the ion-exchange behavior of such compounds is significantly affected by the pH of the mobile phase. Similar separations of ionizable compounds through the use of ion-exchange chromatography with these and other buffers have been reported.[1–7]

Ion-Exchange Resins: Inverse GC

Piotr Słomkiewicz
Zygfryd Witkiewicz
Institute of Chemistry, Jan Kochanowski University, Kielce, Poland

INTRODUCTION

Over the last 20 years ion exchange resins have been used more and more frequently as active catalysts of a number of reactions on a commercial and a laboratory scale.[1] Investigations need defining adsorption equilibrium constants of reactants and adsorption model, as well as determining equilibrium constants of these reactions. In this paper, measuring methods that favor the investigation of catalytic reactions on ion exchange resins using inverse gas chromatography are described.

DETERMINATION OF ADSORPTION ISOTHERMS OF REAGENTS ON ION EXCHANGE RESINS

Being active catalysts of a number of reactions, ion exchange resins are also adsorbents. The determination of adsorption isotherms of reactants on ion exchange resins can be made by the peak profile method, using inverse gas chromatography. It is also possible to determine whether a catalytic reaction likely to accompany adsorption occurs during the measurement of adsorption.

Apparatus

The apparatus for determining the isotherm of adsorption using gas chromatography is shown in Fig. 1. In the apparatus, two gas chromatographs are used, one with a thermoconductivity detector for adsorption investigation and the other with a flame ionization detector for analytical purpose. The apparatus contains three identical carrier gas tracks. Each gas track contains an electromagnetic valve (1), a flow stabilizer (2), and a needle valve (3). These gas tracks supply the detectors in two gas chromatographs. The injector (4) is used to introduce adsorbate samples into a sorption pipe (5) containing the investigated ion exchange resin. The carrier gas flowing out of the sorption pipe is introduced to the thermoconductivity detector (8). The comparative chamber of the thermoconductivity detector is supplied with the carrier gas from the other injector (6) and the tube (7) containing reference sample of exchange resin.

The second gas chromatograph was used for detecting possible products of a catalytic reaction of adsorbate on the surface of ion exchange resin. The carrier gas containing desorbed adsorbate, and possible products of the catalytic reaction on adsorbent, flows out of the thermoconductivity detector and can be flowed through the six-port valve (10) and the four-port valve (11) immediately to a sample injector (12) and a chromatographic column (13) for

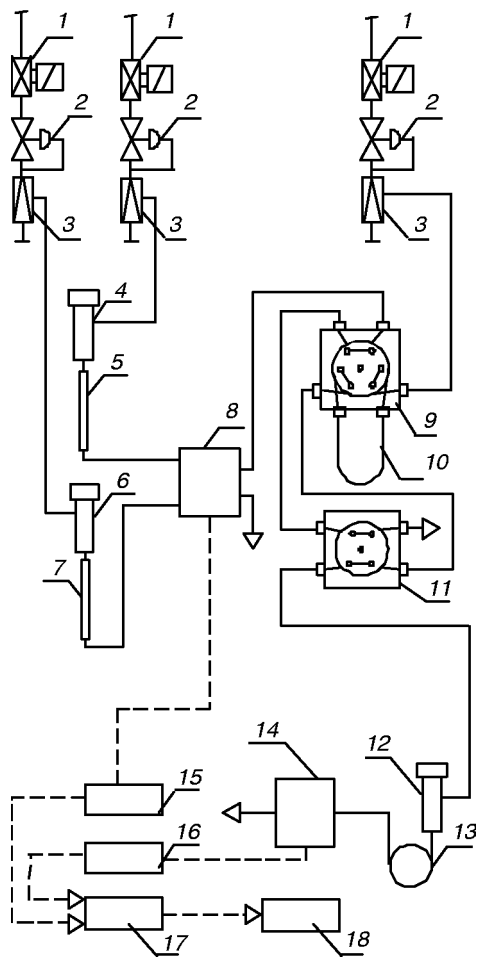

Fig. 1 Scheme of apparatus for adsorption measurement. analysis. A six-port valve (10) with a freezing capillary (10) for taking samples of adsorbate and products of the above-mentioned catalytic reactions can also be used before their injection into a chromatographic column (13). This column is connected to the flame ionization detector (14). Voltage from the amplifier (15) and the electrometer (16) are directed to the analog-to-digital converter (17) and the computer (18).

The measurement of adsorption is taken by injecting with a syringe a sample of adsorbate through the injector (4) into the sorption pipe (5), containing ion exchange resin and the adsorbate peak is recorded after it flows through the adsorbent by the thermoconductivity detector (8) (Fig. 2). The adsorbate flowing out of the detector is collected in a freezing capillary connected to the six-port valve (10). The heating of the capillary and its inclusion in the carrier gas track of a gas chromatograph with a flame ionization detector by means of the six-port valve (10) make it possible to analyze the composition of the sample collected in the capillary. When products of its catalytic reaction on ion exchange resin are found in a sample of adsorbate, the results of adsorption measurement are incorrect.

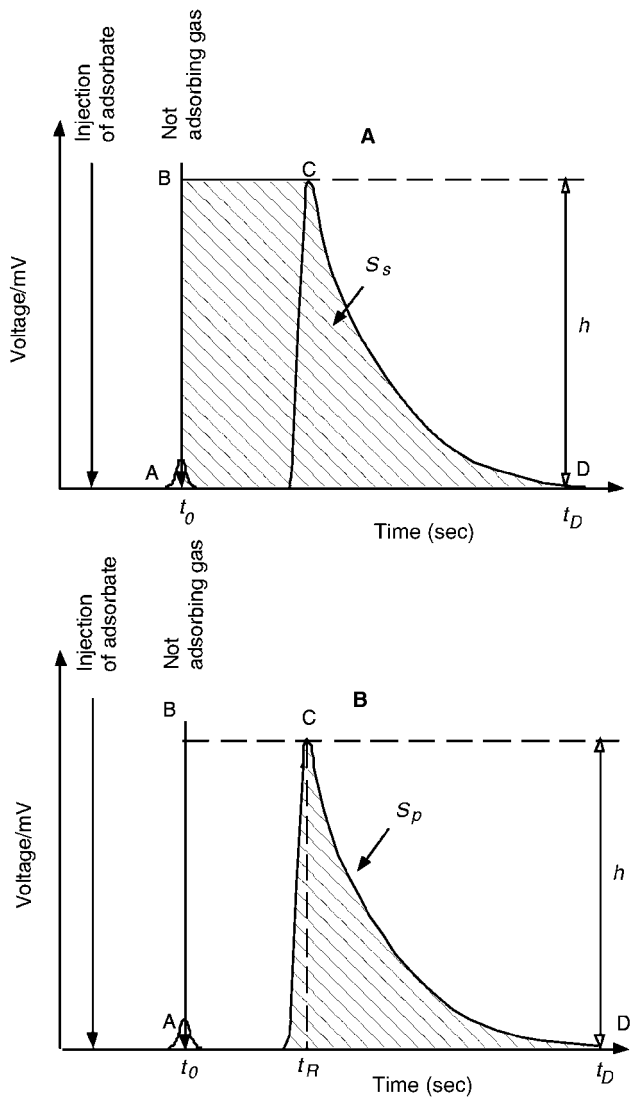

Fig. 2 The method of determination of adsorption data from chromatographic peak. (A) S_s, total adsorption area ABCD; (B) S_p, area of adsorption peak.

Method of Calculations

The method of measuring the quantities of adsorption and partial pressure of adsorbates is described in the work.[2]

The quantity of the adsorption a_i of the substance I, at the equilibrium concentration of adsorbate c_i in the gas phase, is expressed by the following equation:

$$\frac{da_i}{dc_i} = \frac{V_R}{m} \tag{1}$$

where a_i, quantity of moles of adsorbate i [mol/g]; c_i, equilibrium concentration of substance i in gas phase [mol/cm]; m, mass of adsorbent [g]; V_R, retention volume [cm^3].

From Eq. 1 it can be written:

$$a_i = \frac{1}{m}\int_0^{c_i} V_R dc_i \tag{2}$$

Retention volume V_R is expressed by the equation:

$$V_R = t_R F \tag{3}$$

where F, flow rate of carrier gas [cm^3/sec]; t_R, retention time of adsorbate peak [sec].

Detector constant k [mol/cm/mV] necessary for calculations is expressed by the following equation:

$$k = \frac{c_i}{h} \tag{4}$$

where h, height of peak [mV].

The total adsorption surface S_s is the area between points ABCD in Fig. 2.

The area of adsorption surface S_s [mV sec] is defined by the equation:

$$S_s = \int_0^h (t_D - t_0)dh \tag{5}$$

where t_0, hold up time [sec]; t_D, time from the introduction of adsorbate onto the adsorbent to the completion of recording the peak [sec].

After introducing Eqs. 3 and 4, transformed to form $dc_i = kdh$ into Eq. 2, it may be obtained:

$$a_i = \frac{kF}{m}\int_0^h (t_D - t_0)dh \tag{6}$$

And after the integration of Eq. 6 and introducing Eq. 5, it may be obtained:

$$a_i = \frac{kF}{m}S_s \tag{7}$$

The dependence between the quantity of moles n of the injected substance i and the area of chromatographic peak surface corresponding to it (Fig. 2) is expressed by the equation:

$$n = kF\int_0^t hdt = kFS_p \tag{8}$$

where n, quantity of moles of substance i injected on adsorbent [mol]; S_p, total surface of chromatographic peak [mV sec].

Determining the constant of the detector k from Eq. 8 and putting it into Eq. 7, it may be obtained:

$$a_i = \frac{nS_s}{mS_p} \tag{9}$$

Eq. 9 is used to determine from a chromatogram the value of adsorption at specific temperature.

Determining the constant of the detector k from Eq. 8 and putting it into Eq. 4, it may be obtained:

$$c_i = \frac{nh}{FS_p} \tag{10}$$

which can be transformed into the form, making it possible to calculate the equilibrium pressure p_i:

$$p_i = \frac{nh}{FS_p}RT \tag{11}$$

where p_i, partial pressure of adsorbate i [Pa]; R, gas constant [cm^3 Pa/K/mol]; T, temperature of measurement, [K].

As a result, the dependence $a_i = f(p_i)$ being the function of the adsorption isotherm may be obtained. For the determination of this isotherm points the introduction series of samples of adsorbate of different quantity into a sorption pipe is given. One sample of definite quantity of adsorbate corresponds with one point of the isotherm. The method of determining adsorption isotherms mentioned above is a general method used in investigating a great number of adsorbents.

THE VERIFICATION OF THE ADSORPTION MODEL OF REAGENTS ON ION EXCHANGE RESINS

The determination of the number of adsorption sites by the adsorption of adsorbate on ion exchange resin by inverse gas chromatography consists in saturating this resin with vapors of adsorbate under definite conditions of temperature and pressure. Next, an excess of adsorbate is removed from the ion exchange resin by blowing inert gas through its bed and the desorption of adsorbate during the programmed increase of temperature.[3]

Apparatus

The apparatus for investigation is presented in Fig. 3. The carrier gas of the measurement track flows through the electromagnetic valve (1), the flow stabilizer (2) and the needle valve (3). A six-port valve (4) serves to change over the flow of carrier gas and the flow of auxiliary gas, which contains vapors of adsorbate. Both of these flows could be directed through the chamber of the injector (5) to the sorption pipe (6), in which the investigated sample of ion exchange resin is placed. Auxiliary gas flowed by electromagnetic valve (7), flow stabilizer (8), and needle valve (9), is saturated with vapors of adsorbate in the reservoir for vaporizing (10). The reservoir is switched on in the auxiliary gas track by the six-port valve (11). The reference system is made by the parallel track of carrier gas flowed by electromagnetic valve (12), flow stabilizer (13), needle valve (14), and the chamber of the injector (15) with the pipe (16), in which the reference sample of ion exchange resin is placed. From the sorption pipes (6), (16), the carrier gases of the measurement track and of the reference track are introduced into the thermal conductivity detector (17). The electric signal from detector is amplified in the amplifier (18), and is directed to the analog-to-digital converter (19) and the computer (20).

The chromatographic analysis is used to control whether, in desorbed gases, the products of the possible catalytic reaction on ion exchange resin occur or not. The analytical gas chromatograph, is supplied with carrier gas by electromagnetic valve (21), flow stabilizer (22), and needle valve (23). The desorbed gases from thermal conductivity detector (17) are flown immediately by four-port valve (24) to the sample injector (25) and the chromatography column (26) connected with flame ionization detector (27). The six-port valve (24) with freezing capillary (28) is used to improve the conditions of chromatography analysis in the case of considerably stretched desorption peaks. Electric signals from the electrometer (29) are directed to the analog-to-digital converter (19) and the computer (20).

The measurement of adsorption on ion exchange resin needs preparing a samples series of this resin with different quantities of deactivated functional groups. The deactivation of functional groups consists in their blocking so as not to let them participate in adsorption. The deactivation of sulfonic groups of ion exchange resin can be quantitatively made by a base, (e.g., NaOH). Each sample of the series should be introduced into the sorption pipe (6). Once ion exchange resin is saturated with adsorbate steams at a given temperature, the sorption pipe should be blown through with

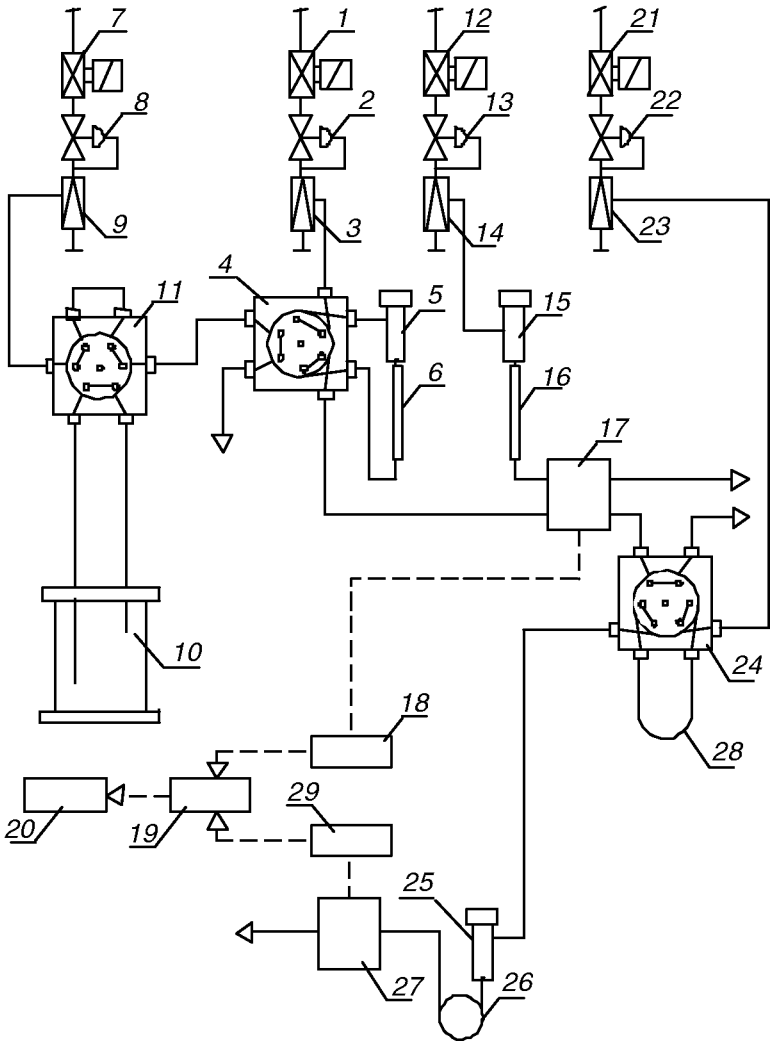

Fig. 3 Apparatus set for the determination of the adsorption model of adsorbate on ion exchange resin by inverse gas chromatography. (1), (7), (12), (21) Electromagnetic valve; (2), (8), (13), (22) flow stabilizer; (3), (9), (14), (23) needle valve; (4), (11), (24) six-port valve; (5), (15), (25) injector; (6), (16) sorption pipe; (10) reservoir for vaporizing; (17) thermal conductivity detector; (18) amplifier; (19) analog-to-digital converter; (20) computer; (26) chromatography column; (27) flame ionization detector; (28) freezing capillary; (29) electrometer.

inert gas as long as adsorbate excess is removed from the resin bed. The thermoconductivity detector (17) is used to check whether the adsorbate is completely rinsed out of the sorption pipe (6) with carrier gas. Next, the thermodesorption of adsorbate from the resin bed is carried out using a programmed increase of temperature. Desorbed adsorbate is collected in a freezing capillary (28) connected to the six-port valve (24). The heating of the capillary, and its inclusion in the gas carrier track of a gas chromatograph with a flame ionization detector by the six-port valve (24), makes it possible to analyze the composition of the sample collected in the capillary. When products of its catalytic reaction on ion exchange resin are found in a sample of adsorbate, the results of adsorption measurement are incorrect.

Method of Calculations

The adsorption of a single molecule of adsorbate (A) without dissociation through a number (n) of functional groups (s) of ion exchange resin proceeds in accordance with the reaction:

$$A + ns \rightleftharpoons A - ns \tag{12}$$

whose course can be shown by the equation:

$$\frac{c_A}{c_L} = \frac{(K_A p_A)^{1/n}}{[1 + (K_A p_A)^{1/n}]} \tag{13}$$

where c_A, concentration of adsorbate adsorbed by functional groups of ion exchange resin (mmol/g); p_A, mean partial pressure of adsorbate (kPa); K_A, constant of adsorption of adsorbate (kPa^{-1}); c_L, ion-exchange capacity of ion exchange resin after partial deactivation (mmol/g), and the deactivation degree of functional groups x of ion exchange resin is expressed by the following formula:

$$x = \frac{c_L}{c_L^0} \tag{14}$$

where c_L^0, total ion-exchange capacity of ion exchange resin [mmol/g].

Changes of concentration of the adsorbate, adsorbed by functional groups in the function of the change of the partial pressure of the adsorbate, for a series of ion exchange resins of the different content of functional groups can be expressed as the following function:

$$\frac{dc_A}{dp_A} = f(K_A, x^n) \tag{15}$$

The number of functional groups n formed an adsorption complex with one molecule of the adsorbate can be determined from this function after its differentiation in relation to dp_A and linear representation.

After the differentiation of Eq. 13 in relation to dp_A within the range of $p_A \rightarrow 0$ and the introduction of

$$m = \frac{1}{n} \tag{16}$$

instead of n, it is obtained:

$$dc_A = c_L(K_A p_A)^m dp_A = x c_L^0 K_A^m (p_A)^m dp_A \tag{17}$$

Assuming that $K_A^m = \text{const.}$ within the range of small partial pressures of adsorbate:

$$\frac{dc_A}{m(p_A)^{m-1} dp_A} = K_A^m c_L^0 x \tag{18}$$

and after taking a logarithm of both members of the equation, for $m = 1$ it is obtained:

$$log(c_A) = m\ log(x) + log\left(K_A^m c_L^0\right) \tag{19}$$

for $m = 2$ it is obtained:

$$log\left(\frac{c_A}{p_A}\right) = m\ log(x) + log\left(K_A^m c_L^0\right) \tag{20}$$

for $m = 3$ it is obtained:

$$log\left(\frac{c_A}{p_A^2}\right) = m\ log(x) + log\left(K_A^m c_L^0\right) \tag{21}$$

The mean equilibrium pressure p_A corresponding with the concentration of adsorbate in the gas phase during the thermal desorption at the temperature range ΔT can be determined by the following formula:

$$p_A = \frac{Rf(S_i)\Delta T}{V} \tag{22}$$

where R, gas constant; ΔT, the temperature range where the thermal desorption peak appears [K]; V, the retention volume of the peak [cm^3]; $f(S_i)$, the quantity of adsorbate moles calculated on the basis of the surface of the peak from the calibration curve [mmol].

According to Eq. 12 it was assumed that the quantity of adsorbate moles adsorbed by ion exchange resin depends on the number of functional groups participating in adsorption. Therefore, the dependence between the quantity of adsorbed adsorbate and the deactivation degree of functional groups of ion exchange resin can be searched for. The independent variable in Eqs. 19–21 is a logarithm of the deactivation degree of functional groups x (Eq. 14), and the dependent variable is a logarithm of the concentration c_A of the adsorbate adsorbed by functional groups of ion exchange resin (Eq. 19) or the quotient of adsorbate concentration c_A and the mean partial pressure p_A raised to a definite power (Eqs. 20 and 21). Eqs. 19-21 are equations of straight lines. The verification of the adsorption model consists in checking which of these equations correlates with the results of adsorption measurements on a series of samples prepared from ion exchange resin with partially deactivated functional groups. The correctness of the adsorption model assumed can be determined by the slope of straight line.

DETERMINATION OF EQUILIBRIUM CONSTANT OF CATALYTIC REACTION ON ION EXCHANGE RESINS

The method described here is used for determining the equilibrium constant of the reaction catalyzed by ion exchange resin. It consists in preparing a reaction mixture of definite molar composition and in introducing it into a reactor (column) with ion exchange resin. Once the equilibrium between reactants of the catalytic reaction is obtained, carrier gas is passed through the column and the composition of the equilibrium mixture is analyzed by gas chromatograph.

Apparatus

The method used relay on introducing into an injector with syringes the standard of substrates and products of the catalytic reaction at the stoichiometric ratio. The injection of reactants with syringes makes it possible to proportion the composition of the mixture freely and to obtain high-composition reproducibility of prepared mixtures. During the injection of reactants, the injector is disconnected from the carrier gas flow (i.e., reactants are arrested in it). The scheme of the injection method is shown in Fig. 4. The injector (1) is connected to the three position six-port valve (2). This valve is fed through two gas tracks—carrier gas track and auxiliary gas track. In position A, the six-port valve (2) disconnects the injector (1) from the carrier gas track and the auxiliary track. In this particular position, samples of reactants can be injected with a syringe. Position B of the six-port valve (2) is used to introduce

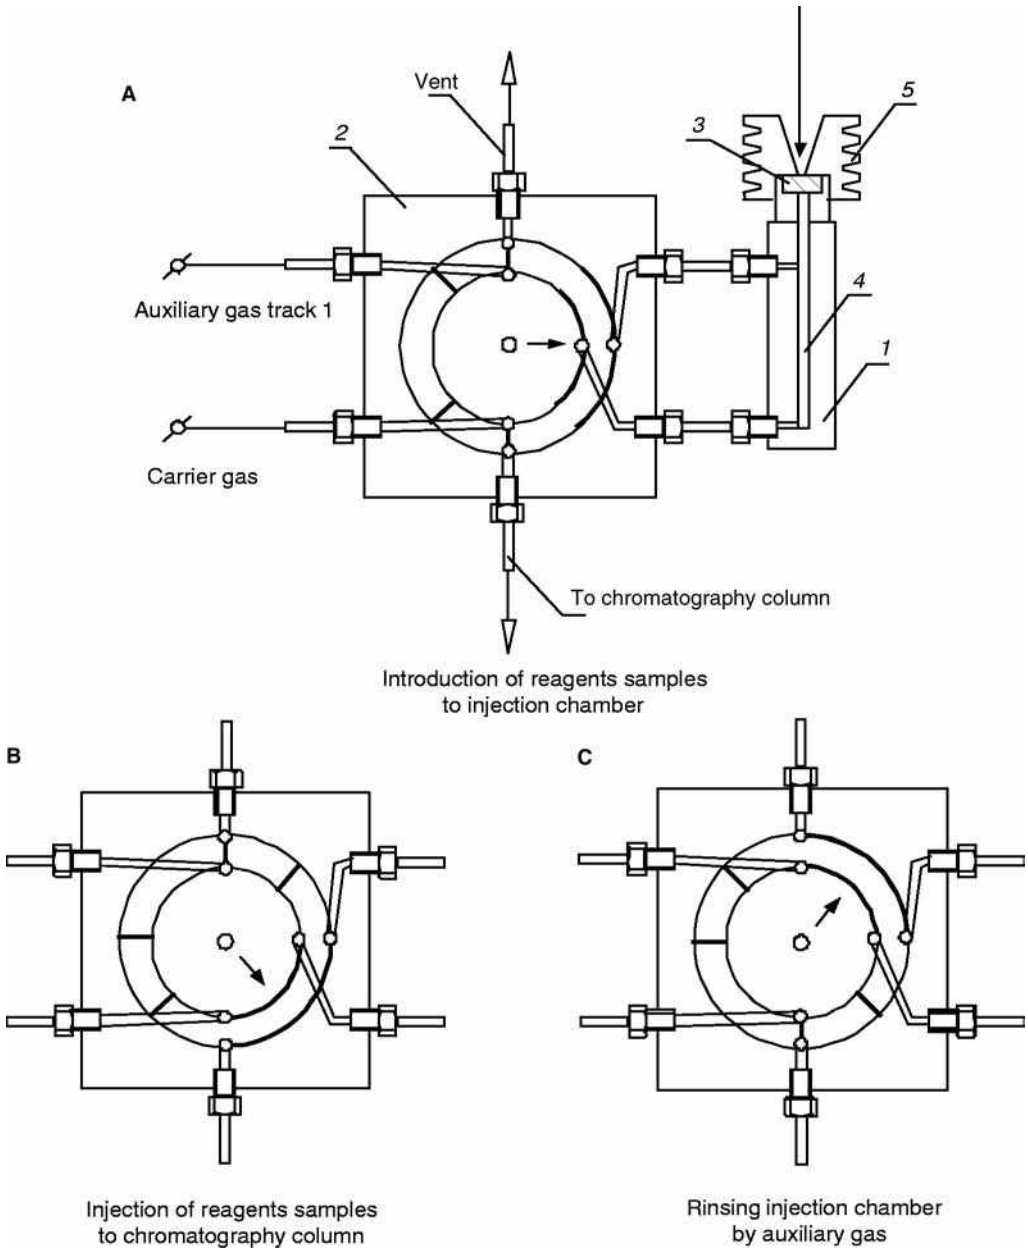

Fig. 4 Three position six-port valve with injection chamber. (1) Injector; (2) three position six-port valve; (3) septa; (4) injector chamber; (5) nut.

reactants from the injector (1) into the carrier gas of the chromatograph, and position C is used to wash the injector with auxiliary gas from track (1). The scheme of apparatus for determining equilibrium constants is given in Fig. 5. Reactants from the injector (5) (1 in Fig. 4) flow together with carrier gas into the column (10) containing ion exchange resin through the three position six-port valve (4) (2 in Fig.4) and through the six-port valve (9). By means of the six-port valve (9) it is possible to disconnect the flux of carrier gas from the column (10). This procedure makes it possible to specify the conditions under which the equilibrium between the injected reactants of the catalytic reaction taking place on ion exchange resin is attained. The switch-over of the six-port valve (9) makes it possible to transfer reactants in the flow of carrier gas through the thermoconductivity detector (16) into the freezing capillary (17) with the six-port valve (18) where the reactants are arrested. The thermoconductivity detector (16) is used to check whether the reactants are completely rinsed out of the column (10) with carrier gas. The electromagnetic valve (11), the flow stabilizer (12), the needle valve (13), the injector (14), and the column with ion exchange resin (15) make up the gas track supplying the comparative chamber of the thermoconductivity detector (16) with

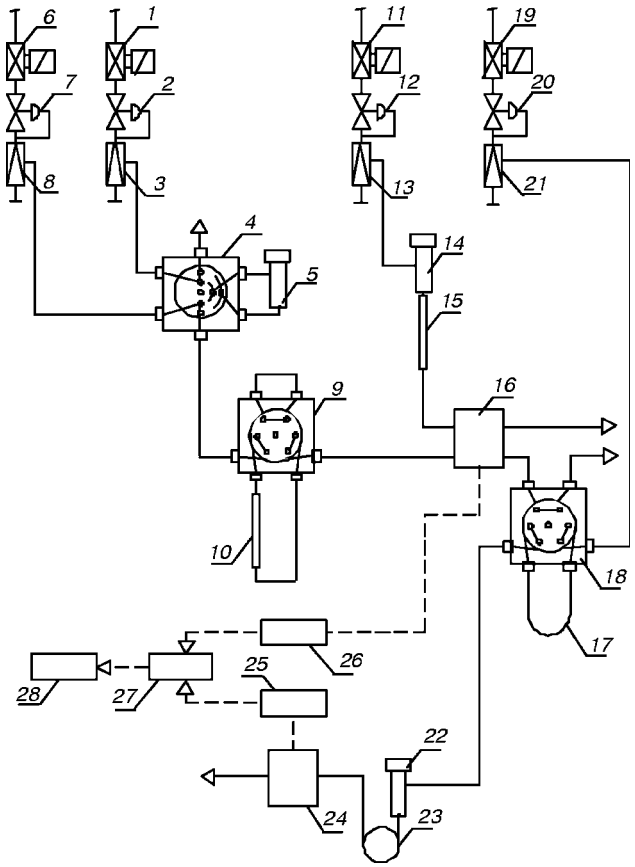

Fig. 5 Scheme of apparatus for the determination of reaction equilibrium constant. (1), (6), (11), (19) Electromagnetic valve; (2), (7), (12), (20) flow stabilizer; (3), (8), (13), (21) needle valve; (4) three position six-port valve; (5), (14), (22) injector; (10), (15) column with catalyst; (9), (18) six-port valve; (16) thermal conductivity detector; (17) freezing capillary; (23) chromatography column; (24) flame ionization detector; (25) electrometer; (26) amplifier; (27) analog-to-digital converter; (28) computer.

carrier gas. The analytical gas chromatograph is supplied with carrier gas by the electromagnetic valve (18), the flow stabilizer (20), and the needle valve (21). The switch-over of the six-port valve (18) makes it possible to direct the reactants from the capillary (17), together with carrier gas, through the injector (22) into the chromatographic column (23) and the flame ionization detector (24). The electric signals from the electrometer (25) of the flame ionization detector and from the amplifier (26) of the thermoconductivity detector are directed into the analogue-to digital converter (27) and the computer (28).

When the reactants are introduced into the column (10) containing ion exchange resin and the flow of carrier gas is cut off, the column acts as a stationary catalytic reactor and the attainment of the equilibrium in it is a time function. It is important to check whether there is equilibrium between the reactants of the reaction taking place on ion exchange resin. It can be done by comparing the results of measurements of reactant concentrations obtained for different times of the catalytic reaction taking place in the column. If the results of measurements are the same, it can be assumed that the reactants of the catalytic reaction taking place on ion exchange resin have reached equilibrium and the results obtained can be used to calculate the equilibrium constant of the reaction.

Method of Calculations

The equation of the reaction between the substrates A and B, as well as the products C and D, can be expressed as follows:

$$aA + bB \rightleftharpoons cC + dD \tag{23}$$

The quantities of reactants used to measure equilibrium are as follows: n_A^0, quantity of substrate moles A [mol]; n_B^0, quantity of substrate moles B [mol]; n_C^0, quantity of product moles C [mol]; n_D^0, quantity of product moles D [mol].

The total quantity of reactant moles present in the column is expressed by the equation:

$$n_T = n_A^0 + n_B^0 + n_C^0 + n_D^0 \tag{24}$$

The quantities of reactants determined when equilibrium has been reached: n_A, quantity of reactant moles B [mol]; n_B, quantity of reactant moles B [mol]; n_C, quantity of reactant moles C [mol]; n_D, quantity of reactant moles D [mol].

The equilibrium constant of the reaction can be calculated from the equation:

$$K = \frac{\left(\frac{n_C}{n_T}\right)^c \left(\frac{n_D}{n_T}\right)^d}{\left(\frac{n_A}{n_T}\right)^a \left(\frac{n_B}{n_T}\right)^b} \tag{25}$$

Ion-Exchange Stationary Phases

Karen M. Gooding

INTRODUCTION

In ion-exchange chromatography (IEC), molecules bind by the reversible attraction of electrostatic charges located on the outer surface of a solute molecule with dense clusters of groups with an opposite charge on an ion-exchange support. To maintain electrical neutrality, the charges on both the analytes and the matrix are associated with ions of opposite charge, termed counterions, which are either provided by preequilibration with the mobile phase or during manufacturing. Because a solute must displace the counterions on the matrix during attachment, the technique is termed "ion exchange." If the support possesses a positive charge, it is used for anion-exchange chromatography, whereas if it carries a negative charge, it is for cation exchange. Generally, the molecule of interest will have a charge that is opposite (positive or negative) to that on the support and the same as the competitively displaced counterions.

There are several major variables which distinguish ion-exchange packings and determine their utility for specific classes of solutes and for analytical or preparative applications. Those variables are as follows:

1. Structure of the bonded phase, including the chemistry of the functional group, its p*K*, and the properties of the spacer arm and/or bonded phase layer.
2. Charge density and related nominal capacity.
3. Properties of the support matrix, including composition and pore diameter.

BONDED PHASE

Functional Groups

The functional groups of an ion-exchange bonded phase are ionizable under specific pH conditions. The extent of their charge dependence on pH is the basis for distinguishing two types of ion exchangers—strong and weak. These designations do not refer to the strength of binding or to the capacity of the gel, but simply to the p*K* of the ionizable ligand group, similar to the designations for acids and bases. The structures and approximate p*K* and pH ranges of some typical strong and weak ion-exchange groups are shown in Table 1.[1–5]

Generally, strong ion-exchange groups retain their charge over a wide range of pH, with binding capacity dropping off at the extremes. For example, quaternary ammonium (Q) resins are strong anion-exchange groups which are effective throughout the pH range of about 2–12. Similarly, sulfonyl groups are strong cation-exchange groups that remain negatively charged until acidic pH levels are used. Strong ion-exchange groups can be considered to possess a permanent positive or negative charge.

The diminished ionization of weak ion-exchange groups near neutral pH result in less predictable separations if operation in this range is necessary for analyte stability, as in the case of many proteins. In these cases, the use of a strong ion exchanger allows the pH of the mobile phase to be manipulated to protonate or deprotonate the analytes without changing the ionic properties of the packing. For example, certain amino acids are most highly charged at pH less than 4, where a weak cation-exchange support would not be fully charged, but a strong cation-exchange group would.

Because weak ion-exchange groups are not fully charged in certain pH ranges, column equilibration may require more mobile phase or time under those conditions. Conversely, highly bound molecules may release more easily from supports which are not totally ionized. Clearly, careful consideration of the titration curves for an ion-exchange support is an essential aspect of designing appropriate conditions for a separation. A complete description of the charged group of an ion exchanger is necessary to understand its pH characteristics because they are dependent on the exact chemical composition of the bonded phase and the matrix. Convenient descriptions such as "strong," "S," "stable weak ion-exchange," and so forth do not sufficiently describe the ionic characteristics of the packing. The exact p*K* and functional pH range are also affected by the chemistry of the remainder of the bonded phase and of the matrix. For example, a silica matrix may ion-pair with cationic functional groups or a polymeric layer with amines may ion-pair with anionic functional groups. The actual titration curves, p*K*, and/or pH range for a given support should always be consulted.

Hydrophobic Spacer Arms

Ion-exchange functional groups are chemically bonded to the support, often through a polymeric layer which totally

Table 1 Properties of ion-exchange groups.

	Functional group	Type	p*K*	pH Range (approximate)
Anion exchange				
DEAE (diethylaminoethyl)	$–O–CH_2–CH_2–N^+ H(CH_2CH_3)_2$	Weak	15–9	2–9
PEI (polyethyleneimine)	$(–NHCH_2CH_2)_n–N(CH_2CH_2–)_{n'}$ $CH_2CH_2NH_2$	Weak	15–9	2–9
Q (quaternary ammonium)	$–CHOH–CH_2–N^+(CH_3)_3$	Strong	>13	2–12
Cation exchange				
CM (carboxymethyl)	$–O–CH_2–COO^-$	Weak	14–6	6–10
SP (sulfopropyl)	$–CH_2–CH_2–CH_2SO_3^-$	Strong	<1	4–13
S (sulfonate)	$–R–CH_2SO_3^-$ (R may be methyl with hydroxyl or amide groups)	Strong	<1	3–11

covers the matrix. The chemical nature of this coupling chemistry and its spatial characteristics can affect the chromatographic properties. Hydrophobic linkages may impart a non-polar aspect to the separations. Spacer arms make the functional groups more accessible by distancing them from the support surface. Tentacle IEC bonded phases are a spacer design incorporating a hydrophilic ligand arm.[6]

Charge Density

The number of charges, as measured by titration, defines the nominal capacity of a support. the charge density of an ion-exchange support is determined by the number of ionic groups divided by the surface area or the volume. Typical values range from 3 to 370 μEq/ml of support. The lower values are generally found in non-porous supports. High loading capacities are associated with IEC, especially for porous supports. Weak ion-exchange groups only have maximum capacity in the pH range where they maintain charge -pH less than 9 for DEAE supports and pH greater than 6 for CM.

Counterions

In certain cases, ion-exchange columns are preequilibrated with distinct counterions by the manufacturer. These ions, such as calcium for amino acids, impart a specific selectivity (see *Ion Exchange: Mechanism and Factors Affecting Separation*, p. 1258). Alternatively, a layer of counterions is applied by the user by conditioning a column with the salt of interest. An intermediate step of washing with a weak acid may accelerate the equilibration process.

MATRIX

Composition

Ion-exchange supports based on derivatized cellulose and agarose have been popular since the 1960s, particularly for protein analysis. For high-performance liquid chromatography (HPLC), less compressible supports, such as silica and cross-linked polymers, are most commonly used.

Carbohydrate Matrix

Carbohydrate supports such as dextran or agarose are very hydrophilic and easily derivatized with ionic functional groups. They have been very popular for analysis and purification of biological molecules like proteins. One major drawback to these supports is that their volume changes with mobile-phase composition. This has been alleviated in part by higher cross-linking.

Silica Matrix

In silica-based ion exchangers, the silica is bonded through a polymeric layer to a charged ligand group. Operating pH is generally limited to pH 2–8 due to the silica backbone. Although some small-pore silica-based ion exchangers have been synthesized with silane bonding, large-pore supports ($\geq$ 300 Å) designed for protein analysis have polymeric layers containing ionic functional groups which are very stable and even protect the silica matrix from erosion. Silica columns have several advantages:

1. High mechanical stability
2. Minimal shrinkage or swelling with changes in counterions
3. Stability to organic modifiers (with the restriction of salt solubility)
4. High capacity
5. Good mass transfer
6. Large variety of particle and pore sizes.

Polymeric Matrix

Polymeric matrices are also widely available for IEC. Polystyrene cross-linked with divinylbenzene (PSDVB) is one such polymer, typically available with pore diameters of

at least 1000 Å. The repetitive structure of polystyrene permits reproducible coupling of both strong and weak ion-exchange groups; cross-linking adds the rigidity required for high-pressure applications. These polymeric supports have most of the same advantages as silica for IEC. Methacrylate copolymers, which are also used as matrices in IEC, are more hydrophilic than PSDVB.

Pellicular Matrix

A third group of ion-exchange supports are pellicular, consisting of a solid inert core made of PSDVB agglomerated with 350 nm functionalized latex. The quaternary amine groups are closely and uniformly bound on the microbeads, improving flow and reducing non-specific retention. These pellicular supports are primarily used for carbohydrate analysis.[7]

Pore Diameter

Pore diameter is a major determinant in ion-exchange capacity because as the pore diameter decreases, there is a tremendous increase in surface area. Nominal loading capacity is directly related to the surface area and the ligand density; consequently, matrices with the smallest pores exhibit the highest ion-exchange capacities for small, totally included solutes.

The ion-exchange capacities of picric acid correlate with surface area. For example, that of a 100 Å pore was seen to be 1415 μmol/g, whereas that of a 300 Å pore was only 656 μmol/g.[8] The capacities for macromolecules such as proteins do not relate directly to surface area because they are excluded by size from portions of small pores and are effectively prevented from reaching all the reactive exchange sites.[5,8] Consequently, larger pores exhibit maximum capacity for macromolecules. For example, a 300Å pore exhibited maximum capacities of 98 and 130 mg/g for ovalbumin (45,000 MW) and bovine serum albumin (65,000 MW) respectively, because they were able to permeate and bind to the optimum available surface area.[5,8]

Ion-Exclusion Chromatography

Ioannis N. Papadoyannis
Victoria F. Samanidou
Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece

INTRODUCTION

Ion exclusion is the term that describes the mechanism by which ion-exchange resins are used for the fractionation of neutral and ionic species. Ionic compounds are rejected by the resin, due to Donnan exclusion, and they are eluted in the void volume of the column. Non-ionic or weakly ionic substances penetrate into the pores of the packing, they are retained and, thus, separation is achieved, as they partition between the liquid inside and outside the resin particles.

Ion-exclusion chromatography is a mode of high-performance liquid chromatography (HPLC) and, thus, the same equipment can be used, with the proper eluent, column, and detection technique. The technique is mostly used for the analysis of organic acids, sugars, alcohols, phenols, and organic bases. It provides a convenient way to separate molecular acids from highly ionized substances. Ionized acids pass rapidly through the column while molecular acids are held up to varying degrees. A conductivity detector is commonly used. Carboxylic acids can be separated by using water, a dilute mineral acid, or a dilute benzoic or succinic acid as eluent.

DISCUSSION

As neutral species, rather than ions, are being separated, ion-exclusion chromatography cannot be considered as a form of ion chromatography; although ion-exchange polymers are used, ion-exchange mechanisms are not involved.

Anions, most commonly simple carboxylic acids (e.g., tartaric, malic, citric, lactic, acetic, succinic, formic, propionic, butyric, etc.), are separated on cation-exchange resins in acidic form. Salts of weak acids can also be analyzed, as they are converted to the corresponding acid by the hydrogen ions in the exchanger. Cations (weak bases and their salts) are separated on anion-exchange resins in the hydroxide form.

In order to understand the mechanism of ion-exclusion chromatography, the behavior of the resin, in an aquatic medium, must be taken into account. In this case, three parts can be distinguished:

1. The resin network.
2. The liquid inside the resin particles.
3. The liquid between the resin particles.

The first acts as a semipermeable membrane between the stationary liquid phase within the resin and the mobile-liquid phase between the resin beads.

Ionic groups are fixed on the resin and movement of ions across the membrane takes place as predicted by Donnan theory. The ion-exclusion mechanism involves interaction between partially ionized species and fully ionized polymer matrix. Electrostatic repulsive forces, between strong electrolytes (e.g., chloride, in the case of using HCl as eluent) and the ionic groups fixed on the resin (e.g., sulfonate), prevent them from entering into the resin, due to high ionic concentration inside the resin. Because ionized analytes are not retained, they are excluded from the polymer, migrate rapidly through the column, and are eluted at the column void volume. Partially ionized and neutral species (e.g., the undissociated forms of the analyte acids), as they penetrate into the pores of the resin, are distributed between the mobile phase in the column and the immobilized liquid in the pores of the packing. Separation is accomplished by differences in acid strength, size, and hydrophobicity.

The degree of retardation increases with the decrease of the ionization degree and, additionally, depends on polar attractions between analyte and fixed functional groups and on different van der Waals forces between an analyte and the hydrocarbon part of the resin. Elution order is related to pK_a values for ionic species and to the molecular size for neutral compounds.

Members of a homologous series, such as formic, acetic, and propionic acids, elute in the order of increasing pK_a (decreasing acid strength). Dibasic acids elute sooner than monobasic acids of the same carbon number. Isoacids elute earlier than normal acids. Double bonds retard elution, whereas keto groups increase elution rate.

Microporous polystyrene divinylbenzene resins are used, operating at pressures sometimes exceeding 3000 psi; unlike silica-based packings, they are stable from pH 0 to 14. For ion-exclusion separation of organic acids and weakly acidic compounds, strongly acidic, high-capacity, sulfonated styrene divinylbenzene in the hydrogen form are used. For organic bases, separation columns are packed with strongly basic copolymer with a quaternary ammonium functional group. The degree of cross-linking (the percentage of divinylbenzene in the copolymer) affects the retention of weakly ionized species; the lower

the degree of cross-linking, the longer the retention time of acid, either strong or weak. This is due to the fact that as cross-linking decreases, ions more readily penetrate the resin, where they are held up.

As aforementioned, a large number of organic and weak inorganic acids can be eluted from the hydrogen form of cation-exchange resin using water as the eluent. However, the addition of mineral acid to the water eluent suppresses the ionization of strong and moderately strong organic acids, allowing them to partition into the resin phase and, thus, improve selectivity, as retention times on the resin are increased. The addition of inorganic salts, such as $(NH_4)_2SO_4$ or organic modifiers (acetonitrile, isopropanol, ethanol, methanol), to the eluent may improve separation. Acetonitrile, for example, decreases the retention time of relatively non-polar compounds.

Ion-exclusion chromatography can couple to ion chromatography to improve the chromatographic resolution of inorganic anions and organic acids in complex matrices. The dual system can be either in the order ion-exchange chromatography (IEC)/ion chromatography (IC) or IC/IEC.

Various detection systems can be used in ion-exclusion chromatography, among them ultraviolet (UV)/vis spectrophotometry, conductivity, electrochemistry, fluorometry, refractive index (RI) measurement, are the most common techniques. Additionally, combined detection systems (e.g., UV/amperometry, UV/RI) may be used, leading to enhanced selectivity.

Ultraviolet detection is useful, especially when water or sulfuric acid, which do not absorb in the UV region, are used. Detection for most non-aromatic carboxylic acids is accomplished at 210 nm.

Conductivity detection is preferred when water is used as eluent; then ionizable analytes are readily detected. However, in the case where HCl is used as the eluent, the analytical column is followed by a suppressor column, packed with a cation-exchange resin in the silver form. The hydrogen ions of the eluent are exchanged for silver ions, which then precipitate chloride ions, thus removing the ions contributed by the eluent and enhancing the analyte's signal.

Electrochemical detectors (coulometric and amperometric) are used when the analytes are electrochemically active or capable of being coupled to an electrochemical reaction.

Refractive index monitors are used in food analysis, for detecting carbohydrates, alcohols, and other substances with weak or no UV absorption.

With the combination of RI and UV, simultaneous detection of organic acids, carbohydrates, and alcohols with one sample injection can be achieved. Postcolumn reactions can be used for fluorometric detection of amino acids, with excellent sensitivity and selectivity.

Ion-exclusion chromatography finds numerous applications for identification and determination of acidic species in complex matrix materials, such as dairy products, coffee, wine, beer, fruit juice, and other commercial products which can be quickly analyzed with minimal sample preparation before injection (usually only filtration, dilution, or centrifugation). Organic acid determination is also of great importance in biomedical research [e.g., physiological samples, in which most of the Krebs cycle acids (tricarboxylic acid cycle) are present].

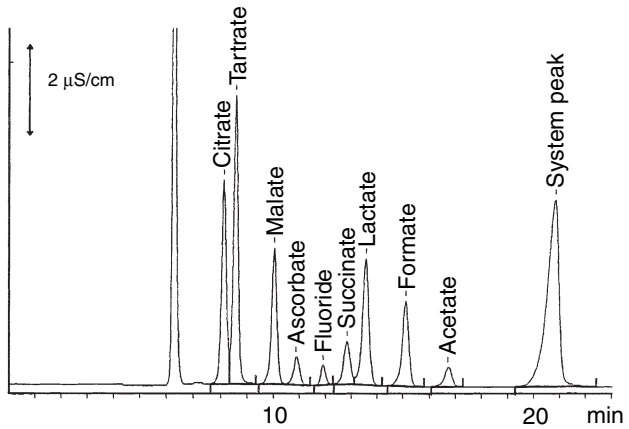

Fig. 1 Determination of organic acids and fluoride using ion-exclusion chromatography with direct conductivity detection, using mmol/L H_2SO_4, and 10% acetone as eluent.

Organic acids can be detected in the parts per billion range. With preconcentration, this limit can be further decreased. A typical ion-exclusion chromatogram of organic acids separation is presented in Fig. 1.

Ion-Interaction Chromatography

Teresa Cecchi
Department of Chemical Science, University of Camerino (UNICAM), Camerino, Italy

INTRODUCTION

Under reversed-phase (RP) high-performance liquid chromatography (HPLC) conditions, ionic compounds are weakly retained. On the contrary, when an ion-interaction reagent (IIR), which is a large lipophilic ion, is added to the mobile phase, ionized species of opposite charge are separated on RP columns with adequate retention. This is the chromatographic approach of RP ion-interaction chromatography (IIC). It has become a widely used separation mode in analytical HPLC because it provides a useful and flexible alternative to ion-exchange chromatography. Better selectivity, enhanced resolution, and retention are usually gained by this separation strategy.

According to the qualitative retention model of Bidlingmeyer, the lipophilic IIR, flowing under isocratic conditions, dynamically adsorbs onto the alkyl-bonded apolar surface of the stationary phase, forming a primary charged ion layer. The corresponding counterions are found in the diffuse outer region to form an electrical double layer. This charged stationary phase can then more strongly retain analyte ions of the opposite charge.

Unlike conventional ion exchange, IIC can be used to separate non-ionic and ionic or ionizable compounds in the same sample, because retention of an analyte involves its transfer trough the electrical double layer and depends on both electrostatic interactions and adsorptive (RP) effects.

In recent's, many examples of applications of IIC have been reported. They essentially concern the separation of organic and inorganic ions in the environmental, pharmaceutical, food, and clinical fields.

RETENTION MECHANISM

The larger number of names (e.g., ion-pair chromatography, dynamic ion-exchange chromatography, hetaeric chromatography, soap chromatography) which have been given to the IIC mode sheds light on the uncertainty concerning the retention mechanism. A majority of the proposed models are stoichiometric. They suggest that the oppositely charged analyte and IIR form a complex, according to a clear reaction scheme, either in the mobile-phase (ion-pair model) or at the stationary-phase surface (dynamic ion-exchange model). According to the first theory, the uncharged ion pair between oppositely charged analyte and IIR, which is formed in the mobile phase, is then more strongly retained by the stationary phase. The second theory presumes that solute ions undergo an ion-exchange process, at exchange sites dynamically generated by the adsorption of the IIR at the stationary phase. Knox and Hartwick demonstrated that both models lead to identical retention equation.

These models, although of practical and intuitive value, are not well founded in physical chemistry. The pioneeristic, even if qualitative, work of Bidlingmayer demonstrated that IIRs adsorb onto the stationary phase. It follows that stoichiometric equilibrium constants, which depend on the change in free energy of adsorption of the analyte, cannot be considered constant if the IIR concentration in the mobile phase increases, because the stationary phase surface properties (including its charge density) are modified. The multibody interactions and long-term forces involved in IIC can better be described by a thermodynamic approach.

A quantitative non-stoichiometric model was developed by Ståhlberg and coworkers. The model applies the Gouy–Chapman electrostatic theory to describe the interactions between charged species and it does not assume the formation of any chemical complexes: The adsorption of the IIR onto the stationary phase establishes a certain electrostatic surface potential, because its counterion has a lower adsorption tendency. An electrical double layer develops and a difference in electrostatic potential is created between the electroneutral bulk of the mobile phase and the net charged surface. The intuitive view of the effect of the IIR on retention is an electrostatic repulsion or attraction of the analyte to the charged stationary-phase surface, according to the analyte and IIR charge status. However, the adsorptive (RP) effects are also considered, to evaluate the total free energy of adsorption of the solute: The latter is partitioned into a "chemical" and an electrostatic free energy. This is a first approximation: The "chemical" part depends on the concentration of the IIR, as it determines a dynamic modification of the stationary-phase properties. This electrostatic theory of IIC has been implemented by taking into account the competition between IIR and analyte for a limited surface area, and the different surface area requirements of analyte and IIR (multisite occupancy model). However, the main drawback of this powerful electrostatic theory is the complex algebraic form of the resulting equations; hence, a series of approximations has to be made to obtain a relationship between the analyte capacity factor and

mobile-phase concentration of IIR, which is of interest for practical work.

Cantwell and coworkers proposed a surface adsorption, diffuse-layer ion-exchange double-layer model in which they underlined the role of the diffuse part of the double layer by assigning a stoichiometric constant for the exchange of ions.

Stranahan and Deming proposed a thermodynamic model for IIC in which the distribution a sample between the mobile and the stationary phase is discussed in terms of chemical potentials in both phases.

Additional peaks relative to the number of components injected are often obtained in IIC. These so-called "system peaks" confirm the proposed mechanism of dynamic functionalization of the stationary phase. They can be explained by taking into account that IIR ions are locally adsorbed onto (desorbed from) the stationary phase by injection of adsorbophilic solute ion of the opposite charge (of same charge). This change in the eluent composition, created by the sample injection, migrates along the column and give a signal if at least one of the eluent components can be detected. The same rationale provides the explanation for the indirect ultraviolet (UV) visualization (or amplification) of otherwise non-UV-absorbing samples, when a UV-absorbing lipophilic ion is added to the eluent.

INFLUENCE OF EXPERIMENTAL PARAMETERS ON RETENTION

The optimization of separations performed with IIC and the rationalization of analytes retention behavior are not easy tasks because they are influenced by many interdependent factors. This allows a fine modulation of their effects to achieve tailor-made separations.

Experimental design can be very helpful, and a number of chemometric optimization methods are present in the literature. Neural network models provided a good prediction power and a great versatility, without the need to develop any equations.

The following presents the effect of varying some individual factors on analyte retention.

ION-INTERACTION REAGENT

Type

The hydrophobic character of the IIR increases with increasing its chain length. More lipophilic reagents have higher adsorption constants, hence the effect of increasing chain length is qualitatively similar to the effect of increasing IIR concentration (see below) with regard to the degree of stationary-phase coverage. The use of multiply-charged IIRs allows the chromatographer to obtain larger changes of analyte retention. If chiral compounds are used as the IIR, the separation of the enantiomeric forms of the analyte may be achieved. The most popular IIRs are listed in Table 1.

Table 1 Commonly used ion-interaction reagents.

Cationic IIRs	Anionic IIRs
Tetramethylammonium	Butanesulfonate
Tetraethylammonium	Pentanesulfonate
Tetrabutylammonium	Hexanesulfonate
Cetyltrimethylammonium	Octanesulfonate
Octylammonium (from octylamine)	Dodecanesulfonate

Concentration

If the eluent concentration of the IIR increases, the amount of the adsorbed IIR also increases, according to its adsorption isotherm. This induces a higher surface potential on the stationary phase but also adsorption competes between analyte and IIR for the available stationary phase sites. Therefore, the following hold:

1. If the charge status of analyte and the IIR is the same, a decrease in retention is observed because of electrostatic repulsion between solute and charged stationary phase, and because of adsorption competition.
2. If the charge status of analyte and the IIR is the opposite, an increase in retention is expected because of electrostatic attraction between solute and charged stationary phase. A parabola-like dependence of analyte capacity factors on IIR concentration is observed if the investigated concentration range is broad. For narrower ranges, a linear increase may hold. Some authors have emphasized that analyte retention passes through a maximum because if the ionic strength is not kept constant when increasing the IIR concentration, there is a competition between analyte ion and IIR counterion; this competition counteracts the retention increase. However, a foldover of the plot may still occur even if the ionic strength is kept constant, because there is a critical value of the IIR concentration at which the positive effect of the electrostatic attraction is balanced by the negative effect of adsorption competition for the available stationary-phase surface area.
3. If the analyte is uncharged, a very weak decrease in retention is usually observed, primarily because of adsorption competition for the stationary phase.

Increasing the IIR above its critical micelle concentration leads into the field of micellar chromatography in

which analyte may partition between the mobile phase and both the stationary phase and the micelle.

MOBILE-PHASE COMPOSITION

Organic-Modifier Concentration

In IIC, the logarithm of the analyte capacity factor is described as a linear function of the organic-modifier concentration in the mobile phase. When the sample ion is in the same charge status as the IIR, the slope of the linear relationship, if compared to the original RP slope, becomes steeper (the contrary is observed for oppositely charged combinations). This can be explained by taking into account that the organic modifier, through desorption effects, decreases the retention of ionic solutes via the simultaneous decrease of the free energy of adsorption of both the analyte and IIR.

Ionic Strength

An increase in salt concentration in the bulk mobile phase provides those counterions which are able to reduce, according to the Gouy–Chapman electrostatic theory, the electrostatic stationary-phase surface potential. Hence, the adsorption of the IIR may increase, even if its concentration in the eluent is the same, because of lower electrostatic "self"-repulsion. However, the net effect is a reduced surface potential: The ion interactions decrease, and analyte retention may be modulated.

From an intuitive point of view, the inorganic ions are eluting agents because they limit the interaction of oppositely charged analyte and IIR, via a competing equilibrium for adsorbed lipophilic ions. This view gives the rationale for the use of mobile-phase additives, such as sodium carbonate, to avoid the unnecessarily high resolution which may be obtained between analytes of different charge.

It has to be emphasized that the nature of the electrolyte ions influences the surface potential value because the effective surface charge concentration is reduced if slight hydrophobic, adsorbophilic electrolytic counterions are included in the eluent.

The influence of moderate increase of ionic strength on the "chemical" part of the free energy relative to the analyte transfer from the mobile to the stationary phase has been usually neglected.

MOBILE-PHASE pH

The eluent pH value affects the degree of ionization of the species involved in ion interaction. Hence, the greatest retention is obtained for completely dissociated species. This is the opposite of what is observed in RP chromatography.

Unexpected pH dependencies were explained by (a) competition between negative analyte ions and OH^- ions for interaction with the electrical double layer and (b) a mixed retention mechanism in which RP partition or interaction with unreacted silanols from the stationary-phase base may play a significant role.

RP STATIONARY PHASE

A number of different packings were used in IIC, including the newly developed graphitized carbon column, which has excellent chemical and physical resistance. The use of polymeric material has the drawback of poor physical resistance. However, a wider pH range is investigable and the affinity for certain IIR is higher, by comparison with the silica-based RP columns. However, discordant results are present in literature reports with regard to the chromatographic efficiency.

With regard to the silica-based RP stationary phase, unreacted residual silanol groups may play a significant role in IIC because it was shown that they are ion-exchange sites not only for analyte cations but also for alkylammonium IIR. The higher retentions that were noticed for the silica-based stationary phase if compared to end-capped or polymer-based packings supports this.

The reproducibility of results obtained with silica-based RP, of the same declared characteristics but from different manufacturers, was sometimes poor, probably because of the properties of the silica used and the different reaction conditions in the alkylation of the support.

Stationary phases with higher hydrophobicities and adsorption capacities show increased retention of both solute and IIR. Hence, an increased capacity factor value should be expected, even if anomalies can be due to direct competition of solute and IIR for the available stationary phase.

TEMPERATURE

Temperature control is very important for obtaining reproducible separations. Indeed, the adsorption of the IIR onto the stationary phase follows an adsorption isotherm; hence, an increase of the column temperature leads to a decreased amount of the adsorbed IIR, even if its concentration in the mobile phase is constant. This, in turn, determines a decreased absolute surface potential and a modification of the solutes' capacity factors. Usually, a temperature increase results in an improved resolution and faster separation, even if a reversal of the

elution sequence of the components of a mixture may sometimes be observed, because of the interplay of electrostatic and RP interaction which are characterized by different enthalpies.

Ion-Interaction Chromatography: Comprehensive Thermodynamic Approach

Teresa Cecchi
Department of Chemical Science, University of Camerino (UNICAM), Camerino, Italy

INTRODUCTION

Reverse-phase (RP) chromatography is, by far, the most widely used separation mode in high-performance liquid chromatography (HPLC). A wide variety of mobile-phase additives that may also modify the surface of the packing material are used in optimization procedures. Ion-interaction chromatography (IIC) is an RP technique that involves the use of ion-interaction reagents (IIRs) that are large lipophilic ions; they are retained much more than their non-adsorbophilic counterions. An electrostatic potential difference between the stationary phase and the bulk mobile phase develops and influences ionic solute retention. When IIR is used, conventional RP columns are able to retain oppositely charged analytes with adequate retention. Improved resolution and selectivity broaden the scope of separation of organic and inorganic ions.

IIC analyses are challenging because of the high number of easily tunable but interdependent mobile-phase variables. Retention models are often sought because there is a need for a detailed understanding of the underlying phenomena that govern solute distribution between the two phases. The retention equations of a theoretical model can also be advantageously used during method development, involving the setup of custom modes in computer-supported software tools.

ION INTERACTION INTERPRETATION

To obtain a simple interpretation of the experimental findings in IIC, theoretical chromatographers first adopted a stoichiometric strategy that pioneered this separation mode. Unfortunately, the reaction schemes of stoichiometric models in both the mobile phase (ion pair model)[1] and stationary phase (dynamic ion exchange model)[2] lack a firm foundation in physical chemistry[3] because they are not able to account for the stationary-phase modification that results from the addition of the IIR to the eluent, and they fail to properly describe experimental results, as pointed out by Bidlingmeyer et al.[4] Key insights on these retention models were also provided by Knox and Hartwick.[5] The contrast between the simplicity and practicality of stoichiometric relationships, and the complexities of the thermodynamics solutes undergo is an important underlying theme of meditation for a model maker. Later, electrostatic theories[3,6] tried to pattern chromatographic findings according to electrostatic interactions between charged IIRs and an analyte, thereby disregarding chemical equilibria in the IIC system, but some predictions of theirs are at variance with experimental evidence.[7–9] Conversely, the recently developed extended thermodynamic approach to IIC[7–18] considers that a major contribution to the distribution of charged solutes between phases is the electrostatic potential difference between them, but also capitalizes on the importance of complex formation at a thermodynamic level, and not a stoichiometric level, to take into account the stationary-phase electrostatic potential that results from IIR adsorption. In the following, we will discuss in detail how this retention model may help the chromatographer to make educated guesses and to simplify the complex task of a successful optimization in the parameter space of IIC separations.

THEORY

Influence of IIR Concentration on the Retention Behavior of Charged, Neutral, and Zwitterionic Analytes

Amphiphilic IIR ions (H) dynamically adsorb onto the stationary phase, forming a primary charged ion layer, and counterions in the diffuse outer region form an electrical double layer. The adsorption isotherm of an IIR can be described by the Freundlich equation:

$$[\mathrm{LH}] = a[\mathrm{H}]^b \tag{1}$$

where a and b are constants; [H] and [LH] are, respectively, the mobile-phase and the stationary-phase concentrations of the IIR. The use of the Freundlich adsorption isotherm is not empirical[19] because it is related to the potential modified Langmuir adsorption isotherm, which holds for the adsorption of ions that have a substantial hydrophobic moiety. Because IIR counterions have a negligible adsorbophilic aptitude, an electrical potential difference Ψ° develops between the surface and the bulk solution. This potential is given by the rigorous Gouy–Chapman theory equation: if the ionic strength is high enough and the Debye

length is low, we are allowed to use a planar surface geometry;[3] we have the following relationship:[3,7]

$$\Psi = \frac{2RT}{F}\ln\left\{\frac{[\mathrm{LH}]|z_\mathrm{H}|F}{\left(8\varepsilon_0\varepsilon_\mathrm{r}RT\sum_i c_{0i}\right)^{\frac{1}{2}}} + \left[\frac{([\mathrm{LH}]z_\mathrm{H}F)^2}{8\varepsilon_0\varepsilon_\mathrm{r}RT\sum_i c_{0i}} + 1\right]^{\frac{1}{2}}\right\} \quad (2)$$

where F is the Faraday constant, R is the gas constant, T is the absolute temperature, z_H is the charge of the IIR, ε_r is the dielectric constant of the medium, ε_0 is the vacuum permittivity, and $\sum c_{0i}$ is the mobile-phase concentration of singly charged electrolytes. For the sake of simplicity, we will indicate the following:

$$f = \frac{|z_\mathrm{H}|F}{\left(8\varepsilon_0\varepsilon_\mathrm{r}RT\sum_i c_{0i}\right)^{\frac{1}{2}}} \quad (3)$$

where f (m^2/mol) is a constant, which can be evaluated from experimental conditions.

The complex equation Eq. 2 can be advantageously approximated, for high surface potential, by the following very simple expression:[10,12,14,19]

$$\Psi = \alpha + \beta\ln[\mathrm{LH}] \quad (4)$$

where α and β are constants[10] that depend on experimental conditions.

For surface potential below 25 mV, Eq. 2 can be linearized[3,11,15] and approximated by the following:

$$\Psi = \frac{z_\mathrm{H}[\mathrm{LH}]F}{\kappa\varepsilon_0\varepsilon_\mathrm{r}} \quad (5)$$

where κ is the inverse Debye length.

It has been demonstrated[7] that the course of analyte retention on the mobile-phase and stationary-phase concentrations of the IIR can be described, respectively, by the following two expressions

$$k = \phi[\mathrm{L}]_\mathrm{T}\frac{K_\mathrm{LE}\frac{\gamma_\mathrm{L}\gamma_\mathrm{E}}{\gamma_\mathrm{LE}}\exp(-z_\mathrm{E}F\Psi/RT) + K_\mathrm{EHL}\frac{\gamma_\mathrm{E}\gamma_\mathrm{H}\gamma_\mathrm{L}}{\gamma_\mathrm{EHL}}[\mathrm{H}]}{\left(1 + K_\mathrm{EH}\frac{\gamma_\mathrm{E}\gamma_\mathrm{H}}{\gamma_\mathrm{EH}}[\mathrm{H}]\right)\left(1 + K_\mathrm{LH}\frac{\gamma_\mathrm{L}\gamma_\mathrm{H}}{\gamma_\mathrm{LH}}\exp(-z_\mathrm{H}F\Psi/RT)[\mathrm{H}]\right)} \quad (6)$$

$$k = \phi\frac{K_\mathrm{LE}\frac{\gamma_\mathrm{L}\gamma_\mathrm{E}}{\gamma_\mathrm{LE}}\exp(-z_\mathrm{E}F\Psi/RT) + \frac{K_\mathrm{EHL}}{a^{1/b}}\frac{\gamma_\mathrm{E}\gamma_\mathrm{H}\gamma_\mathrm{L}}{\gamma_\mathrm{EHL}}[\mathrm{LH}]^{1/b}}{\left(1 + \frac{K_\mathrm{EH}}{a^{1/b}}\frac{\gamma_\mathrm{E}\gamma_\mathrm{H}}{\gamma_\mathrm{EH}}[\mathrm{LH}]^{1/b}\right)} \times([\mathrm{L}]_\mathrm{T} - [\mathrm{LH}]) \quad (7)$$

where ϕ is the phase ratio of the column; K_EL, K_EHL, K_EH, and K_HL, are the thermodynamic equilibrium constants for adsorption of the analyte E onto the stationary phase, ion pair formation in the stationary phase, ion pair formation in the eluent, and adsorption of the IIR onto the stationary phase, respectively; γ represents the activity coefficient for each species; z_E is the charge of the analyte; and $[\mathrm{L}]_\mathrm{T}$ estimates the total ligand surface concentration.

The first term in the numerator of Eqs. 6 and 7 describes the electrostatic interaction between the analyte and the charged stationary phase. This interaction will be attractive (repulsive) if the analyte is oppositely (similarly) charged to the IIR; hence, its retention increases (decreases) with increasing IIR concentration. The second term in the numerator of Eqs. 6 and 7 accounts for ion pair formation at the stationary phase that results in a retention increase. The left factor of the denominator of Eq. 6 and the denominator of Eq. 7 accounts for ion pair formation in the mobile phase that tends to reduce retention because the analyte is withdrawn from the stationary phase toward the eluent. Both terms concerning ion pair formation are missing if the analyte and IIR are similarly charged, or if the analyte is neutral. The right-hand factor of the denominator of Eq. 6 and the right-hand factor of Eq. 7 describe adsorption competition between the analyte and the IIR. From Eq. 6, it is clear that Ψ° always runs counter to further adsorption of the IIR because Ψ° is of the same sign as z_H. From Eq. 7, it is evident that adsorption competition, if it applies, shows only if [LH] is high, compared to $[\mathrm{L}]_\mathrm{T}$.

Eluent pH is an important optimization parameter because it influences the analyte ionization, which, in turn, controls the magnitude of electrostatic interactions.

When Eqs. 1–3 are substituted into Eqs. 6 and 7, the following two expressions are obtained:

$$k = \frac{c_1\left(a[\mathrm{H}]^b f + \left((a[\mathrm{H}]^b f)^2 + 1\right)^{\frac{1}{2}}\right)^{(\pm 2|z_\mathrm{E}|)} + lc_2[\mathrm{H}]}{(1 + c_3[\mathrm{H}])\left(1 + c_4[\mathrm{H}]\left(a[\mathrm{H}]^b f + \left((a[\mathrm{H}]^b f)^2, +1\right)^{\frac{1}{2}}\right)^{(-2|z_\mathrm{H}|)}\right)} \quad (8)$$

$$k = \frac{d_1\left([\mathrm{LH}]f + \left(([\mathrm{LH}]f)^2 + 1\right)^{\frac{1}{2}}\right)^{\pm 2|z_\mathrm{E}|} + d_2[\mathrm{LH}]^{1/b}}{(1 + d_3[\mathrm{LH}]^{1/b})} \times (d_4 - [\mathrm{LH}]) \quad (9)$$

In the exponent of the first term of the numerator, the plus sign applies for oppositely charged analytes and IIRs, whereas the minus sign applies for similarly charged analytes and IIRs, as expected according to the electrostatic behavior; Eqs. 8 and 9 are also able to take into account, via the magnitude of z_E in the exponents, that the electrostatic interaction is stronger for multiply charged analytes.

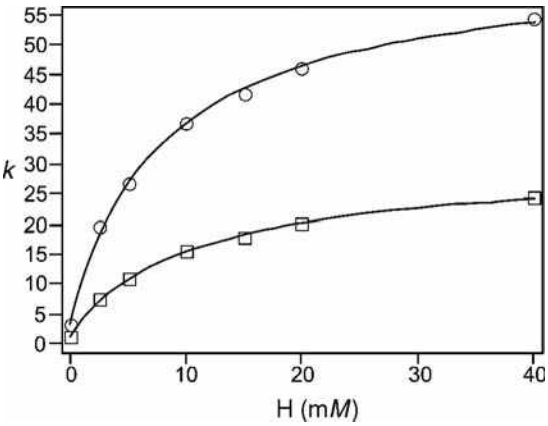

Fig. 1 Dependence of k on adrenaline (squares) and L-tyrosine hydrazide (circles), on mobile-phase concentration of 1-hexanesulfonate. Column: Synergi Hydro-RP (Phenomenex) 150 × 4.6 mm I.D., particle size 4 μm, and bonded phase coverage 4.05 μmol/m^2. Eluent: phosphate buffer 37.10 m*M* KH_2PO_4 and 4.29 m*M* Na_2HPO_4 calculated to provide a pH of 6.0. After addition of the desired amount of sodium 1-hexanesulfonate, NaCl was added so that the total sodium concentration was 50 m*M* (constant ionic strength). Experimental data were fitted by Eq. 8.

When Eqs. 8 and 9 are fitted to experimental data, excellent results are obtained, as shown in Figs. 1 and 2 for analytes charged oppositely to the IIRs; in Figs. 3 and 4 for analytes charged similarly to the IIRs; and in Fig. 5 for a doubly charged analyte, as detailed in the captions. Tables 1 and 2 detail parameter estimates and their standard deviations, correlation coefficients, and sum of square errors obtained from the best fit of these experimental data by Eqs. 8 and 9, respectively. Fitting parameters $c_1 - c_4$ and $d_1 - d_4$ are not simple adjustable constants, but have a clear physical meaning,[7] and this allows the parameter estimates to be commented on. As expected, $c_2 - c_3$ and

$d_2 - d_3$, which are related to ion pair equilibrium constants, decrease with decreasing analyte lipophilicity; d_4, which represents the total ligand concentration, compares well with the bonded phase coverage of the column (4.05 μmol/m^2), as expected; from the estimated c_4, which represents the equilibrium constant for the IIR adsorption, we obtain an averaged $\Delta G^\circ = -15.6$ kJ/mol, which is a very reasonable value for the standard free energy of adsorption of hexanesulfonate.[19,20] In Table 1, c_1 is missing for all analytes except 2,6-naphthalenedisulphonate because it was not considered an optimization parameter, since it represents k_0 that is analyte retention without the IIR in the mobile phase and it can

be obtained from experimental results. When c_1 was estimated by the model (as for the doubly charged 2,6-naphthalendisulphonate, for which other fitting parameters do not apply because electrostatic repulsion entirely models its retention behavior), the percent error is very low (0.6%).

When Eq. 4 is used to obtain the surface potential that has to be substituted into Eq. 6, we obtain[10] the following expression (a parallel expression can also be obtained from Eq. 7 to model retention data as a function of the stationary-phase concentration of the IIR):

$$k = \frac{c_1[\mathrm{H}]^{z_\mathrm{E}/z_\mathrm{H}(b-1)} + c_2[\mathrm{H}]}{(1 + c_3[\mathrm{H}])(1 + c_4[\mathrm{H}]^b)} \qquad (10)$$

For a detailed description of $c_1 - c_4$ in Eq. 10, the reader is referred to Ref.[10] Fig. 6 details how this equation properly describes the retention of neutral analytes in IIC;[12] in this case the above expression can be simplified because z_E, c_2, and c_3 are all zero and only adsorption competitions model the retention decrease with increasing IIR concentration.

The surface potential is easily predicted to alter the retention behavior of zwitterions.[13–15,21] The molecular electrical dipole is subjected to a torque moment that arranges it parallel to the lines of the non-homogeneous electrical field, with the head oppositely charged to the electrostatic surface potential facing the stationary phase. Hence, the electrical force is always attractive and it pushes the dipole toward the interphase, where the field is stronger. This force was used to calculate the electrostatic contribution to the electrochemical potential of the analyte, and to the thermodynamic equilibrium constant for its adsorption. It was demonstrated that, from Eq. 6, the following relationship is quantitatively able to model zwitterions retention and can be advantageously used in life science chromatography:

$$k = \frac{c_1\left(a[\mathrm{H}]^b f + \left((a[\mathrm{H}]^b f)^2 + 1\right)^{\frac{1}{2}}\right)^{2c_2\kappa/F}}{1 + c_4[\mathrm{H}]\left(a[\mathrm{H}]^b f + \left((a[\mathrm{H}]^b f)^2 + 1\right)^{\frac{1}{2}}\right)^{-2|z_\mathrm{H}|}} \qquad (11)$$

In Eq. 11, c_1 and c_4 are the already discussed parameters, whereas c_2 is related to the molecular dipole: the higher it is, the stronger is the retention increase on IIR addition. A parallel expression can also be obtained from Eq. 7 to model retention data as a function of the stationary-phase concentration of the IIR.[13] A fractional charge approach to the IIC of zwitterions was also recently put forward.

Influence of Organic Modifier Concentration

A bivariate treatment of the simultaneous effects of IIR mobile-phase concentration and organic modifier percentage in the eluent on analyte retention gives the following relationship[16]

Table 1 Summary of parameter estimates and their standard deviation, correlation coefficient (r), and sum of square errors (SSE) for the best fit of experimental retention data (some of which are shown in Figs. 1, 3, and 5) as a function of the mobile-phase concentration of the IIR by Eq. 8.

$$k = \frac{c_{1_0}e^{-m_1\varphi}\left(\frac{a_o e^{-m_2\varphi}[H]^{(b_0+m_3\varphi)}}{\left(h(\varepsilon_{H_2O}-(\varepsilon_{H_2O}-\varepsilon_{MeOH})\varphi)\right)^{\frac{1}{2}}}+\left(\left(\frac{a_o e^{-m_2\varphi}[H]^{(b_0+m_3\varphi)}}{\left(h(\varepsilon_{H_2O}-(\varepsilon_{H_2O}-\varepsilon_{MeOH})\varphi)\right)^{\frac{1}{2}}}\right)^2+1\right)^{\frac{1}{2}}\right)^{(\pm 2|z_E|)}+c_{2_0}e^{-m_4\varphi}[H]}{(1+c_{3_0}e^{-m_5\varphi}[H])\left(1+c_{4_0}e^{-m_6\varphi}[H]\left(\frac{a_o e^{-m_2\varphi}[H]^{(b_0+m_3\varphi)}}{\left(h(\varepsilon_{H_2O}-(\varepsilon_{H_2O}-\varepsilon_{MeOH})\varphi)\right)^{\frac{1}{2}}}+\left(\left(\frac{a_o e^{-m_2\varphi}[H]^{(b_0+m_3\varphi)}}{\left(h(\varepsilon_{H_2O}-(\varepsilon_{H_2O}-\varepsilon_{MeOH})\varphi)\right)^{\frac{1}{2}}}\right)^2+1\right)^{\frac{1}{2}}\right)^{(-2|z_H|)}\right)} \quad (12)$$

where φ is the percentage (% vol/vol) of methanol in the mobile phase; $c_{1_0} - c_{4_0}$ are the already discussed parameters $c_1 - c_4$ when the organic modifier is not present in the eluent; a_o and b_0 are a and b when the organic modifier is not present in the eluent; and h is a parameter that accounts for the eluent ionic strength. If the latter is not constant and the dependence of h on total ionic concentration is explicitly introduced in Eq. 12, (see above) allows a multivariate approach to IIC; m_1, m_2, m_3, m_4, m_5, and m_6 are parameters that depend on experimental conditions: m_1 depends on the analyte characteristic, m_2, m_3, and m_6 depend on the peculiarity of IIR, whereas m_4 and m_5 depend on the nature of both the analyte and the IIR. For analytes oppositely charged to the IIR, the active fitting parameters are m_1, m_4, m_5, c_{2_0}, and c_{3_0} because m_2, m_3, a_0, and b_0 are readily obtained from the fitting of the Freundlich constants as functions of the organic modifier concentration in the eluent. The bivariate non-linear regression of the retention of a typical analyte oppositely charged to the IIR gives parameter estimates that were used to graphically present Eq. 12 in Fig. 7: it is rewarding to observe that retention decreases with increasing organic modifier concentration and increases with increasing IIR concentration. This increase is steeper at low organic modifier percentages because the organic modifier reduces analyte retention both directly (it decreases the analyte free energy of adsorption) and indirectly (it decreases the IIR free energy of adsorption: a lower surface concentration of the IIR results in a lower electrostatic attraction of the analyte and hence in a lower retention).

Noteworthy, in the absence of the IIR, Eq. 12 reduces to one which describes the influence of the organic modifier on RP-HPLC retention. A relationship similar to Eq. 12 can be obtained to describe the simultaneous effects of the IIR stationary-phase concentration and organic modifier percentage in the eluent on analyte retention.[16]

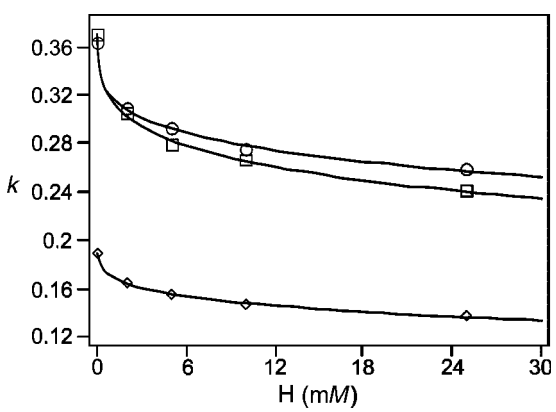

Fig. 6 Dependence of k on dimethylformamide (squares), dimethylchetone (circles), and dimethylsulfoxide (rhombs), on mobile-phase concentration of tetrabutylammonium bromide. Influence of Ionic Strength

In IIC method development, when a compensatory electrolyte is not added to the eluent, the ionic strength is not constant; hence, the dependence of f Eq. 3 on the ionic

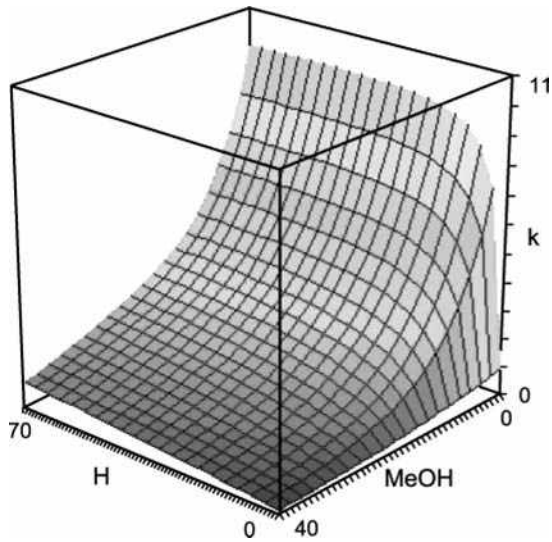

Fig. 7 Retention behavior of a typical analyte in IIC as a function of IIR mobile-phase concentration and organic modifier percentage in the eluent, according to Eq. 12.

concentration must be explicitly addressed.[17] At a fixed IIR surface concentration, the electrostatic potential decreases with increasing electrolyte concentration because counterions in the diffuse layer shield the surface charge. However, with increasing ionic strength, there is an increased surface concentration of the IIR because counterions lower the self-repulsion forces between the similarly charged adsorbed IIR ions. Yet, this Donnan effect is not able to compensate the decreased surface potential due to a higher concentration of counterions in the diffuse layer. The strong interplay between these issues can be easily taken into account using the adsorption isotherm of the IIR obtained when its counterion concentration is not kept constant in the eluent.[17] The retention of a solute oppositely (similarly) charged to the IIR is predicted to decrease (increase) with increasing ionic strength because of the lower net electrostatic attraction (repulsion).

CONCLUSIONS

The distinguishing features that set this retention model apart are the following:[7–18,21]

1. It is general. From two equations, quantitative predictions can be made for the retention behavior of charged, multiply charged, neutral, and zwitterionic solutes in IIC as a function of both the mobile-phase and the stationary-phase concentrations of the IIR. Retention equations can also quantitatively take into account the influence of the organic modifier concentration and the ionic strength; in the absence of IIR, they reduce to the well-known relationships of RP-HPLC.
2. It reduces to the relationships of stoichiometric or electrostatic approaches in IIC, respectively, if the surface potential or ion pairing equilibria are disregarded.
3. It is able to rationalize experimental behaviors that cannot be explained by other outstanding electrostatic retention models: 1) different theoretical curves when k is plotted as a function of the stationary-phase concentration of the IIR, for different IIRs; 2) dependence of the ratio of the retention of two different analytes on the IIR concentration; 3) dependence of the k/k_0 ratio on the analyte nature if the experimental conditions are the same; and 4) better agreement between electrostatic retention model predictions and experimental findings for analytes similarly charged as the IIR.
4. It is able to explain why the electrostatic approach is sometimes at variance with experimental evidence (this happens if experimental data underscore and involve complex formation).
5. Adjustable parameters have a clear physical meaning and their estimates are reliable because they compare well with literature estimates and with direct experimental measurements.
6. It is able to rationalize, in a quantitatively unprecedented way, with very low percent errors, experimental evidence qualitatively or semiquantitatively explained by other models.

As a concluding remark, it has to be emphasized that every acceptable retention theory must be consistent with fundamental physics, as well as describe experimental findings. The complex multiplicity of phenomena involved in an IIC system requires a complex description of the thermodynamics solutes have undergone: this description is epistemologically acceptable if the model is well founded in physical chemistry and if it is able to describe experimental data better than previous models.

Ion-Pairing Techniques

Ioannis N. Papadoyannis
Anastasia Zotou
Laboratory of Analytical Chemistry, Chemistry Department, Aristotle University of Thessaloniki, Thessaloniki, Greece

INTRODUCTION

Ion-pair chromatography (IPC) is of relatively recent origin, being first applied in the mid-1970s. Much of the development work in both theory and practice was performed by Schill and coworkers. At various times, IPC has also been called extraction chromatography, chromatography with a liquid ion exchanger, soap chromatography, paired-ion chromatography and ion-pair partition chromatography.

BACKGROUND INFORMATION

When solute ions (A^-) are added to a chromatographic system containing pairing ions (B^+) and associated counter ions (C^-), the degree of retention of (A^-) depends on the following equilibrium:

$$A^-_{aq} + B^+_{aq} = AB_{org} \tag{1}$$

with an extraction constant

$$E_{AB} = \frac{[AB_{org}]}{[A^-_{aq}][B^+_{aq}]} \tag{2}$$

In the simplest case of IPC, it can be assumed that the sample and counterions are soluble only in the aqueous mobile phase and the ion pair formed is soluble only in the organic stationary phase.

Assuming that the concentration of the pairing ion in the aqueous phase is high compared to that of the solute ion, the *distribution coefficient* of A^-, D^-_A, is given by

$$D^-_A = \frac{[AB_{org}]}{[A^-_{aq}]} = E_{AB}[B^+_{aq}] \tag{3}$$

The *capacity factor* k' is related to E_{AB} as follows (in the reversed-phase mode):

$$k' = \frac{V_S}{V_m}\left(\frac{[AB_{org}]}{[A^-_{aq}]}\right) \tag{4}$$

$$= \frac{V_S}{V_m}(E_{AB}[B^+_{aq}]) \tag{5}$$

or

$$k' = D^-_A \frac{V_S}{V_m} \tag{6}$$

Because the capacity factor k' is proportional to $1/D$ in normal-phase chromatography and to D in reversed-phase chromatography, it follows that k' in IPC is inversely proportional to the pairing ion concentration in the normal-phase situation but directly proportional in the reversed-phase case.

When the pairing ion is very hydrophobic, B^+ will be extracted into the organic phase with its normal counterion C^-, according to

$$C^-_{aq} + B^+_{aq} = CB_{org}(\text{ion pair}) \tag{7}$$

Subtracting it from Eq. 1 gives

$$A^-_{aq} + CB_{org} = AB_{org} + C^-_{aq} \tag{8}$$

This is very similar to ion-exchange chromatography with an equilibrium constant:

$$K_{IE} = \frac{[AB_{org}][C^-_{aq}]}{[CB_{org}][A^-_{aq}]} \tag{9}$$

This gives

$$D^-_A = \frac{[AB_{org}]}{[A^-_{aq}]} = K_{IE}\frac{[CB_{org}]}{[C^-_{aq}]} \tag{10}$$

from which it follows that k' is inversely proportional to the concentration of the counterion in the aqueous phase.

The latter situation is usual in the reversed-phase mode, where the hydrophobic ion is adsorbed onto the bonded

hydrocarbon of the packing material. Thus, we can distinguish three different techniques:

1. Normal-phase IPC, where the support is coated with an aqueous stationary phase containing the pairing ion and the ion pairs are partitioned between the stationary phase and an organic mobile phase.
2. Reversed-phase IPC, where the liquid stationary phase is organic and the pairing ion is introduced in the aqueous mobile phase.
3. Reversed-phase IPC, using a chemically bonded stationary phase and a hydrophobic pairing ion in the aqueous mobile phase.

The use of bonded-phase partition systems is generally preferred over mechanically held stationary phases; this gives advantage to technique 3.

NORMAL-PHASE ION-PAIR CHROMATOGRAPHY

The support is loaded with the aqueous stationary phase containing the pairing ion by one of the following three methods:

1. The stationary phase or a concentrated solution of the stationary phase in acetone is pumped through the packed column bed. The excess is then removed by passing eluent or hexane, followed by eluent saturated with stationary phase, until equilibrium is reached. Equilibrium is normally achieved when stable k' values are obtained for a series of representative solutes. This usually requires passage of several hundred milliliters of eluent.
2. The stationary phase can be loaded onto the column in several large plugs (0.1–1.0 ml) using a stopped-flow technique and equilibrium is achieved in the same way as previously.
3. The eluent, which has been preequilibrated with the stationary phase, is pumped through the column until stable k' values are obtained. The stationary phase is adsorbed onto the support surface, but at equilibrium, the pores of the support are not as completely filled as they are in the columns obtained by the first two methods. The equilibration can be a very time-consuming procedure, but the columns thus obtained are stable and reproducible.

Because the columns are in an equilibrium situation, it is obvious that gradient elution is not possible. In the normal-phase situation, the k' value of a solute is inversely proportional to the pairing ion concentration. Because the pairing ion is in the stationary phase, this concentration is not readily changed, and for this reason, retention is normally controlled by modification of the eluent. Hydrocarbon or chlorinated hydrocarbon solvents are usually employed with a small percentage of alcohol as a modifier. Varying the concentration or nature of the alcohol can produce the required changes in retention or selectivity.

Very high efficiencies have not usually been achieved with normal-phase IPC; the advantage of the reversed-phase mode, where the pairing ion concentration can be easily altered, has led to almost total takeover in the ion-pair field. The normal phase has two advantages compared to the reversed-phase mode:

1. The use of ultraviolet (UV) absorbing or fluorescent ions to enhance or enable the detection of non-absorbing solutes.
2. The possibility of varying selectivity by varying the organic-phase composition.

REVERSED-PHASE ION-PAIR CHROMATOGRAPHY

Most often, pentanol or butyronitrile is used as the stationary phase loaded onto a hydrophobic support such as silanized silica.

The equilibration time depends on the hydrophobicity of the support (the coating of pentanol on a hydrocarbon-bonded silica takes no longer than 2 hr at a flow rate of approximately 1 ml/min).

The retention of analytes can be regulated by varying the following factors:

1. The capacity factor increases with the hydrophobicity of the pairing ion. For hydrophilic solutes, hydrophobic pairing ions are chosen, and vice versa.
2. The capacity factor increases linearly with pairing ion concentration. Alternatively, gradient elution can be performed by decreasing the pairing ion concentration.
3. The choice of the organic phase affects the selectivity of the system.

REVERSED-PHASE ION-PAIR CHROMATOGRAPHY USING A CHEMICALLY BONDED STATIONARY PHASE

This is, by far, the most commonly used form of reversed-phase IPC. This technique has been also called *soap chromatography* although, in soap chromatography, the use of detergents as counterions is introduced. Here, the columns (with C_8 or C_{18} packings) are prepared by equilibrating the stationary bonded phase with the mobile phase containing the pairing ion. The ion-pair reagent is attracted to the stationary phase because of its hydrophobic alkyl group

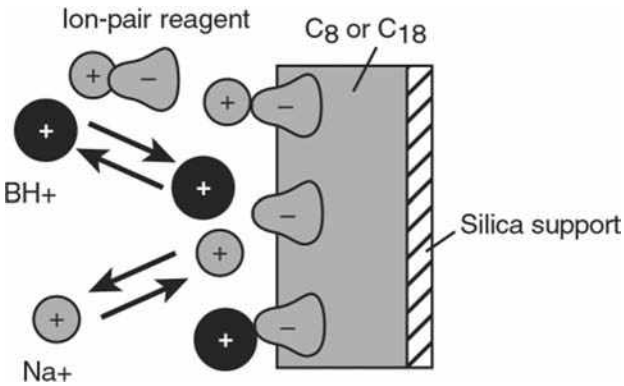

Fig. 1 Pictorial representation of IPC retention of a protonated base (BH^+); Na^+ is the mobile-phase cation; the IPC reagent is hexane sulfonate.
Source: From *Practical HPLC Method Development*,[1] by permission of John Wiley & Sons, Inc.

and the charge carried by the reagent thereby attaches to the stationary phase.

The surface of a C_8 or C_{18} column packing is shown in Fig. 1 as a rectangle covered by sorbed molecules of a negative ion-pair reagent (e.g., hexane sulfonate, C_6-SO_3^-).[1] The negative charge on the stationary phase is balanced by the positive ions (Na^+) from the reagent and/or buffer. A positively charged sample ion (protonated base BH^+) can exchange with a Na^+ ion as shown (arrows), resulting in the retention of the sample ion by an ion-exchange process.

For each ion-pair reagent, the column uptake increases for a higher reagent concentration in the mobile phase, but then levels off as the column becomes saturated with the reagent. The more hydrophobic reagents are retained more strongly and saturate the column at a lower mobile-phase reagent concentration ($10^{-5}M$), but equilibration may take several hours. Less hydrophobic ion-pair reagents are added at a slightly higher concentration (10^{-4}–$10^{-3}M$) and equilibrium is reached much faster (1–2 hr at a flow rate of 1ml/min). This is shown in Fig. 2a, where the concentration of reagent in the stationary phase $(P^-)_S$ is plotted vs. the concentration of reagent in the mobile phase $(P^-)_m$ for two reagents of different hydrophobicity.

The change in sample retention, as the ion-pair reagent concentration increases, is shown in Fig. 2b for a hydrophilic sample compound BH^+. Once the column becomes saturated with the reagent, the sample retention levels off. Because IPC retention involves an ion-exchange process, further increases in reagent concentration lead to an increase in the counterion concentration (Na^+), which competes with the retention of the sample ion on the column.

In practice, when very hydrophobic pairing ions are used, the columns are irreversibly altered, because the ions can never be completely removed. Once equilibrium

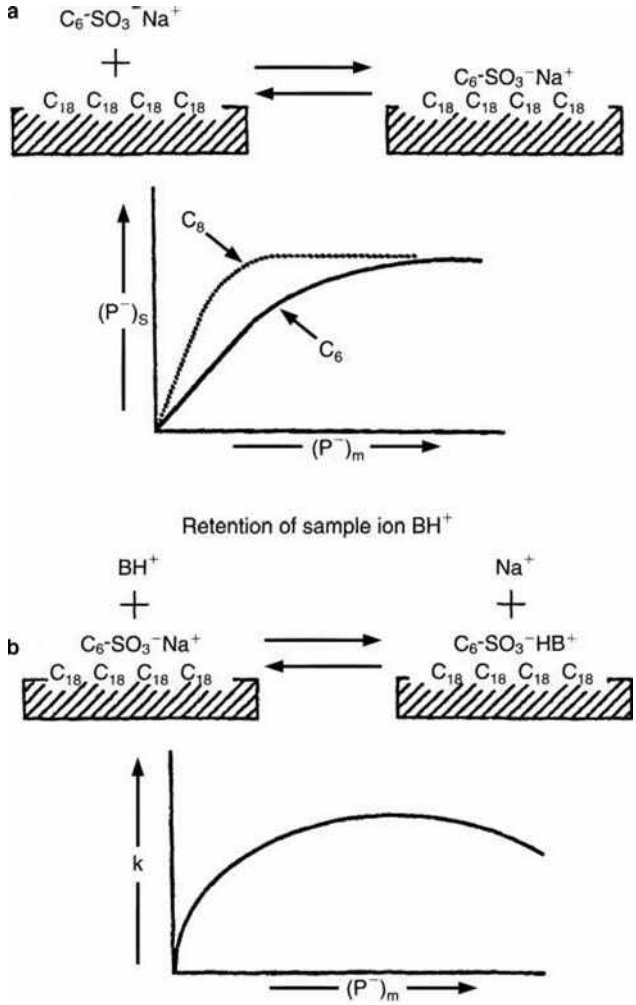

Fig. 2 Effect of ion-pair reagent concentration on separation. (a) Sorption of the ion-pair reagent as a function of concentration for reagents of different hydrophobicity (C_6- and C_8-sulfonates); (b) retention as a function of reagent concentration.

is reached, the columns are stable and can be used for several months. The columns should be stored in the mobile phase because of the lengthy equilibration times. Only if the column is not used for an extended period of time should one consider storing the column in an organic solvent.

DESIGN OF AN ION-PAIR SEPARATION

Unless there is a specific reason to choose a normal-phase system, IPC should be carried on in the reversed-phase mode, using chemically bonded stationary phases.

The best counterion and pH depend on the kind of sample to be separated. Most ion-pair reagents used today

are either alkyl sulfonates or tetraalkyl ammonium salts, either of which allow UV detection above 210 nm. The IPC aqueous phase must be adequately buffered with respect to both pH and concentration of the counterion.

Inadequate buffering of the aqueous phase is a source of band tailing in IPC. Conventional buffers, such as citrate and phosphate, have been used and, in some cases, the counterion itself is an adequate buffer. For separations at low pH, 0.1–0.2 *M* solutions of a strong acid provide adequate buffering. Inadequate buffering of the aqueous phase is a source of band tailing in IPC.

In reversed-phase IPC, maximum k' values are obtained at intermediate values of pH, where the sample compounds are completely ionized and ion-pair formation is at a maximum. As the pH of the mobile phase is lowered, sample anions A^- begin to form the unionized acids HA, leading to a smaller number of sample ion pairs in the stationary phase. Acids are usually separated at a pH of 7–9, whereas bases are separated at a pH of 1–6.

In reversed-phase systems, the solvent strength is readily varied by changing the counterion or its concentration. When all sample ions are fully ionized, a change in solvent strength via a change in counterion concentration leads to minimal changes in separation selectivity. The concentration of the counterion is usually 0.005–0.05 *M*, except for perchlorate (0.5–1 *M*) or the detergents used in soap chromatography (e.g., 1 wt% of counterion). Buffer concentrations are similar to those used in ion-exchange chromatography (0.001–0.5 *M*).

An increase in the alkyl chain length of the counter-ion increases retention in reversed-phase IPC by up to 2.5 times per added $-CH_2-$ group in the counterion.

Apart from an increase in the counterion concentration, an increase in ionic strength of the aqueous phase generally reduces the formation of ion pairs, as a result of the competition of secondary ions in forming ion pairs with the counterion. One study showed a twofold to threefold change in k' for each doubling of ionic strength.

For reproducible separations by IPC, it is important to thermostat the column. Temperature effects in IPC are more important than in some other methods.

Isocratic HPLC: System Selection

Pavel Jandera
Department of Analytical Chemistry, University of Pardubice, Pardubice, Czech Republic

Abstract
The effects of various factors on the separation in isocratic high-performance liquid chromatography (HPLC) are discussed. Various separation modes, including aqueous-organic and non-aqueous reversed-phase (RP) chromatography, adsorption normal-phase liquid chromatography (NPLC), hydrophilic interaction liquid chromatography (HILIC), ion-exchange, ion-pair, and size-exclusion chromatography (SEC) for non-ionic samples differing in the size and polarities and for partially or fully ionized acidic or basic compounds are addressed. Selection of the column length, inner diameter (I.D.), character of the column bed, and the type of stationary phase are discussed, using the information on the sample properties, such as solubility, polarity, presence of specific functional groups in sample compounds, sample amount and concentration, and so on. Empirical and model-based approaches to the optimization of the operation parameters controlling the separation selectivity, efficiency, and resolution in HPLC are outlined, including column characteristics, selectivity of the stationary phase, composition of binary or more complex mobile phases, and operation temperature.

INTRODUCTION

Any new sample type delivered for high-performance liquid chromatography (HPLC) analysis requires an adequate separation method. Previous experience with similar samples is very useful, and many methods can be looked up in the literature; however, it is often necessary to modify earlier established methods to suit laboratory equipment or sample matrices, or to improve sample throughput in the laboratory. In many cases, a desired separation can be achieved with a few experiments, but some separation problems are more difficult and their solution may require considerable experimental effort. Nowadays, effects of experimental conditions on HPLC separations are well understood, and this knowledge can be used for effective method development. First, the objective of the separation should always be kept in mind. Any information available on the sample is very helpful in HPLC method development: the matrix, the approximate number of sample components and their chemical structures, concentrations, solubilities, and other properties provide clues for the selection of sample pretreatment approach (if necessary), suitable detection conditions, and a separation system. Most often, variable-wavelength or diode array ultraviolet (UV) absorbance detectors are used, but mass spectrometry (MS) coupled to HPLC is becoming increasingly popular because it offers valuable structural information for unknown samples. Other detection techniques are used less frequently—mainly fluorimetric and electrochemical detection for sensitive and selective environmental, biological, and food analyses, or light-scattering detection for the analysis of compounds that do not absorb in the UV region and can neither be oxidized nor reduced. For adequate separation, suitable chromatographic mode, stationary phase, mobile phase, flow rate, column dimension, and temperature should be selected. Many analyses can be performed at constant operating conditions using the so-called isocratic elution.

SELECTION OF A COLUMN AND PACKING MATERIAL

Many HPLC separations are performed with conventional analytical columns, which are 10–25 cm long and 3–4.6 mm in diameter. The column plate number, the pressure drop across the column, and the separation time at a constant flow rate are directly proportional to the column length. With short (2–6 mm), high-speed columns of the same diameter, simple separations can be accomplished in 1–3 min, so that the productivity of the laboratory increases considerably and solvent consumption per analysis is reduced.

The flow rate, consumption of the mobile phase at a constant flow rate, and the pressure drop increase with the second power of the column diameter. Separations on microbore columns (15–25 cm long and 1–2 mm I.D.) need less mobile phase and allow high mass sensitivity of detection, which is useful for analyses of small sample amounts with mass spectrometric detection. Separations on high-speed microbore, and especially on capillary HPLC columns of 0.1–0.5 mm internal diameter, are subject to more significant extracolumn contributions of the injector, detector, and connecting tubing to band broadening in comparison to conventional analytical columns, so that miniaturized HPLC requires specially designed

low-volume injectors and detectors, often at the cost of decreased sensitivity of detection. Hence, microbore and capillary HPLC columns have so far been more frequently used for HPLC–MS trace analysis than for other routine quantitative analytical applications.

Usually, HPLC columns contain spherical particle packings which are carefully sorted to fractions with narrow size distribution to provide high separation efficiency. Totally porous packing materials most frequently used for separation of small molecules in contemporary HPLC have pore sizes of 7–12 nm and specific surface area of 150–400 m^2/g, but wide-pore particles with pore sizes of 15–100 nm and relatively low specific surface area of 10–150 m^2/g, or non-porous materials are used for separation of macromolecules. Perfusion materials, designed especially for the separation and isolation of biopolymers, contain very broad pores (400–800 nm) throughout the whole particle, which are interconnected by smaller pores. Column efficiency and flow resistance increase with small particles, and a high pressure has to be applied for maintaining the required flow rate and keeping the time of analysis within an acceptable limit. However, the maximum operating pressure is 30–40 MPa with the common instrumentation for HPLC. Hence, short columns should be used with small-diameter particles. Five-micrometer particles are most often used in conventional analytical columns, and particles of 3–4 μm are common in short, high-speed columns for rapid separations (columns packed with 1–2 μm particles are employed in ultrahigh-pressure liquid chromatography, UHPLC, with instrumentation designed for maximum operation pressures up to 150 MPa).

Unlike packed columns, monolithic (continuous bed), analytical, or capillary columns in the form of a rod with flow-through pores offer high porosity and improved permeability. Silica-based monolithic columns are generally prepared by gelation of a silica sol to a continuous sol–gel network, onto which a C18 or another stationary phase is subsequently chemically bonded. Such columns provide efficiency and sample capacity comparable to those of conventional columns packed with 5 μm particle materials, but have 3 to 5 times lower flow resistance, thereby allowing higher flow rates and faster HPLC analysis. Rigid polyacrylamide, polyacrylate, polymethacrylate, or polystyrene monolithic columns are prepared by in situ polymerization in desired column format.

SELECTION OF HPLC SEPARATION MODE

The first step in HPLC method development consists of selecting an appropriate separation mode. Many neutral compounds can be separated either by reversed-phase (RP) or by normal-phase (NP) chromatography. An RP system is usually the best first choice because it is likely to result in a satisfactory separation of a great variety of non-polar, polar, and even ionic compounds. Lipophilic samples often can be separated either by non-aqueous RP chromatography or by NP chromatography. Weak acids or weak bases can be analyzed by RP chromatography with buffered mobile phases, and strong acids or strong bases by ion pair or ion exchange chromatography (IEC). Special chiral columns or chiral selector additives to the mobile phase can be used for separation of optical isomers (enantiomers).

Macromolecules are usually separated and characterized by size-exclusion chromatography (SEC) on columns packed with inert materials (gels) characterized by controlled pore distributions, based on different accessibilities of the pores for molecules of different sizes, with the larger molecules eluting first. For some lower polymers with molecular masses in the range 10^3–10^4 Da, interactive (i.e., RP-HPLC or NP-HPLC) modes provide better selectivity of separation than SEC. Many ionizable biopolymers such as peptides, proteins, oligonucleotides, and nucleic acids can be separated by IEC or RP chromatography on wide-pore packing materials, with the mobile phases containing trifluoroacetic acid or triethylammonium acetate as ion pair reagents.

REVERSED-PHASE LIQUID CHROMATOGRAPHY (RPLC)

The stationary phase in RP chromatography—usually an alkyl immobilized on an inorganic support—is less polar than the aqueous–organic mobile phase. Non-polar samples are more strongly retained than the polar ones, and the retention increases with increasing polarity of the mobile phase, so that very lipophilic samples may require non-aqueous mobile phases.

Silica gel-based materials for RP chromatography with non-polar (most often C8 or C18 alkyls) or moderately polar stationary phases covalently bonded via Si–O–Si–C bonds are prepared by chemical modification of the silanol (Si–OH) groups on the silica gel surface by chloro-silane or alkoxy-silane reagents, and are relatively stable to hydrolysis. The retention in RP increases with increasing surface coverage and length of the bonded alkyl chains, so that C18 phases show greater retention than C8-bonded phases.

Monofunctional silane reagents yield efficient stationary phases with flexible fur-like or brush-like structure of the chains bonded on the silica surface. When bifunctional or trifunctional silanes are used for modification, Cl or alkoxy groups are introduced into the stationary phase, which are subject to hydrolysis and react with excess molecules of reagents to form a polymerized sponge-like bonded phase structure. Stationary phases prepared in this way usually show stronger retention but lower separation efficiency (plate number) than do monomerically bonded stationary phases.

Bonded phases prepared by modification of silica gel type A, in turn prepared by gelation of soluble silicates, are acidic because of contamination with certain metals that activate surface silanol groups, and can complex with some chelating solutes, causing strong retention or asymmetrical peaks. They are not stable in mobile phases with pH > 8, where the silica gel slowly dissolves. However, chemically bonded groups on silica support can hydrolyze at pH < 3, causing stationary phase bleeding. The hydrolysis is enhanced at higher temperatures, so that many bonded phases are not stable at temperatures higher than 60°C. Newer, highly purified, less acidic silgel spherical silica particles (type B) are formed by the aggregation of silica sols in the air; they contain only low amounts of metals; and are more stable than the type A silica materials at intermediate and higher pH, up to at least pH 9. They generally provide better separations, especially of basic samples. Silica gel type C with a hydrosilated surface populated with non-polar silicon hydride Si-H groups (instead of silanol groups) may have up to 95% of original silanols removed, so that it is less polar than silica gels with higher population of silanol groups.

Rather bulky silanization reagents can chemically modify no more than 50% of the original silanol groups. The residual silanol groups may interact with polar solutes, especially basic solutes, often causing strong and irreversible retention and poor separation with tailing or distorted peaks. Some residual silanol groups can be removed by a subsequent end-capping reaction with small-molecule trimethylchlorosilane or hexamethyldisilazane reagents. Another approach relies on using an alkyl di-isopropyl monochlorosilane or an alkyl di-tert-bertyl monochlorosilane reagents in a single silanization step to provide steric shielding of residual silanols.

Stationary phases prepared by modification of the silica gel surface with bidentate silanes containing C18 or C8 alkyls and two reactive groups separated by a $–CH_2–CH_2–$ or a $–CH_2–CH_2–CH_2–$ bridging group show high bonding density and improved stability over a broad pH range. With alkenes used in the silanization/hydrosilation process, bonded phases attached to the surface of the hydrosilated silica type C by one point are produced, whereas double-point attachment of a bidentate bonded phase occurs when an alkyne is used instead. Bridged bidentate bonded phases efficiently shield the non-reacted silanol groups and protect the surface of the silica gel support from direct contact with the mobile phase, thus improving the column stability over a broad pH range.

In highly aqueous mobile phases, which are often necessary for RPLC separations of polar compounds, non-polar bonded alkyls are poorly solvated and may collapse and stick together, changing significantly the properties of the bonded stationary phases. The so-called aqua bonded phases are designed to improve the solvation of the bonded material and to improve the retention of hydrophilic compounds when using highly aqueous mobile phases. Incorporating amide or carbamate groups between the alkyl chain and the surface of the silica gel support improves the retention behavior in highly aqueous mobile phases. Another approach for improving the performance of bonded phases in highly aqueous media relies on end capping of the non-reacted residual silanol groups with polar hydrophilic ligands instead of hydrophobic short alkyl groups.

Stationary phases with methyl groups incorporated into the silica gel structure contain lower concentrations of silanol groups and show improved pH stability. Hybrid particles with both inorganic (silica) components and organic (organosiloxanes) components such as 1,2-bis(siloxy)ethane incorporated in their skeleton, chemically modified with the desired functionality and endcapped in separate steps, possess ethylene bridge moieties shielding residual silanol groups and show improved pH and mechanical stability.

Stationary phases with chemically bonded branched hydrocarbons, perfluoroalkanes, polyethylene glycol, cholesterol, or alkylaryl groups show different separation selectivities which can be useful for specific separations. For example, chemically bonded phenyl groups show preferential retention of aromatic compounds and increased shape selectivity for planar and rigid rod-like molecules.

Materials with inorganic or porous hydrophobic or (less frequently) hydrophilic organic polymer matrices and graphitized carbon are stable over a broad pH range from 0 to 12–14; hence, they are useful in separations of basic compounds. Reversed phases on aluminum and zirconium oxide supports exhibit hardness and mass transfer properties comparable to silica, and can be prepared by forming a cross-linked polystyrene, polybutadiene, or alkylated polymethylsiloxane layer on the support surface to which alkyls are attached. The inorganic surface, encapsulated by a non-polar stationary phase, does not come into contact with the mobile phase or with the analyte; so these materials can be used in the pH range 1–14.

Porous graphitized carbon adsorbents with sufficient hardness and well-defined and stable pore structures without micropores are now available with increased affinity for aromatic and polar substances, allowing difficult separations of some hydrophilic or isomeric compounds.

Chromatographic tests of the properties of chemically bonded phases usually are intended to determine the hydrophobic selectivity (relative retention of two hydrocarbons), hydrogen-bonding acceptor and donor selectivity (e.g, relative retention of butyl paraben and dipropyl phthalate) and silanol activity (relative retention of basic vs. neutral compounds); metal chelating activity can be measured, e.g., as the relative retention of 2,2′dipyridyl to 4,4′dipyridyl.

The mobile phase in RP chromatography contains water and one or more organic solvents, most frequently acetonitrile, methanol, tetrahydrofuran, or propanol. By the choice

of the organic solvent, selective polar interactions (dipole–dipole, proton–donor, or proton–acceptor) with analytes can be either enhanced or suppressed, and the selectivity of separation can be adjusted. Binary mobile phases are usually well suited for the separation of a variety of samples, but ternary or, less often, quaternary mobile phases may offer improved selectivity for some difficult separations. The retention times t_R are controlled by the concentration of the organic solvent in the aqueous–organic mobile phase. Eq. 1 is widely used to describe the effect of the volume fraction of methanol or acetonitrile ϕ on the retention factors $k = (t_R/t_0) - 1$ where t_0 is the column dead (holdup) time. [1]

$$k = k_0 \times 10^{-m\varphi} \quad (1)$$

The constants m and k_0 in Eq. 1 increase as the polarity of the solute decreases, or as its size increases. Furthermore, the constant m increases with decreasing polarity of the organic solvent.

NORMAL-PHASE LIQUID CHROMATOGRAPHY (NPLC)

In NP chromatography (also called adsorption or liquid–solid chromatography), the stationary phase is more polar than the mobile phase. The retention increases as the polarity of the mobile phase decreases, and polar analytes are more strongly retained than non-polar ones (i.e., the opposite of RP chromatography; Fig. 1). The column packing is

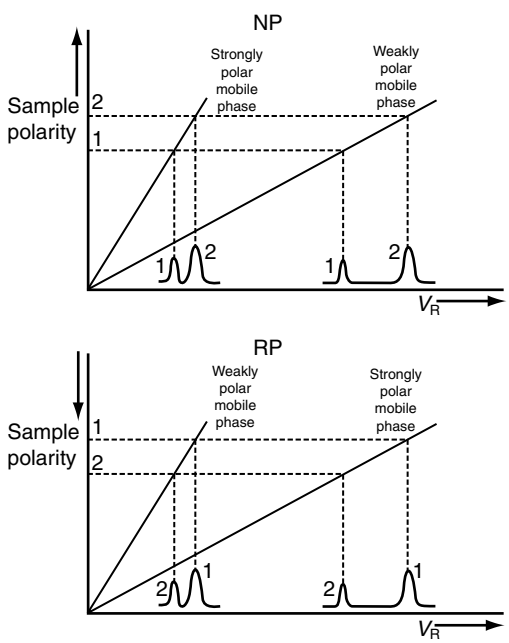

Fig. 1 Schematic diagram of the effects of sample and mobile phase polarities on retention in NPLC and RPLC. V_R = retention volume.

either an inorganic adsorbent (silica gel or, less often, aluminum oxide) or a moderately polar bonded phase [cyanopropyl–$(CH_2)_3$–CN, diol –$(CH_2)_3$–O–CH_2–CHOH–CH_2–OH, or aminopropyl–$(CH_2)_3$–NH_2] chemically bonded onto the silica gel, and the mobile phase usually is a mixture of a non-polar solvent and one or more strongly or moderately polar solvents. Normal-phase behavior can be sometimes observed also in non-aqueous RP liquid chromatography (NARPLC), probably because of the activity of polar residual silanol groups.

For the separation of molecules differing in their hydrophobic parts, RP chromatography generally offers a better selectivity than NPLC, but there are some practical reasons for selecting NP chromatography methods in specific cases, as follows:

1. A lower organic-mobile-phase viscosity offers a lower pressure drop across the column than that obtained in aqueous–organic mobile phases used in RPLC at a comparable flow rate.
2. HPLC columns are usually more stable and have longer lifetimes in organic solvents than in aqueous–organic mobile phases.
3. Many samples are more soluble or less prone to decompose in organic mobile phases than in aqueous mobile phases and do not cause injection problems in NPLC, as is occasionally observed in RPLC.
4. Unlike RP chromatography, NP chromatography enables the direct injection of samples extracted into a non-polar solvent.
5. NPLC is usually better suited for the separation of positional isomers or stereoisomers than RPLC.

Very large changes in separation selectivity are possible by changing either the mobile phase or the stationary phases in NPLC. Proton donor–acceptor interactions cause strong retention of basic compounds on silica gel in non-aqueous mobile phases, whereas acidic compounds show higher affinities to aminopropyl columns. The elution strength is proportional to the polarity of the mobile phase. Wide variations in the selectivity of NP chromatography separations can be achieved by selecting solvents with appropriate types of selective polar interactions. Usually, binary organic mobile phases, comprised of a less polar solvent A (a hydrocarbon such as hexane) and a more polar solvent B (propanol, dioxane, dichloromethane, acetonitrile, etc.), are employed in NP chromatography. With some simplification, the dependence of the retention factor k on the volume fraction φ of the polar solvent B in binary mobile phases can be described by Eq. 2:[2]

$$k = k_0\varphi^{-m} \quad (2)$$

The constants k_0 and m depend on the nature of the solute and on the chromatographic system, but are independent of the concentration, φ, and k_0 is the retention factor in pure

solvent B. The parameter *m* theoretically corresponds to the number of molecules of the strong solvent B necessary to displace one adsorbed sample molecule.

Highly hydrophilic samples are usually too weakly retained in RPLC to allow their separation, whereas they are often retained too strongly in non-aqueous mobile phases used in conventional adsorption NPLC and/or are not sufficiently soluble in the non-aqueous mobile phases. This problem can be solved by using polar stationary phases, such as silica gel with decreased surface concentration of silanol groups, or chemically bonded amino-, amido-, cyano-, carbamate-, diol-, polyol-, poly(2-sulphoethyl aspartamide), zwitterionic sulfobetaine, etc. ligands in aqueous–organic mobile phases rich in organic solvents (usually acetonitrile). This separation mode is called hydrophilic interaction liquid chromatography (HILIC) and can be characterized as NPLC with conventional RP mobile phases. Since its introduction in the early 1980s, HILIC has been successfully applied in the analysis of carbohydrates, amino acids, peptides, polar drugs, toxins, natural compounds in plant extracts, and other compounds important to food and pharmaceutical industries.

In contrast to RP chromatography, water is the stronger solvent in HILIC mobile phases, where it is usually contained in concentrations of 1–30%. Hence it forms an adsorbed layer on the surface of a polar adsorbent, which is thick enough to induce liquid–liquid partition between the bulk mobile phase and the adsorbed aqueous liquid layer. Consequently, the retention in HILIC is often due to the combination of adsorption and liquid–liquid partition mechanisms with possible additional effects of ion exchange (especially on bonded amino, zwitterionic, or weak ion exchange columns). The transition between the adsorption and partition retention mechanisms is probably continuous as the water concentration in the mobile phase gradually increases.

In RP chromatography with binary mobile phases (methanol–water or acetonitrile–water), retention decreases as the concentration of the less polar organic solvent increases, whereas in aqueous NP (HILIC) chromatography retention decreases with increasing concentration of the more polar water. Consequently, U-shape plots of the retention times vs. the concentration of the organic solvent are often observed on HILIC columns over the full composition range of the mobile phase, with the minimum corresponding to the transition from the RP to the NP mechanism. The U-turn mobile-phase composition shifts to higher concentrations of water in the mobile phase when less polar stationary phases are used, allowing HILIC separations in mobile phases with higher water concentrations. Stationary phases with various functionalities show significant differences in retention and separation selectivity. Silica gel has the least retention, but often has higher selectivity differences for small polar compounds such as carboxylic acids, nucleosides, and nucleotides, with respect to other polar bonded stationary phases commonly used in HILIC (amide, amino, aspartamide, or sulfobetaine).

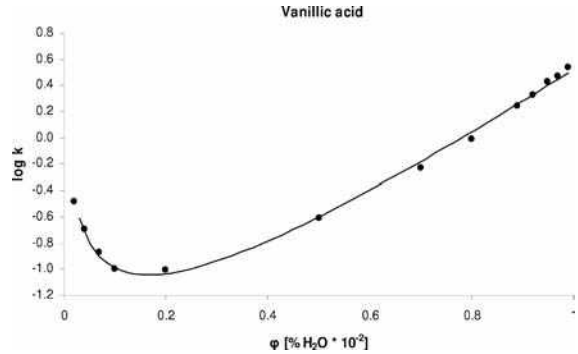

Fig. 2 Effects of the volume fraction of water, ϕ, in binary acetonitrile–water mobile phases on the retention factor, k, of vanillic acid on a bonded polyethylene glycol column. HILIC mode at $\phi < 0.2$, RP mode at $\phi > 0.2$.

The retention dependence on the volume fraction of water ϕ can be described by Eq. 2 in the HILIC range to a first approximation. To characterize the effects of water on the retention over the full composition range of binary mobile phases, as described in Eq. 3 can be obtained by combining Eqs. 1 and 2 for the RP and HILIC range, respectively:

$$\log k = a + m_1 \cdot \varphi_w - m_2 \cdot \log \varphi_w \quad (3)$$

ϕ_w is the volume fraction of water in the mobile phase. Fig. 2 shows an example of the validity of Eq. 3 for vanillic acid on a bonded polyethylene glycol column.

Suitability of a HILIC system for particular samples can be evaluated using a gradient of increasing concentration of water in acetonitrile (from 2–10% to 50% in 10 min). Increasing concentration of the organic solvent or of a salt in the mobile phase enhances the retention of polar compounds, except for the bonded amino phase, where the retention of the acid compounds decreases with increasing concentration of salts due to the ion exchange effects. In HILIC, mobile phases should be buffered, as pH affects the ionization and hence the retention of weakly acidic or weakly basic polar compounds.

LC SEPARATION OF IONIC COMPOUNDS

Ionized compounds are usually much less retained than non-charged compounds; their separation in RP chromatography is usually possible only with ionic additives to the mobile phase. Basic compounds can interact with residual silanols in alkyl silica-bonded phases ionized to SiO^- anions; consequently, strong retention and tailing peaks are observed. Alkylamine additives to the mobile phase sometimes improve peak shape by blocking the silanol groups. Repulsive interactions with the negatively charged

residual-SiO^- groups in the alkyl silica-bonded phases cause ionic exclusion, owing to which a part of the inner pore volume is not accessible to anionic samples. Ion exclusion may result in poor separation of strong acids, which elute close to, or even before the column holdup time, usually as asymmetrical peaks. Ion exclusion may be suppressed at a higher ionic strength of the mobile phase, which decreases the negative surface zeta potential of the residual silanol groups on the surface of silica-based chemically bonded phases. Hence, addition of salts to the mobile phase often improves separations of anionic compounds.

In mobile phases containing 5–50 m*M* phosphate or acetate buffers of pH 2–8.5, the ionization of weak acids (at pH < 7) or weak bases (at pH > 7) can be more or less suppressed to improve separation and peak symmetry. By adjusting the pH in the range ± 1.5 around the pK_a, differences in the degree of ionization of the individual sample components can often be utilized to control the separation selectivity. The retention is usually adjusted by the addition of up to 30–40% acetonitrile, methanol, or tetrahydrofuran to the mobile phase.

Strong acids and strong bases are completely ionized over a broad pH range and their chromatographic behavior is usually affected very little by adding a buffer to the mobile phase. Such compounds can be separated by RP ion pair or IEC. In ion pair chromatography (IPC), ion pair reagents whose molecules contain a strongly acidic or strongly basic group and a bulky hydrocarbon part are added to the mobile phase. Basic substances can usually be separated using C6–C8 alkanesulphonates, and acidic substances using tetralkylammonium salts. Ion pair additives significantly increase retention and improve peak symmetry through the formation of neutral ionic-associated species, called ion pairs, with increased affinity to a non-polar stationary phase. The retention in IPC can be controlled by the type and concentration of the ion pair reagent or of the organic solvent in the mobile phase. Increasing the number and size of alkyls in the reagent molecules enhance retention in the reagent concentration range between 10^{-4} and 10^{-2} *M*.

Nowadays, IEC is used mainly for the separation of small inorganic ions or ionic biopolymers such as oligonucleotides, nucleic acids, peptides, and proteins, rather than in the analysis of small organic ions, for which RP chromatography and IPC usually offer higher efficiency and better resolution. The columns in IEC are packed with fine particles of ion exchangers, which contain charged ion exchange groups covalently attached to a solid matrix (either an organic cross-linked styrene–divinylbenzene or ethyleneglycol–methacrylate copolymer), or inorganic support to which a functional group is chemically bonded via a spacer (a propyl, or phenylpropyl moiety). Strong cation exchangers contain $-SO_3^-$ sulfonate groups and strong anion exchangers contain $-N(CH_3)_3+$ quaternary ammonium groups, completely ionized over a broad pH range (pH = 2–12). Weak cation exchangers contain carboxylic or phosphonic acid groups, which are ionized only in alkaline solutions, and tertiary or secondary amino groups (e.g., diethyl aminoethyl) in weak anion exchangers are ionized only in acidic mobile phases. Ion exchange separations require aqueous or aqueous–organic mobile phases containing counterions (10^{-2}–10^{-1} *M* salts, buffers, ionized acids, or bases), which compete with the sample ions for the ion exchange groups. The retention in IEC decreases with increasing concentration of counterions in the mobile phase and with decreasing ion exchange capacity of the column (1–5 mEq/g for organic polymer ion exchangers and 0.3–1 mEq/g for silica-based ion exchangers). Weak acids are usually separated by anion exchange chromatography at pH > 6, and weak bases are separated by cation exchange chromatography at pH < 6; their retention increases with increasing ionization. By varying the pH of the mobile phase the separation selectivity can be adjusted, whereas the retention is controlled by the ionic strength.

STRATEGIES FOR SELECTING AND OPTIMIZING ISOCRATIC SEPARATION CONDITIONS

Once a suitable HPLC separation mode has been selected, experimental conditions can be adjusted using either an empirical method or a systematic method development approach. The separation of two sample compounds is conveniently characterized by resolution R_S:[4]

$$R_s \cong \frac{\sqrt{N}}{4}(r_{1,2}-1)\frac{k}{1+k} \quad (4)$$
$$= \text{Efficiency} \times \text{Selectivity} \times \text{Capacity}$$

Here, N is the column efficiency expressed in terms of plate number; $r_{1,2}=k_2/k_1$ is the separation factor, which characterizes the selectivity of separation; and k is the average retention factor of the two sample compounds 1 and 2 as a measure of capacity contribution to the resolution. The three terms contributing to the resolution depend on many experimental conditions which can be adjusted either simultaneously or in consecutive steps.

For accurate quantitative analysis the resolution usually should be 1–1.5. However, too high a resolution may result in excessive analysis time. The chromatogram in Fig. 3A schematically illustrates adequate separation of a three-component sample. If the separation is not satisfactory, it can be improved according to the following strategy:

1. Poorly resolved peaks appearing close to the column holdup volume, such as the one in the example in Fig. 3B, show that the retention is too low and should be increased; this is best done by decreasing the elution strength of the mobile phase, whereas the elution strength should be increased if the retention volumes are too large (Fig. 3C).

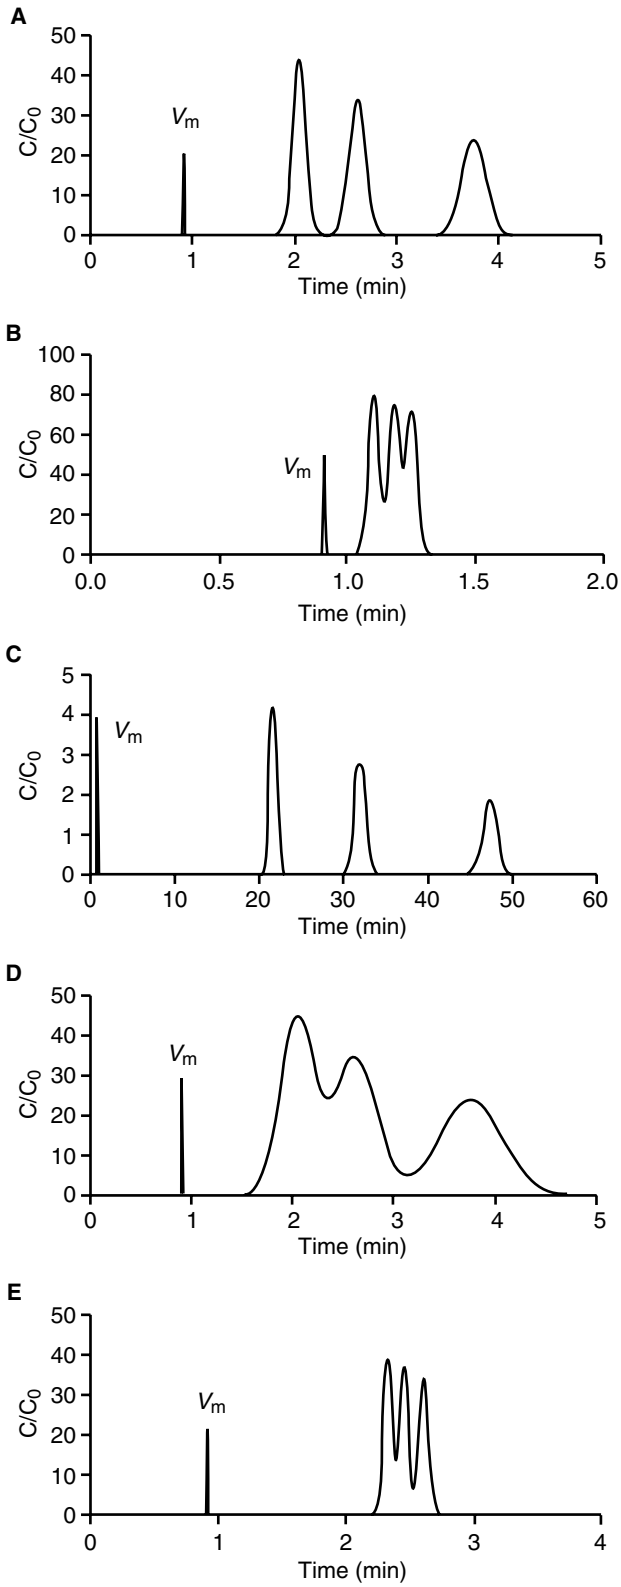

Fig. 3 Examples of chromatographic separation of a three-component sample. (A) Satisfactory separation. (B) Unsatisfactory separation, too low retention. (C) Good resolution, but too long time of separation. (D) Unsatisfactory separation, too low column efficiency. (E) Unsatisfactory separation, good retention and column efficiency, but too low separation selectivity.

2. If the retention times are adequate and partial separation of the bands is apparent but the bands are relatively broad (Fig. 3D), the resolution can possibly be improved by increasing the efficiency (i.e., the plate number of the column).
3. If the bands are narrow, but are not well-separated from each other, such as in Fig. 3E, the selectivity should be improved

    a. By changing the components of the binary mobile phase.
    b. By using ternary or more complex mobile phases or mobile phase additives inducing specific interactions with sample components.
    c. By using another HPLC column with a different stationary phase.

4. If the resolution of early eluted bands is unsatisfactory and the separation time is long, the sample separation is usually improved by temperature or solvent gradients.

CONTROL OF SEPARATION EFFICIENCY

The efficiency contribution to the resolution (i.e., the column plate number, N) is directly proportional to column length, and increases with decreasing particle size of the column packing. Further, column efficiency often improves as the temperature increases because of decreasing viscosity of the mobile phase and increasing diffusion coefficient.

The efficiency contribution to the resolution, i.e., the column plate number, N, is directly proportional to the column length, L, and increases with decreasing particle size of the column packing and—to a lesser extent—with decreasing flow rate of the mobile phase. The dispersion of a solute band as it migrates along the column is characterized by the height equivalent to theoretical plate, $H = L/N$, and depends on experimental conditions, such as the velocity of the mobile phase, u, described to a first approximation by the well-known van Deemter equation:

$$H = A + \frac{B}{u} + Cu = \lambda d_p + 2\gamma\left(\frac{D_M}{u}\right) + c\left(\frac{d_p^2}{D_M}\right)u \quad (5)$$

A, B, and C represent three additive contributions to band broadening. The velocity-independent term A represents the contribution of eddy (radial) diffusion to band broadening and is a function of the size and distribution of interparticle channels and the possible non-uniformities

in the packed bed (coefficient λ); it is directly proportional to the mean diameter of the column-packing particles, d_p. The term B describes the effect of molecular (longitudinal) diffusion in the axial direction and is directly proportional to the solute diffusion coefficient in the mobile phase, D_M. The obstruction factor γ takes into account the hindrance to the rate of diffusion caused by the particle skeleton.

The third term, C, is a measure of the resistance to mass transfer between the stationary phase and the mobile phase. To a first approximation, it is inversely proportional to the diffusion coefficient, D_M, and directly proportional to the second power of the distance a solute molecule should travel from the mobile phase to reach the interaction site in the particle. For a totally porous particle, this distance is proportional to the mean particle diameter, d_p. More exactly, average pore depth should be used instead, but this quantity is difficult to determine.

The minimum on the H–u plot (Eq. 5) corresponds to the best separation efficiency, but separations are often performed at a higher-than-optimum flow rate to decrease the run time. The speed vs. efficiency characteristics of various HPLC columns can be optimized using kinetic plots proposed by Poppe.[3] There, the minimum column holdup time, t_0, necessary to produce the desired number of theoretical plates, N, can be determined from the diagonal line at the point on the plots of H/u, characterizing the speed of separation vs. N in logarithmic coordinates.[3] The plots are charted for different column types assuming a maximum allowed instrumental pressure, $\Delta P_{max} = 40$ MPa, as is usual in conventional LC, and at the optimum flow velocity, u, corresponding to the minimum height equivalent to theoretical plate, H, on the van Deemter H–u curve (Eq. 5). An example of the kinetic plots for columns packed with materials of different mean particle diameter is shown in Fig. 4.

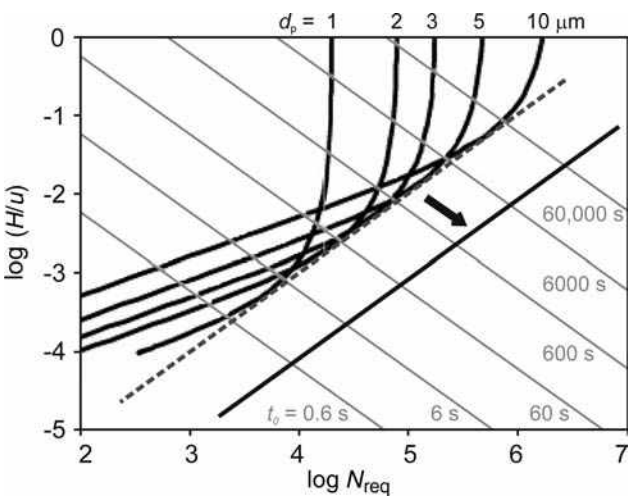

Fig. 4 Kinetic plots for columns packed with different particle sizes, d_p, at a maximum instrumental operation pressure of 40 MPa and optimum flow velocity, u, at the minima of H–u plots; t_0 is column holdup time, N_{req} is the maximum number of theoretical plates.

The kinetic plots divide the plane into two regions. The part on the right side below the dashed envelope line corresponds to the forbidden region, where the desired N vs. t_0 performance cannot be accomplished within the experimental pressure limits. The plots show that very high numbers of theoretical plates can be achieved in long columns packed with relatively large-diameter particles (>10 μm), however at the cost of very long separation times. On the other hand, fast separations in less than 1 min require short columns packed with particles of diameters less than 2 μm, with relatively low N at 40 MPa. To achieve the efficiency of several thousands of theoretical plates with particle diameters of 1–2 μm, longer columns are necessary. This means that the kinetic plots should be moved deeper to the forbidden region, as indicated by the full line in Fig. 4. This can be accomplished using instrumentation for UHPLC technique, with pressure limits up to 150 MPa. Another way to achieve this goal, using the conventional equipment, is decreasing the flow resistance of the columns. Monolithic columns with large flow pores and better permeabilities or columns packed with fused-core particles of small size (2.7 μm) with a thin porous shell (0.5 μm), which provide shorter diffusion paths inside the particles and reduced axial dispersion of solutes, have less stringent pressure limitations and offer faster separations at the same pressure drop in comparison to the columns with totally porous structure. Column permeability is also enhanced at high temperatures, owing to reduced viscosity of mobile phases.

CONTROL OF RETENTION AND SEPARATION SELECTIVITY: STATIONARY PHASE

The retention and the selectivity of separation in RP and NP chromatography depend primarily on the chemistry of the stationary phase and the mobile phase, which control the polarity of the separation systems. There is no generally accepted definition of polarity, but it is agreed that it includes various selective contributions of dipole–dipole, proton–donor, proton–acceptor, π–π electron, or electrostatic interactions. Linear Free-Energy Relationships (LFER) widely used to characterize chemical and biochemical processes were successfully applied in liquid chromatography to describe quantitative structure–retention relationships (QSRR) and to characterize the structural contributions to the retention and selectivity, using multiple linear correlation, such as Eq. 6:[4]

$$\log k = (\log k)_0 + \frac{m_1 V_X}{100} + s_1\pi_2^* + a_1\alpha_2 + b_1\beta_2 \qquad (6)$$

The molecular structural descriptors in Eq. 6 characterizing various structural effects influencing the retention are molar volume of a solvated solute, V_X, polarity, π_2*, hydrogen

bonding basicity, β_2, and hydrogen bonding acidity, α_2. Eq. 6 allows predictions of retention of different solutes on the same column and in the same mobile phase using these molecular descriptors, which can be found in published data bases of properties.[4] The parameters of the LFER equation (Eq. 6), m_1, s_1, a_1 and b_1, obtained using multivariate simultaneous least squares regressions of the experimental retention data for selected standard compounds are characteristic for specific combinations of mobile and stationary phases and can be therefore used for HPLC method development. Stationary phases providing large differences in the LFER parameters for the individual sample components are likely to provide high specific polar selectivity for the separations of specific sample types.

To better distinguish the contributions of polar interactions to retention, the LFER model was transformed into the so-called hydrophobic subtraction model (HSM) for RPLC, where the hydrophobic contribution to retention is compensated for by relating the solute retention to a standard nonpolar reference compound. This approach was applied to characterize more than 300 stationary phases for RPLC, including silica gel supports with bonded alkyl-, cyanopropyl-, phenylalkyl-, and fluoro-substituted stationary phases and columns with embedded or end-capping polar groups. The QSRR models can be used to characterize and compare the suitability of columns not only for reversed-phase, but also for NP and HILIC systems.

Recently, phase optimized liquid chromatography (POPLC) strategy was introduced for selecting the suitable column for specific RP separations. The principle is basically similar to the PRISMA approach suggested earlier by Nyiredy[5] for the selection of optimum composition of ternary mobile phases (see below). A sample is injected under the same isocratic conditions on five bonded-phase columns with different chemistries: 1) an end-capped C18 column with predominant hydrophobic interactions, 2) a C18 column with an embedded amide group providing, in addition, preferential interactions with carbonyl, carboxylic acid, and amino compounds, 3) a phenyl column with preferential adsorption of aromatic compounds on account of π–π interactions, 4) a nitrile column with enhanced dipole–dipole interactions, and 5) a C30 column with enhanced retention of planar compounds in comparison to non-planar ones. Based on the experimental retention data, software calculations are performed to design a POPLC column comprising combinations of various lengths of the five basic stationary phases in up to 25 segments of 10 mm each, tailor-made to provide optimum resolution of a specific sample.

CONTROL OF RETENTION AND SEPARATION SELECTIVITY: MOBILE PHASE

For a successful HPLC separation, the appropriate selection of a mobile phase is equally important as the correct choice of a separation column. Single-component mobile phases do not allow a fine adjustment of the elution strength, as there is only a limited selection of solvents compatible with UV and other common detection techniques, so mixed mobile phases composed of solvents with different elution strengths should be used. Increasing the concentration of the strong solvent in a mixed mobile phase speeds up the elution. The retention of weak acids and weak bases in RPLC increases when the pH of the mobile phase is adjusted to suppress their ionization. A change in the retention, induced by an increase or decrease in the concentration of the strong solvent, is often accompanied by a change in the separation selectivity. The effects of the mobile phase on separation can be predicted, and the separation can be optimized using either a commercial software such as Dry Lab I or simple predictive calculations employing, e.g., Eq. 1 or Eq. 2.

Ternary and more complex mobile phases contain at least two different strong solvents with different predominant selective polar contributions (dipole–dipole, proton–donor, and proton–acceptor) in a weak solvent. Fine selectivity tuning is often possible by appropriate selection of the concentration ratios of the strong solvents.[6] In RP chromatography, acetonitrile with dipole–dipole properties, tetrahydrofuran with proton–acceptor properties, and methanol with both proton–donor and proton–acceptor properties are used as strong solvents in water; in NP chromatography, a non-localizing solvent (dichloromethane), a basic localizing solvent (methyl-*t*-butyl ether), and a non-basic localizing solvent (acetonitrile or ethyl acetate) are mixed and diluted with hexane or heptane to adjust the elution strength. For any three-component or four-component mobile phase, the proportions of the individual selective contributions to the polarity are determined by the concentration ratios of the three strong solvents, whereas the elution strength is controlled by the concentration of water in RPLC and of alkane in NPLC, e.g., using the PRISMA optimization approach.

Single-parameter optimization employs several experiments at preselected values of the optimized parameter (such as the concentration of the strong solvent in a binary mobile phase, pH, temperature) to predict the resolution as a function of the optimized parameter using empirical or simple model-based calculations. Then, plots are constructed (the window diagrams [7]) in which the range of the optimized parameter is searched for the value that provides the desired resolution for all adjacent bands in the chromatogram in the shortest time. An example of a window diagram (Fig. 5) illustrates the approach adopted for the optimization of a binary mobile phase in NPLC.

Some parameters may show synergistic effects on separation. In this case, simultaneous optimization of two or more parameters can provide better results than their sequential optimization. Simple methods can be used for sequential multiparameter optimization in HPLC.

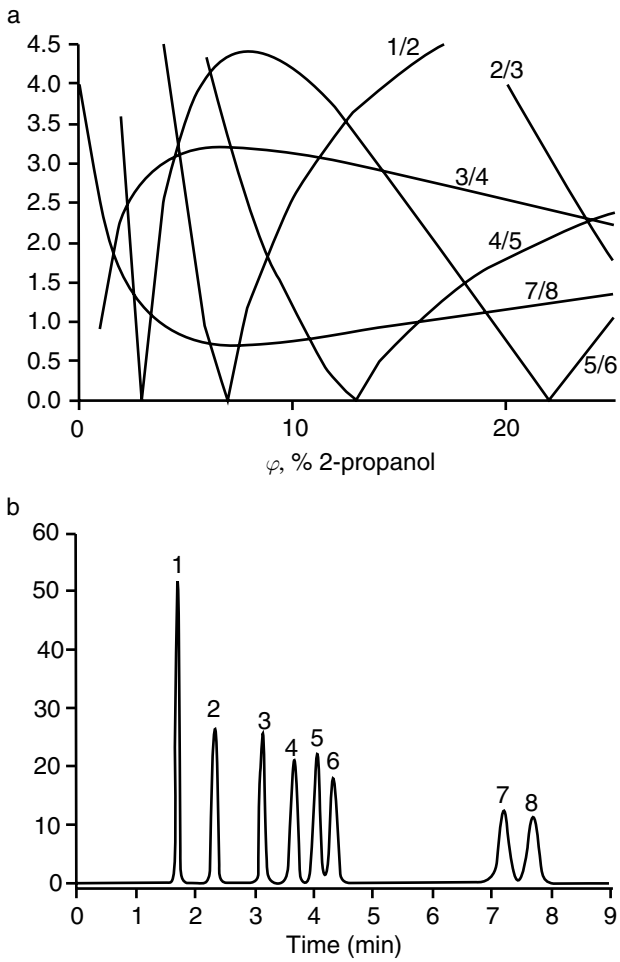

Fig. 5 (a) The window diagram (the dependence of the resolution on the concentration) of 2-propanol in *n*-heptane as the mobile phase, for a mixture of eight phenylurea herbicides on a Separon SGX 7.5 μm silica gel column (150 × 3.3 mm I.D.). (b) The separation with an optimized concentration of 19% 2-propanol in the mobile phase for maximum resolution. Column plate number $N = 5000$, $T = 40°C$, flow rate 1 ml/min. Sample compounds: neburon (1), chlorobromuron (2), 3-chloro-4-methylphenylurea (3), desphenuron (4), isoproturon (5), diuron (6), metoxuron (7), and deschlorometoxuron (8).

Alternatively, the composition of mixed mobile phases can be optimized using an overlapping resolution mapping strategy to adjust the optimum separation selectivity based on seven or more initial experiments with solvent mixtures of approximately equal elution strength. Based on the retention data from the initial experiments, either 3-D diagrams or contour resolution maps are constructed for all adjacent bands in the selectivity triangle space as a function of the concentration ratios of three solvents or two solvents and the pH of the mobile phase, from which the composition of the mobile phase that provides maximum resolution is selected.

Structure-based commercial optimization software (e.g., Chromdream, Chromsword, or Eluex) incorporate some features of the expert system, as the retention is predicted based on the additive contributions of the individual structural elements and, consequently, the optimum composition of the mobile phase is suggested. Such predictions are only approximate and do not take into account stereochemical and intramolecular interaction effects.

TEMPERATURE AS A TOOL FOR CONTROLLING EFFICIENCY, RETENTION, AND SELECTIVITY IN HPLC

The regulation of temperature is convenient and simple, but is usually less effective for improving HPLC separations than is varying the composition of the mobile phase. Further, thermal instability of some solutes can limit the use of high temperatures in HPLC. Another limiting factor is the limited practical temperature range, dictated by the poor stability of many HPLC stationary phases chemically bonded on silica gel supports at temperatures above 60°C (except for some new polydentate bonded phases with bridged structure showing improved resistance against hydrolysis and dissolution). Organic polymer, carbon, or the newly developed zirconium dioxide (zirconia) adsorbents with carbon deposited on the surface or modified with C18, polybutadiene, polystyrene, and other ligands are now commercially available, which show excellent long-term chemical and thermal stability and withstand extended exposure to column temperatures as high as 200°C, unfortunately, often at the cost of inferior efficiency in comparison to bonded silica gel columns.

High-temperature liquid chromatography (HTLC) offers distinct advantages with respect to ambient temperature operation for thermally stable compounds, because mobile phase viscosity and, hence, operating pressure decrease at elevated temperatures, allowing small particle size columns to be used at relatively high flow rates, with improved efficiency. Increased temperature usually affects favorably the separation selectivity of ionic or partially ionized compounds. High temperature enhances the high-speed potential of UHPLC, so that separations of a large variety of samples, such as drugs and chiral compounds, are possible in less than 2 min. At elevated temperatures water polarity decreases, so that pure water can be often used as mobile phase providing retention comparable to aqueous–organic solvent mixtures containing methanol or acetonitrile.

Linear relationships between ln k and the reciprocal value of the thermodynamic temperature T (in Kelvins), have been observed in many chromatographic systems, according to van't Hoff equation (Eq. 7):

$$\ln k = -\frac{\Delta H}{RT} + \frac{\Delta S}{R} + \ln \Phi \qquad (7)$$

where R is the universal gas constant; $-\Delta H$ and ΔS are the enthalpy and entropy, respectively, connected with the solute transfer from the mobile phase to the stationary phase; and Φ is the ratio of the volumes of the stationary to the mobile phase, $\Phi = V_s/V_m$ in the column. Eq. 7 can be used to distinguish the enthalpic and entropic contributions to the retention. However, if the molecular conformation changes with changing temperature, non-linear ln k vs. $1/T$ plots may be observed, such as with biopolymers (proteins). The retention factors, k, of small molecules usually decrease by approximately 1–2% when the column temperature increases by 1°C, but for the same change in temperature, the retention factors of solutes with large $-\Delta H$ are more strongly affected. A change in temperature may be accompanied by a change in separation selectivity, $r_{1,2}$, when sample molecules have different functional groups, relative size, or shape, or if the conformation of the stationary phase changes at increased temperatures. Temperature regulation can be used for optimizing the resolution, e.g., using window diagram strategy, as in the optimization of the composition of the mobile phase.

Column temperature together with mobile phase composition can be optimized simultaneously in RPLC using the optimization software based on Eq. 8:

$$\ln k = a_1 + \frac{a_2}{T} + m\,\varphi\left(1 - \frac{T_C}{T}\right) \quad (8)$$

where ϕ is the volume fraction of the organic solvent in the aqueous–organic mobile phase, T_C is the enthalpy–entropy compensation temperature and a_1, a_2, and m are parameters depending on solutes and stationary phase. For a given sample, four initial experiments should be run at two different temperatures and mobile phase compositions to allow designing of the resolution map as a function of both temperature and mobile phase composition.

Simultaneous optimization of temperature and stationary phase can be carried out for two tandem columns with different selectivities for the sample compounds by adjusting the temperature individually for each column at a constant composition of the mobile phase.

CONCLUSIONS

Suitable detection conditions, separation mode, appropriate column dimensions, and packing materials (stationary phase) in isocratic LC should be selected keeping in mind the objective of separation, using the information on sample properties, such as solubility, polarity, and presence of specific functional groups in sample compounds, sample amount, concentration., etc. For the control of separation selectivity, resolution, and time of analysis, appropriate selection of the mobile phase is as important as the choice of the stationary phase. Isocratic separations can be optimized using single-parameter or multiparameter strategies, using either commercial software or simple computer-aided predictive calculations.

Katharometer Detector for GC

Raymond P.W. Scott
Scientific Detectors Ltd., Banbury, Oxfordshire, U.K.

INTRODUCTION

The katharometer detector [sometimes spelled "catherometer" and often referred to as the *thermal conductivity detector* (TCD) or the *hot-wire detector* (HWD)] is the oldest commercially available gas chromatography (GC) detector still in common use. Compared with other GC detectors, it is a relatively insensitive detector and has survived largely as a result of its almost universal response. In particular, it is sensitive to the permanent gases to which few other detectors have a significant response. Despite its relatively low sensitivity, the frequent need for permanent gas analysis in many industries probably accounts for it still being the fourth most commonly used GC detector. It is simple in design and requires minimal electronic support and, as a consequence, is also relatively inexpensive compared with other detectors.

DISCUSSION

In the late 1940s and early 1950s, the katharometer was developed for measuring the amount of carbon dioxide in flue gases. However, with the advent of GC, its use as a detector was investigated by Ray.[1] It was soon established as a very effective GC detector and was found to be simpler to fabricate than the gas density bridge, but had about the same sensitivity and linearity. For a while, it was the only detector that was commercially available. At the time, its mode of action was the subject of some controversy, as it was not clear whether it responded to changes in the *thermal conductivity* or the *specific heat* of the column eluent. The response of the detector was examined in detail by Mellor[2] and Harvey and Morgan[3] in 1956 and it would appear that no such detailed studies have been carried out since that time. It was concluded that the katharometer responded to both changes in thermal conductivity *and* to changes in the specific heat of its surroundings. In any particular system, depending on the operating conditions employed, one or the other property may dominate in controlling the response of the detector. The relationship, however, is not simple and it was not found possible to accurately predict the response of the detector from a knowledge of the specific heat and thermal conductivity of the gases or vapors involved.

The basic design of a katharometer is as follows. A filament carrying a current is situated in the column eluent. Under equilibrium conditions, the heat generated in the filament will equal the heat lost by conduction, convection, and radiation and the filament will assume a constant temperature. The filament is constructed from a metal, such as platinum, that has a high temperature coefficient of resistance, and at the equilibrium temperature, the resistance of the filament and, thus, the potential across it will be constant. The heat lost from the filament will depend on the thermal conductivity of the gas, its specific heat, and the thermal emissivity of the filament surface. Both the thermal conductivity and the specific heat of the gas will change in the presence of a different gas or solute vapor. As a result, the temperature of the filament will change, causing a change in potential across the filament. This potential change is amplified and either fed to a suitable recorder or regularly sampled by an appropriate data acquisition system.

As the device responds to the heat lost from the filament, the katharometer detector is extremely *flow* and *pressure* sensitive. Consequently, all katharometer detectors must be carefully thermostatted and must be fitted with reference cells to help compensate for changes in pressure or flow rate. There are two basic katharometer designs: the "in-line" cell, where the column eluent actually passes directly over the filament, and the "off-line" cell, where the filaments are situated away from the main carrier gas stream and the gases or vapors only reach the sensing element by diffusion. Due to the high diffusivity of vapors in gases, the diffusion process can be considered as almost instantaneous. Diagrams of the two katharometer designs are shown in Fig. 1.

The sensitivity of the katharometer is only about 10^{-6} g/ml (probably the least sensitive of all GC detectors) and has a linear dynamic range of about 500 (the response index lying between 0.98 and 1.02). It is, however, a general detector and will sense all permanent gases and vapors other than the gas that is used as the carrier gas. Its universal response is one reason for its survival as a GC detector, despite its very limited sensitivity. Although the least glamorous, this detector can be used in most GC analyses that utilize packed columns and where there is no limitation to sample availability. Although small-volume katharometers have been designed for use with capillary columns, the katharometer is rarely used with such columns, again due to its relatively low sensitivity. The device is simple, reliable, rugged, and, as already stated, comparatively inexpensive. As a consequence, it has found use in less than ideal environments where GC

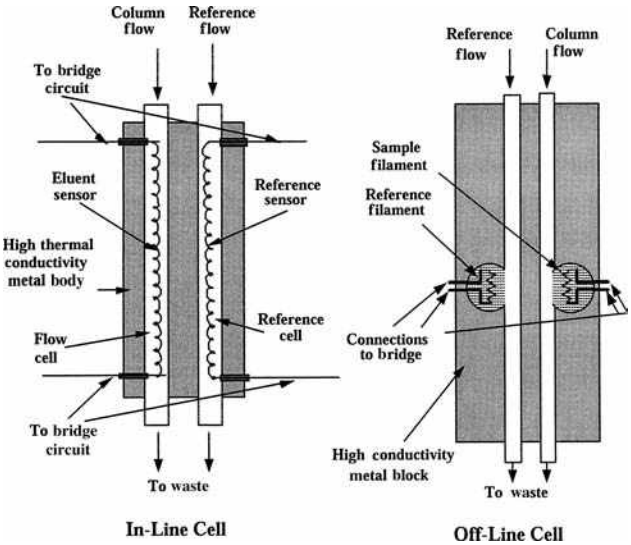

Fig. 1 Katharometer cells.

is employed for process monitoring and process control. If constructed of platinum and Teflon, the katharometer is one of the few detectors that can be used for detecting very corrosive materials such as the halogens, uranium hexafluoride, volatile inorganic acids, and so forth.

Kovats' Retention Index System

Igor G. Zenkevich
Chemical Research Institute, St. Petersburg State University, St. Petersburg, Russia

INTRODUCTION

In "classical" chromatographic methods (excluding hyphenated techniques), analytical signals are two dimensional. Each chromatographic peak may be characterized by two parameters: area, which is proportional to the quantity of substance being eluted from column, and its position on the chromatogram (retention time, t_R), which reflects the interaction between the sorbate (analyte) and sorbent (stationary phase). This interaction is the principal source of information about the chemical nature and structure of the analytes.

However, the "raw" retention times by themselves are not useful for any chemical interpretation owing to their dependence on numerous conditions of analysis. In Gas Chromatography, for example, these conditions include type of stationary phase, its content in packed columns or film thickness in the capillary columns, length of the column, oven temperature (constant temperature in isothermal conditions or initial temperature and ramp at temperature programming), carrier gas flow, and even the pressure gradient between the inlet and outlet of the chromatographic system. The characterization of analytes in chromatography by net retention times may be compared to the measurements of temperature by thermometers with different arbitrary scales or even without any scales at all. Thus, the standardization of chromatographic retention parameters is a problem of extremely high importance.

One possible solution is based on the complete interlaboratory standardization of all above-mentioned experimental conditions. The realization of the so-called retention time locking (RTL) concept became possible only during the mid-1990s by using high precision chromatographic equipment. At present, it is rarely used for determination of only restricted sets of analytes (typical examples of confirmatory analysis), for instance, pesticides or drugs.[1] The second most widely used and conventional approach requires the recalculation of the raw retention data, which are measured at different conditions using an interlaboratory comparable scale. The mathematical method suitable for this recalculation—linear interpolation—has been known long before the appearance of chromatography.

Given pairs of function (y) and argument (x) values—$y_1(x_1)$, $y_2(x_2)$,..., $y_n(x_n)$—that are connected by a known or unknown functional dependence $y = f(x)$, we can estimate the unknown values y_i, which are located between the known values $y_k < y_i < y_{k+1}$ from the value $x_i (x_k < x_i < x_{k+1})$ by following a simple linear interpolation relationship:

$$y_i = y_k + (y_{k+1} - y_k) \times (x_i - x_k)/(x_{k+1} - x_k) \quad (1)$$

In the case of a non-linear or unknown dependence $y = f(x)$, the application of a simple linear interpolation leads to some uncertainty in the results. However, if the equation for non-linear dependence $f(x)$ is known, a transformation of Eq 1 into Eq. 2 can be used to remove the non-linearity and, hence, errors of interpolation. This approach gives results of the same precision as that of direct calculation with $y = f(x)$:

$$y_i = y_k + (y_{k+1} - y_k) \times \{[f(x_i) - f(x_k)]/[f(x_{k+1}) - f(x_k)]\} \quad (2)$$

The application of this concept in chromatography requires the introduction of some extra components with previously known (postulated) retention indices (RIs) into the samples being analyzed. Their peaks form a "mobile" co-ordinate system for the recalculation of t_R data of the target analytes. Hence, the establishment of any retention index system needs the following:

1. The choice of set of reference compounds (most often they are members of the same homologous series that differ by a homologous difference CH_2).
2. The attribution of standard (conventional) RI values for these compounds.
3. The choice of a formula for the calculation of RI values for all other analytes.

The basis of RI systems in chromatography is similar to the mode of the definition of commonly used temperature (T) scales, namely centigrade (Celsius), where:

1. Reference points for this scale are melting and boiling temperatures (T) of water.
2. Standard (conventional) T values for these reference points are 0°C (melting) and 100°C (boiling).
3. The formula for calculation of other T values between and outside accepted reference points is that for linear interpolation (1).

KOVATS' RETENTION INDICES

The first RI system was proposed by Kovats in 1958[2] for isothermal conditions of gas chromatography (GC) analysis.

The easily accepted *n*-alkanes (*n*-C_nH_{2n+2}), with postulated RI values $RI = 100 \times n_C$ [e.g., methane (CH_4)—100, *n*-non-ane (C_9H_{20})—900, *n*-hentriacontane ($C_{31}H_{64}$)—3100, etc.], were recommended as reference compounds. This is because, under isothermal conditions of GC analysis, a linear dependence of logarithms of corrected retention times $t_R' = t_R - t_0$ (t_0 is the hold up time of chromatographic system) on the number of carbon atoms in the molecule of homolog is observed, i.e., $\log t_R' = an_C + b$. Keeping in mind that (by definition) $100n_C = RI$, the existence of the following linear dependence is implied:

$$RI = a \log t_R' + b \tag{3}$$

If we consider the last relationship as the function $y = f(x)$ in Eq. 2, we come to the final equation of Kovats' Retention Index (KRI) System:

$$RI_x = RI_k + (RI_{k+1} - RI_k) \times \{[\log(t_{R,x}') - \log(t_{R,k}')]/[\log(t_{R,k+1}') - \log(t_{R,k}')]\} \tag{4}$$

where $t_{R,\,x}' < t_{R,\,k}' < t_{R,\,k+1}'$ are the corrected retention times of reference *n*-alkanes with k and $k + 1$ the number of carbon atoms being eluted immediately before ($t_{R,\,k}'$) and after ($t_{R,\,k+1}'$) the target compound ($t_{R,\,x}'$).

Because the basis of formula (4) is linear dependence (Eq. 3), it is possible to use retention times of those reference *n*-alkanes that differ not by one, but by a greater number of carbon atoms, i.e., RI_{k+m} and RI_k with $t_{R,k+m}$ and $t_{R,k}$ ($m > 1$). In the original publication of Kovats[2] the difference $m = 2$ was only used. But when $m = 1$, Eq. 3 may be simplified to the various seemingly different, but same, relationship formulas. For example:

$$RI_x = 100 \times \{k + [\log(t_{R,x}'/t_{R,k}')]/[\log(t_{R,k+1}'/t_{R,k}')]\} \tag{5}$$

where k is the number of carbon atoms in the *n*-alkane that elutes before the compound undergoes characterization, and 100 is the RI equivalent of homologous difference CH_2.

The numerical coefficient 100 included in the formula for calculation of RIs has only conventional sense. The same relationships can be used for presentation of retention data without this coefficient in the form of the so-called MU (molecular units) values. In this form, reference *n*-alkanes are characterized by standard values $MU = n_C$, and, hence, MU equivalent of homologous difference CH_2 is equal to 1. Other relationships that need to be calculated are the same as those in KRI. Organic compounds of some selected groups (for instance, steroids and their derivatives[3]) are historically often characterized not by RIs, but just by MU values.

The proposed form of data presentation has become highly popular and useful in GC. To date, thousands of citations have been made to Ref.[2] The RI values are proportional to the free energies of sorption, that is their thermodynamic interpretation. However, the principal restriction of KRI seems to be that they can be applied only in isothermal conditions of GC separation, whilst most of the real analyses of complex mixtures need temperature programming (linear programming used preferably), or, in general cases, non-isothermal regimes. The generalization of RI concept on these conditions implies using the same linear interpolation relationship (1).

LINEAR AND OTHER RETENTION INDICES

For linear temperature programming regimes [which are characterized by two variables: initial temperature, T_0, and rate of its increase (ramp), r, deg/min], linear relationship (3) does not hold. In some partial cases, another linear dependence seems more precise for retention time approximation:

$$RI \approx at_R + b \tag{6}$$

This is a reason to change the formula for RI calculation (the set of reference compounds and their attributed RI values remain the same). This version of RIs especially for linear temperature programming regime (linear RIs) had been proposed by Van den Dool and Kratz in 1963:[4]

$$RI_x = RI_k + (RI_{k+1} - RI_k) \times (t_{R,x} - t_{R,k})/(t_{R,k+1} - t_{R,k}) \tag{7}$$

Or after the same simplifications as those that were used for Eq. 4, one gets:

$$RI_x = 100 \times [k + (t_{R,x} - t_{R,k})/(t_{R,k+1} - t_{R,k})] \tag{8}$$

Owing to the approximate character of dependence (6), Eqs. 7 and 8 give less comparable results for the same compounds in different temperature programming regimes. As a consequence, the replacement of k, $k + 1$ pair of reference *n*-alkanes on the k, $k + m$ ($m > 1$) also increases the errors to an unpredictable extent and is usually not recommended.

At any non-isothermal conditions of GC analysis, all analytes can be characterized not only by retention times (t_R), but also by the so-called retention temperatures, T_R, especially those that are directly proportional to the retention times at linear temperature programming ($r = \text{const}$), $T_R = T_0 + rt_R$, where T_0 is the initial temperature. Hence, relationships (7) and (8) can be rewritten by including T_R values instead of t_R, for example:

$$RI_x = 100 \times [k + (T_{R,x} - T_{R,k})/(T_{R,k+1} - T_{R,k})] \tag{9}$$

However, this replacement of variables is only in the theoretical sense, because of less precision of T_R value measurement in comparison with that for retention times.

Complex dependencies $RI = f(t_R)$ in non-isothermal conditions of GC analysis may be described by polynomials of different degrees (up to 13 have been tested) or splines (cubic splines seem most convenient[5]). However, the calculation of coefficients of an N-degree polynomial needs t_R data for at least $N + 1$ reference compounds instead of only two t_R values in "classical" RI systems. In connection with this fact, it is interesting to mention the combined lin-log RI system, which was proposed in 1984.[6,7] If both dependencies (3) and (6) are non-linear at temperature programming, each local window of retention times of reference compounds may be precisely approximated by linear and logarithmic addends in variable proportion:

$$RI = a(t_R + q \log t_R') + c \quad (10)$$

and

$$RI_x = RI_k + (RI_{k+m} - RI_k) \times \{[f(t_{R,x}') - f(t_{R,k}')]/[f(t_{R,k+m}') - f(t_{R,k}')]\} \quad (11)$$

where $f(t_R') = t_R + q \log t_R'$. The variable parameter q may be calculated in different ways, but in the simplest case it only needs t_R data for three successive reference compounds with retention times $t_{R,k-1}$, t_R, and $t_{R,k+1}$:

$$q = (2t_{R,k} - t_{R,k-1} - t_{R,k+1})/(\log t_{R,k-1}' + \log t_{R,k+1}' - 2 \log t_{R,k}') \quad (12)$$

This formula for the calculation of parameter q can be generalized on the various sets of reference n-alkanes.

The most convenient advantage of lin-log RI system is the possibility of its application in any temperature regime of GC analysis without special choice of formulas for calculations. Under isothermal conditions, the logarithmic contribution in the total dependence $RI = f(t_R)$ exceeds the linear one by many times, which automatically reflects on the value of $q(|q| \to \infty)$. Only lin-log RI system provides the most comparable results in different temperature conditions of analyses.

The last statement can be illustrated by the following example. The analytical problem is the characterization of 2,4,4-trimethyl-2-pentene (diisobutylene, *I*) by RI values on packed column with polar inorganic sorbent Silipor-600 (LaChema, Czech Republic) in temperature programming regime from 50 up to 220°C (ramp 8 deg/min). Raw retention times of (*I*) and reference *n*-alkanes (min) are: (*I*)—20.16; C_6—12.70; C_7—15.94; C_8—18.73; C_9—none; C_{10}—23.74; $t_0 \approx 1.01$. The results of RI calculation with various sets of *n*-alkanes illustrate the maximal reproducibility of just lin-log RIs in the absence of the influence of the choice of reference compounds. The negative value of parameter q is typical for temperature programming regimes with high ramps (8 deg/min in the case under consideration).

Set of reference n-alkanes	RI_{linear}	$RI_{logarithmic}$
7,8	851	846
7,10	862	877
8,10	857	862
Average RI values	857 ± 6	862 ± 15
Set of reference n-alkanes (q)	$RI_{lin\text{-}log}$	
6,7,8 (–6.14)	855	
6,8,10 (–6.15)	855	
7,8,10 (–6.09)	855	
Average RI values	855	

These large differences in the reproducibility are caused by principal non-linearity of the dependencies $RI = f(\log t_R')$ and $RI = f(t_R)$, whilst the appropriate choice of parameter q provides the real linear dependence $RI = f(t_R' + q\log t_R')$ in any temperature programming regimes, as is illustrated in Fig. 1 for the example of retention times of reference *n*-alkanes C_6, C_8, and C_{10} presented above.

Retention indices of various systems sometimes are considered as different characteristics of chemical compounds. However, it is rational to neglect the differences in these parameters for the same compounds, measured in unequal conditions (in various laboratories) with the same stationary phases. Statistical processing of all of them (so-called randomization) gives averaged RI values (together with corresponding standard deviations), which can be considered as GC constants of organic compounds, as well as their other physicochemical parameters (Table 1).

Retention indices values of all systems can be calculated using the simplest auxiliary computer programs, even with those used for pocket programmable calculators. Unfortunately, this very fact (the necessity of additional calculations) is often declared as the principal reason for restricted application of these GC parameters in real analytical practice.

PROPERTIES AND APPLICATIONS OF RETENTION INDICES

The maximal influence on RI values is the nature of stationary phase in the chromatographic column (few hundred phases are recommended in contemporary analytical practice). Use of these parameters as the constants of chemical compounds (similar to other known physicochemical constants like boiling point, T_b, refractive index, n_D^{20}, density, d_4^{20}, etc.) implies the choice of standard phases for their determination. In accordance with the criteria of most common application, two types of phases may be classified as standard ones:

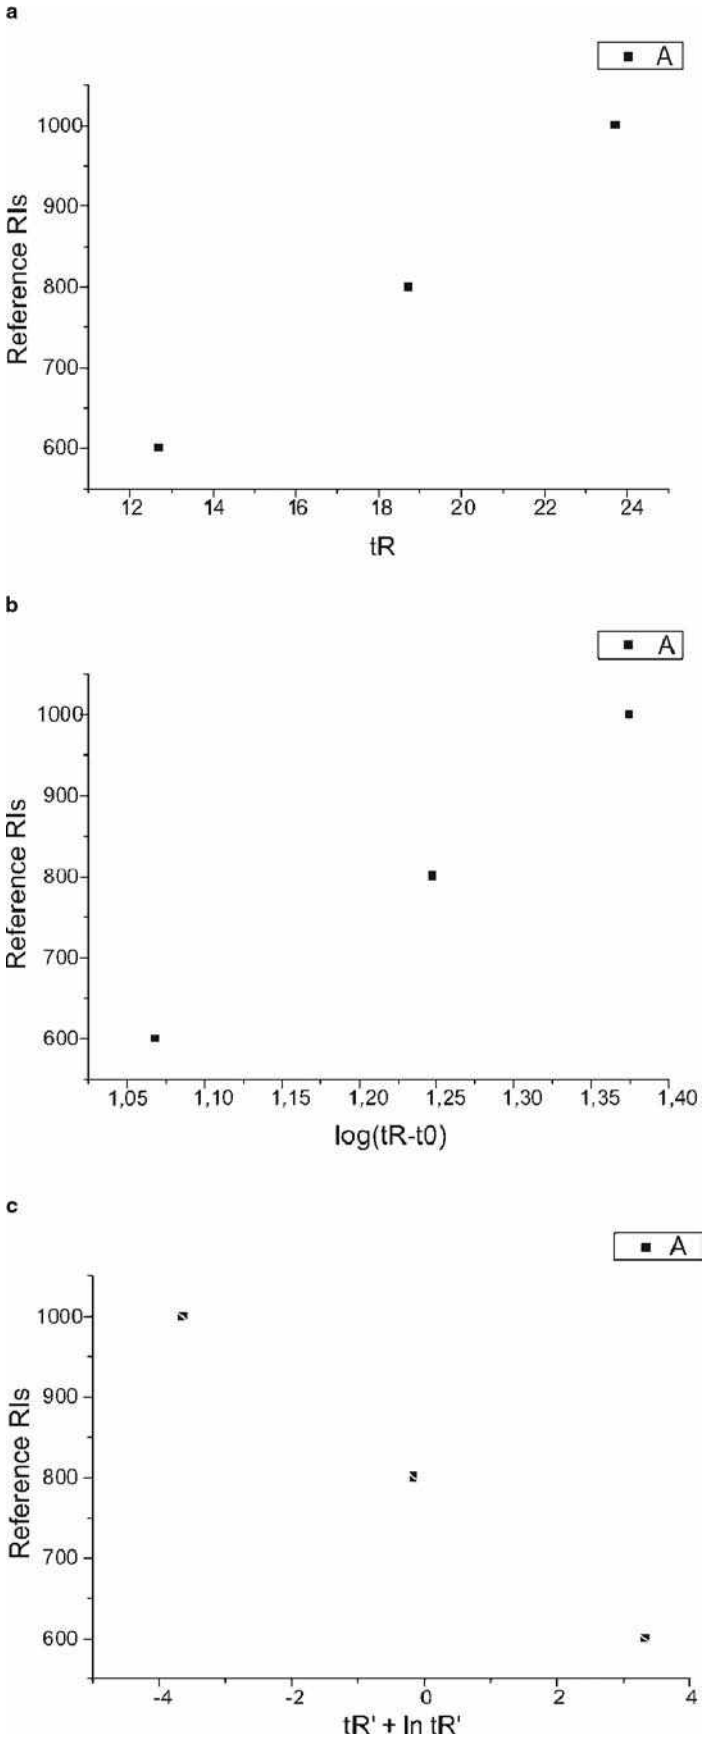

Fig. 1 Graphical illustration of the linearity of the interpolation of retention times of reference *n*-alkanes in temperature programming regime by various functions: (a) $RI = f(t_R)$ (non-linear); (b) $RI = f(\ln t_R')$ (non-linear) and (c) $RI = t_R' + q\ln t_R'$ (linear, $\rho = -1.0000$, $q = -6.15$).

Table 1 GC retention indices as constants of some organic compounds.

Molecular weight	Molecular formula	Compound	RI $\pm$ s_{RI} (N)[a]
137	$C_9H_{15}N$	Pyridine-1,2-dihydro-2,2,4,6-tetramethyl	942 $\pm$ 4 (3)
138	$C_{10}H_{18}$	Cyclodecene	1114 $\pm$ 6 (6)
140	C_8H_9Cl	Benzene-1-chloro-2-ethyl	1016 $\pm$ 6 (3)
140	$C_3H_9O_4P$	Trimethylphosphate	902 $\pm$ 10 (5)
142	$C_7H_{10}O_3$	2,4-Pentanedione-2-acetyl	1045 $\pm$ 3 (4)
148	$C_{11}H_{16}$	Benzene-1-ethyl-2,3,5-trimethyl	1184 $\pm$ 2 (5)
149	$C_{10}H_{15}N$	Benzenemethanamine-*N*-(1-methylethyl)	1148 $\pm$ 5 (3)

[a]N is the number of initial RI values taken for statistical processing.
All data are taken from the author's database.

1. Polydimethyl siloxanes $[–Si(CH_3)_2–O–]_n$ (standard non-polar phases) (maximal temperature of application ≈300–350°C).
2. Polythylene glycols $[–CH_2CH_2–O–]_n$ (standard polar phases) (maximal temperature of application ≈225–250°C).

Each of these groups of phases includes numerous items of various trade names, different average molecular weights, viscosity, thermal stability, and so forth, but having similar polarity. Up to the mid-1970s, the preferred non-polar phase was squalane (isoprenoid alkane $C_{30}H_{62}$), but this phase is no longer used because of its low thermal stability (only about 110°C). However, this obsolete phase maintains its importance as a non-polar standard in GC. Other phases are characterized by differences of RI values (so-called Rohrschneider constants,[8] later generalized by McReynolds) of specially selected 5 or 10 test compounds between the phase under consideration and squalane, for example:

Test compounds	ΔRI
Benzene	16 $\pm$ 1
1-Butanol	53 $\pm$ 2
2-Pentanone	44 $\pm$ 1
Nitropropane	65 $\pm$ 2
Pyridine	42 $\pm$ 1

The comparison of RI values of the same compounds measured with the same stationary phase but at different conditions of analysis indicates some deviations. Most significant of them are temperature dependence of RIs, non-controlled sorption of analytes in GC columns and variations of ratio of analytes and reference alkanes,[9] and, of course, the features of RI approximation in temperature programming regimes (see above). The first of these seems to make the most important contribution (coefficient β is a measure of this dependence; typically $\beta > 0$):

$$\beta = dRI/dT \approx [RI(T_2) - RI(T_1)]/(T_2 - T_1) \quad (13)$$

Among the multitude of organic compounds, there is a small number of objects with $\beta \approx 0$ (all types of acyclic compounds most topologically relevant to *n*-alkanes). The increase in number of cycles in the molecules leads to the increase of β up to 0.3–0.5 (cycloalkanes, arenes, etc.), 0.5–0.8 (naphthalenes, biphenyl, etc.), and 1.0 and more retention index units per degree (i.u./deg) for tri- and polycyclic structures. Hence, it is not surprising that RI data for isoalkanes, ethers, esters, etc. being measured at different conditions, are in good accordance with each other (standard deviations of randomized interlaboratory values are not more than 1–3 i.u.). The same statistical characteristics for substituted benzenes is about 8 i.u., and for naphthalenes and other condensed arenes, it may exceed 10–15 i.u.

The choice of *n*-alkanes as a reference set of compounds for the determination of RI values has been accepted up to the present. Meanwhile, numerous other homologous series have been recommended for different specific applications. For example, GC analysis with electron capture detectors (selective to halogenated compounds) needs other reference compounds of similar chemical origin. These series are alkyl trichloroacetates $(CCl_3CO_2C_nH_{2n+1})$,[10] trialkylamines,[11] alkyl methyl phosphonofluoridates $[CH_3P(O)(F)OC_nH_{2n+1}]$ (so called P series), *O*-alkyl *bis*(trifluoromethyl)phosphinothionates $[(CF_3)_2P(S)\ OC_nH_{2n+1}]$ (A series), alkyl *bis*(trifluoromethyl)thiophosphines $[(CF_3)_2P(S)\ C_nH_{2n+1}]$ (M series), and others (see review[12]). The last two series seem most universal for different types of GC detectors owing to the simultaneous presence of various elements in the molecule (Hal, P, S, CH). A special set of reference objects has been proposed by Lee, Novotny, and Bartle[13,14] for the analysis of polycyclic aromatic compounds to eliminate the strong temperature dependence of their RIs in the *n*-alkane scale. This system is based on benzene (postulated RI value 100 = 100 × number of cycles), naphthalene (200), phenanthrene (300), chrysene (400), picene (500), benzo[b]-picene (600) and dinaphtho[2,1-a : 2,1-h]anthracene (700) (i.e., condensed aromatic hydrocarbons) and formulas of

linear RI system (7) and (8). Of course, RI values, being measured with different reference series, are not directly comparable to each other; but, if necessary, they may be recalculated.

As can be seen, reference compounds in Lee's RI system belong not to the same homologous series, but rather to the special group of structural analogs. In fact, all formulas for RI calculation [(4), (5), (7), and (8)] do not include mathematical restrictions on the choice of reference compounds. However, the non-equidistant choice of reference points decreases the precision of recalculation of these indices into other scales. Another example of the similar choice of non-homologous reference compounds is, for instance, the system presented in he work[15] and based on trifluoroacetic esters of 4-fluorophenol (100), 1-naphthol (200), 4-phenanthrol (300), and 3-hydroxybenzo[c]phenanthrene (400).

Since the 1980s, some applications of the RI system have been reported for reversed phase HPLC (RP-HPLC). The principal requirement for the reference compounds in this method with UV detection is the presence of chromophores in the molecules. The most widely accepted RI system in HPLC is based on homologous alkyl phenyl ketones $PhCOC_nH_{2n+1}$ (so called Smith's system of RIs; by analogy with GC, the RI values, attributed for reference compounds, are $100 \times n_C$).[16] Other RI scales imply the use of homologous monoalkylbenzenes (PhC_nH_{2n+1}), 1-nitroalkanes ($C_nH_{2n+1}NO_2$), glycerol-1-(4-acylphenyl) ethers [4-$C_nH_{2n+1}CO$–C_6H_4–OCH_2–CH(OH)–CH_2OH], and so forth. The last set of substances is convenient for determination of RIs of most hydrophilic organic compounds; the first member of this set is eluted before the simplest reference components of other series. In the isocratic regimes of HPLC separation, which are analogous to isothermal conditions in GC, linear dependence (3) is correct and RIs must be calculated with formulas (4) and (5). With gradient elution, by analogy with temperature programming, formulas (7) and (8), which are based on dependence (6), are preferable. Of course, lin-log RI system may be used in any regimes of RP-HPLC as well as in GC.

Statistical processing of these RIs similar to that in GC gives values, which can be considered as chromatographic constants in RP-HPLC (Table 2).

It is interesting to note that by analogy with chromatographic retention parameters, the values of some other properties of organic compounds may be presented in the linear interpolated form relative to the set of reference compounds. Those equivalent to indices' forms have values known for boiling points,[17] molecular weights,[18] and molar refractions, $MR_D = (MW/d) \times (n^2–1)\ /(n^2 + 2)$, where MW is the molecular weight, n_D^{20} is the refractive index, and d_4^{20} is the density.[19] For example:

$$I(T_b) = 100\times[k + (\log(T_{b,x}/T_{b,k})/(\log(T_{b,k+1}/T_{b,k})] \quad (14)$$

where $T_{b,k} < T_{b,x} < T_{b,k+1}$ are the boiling points of *n*-alkanes with k and $k + 1$ carbon atoms in the molecule and the target compound.

For non-polar compounds, the values $I(T_b)$ are close to experimental RI data being measured on non-polar stationary phases, which is an important feature for their precalculation.

The possibility of precalculation of RIs both from other physicochemical parameters and molecular topological parameters[20] and by different additive schemes, which is impossible for net retention times, seems to be their most significant feature. The methods of RI precalculation form complex algorithms, and as very simple but useful rules. For instance, it is interesting to note that even in the first publication of Kovats,[2] the rule for precalculation of RIs for compounds of general type A–B by arithmetic averaging of data for compounds A–A and B–B has been recommended, i.e., RI(A–B) = [RI(A–A) + RI(B–B)]/2. However, this

Table 2 Retention indices as constants of some organic compounds in reversed phase HPLC with *n*-alkylphenyl ketones as reference compounds.

Molecular weight	Molecular formula	Compound	RI ± s_{RI}
94	C_6H_6O	Phenol	688 ± 16
96	$C_5H_4O_2$	Furfurol	593 ± 9
135	C_8H_9NO	Acetanilide	689 ± 10
146	$C_9H_6O_2$	Coumarin	791 ± 13
148	$C_{10}H_{12}O$	Anethol	1142 ± 10
150	$C_{10}H_{14}O$	Thymol	1027 ± 10
152	$C_8H_8O_3$	Methyl salicylate	934 ± 9
152	$C_8H_8O_3$	Vanillin	702 ± 22
164	$C_{10}H_{12}O_2$	Eugenol	910 ± 14
165	$C_9H_{11}NO_2$	Benzocaine	823 ± 11
194	$C_8H_{10}N_4O_2$	Caffeine	633 ± 27

All data are taken from the author's database.

rule can be used in the mathematically transformed form, namely RI(B–B) = 2RI(A–B) –RI(A–A). If B is a more complex structural fragment than A, this is the simplest way to precalculate RIs of high molecular weights compounds from data for simpler precursors.

This general statement may be illustrated by following example: The estimation of unknown RI value of 1,1,1,3,3,3-hexachloropropane CCl_3–CH_2–CCl_3 needs the data of 1,1,1-trichloropropane and non-substituted propane, as $2 \times CCl_3$–CH_2–$CH_3 - C_3H_8 = CCl_3$–CH_2–CCl_3, namely $2 \times (736 \pm 3) - 300 = 1172 \pm 4$. The same logical scheme of evaluation starting from 1,1,1-trichloroethane and methane, $2 \times CCl_3$–$CH_3 - CH_4 = CCl_3$–CH_2–CCl_3, gives a similar RI value of $2 \times (638 \pm 9) - 100 = 1176 \pm 13$.

CONCLUSIONS

The Kovats Retention Index System, which was proposed in the early period of the development of GC (1958), has become a useful tool for retention data processing, presentation, and interpretation. Use of these analytical parameters at present should be considered as obligatory in the reliable identification of analytes in contemporary hyphenated techniques, especially GC/MS. There are a lot of complex mixtures of organic compounds, whose identification of components cannot be made without taking into account the reference RI data, namely petroleum products, essential oils, flavors and fragrances, pharmaceutical metabolites, and so forth. As a confirmation of this conclusion, the following fact may be noted: The rules of paper presentation in some journals like *Journal of Essential Oil Research*, *Flavor and Fragrance Journal*, *Agricultural and Food Chemistry*, etc. imply the obligatory presentation of retention parameters, preferably in the form of RIs.

The real contemporary problems in perfecting GC retention index system seem to be the formation of available and representative databases by analogy with well-organized databases in mass spectrometry and improvement in the methods of their precalculation. It means at first obtaining the higher precision of the results and then expanding the domains of chemical determination of corresponding algorithms, i.e., their applicability to the larger multitudes of organic compounds of various chemical origin.

Lanthanides: HPLC Separation

P.R. Vasudeva Rao
N. Sivaraman
T.G. Srinivasan
Chemistry Group, Indira Gandhi Center for Atomic Research (IGCAR), Kalpakkam, India

INTRODUCTION

Lanthanides are a series of elements ($Z = 57$–71), starting with lanthanum, in which the 4f orbitals are being filled. Lanthanide chemistry is dominated mainly by the +3 oxidation state. Lanthanides have common chemical properties, because of their same charge and similarity in size. The lanthanide cations are prototypical hard acids, bonding preferentially with hard bases such as oxygen donor ligands. They have coordination numbers between 6 and 12. The chemistry of lanthanides is well documented.[1] Lanthanides are extensively used in commercial applications, such as alloys for aeronautical components, permanent and superconducting magnets, catalysts, phosphors, lasers, batteries, chemicals, ceramics, glass, glazes, lighting, medical imaging, thermal spray powders, etc.[2] The separation and the determination of lanthanides are very important for measuring the burn-up of nuclear reactor fuels[3] and in geological studies.[4]

LANTHANIDE SEPARATIONS

Perhaps the most striking feature of lanthanide chemistry is the similarity in the properties of the lanthanide ions, owing to the small differences in the sizes of their hydrated lanthanide ions. The size of the trivalent lanthanide ion decreases gradually from 1.032 Å for lanthanum to 0.861 Å for lutetium (effective ionic radii in crystals for Ln^{3+}, CN: 6) owing to the well-known "lanthanide contraction."[5] The similarity in properties makes the isolation of pure lanthanide elements challenging; conventional separation techniques do not yield individual lanthanides of very high purity. Nuclear fuel cycle studies, such as burn-up measurements on highly radioactive solutions, also demand rapid and high-resolution separation of lanthanides to ensure minimization of the radiation dose to the operator. Major advantages of high-performance liquid chromatography (HPLC) techniques are their ability to provide rapid, high performance separations and the ability to extend the separations and purifications from laboratory scale to large scale. Developments and advances in the process of lanthanide separation by liquid chromatography have been reviewed in the literature.[6,7] To complement these excellent resources, this entry will focus mainly on the methods for individual separation of lanthanides using dynamic ion-exchange chromatographic methods employing HPLC.

Separation of Lanthanides—Need for a Complexing Reagent

It is possible to use the differences in the stabilities of the complexes formed by lanthanides to effect their separation. Lanthanides form complexes with weak organic acids, such as α-hydroxy isobutyric acid (α-HIBA), citrate, lactate, tartrate, and α-hydroxy-α-methyl butyric acid, to name a few. The decreasing ionic size across the lanthanide series results in increasing ionic potential; consequently, the stabilities of the complexes formed by lanthanides with the ligands mentioned above increase as we proceed across the series. This difference in the stabilities of the complexes of lanthanides can be effectively used to enhance the separation of the lanthanides in chromatography. In the presence of the complexing agent, e.g., α-HIBA, lutetium is eluted first and lanthanum last, because of the formation of complexes of high stability in the case of Lu as compared with the case of La. Among the various organic acids which have been used, α-HIBA has been shown to provide a good degree of separation between adjacent lanthanides, and hence is the most extensively used complexing reagent for individual separation of lanthanides.

Any factor that influences the stability of the complex formed would obviously affect the retention behavior in a cation exchange column. Thus, retention of lanthanides from a column will decrease when the mobile phase pH is increased (typically from 3 to 4.5). This effect occurs until the dissociation of the protonated ligand is complete, beyond which further increase in pH does not significantly alter retention times. In a similar manner, the changes in concentration of the mobile phase containing the complexing reagent can be used to alter the retention time; increasing the concentration of complexant in the mobile phase generally results in reduction of retention time. The separation efficiencies can be improved by operating at elevated temperatures (40–60°C). However, most dynamic ion-exchange separations have been carried out at ambient temperatures.

Development of Dynamic Ion-Exchange Methods

An average separation factor of 1.28 was reported for separation of lanthanides on polystyrene-divinylbenzene (PS-DVB) based cation exchange resin.[8] The separation efficiency was improved later with an ion exchanger of lower cross linkage.[9] In both cases, α-HIBA was used as the eluent. The HPLC technique was applied in the early 1970s to separate lanthanides.[10] The bonded phase ion-exchange columns that were subsequently developed were quite rigid and exhibited good mass transfer properties, compared with the PS-DVB cation exchange resins.[11] Subsequently, dynamic ion-exchange (also referred to as ion-pair/ion-interaction) chromatographic techniques using coated columns have been developed for the rapid separation of lanthanides[3,12–17] and they offer several advantages when compared to traditional ion-exchange techniques; they are described in detail in the following sections.

Principle of Lanthanide Separation Using Dynamic Ion-Exchange Chromatography

In this technique, a hydrophobic stationary phase, generally a C_{18} column, is used with a suitable ion-pairing reagent (IPR) for metal ion separations.[3,12,13] Some examples of ion-pairing reagents used for cation exchange separation include pentanesulfonate, hexanesulfonate, and octanesulfonate (Table 1). The stationary phase provides a neutral surface, which can be modified to form an ion-exchange support, with both cation as well as anion exchangers by the use of suitable modifiers. The modifiers can be continuously passed through the column or coated "permanently" onto a column, depending on their aqueous solubility. Passing a solution of a water-soluble modifier, e.g., octanesulfonate (10^{-2} to 10^{-3} *M*) through a C_{18} support results in the formation of a cation exchange surface. This method is generally referred to as a "dynamic ion-exchange" technique. Lanthanides can be subsequently separated by exchange with the hydrogen ions (or sodium) present in the modifier, similar to the exchange that takes place in the conventional cation exchange resins. Use of a suitable complexing reagent, e.g., α-HIBA, leads to the elution and separation of lanthanides. The water insoluble modifiers, e.g., dodecylsulfate ($C_{12}H_{25}SO_4^-$), are dissolved in methanol–water mixtures and are passed through a C_{18} column.[18,19] Depending on the concentration of the modifier, the methanol content is varied, generally between 50 and 70 vol.%. A solution of about 10^{-3} to 10^{-4} *M* of modifier is used for modifying the column by passing about a liter through the column, to establish an ion-exchange support. The volume required for the equilibration varies with the solvent composition and the concentration of the modifier. After the modification step, a mobile phase containing the complexing reagent is passed for achieving the separation. The ion-exchange columns prepared by these methods are generally referred to as "permanently" coated columns in which separation of lanthanides occurs through an ion-exchange mechanism.

The following effects on retention are observed in the dynamic ion-exchange separation: The total concentration of the IPR adsorbed onto the stationary phase is dependent on 1) its concentration in the mobile phase; 2) concentration of organic solvent such as methanol in the mobile phase (higher concentration of methanol results in lower concentrations of IPR on the stationary phase); and 3) hydrophobicity of the IPR (the larger the hydrophobicity, greater will be the adsorption onto the stationary phase). However, for a given eluent composition, the concentration of the adsorbed IPR remains constant. The retention of lanthanides increases with an increase in the concentration of the ion-pairing reagent and retention of solute decreases with increasing content of methanol in the mobile phase.

Advantages of Dynamic System over Conventional Ion-Exchange System

The important features of dynamically modified columns are their high column efficiency (height equivalent to a theoretical plate (HETP) is approximately 0.02–0.03) and easily variable ion-exchange capacity.[3] The high column efficiency is a result of thin layer of modifier being coated onto the surface of the stationary phase, leading to significant reduction in stationary phase mass transfer. The ion-exchange capacity depends on the surface concentration of the sorbed modifier and this concentration can be

Table 1 Some ion-pairing reagents used for separation of metal ions.

Name	Structure	Number of carbon atoms
1-Pentanesulfonate	$CH_3(CH_2)_4SO_3^-$	C_5
1-Hexanesulfonate	$CH_3(CH_2)_5SO_3^-$	C_6
1-Octanesulfonate	$CH_3(CH_2)_7SO_3^-$	C_8
1-Dodecylsulfate	$CH_3(CH_2)_{11}SO_4^-$	C_{12}
1-Eicosylsulfate	$CH_3(CH_2)_{19}SO_4^-$	C_{20}
Camphor-10-sulfonic acid	$C_{10}H_{15}SO_3H$	C_{10}
Di-(2-ethylhexyl)phosphoric acid (liquid cation exchanger)	$C_{16}H_{34}O_3POH$	C_{16}

"quickly" changed over a wide range, by changing the mobile phase concentration. This feature is not available with conventional ion-exchange resins. The variation of ion-exchange capacity can be effectively used to optimize the column efficiency and the selectivity. Another important advantage of this technique is that the column can be reused for other reverse phase applications after washing it with water (in the case of dynamic ion-exchange) or with methanol (in the case of "permanently" coated columns).

Separation Mechanism

The mechanisms of separation using ion-pairing reagents are discussed in the literature.[20,21] In the dynamic ion-exchange mode, the modifier is assumed to be adsorbed onto the C_{18} support to create an ion-exchange surface. The adsorbed IPR imparts a charge to the stationary phase, causing it to behave as an ion exchanger. A constant interchange of IPR occurs between the eluent and stationary phase and the stationary phase can be considered to be a dynamic ion exchanger. The sample ions are then exchanged between the stationary phase and the mobile phase by an ion-exchange process. The ion-pair model leads to the formation of ion-pair complex between analyte ion and modifier, which is subsequently partitioned between stationary phase and mobile phase. Retention, therefore, results mainly as a consequence of interaction taking place in the eluent between solute and IPR and the subsequent partition of the complex to the stationary phase. The degree of retention of the ion-pair is dependent on its hydrophobicity, which in turn depends on the hydrophobicity of the ion-pairing reagent. An increase in the percentage of methanol in the eluent generally decreases the interaction of the ion-pairs with the stationary phase. The ion-interaction model may be viewed as an intermediate between the dynamic ion-exchange and ion pairing models. It incorporates both the adsorptive effects, which forms the basis of dynamic ion-exchange, and the electrostatic effects, which are the basis of the ion-pair model. The schematic of ion-pair, dynamic ion-exchange, and ion-interaction models for the retention of anionic solutes is shown in Fig. 1. Although many of these models define the solute retention under certain conditions, it is likely that the exact mechanism could be a combination of dynamic ion exchange, ion-pair formation, etc.

EXPERIMENTAL METHODS

The HPLC technique, with postcolumn derivatization, is well discussed in the literature.[3,13,22] In brief, the HPLC technique employs columns that contain stationary phase materials of small and uniformly sized particles, necessitating high operating pressures. These columns provide high efficiency, as well as faster and high-resolution separations. Some typical stationary phase and mobile phase systems used for lanthanide separations are given next.

Stationary Phase

The dynamic ion-exchange separations are performed successfully on a wide range of stationary phases, which include PS-DVB copolymers (e.g., Hamilton PRP columns), and chemically bonded silica materials (C_{18}, C_8, and phenyl groups). C_{18} supports are the most popular choice (e.g., hypersil, merck, and phase separation). Columns packed with 3 or 5 μm particles are used for analytical scale separation of lanthanides.

Mobile Phase

Aliphatic sulfonic acids and their salts (Table 1) are used as water-soluble ion-pairing reagents in dynamic ion-exchange chromatography, e.g., sodium octanesulfonate. The complexing reagent, e.g., α-HIBA, is dissolved along with the ion-pairing reagent in HPLC grade water. The pH of the mobile phase is generally adjusted using dilute ammonia/sodium hydroxide. The mobile phase solution is passed through the reverse phase column (typically 100–125 ml) to establish a dynamic ion-exchange surface, after which samples are introduced into the HPLC system for separation. In the case of "permanently" coated columns, about 60 ml of the mobile phase containing the complexing reagent is passed through the coated column prior to the introduction of sample.

Injection of Lanthanide Samples

Generally, lanthanide samples in the form of their nitrates are injected into the HPLC system. For preparing a calibration, lanthanide samples over the concentration range of about 1–10 ppm (injected amount 20 μl) are introduced into the system, though the linear dynamic range exceeds well beyond this region.

Detection of Lanthanides

Postcolumn derivatization has been an extensively used technique for the detection of lanthanides.[3,13] Commonly used chromogenic reagents are Arsenazo I, Arsenazo III, and 4-(2-Pyridylazo)-resorcinol (PAR); the lanthanide complexes are detected at 590, 658, and 520 nm, respectively. Arsenazo III is generally employed in the aqueous as well as in acetic acid medium. The postcolumn reagents are added to the eluate with a reciprocating pump/peristaltic pump. The rapid and efficient mixing of color-producing reagent with eluent is essential and dead volume must be minimized for achieving better resolution and sensitivity. The molar absorptivity of the complexes is generally in the region of 30,000–60,000 L/mol/cm, which permits a detection limit as low as 10–20 ng for various lanthanides.

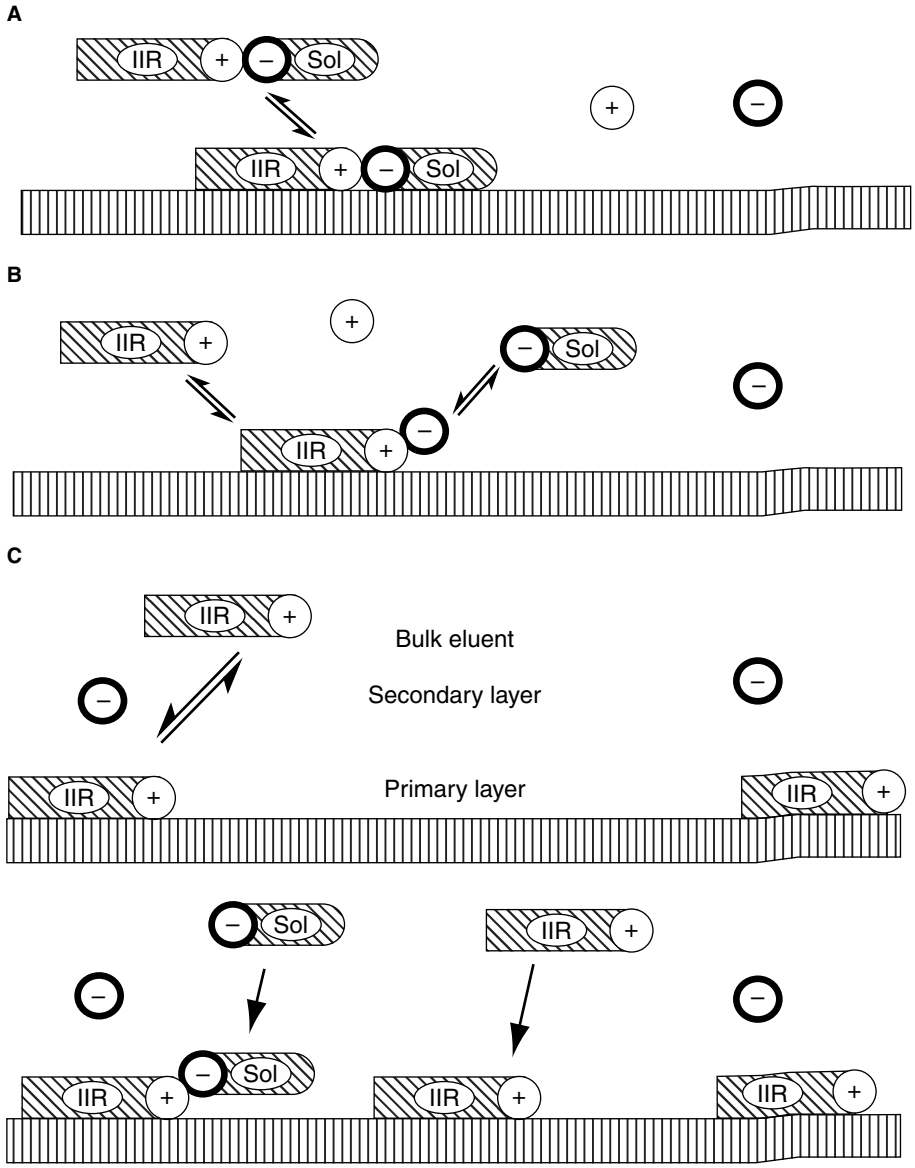

Fig. 1 Schematic of (A) the ion-pair model; (B) the dynamic ion-exchange model; and (C) the ion-interaction model for the retention of anionic solutes in the presence of a lipophilic cationic IIR. The solute and the IIR are labeled on the diagram. The large hatched box represents the lipophilic stationary phase, the black circle with the negative charge represents the counter–anion of the IIR, whilst the white circle with the positive charge represents the counter cation of the solute.

Some Typical Separations of Lanthanides

In this section, detailed descriptions of typical procedures involving dynamic ion-exchange and "permanently" coated columns are given.

Separation of lanthanides using dynamic ion-exchange HPLC

An efficient separation of mixtures of lanthanide ions using sodium octanesulfonate as the ion-pairing reagent and α-HIBA as the complexing reagent was reported.[3] A 15 cm reverse phase column was employed with sodium octanesulfonate (0.01 *M*) and α-HIBA (0.05–0.4 *M*); the pH of the mobile phase was kept at 4.6. Complete separation of lanthanides was obtained before 9 min (Fig. 2). The lanthanides could be eluted with sharp symmetrical peaks, reflecting the rapid mass transfer characteristics with high column efficiencies, i.e., HETP of about 0.02–0.03 mm. An average detection limit of approximately 2.5 ng was obtained for lanthanides in this study. A dynamic ion-exchange technique using sodium octanesulfonate-α-HIBA has also been employed for the individual separation from a mixture containing the lanthanides yttrium, uranium, and thorium.[23] It was also demonstrated that the peak positions of Th(IV) and U(VI) in the lanthanide elution chromatogram could be optimized by appropriate adjustments in the concentration of octanesulfonate, methanol, and eluent pH. In another study, the performance of α-hydroxycarboxylic acids, such as α-HIBA, α-hydroxy-α-methylbutyric acid, and lactic acid were compared for the separation of lanthanides using octanesulfonate as the ion-pairing reagent.[16] It is also understood that a longer alkyl group in the hydroxycarboxylic acids improves the resolution, particularly for the lighter

lanthanides. In another study, mandelic acid was employed instead of α-HIBA, with octanesulfonate as the ion-pairing reagent for the separation.[15] Using a mandelic acid gradient, all 14 lanthanides were separated. The Th(IV) and U(VI) were well separated from lanthanides. The separation of lanthanides obtained, however, is inferior to that obtained with α-HIBA. This is possibly because of the fact that, with α-HIBA, the lanthanides are retained mainly through an ion-exchange mechanism; however, with mandelic acid, lanthanides may be retained through a hydrophobic interaction mechanism in addition to an ion-exchange mechanism. A rapid separation procedure for the isolation of individual lanthanides using camphor-10-sulfonic acid (CSA) as the ion-pairing reagent has also been developed.[17] A binary gradient with a mobile phase composition of 0.05 *M* CSA and 0.07–0.3 *M* α-HIBA (pH 3.8) was employed and the lanthanides could be separated in about 8 min (Fig. 3). Excellent peak profiles with baseline resolution for individual lanthanides have been achieved with this method.

Separation of lanthanides using "permanently" coated columns

The separation of lanthanides on a reverse phase column modified with eicosylsulfate was reported, with α-HIBA (0.025–0.25 *M*, pH 3.8) as the mobile phase.[18] The lanthanides could be eluted within approximately 32 min with this method (Fig. 4). In another study, a column coated with Di-(2-ethylhexyl)-phosphoric acid (HDEHP) was employed for the individual separation of lanthanides.[19] A binary gradient in concentration of α-HIBA (0.07–0.3 *M*, pH 3.5) was employed in that study for the separation (Fig. 5). The separation of the entire lanthanide series was completed in about 20 min. It was reported that these coated columns are quite stable and can be employed for longer periods.[19]

Some Applications of Determination of Lanthanides by HPLC

Lanthanides in silicate rocks, commercial phosphoric acid, geological materials, refractory alloys, steel alloys, minerals, ores, monazite, and luminescent phosphors have been determined by HPLC. Determination of trace lanthanide impurities in nuclear grade uranium has been studied.[18] An HPLC technique using the dynamic ion-exchange approach was also employed for the determination of ^{147}Pm in urine.[24] A typical application of lanthanide assay in nuclear industry is described next.

Burn-up measurements on nuclear reactor fuels

Lanthanides (La, Ce, Pr, Nd, Sm, and Eu) constitute about one-fourth of the total fission products produced in nuclear fission of uranium or plutonium. Thus, accurate estimation of Nd or La in the dissolver solution of spent fuel can be used to determine the number of fissions that have occurred in nuclear reactor fuel. The burn-up or atom percent fission (number of fissions per 100 initial heavy element atoms such as U and Pu) is an important parameter and the

Experimental conditions: column, reverse phase C_{18}; mobile phase, camphor-10-sulfonic acid (0.05 *M*); α-HIBA varied from 0.07 to 0.3 *M*, pH 3.8; flow rate: 2 ml/min. Postcolumn reagent: Arsenazo III (1.8×10^{-4} *M*); flow rate: 1.5 ml/min; detection: 655 nm.

experimental methods have been found to be more accurate and reliable for determining this parameter. High performance liquid chromatography based techniques have been developed for determining the number of fissions in uranium dioxide, thorium–uranium dioxide, and fast reactor fuels such as mixed carbides of uranium and plutonium.[3,13,17] Ion-pair HPLC techniques using CSA–α-HIBA/sodium octanesulfonate–α-HIBA systems were employed for separation and assay of lanthanide fission products. In one of the studies, the HPLC method was used to separate and estimate a lanthanide fission product, e.g., lanthanum and a heavy element, e.g., uranium.[3] The burn-up obtained was found to be in good agreement with the conventional mass spectrometric method. In another study,

terbium (which is not a fission product) was employed as an internal standard for the quantitative determination of fission products such as Nd, Sm, and La.[17] An HPLC method has also been developed for determining the fractional fissions from uranium and plutonium by the measurement of the Nd/Sm ratio.[17] High performance liquid chromatography techniques have been employed for the rapid isolation of lanthanide fractions for their isotopic composition using mass spectrometric measurements.[25] The separation of lanthanide fission products present in dissolver solution of a thermal reactor fuel by HPLC is illustrated in Fig. 6. An important advantage of employing the HPLC technique for determining the number of fissions is the reduction in analysis time and, hence, a considerable reduction in radiation exposure to the personnel.

CONCLUSIONS

The increasing technological significance of lanthanides will continue to pave the way for development of rapid and efficient separation methods with sensitive detection. Several reviews on lanthanide analysis indicate the importance of these materials and the need for the development of new and better techniques. Many HPLC based techniques have been developed for the separation of individual lanthanides using cation exchange, dynamic ion-exchange methods, etc. The selection of gradient elution techniques has been

commonly identified as an important factor for achieving rapid and high-resolution separations. It is to be noted that α-HIBA is being used as the most efficient complexing agent during a period of 40 yr, since its early use for discovery of trans-plutonium elements. There is still scope for understanding the nature of α-HIBA complexes of lanthanides and its interaction with the support. Complexing reagents alternate to α-HIBA and the development of better stationary phase supports may continue to offer excitement in the years to come.

Large Volume Injection for GC

Yong Cai
Department of Chemistry, Florida International University, Miami, Florida, U.S.A.

INTRODUCTION

Trace or ultratrace analyses for environmental and biological samples require sensitive methods, including sample preparation and detection techniques, to be used. The enhancement of the detectability of analytical procedure is often brought about by some form of preconcentration, such as Soxhlet extraction, liquid–liquid extraction, and solid–phase extraction. Capillary gas chromatography (GC) coupled with different detectors is one of the most frequently employed techniques for trace analysis of micropollutants. However, because of the limited sample capacity of the capillary column, only a small portion (1–5 μl) of the final sample extract is introduced into the gas chromatographic system. This means that after careful workup, which often comprises analyte isolation by extraction and changing to a GC-compatible solvent, a maximum few percent could be injected and reach the detector.[1] The concentration detection limit of the method can be improved by increasing the concentration factor of the extraction and cleanup procedure. This is generally achieved by using a larger amount of sample or/and by reducing the volume of final extract through evaporation. Both methods have limitations for practical application. Extraction of a large amount of sample is very time consuming and requires a large volume of toxic organic solvents. Sampling a large amount of sample is sometimes difficult or even impossible. Although solvent evaporation is frequently used, it is a rather critical step in which the more volatile compounds may be lost from the sample because of the coevaporation with the solvent.[1,2] Recently, there has been increased interest in the introduction of large sample volumes in capillary GC.[1–6] Several hundred microliters of sample can be introduced by using these techniques. Among the several techniques for the introduction of a large volume of sample, on-column injection and programed-temperature vaporization (PTV) injection are best developed.

ON-COLUMN INJECTION

The on-column injection techniques, in which the solvent is generally vaporized in a few meters of uncoated deactivated capillary (retention gap) and vented via an early vapor exit valve, are of good accuracy and reproducibility.[3–5] A schematic diagram for on-column injection is shown in Fig. 1. The on-column large-volume injection system generally consists of a regular gas chromatograph equipped with an on-column injector, a retention gap, a retaining precolumn, an analytical column, and a heated early solvent vapor exit.

The introduction of a large volume of sample can be performed using a technique called partially concurrent solvent evaporation (PCSE). With PCSE, some 90% of the solvent injected is evaporated during the injection through the early solvent vapor exit.[1] The injection rate of the sample is controlled based on the length of the retention gap and the boiling points of the analytes. If the sample volume exceeds the capacity of the uncoated retention gap to retain liquid (it is true for most large-volume injection applications), the injection speed should be adjusted to result in a sufficiently large proportion of concurrent evaporation to prevent liquid solvent from spreading into the analytical column.[2] Most of the vapor escapes through the open solvent vapor exit. After large-volume on-column injection, the analytes are spread out over several meters of the uncoated retention gap. Solvent evaporation continues, removing solvent from the rear to the front of the sample film. Relatively volatile analytes evaporate and are reconcentrated by the liquid ahead. This process is described as the solvent-trapping effect. Less volatile components do not evaporate with the solvent and remain on the dry retention gap surface. The vapor exit valve is closed shortly before the end of solvent evaporation when the residual liquid still remains the volatile components. The rest of the solvent is discharged through the analytical column. Reconcentrations of the less volatile compounds are carried out by phase-ratio focusing; that is, the difference in migration speed in the retention gap and in the coated column causes the rear end of the zone to catch up with the front end at an appropriately increased oven temperature.[1,2] As soon as the front end of the zone reaches the stationary phase, its migration speed reduces dramatically, while the remaining part, which is still in the retention gap, continues to migrate at a higher speed.

With on-column large-volume injection, the selection of appropriate experimental conditions is complicated.[2] Generally, the following parameters need to be carefully optimized.

1. The sample must be introduced at a rate slightly exceeding the evaporation rate. Slower injection causes the loss of solvent trapping because all solvent evaporate concurrently, whereas a too high introduction

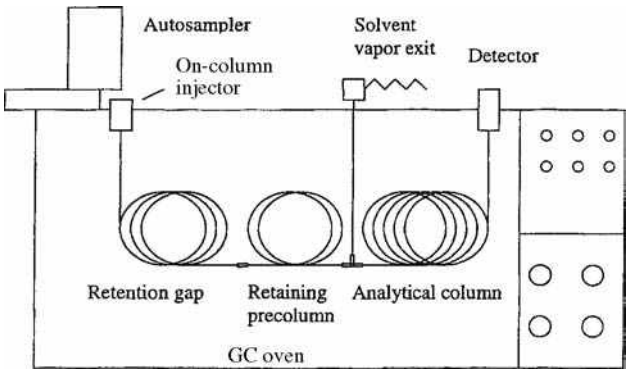

Fig. 1 Schematic diagram of GC with on-column large-volume injection.

rate results in flooding of the solvent into the retaining precolumn and, eventually, the analytical column and the vapor exit.

2. The temperature of the column oven during injection should be set slightly below the pressure-corrected boiling point of the solvent used. At too high temperatures, the solvent starts to boil and causes the backflush of solvent into the injector.
3. The vapor exit valve must be closed at a right time. Early closing of the valve may cause the remaining solvent in the retention gap to exceed the capacity of the analytical column. However, delayed closure will result in the loss of volatile components.

On-column large-volume injection has wide applications in terms of volatility and thermostability of the analytes.[4] If the solvent exit valve is operated carefully, compounds with boiling points only slightly above that of the solvent can be recovered quantitatively. However, the technique is generally not very suitable for dirty samples. Frequent analysis of samples with high contents of matrix compounds can rapidly decrease the column performance.[3–6]

PROGRAMED-TEMPERATURE VAPORIZATION

Vogt and co-workers in 1979 described an injector that allowed the injection of up to 250 μl into a cold glass insert filled with glass wool.[7,8] This technique has been modified and refined in the recent years.[3–6,9,10] In fact, the large-volume sampling technique using PTV injectors is modified from a conventional split/splitless injector.[1] The main differences between the conventional split/splitless and the PTV injectors are the temperature control of the injector and the solvent venting capacity of the split/splitless valve. In PTV injectors, the injection port should be heated or cooled rapidly, and the split/splitless valve should be large enough to be able to vent the solvent vapor produced during injection. Before a large volume of sample is introduced, the temperature of the injection port is reduced to below the boiling point of the solvent. The sample is injected into the liner of the injector at a controlled rate. Upon introduction, the solvent is selectively eliminated and solvent vapor is vented via the split/splitless valve. The less volatile components are retained in the cold liner. When solvent elimination is finished, the components retained in the liner are transferred to the analytical column by rapid temperature-programed heating of the injector.

In order to obtain a quantitative analysis for the analytes with a wide range of volatility using the PTV injection technique, the following parameters are of great importance: injection speed, liner packing material, solvent venting temperature, and solvent venting time. The speed of sample introduction should roughly equal the rate of solvent elimination.[1] If the sample is injected at a rate exceeding the evaporation rate, the sample will accumulate in the liner, which eventually will result in overloading of the liner. This will cause flooding of the analytical column and severe losses of both volatile and non-volatile components via the split exit. On the other hand, a too slow sample introduction rate will cause losses of volatile sample components. The use of liners packed with an absorbent is an efficient means to retain the liquid sample and minimize losses of volatile compounds.[1,10] A number of packing materials, such as glass wool, quartz wool, cup liner, Tenax TA, PTFE wool, have been investigated in terms of their interaction with different types of analytes.[10] An unsuitable choice of the packing material can cause degradation of the analyte in the liner. The solvent venting temperature and solvent venting time must be carefully optimized. The liner temperature is held below the boiling point of the solvent during the solvent venting time. The split/splitless valve must be closed at the right time. Early closing will cause accumulation of the solvent, which may exceed the capacity of the column, whereas delayed closure can result in losses of the volatile sample components.

It has been shown that the PTV injector is a very useful technique for large-volume injection, especially for the analysis of a dirty sample. Because the vaporization of the solvent is carried out at a low temperature, nonvolatile matrix constituents remaining in the liner will not contaminate the GC column. However, the PTV injection technique is less suited when analyzing volatile compounds because only components with volatility significantly below that of the solvent are trapped in the cold liner, unless liners packed with a selective adsorbent is used.[4]

Large Volume Sample Injection in FFF

Martin Hassellöv
Department of Chemistry, Analytical and Marine Chemistry, Göteborg University, Göteborg, Sweden

INTRODUCTION

Field-flow fractionation (FFF) techniques are used for a range of sample types including polymers, macrobiomolecules, glass beads, silica, and other inorganic particles due to their good separation characteristics (e.g., high molecular weight, separation selectivity, and large dynamic operating range). These analytes are dissolved or suspended in an appropriate liquid, and small aliquots of the suspensions (typically 10–50 μl) are injected into the FFF channel. For these applications, it has usually been possible to adjust the analyte concentration to ensure an acceptable signal-to-noise ratio, given detector sensitivity and the dilution in the FFF system. However, there are a number of applications where the solutes are very dilute, and any preconcentration may cause perturbation of the size distribution or other changes of the sample characteristics. Such applications could include most of the groups of sample types mentioned earlier, and especially environmental particles and colloids, which are often present in low concentrations and are easily disturbed. Here, we discuss approaches taken to counteract the dilution effect in FFF to overcome detection problems.

Schure[1] had recently evaluated dilution factors and detection limits for FFF in comparison with LC and capillary electrophoresis. It is obvious that samples are subject to much higher dilution in FFF channels (~200–1000 times) compared with most LC techniques (~3–25) due to the rather low efficiency and large elution volumes. A more narrow and thin channel than that with more conventional dimensions would improve the dilution factors. But there are practical problems involved in the production and maintenance of such a channel. There is the option of using any of the outlet flow splitting devices that have been developed. These are different approaches having in common removal of some of the overlying liquid at the end of the channel and thus reducing the dilution. The principles build on horizontal flow splitters, capillaries exiting both above and below the channel, a second porous frit section (frit outlet), or a so-called slot outlet in the overlying channel wall letting out excess liquid. There had been difficulties in accurate production, maintenance, and precision of some of these technical solutions. But there are now systems commercially available using the frit-outlet system in symmetrical flow FFF (FlFFF) and a slot-outlet system in asymmetrical FlFFF for removal of excess liquid,[2] with which up to a 10-fold reduction in dilution can be achieved.

SAMPLE INJECTION

The injection volume of the conventional stop–flow sample injection technique is limited typically to 10–100 μl. This procedure is carried out using a sample loop and injecting the sample plug just onto the channel carried with the channel flow before stopping that flow and letting the sample attain its equilibrium distribution relative to the accumulation wall (relaxation). Sedimentation FFF (SedFFF) is the only technique where the field is not applied during the complete stop–flow procedure; however, the centrifuge is started as soon as the sample is injected and the channel flow is switched off for practical reasons.

Kirkland, Yau, and Doerner[3] introduced an injection technique for SedFFF where the sample is slowly injected with the centrifuge spinning at a high field thereby retaining the analytes in a narrow band at the entrance of the channel. When the sample is injected, the flow is stopped, the centrifuge speed is decreased to the initial elution speed, and an appropriate relaxation time is allowed. This technique has been further refined and developed by Giddings, Karaiskakis, and Caldwell[4] into an on-channel preconcentration step for concentrating dilute particulate samples in SedFFF.

Another injection technique, which involves a sample injection port a small distance downstream of the channel inlet, where the sample was injected and relaxed between two focusing flows with a reversed flow from the channel outlet, was first employed for asymmetrical FlFFF.[5] The theoretical basis of the horizontal transport was derived and fundamental practical aspects were discussed. This procedure is now standard for asymmetrical FlFFF, partly due to the difficulties of adapting the stop–flow injection mode. This was further optimized by Wahlund and Litzén[6] to include injection of up to 5 ml of sample in a 0.8 ml channel.

This approach has been subsequently used in symmetrical FlFFF[7,8] where the sample is injected in either the forward or backward focusing flow streams (Fig. 1). Lyvén et al.[7] showed a virtually quantitative recovery for preconcentration of 1.7 to over 100 ml of low-

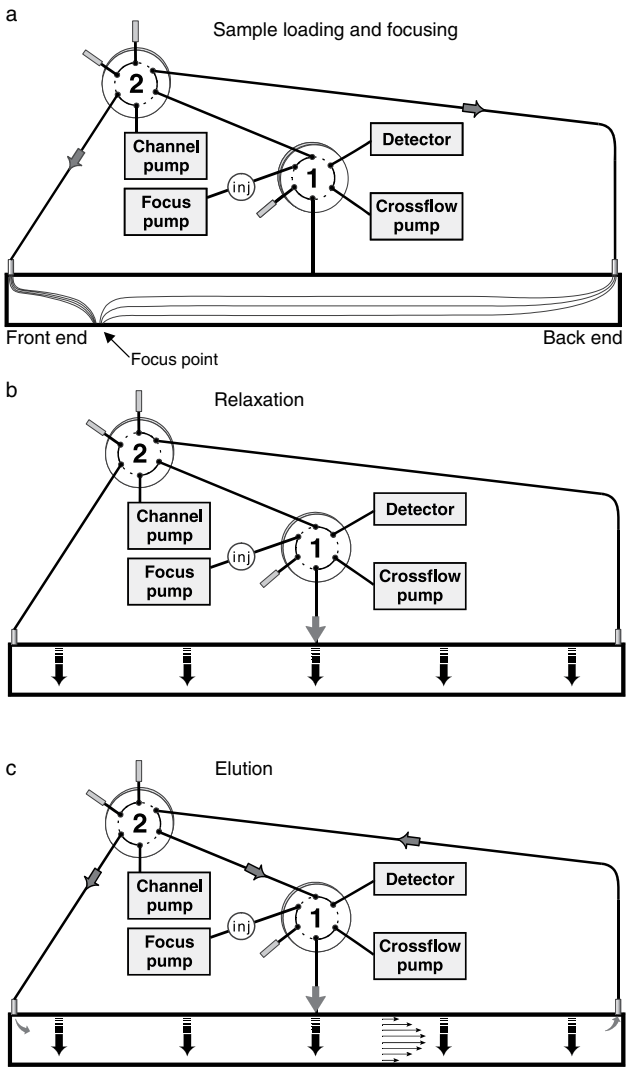

Fig. 1 Instrumental schematics of FlFFF with on-channel preconcentration showing the three different steps. The first involves emptying of the sample loop into either the forward or backward flows and subsequent focusing of the sample material at the focusing point. In the next step, the samples are allowed to relax at the equilibrium position by applying cross-flow only, and then the channel flows are switched on and elution is commenced.

molecular-weight polymers and natural water colloids (Fig. 2) with a molecular weight of the same order as the membrane cut-off by optimizing injection flows, membrane, and carrier. Injection in both the forward and backward focusing flow stream was evaluated. An experimental approach was used to determine the minimum time for sample loading and focusing. In order to ensure sufficient focusing time for all colloids, the focusing time was increased until a stabile retention time was attained for the largest reference standard. This on-channel preconcentration method has been later used in an FlFFF coupling with inductively coupled plasma mass spectrometry for trace element size distributions for natural water colloids[9,10] The colloids and the associated metals would have been impossible to study without the preconcentration procedure due to the very low concentrations of both colloids and trace metals often found in natural waters. Lee, Ratanathanawongs Williams, and Giddings[8] presented a method for preconcentrating 10 ml samples of dilute polystyrene latex beads, river sediment particles, and proteins, which are injected in the channel inlet stream with an opposed focusing flow from the channel outlet. Results of recoveries are shown for different membrane materials. On-channel preconcentrations for FlFFF and SedFFF are rather simple to incorporate in a conventional instrument, just with the addition of a second switching valve and a liquid pump. The sample is exposed to the same media as in the separation step, and the preconcentration step is carried out just prior to analysis, which is not always the case for external preconcentration techniques such as ultrafiltration or centrifugation.[11,12]

Precautions must be taken in all FFF analyses when injecting large amounts of material with any injection technique. During the sample relaxation, local concentrations of analytes can become very high, and at some point the

sample components start affecting each other. Then, conformational changes or intermolecular repulsion can occur, preventing the analytes from attaining a true equilibrium distribution in the channel. This phenomenon is often referred to as overloading and is usually indicated by a earlier eluting peak with a fronting peak shape.

Overloading in polymer analysis using flow and thermal FFF is thoroughly described by Caldwell et al.,[13] where different overloading mechanisms during relaxation and elution are theoretically and experimentally evaluated. Usually, for FFF separations, the detector sensitivity is sufficiently high to detect the separated components at sample concentrations well below the overloading concentration. For further characterization of the particulate material by other detection systems, e.g., mass spectrometry, or subsequent analysis of collected fractions, it is often necessary to inject large amounts of sample material to exceed the detection limits, and then it is essential to be observant of overloading effects. The best way of investigating the elution behavior in order to rule out overloading is to inject various amounts of the sample and follow the retention time as well as the shape of the peak. The applied field in stop–flow relaxation or focusing flows in on-channel preconcentration could also have an effect on non-ideal behavior, e.g., the sample components are compressed during high fields, causing both higher local concentrations and potential interaction with the accumulation wall. When working with sample amounts near the overloading point, varying the field strength acting on the analytes can be used to find conditions where overloading starts and thereby avoid it.

CONCLUSIONS

To lower the detection limits of an FFF analysis, it is best to first apply one of the postchannel flow splitters (e.g., slot outlet or frit outlet) to remove excess liquid and thus reduce the dilution. If this is still not enough, a preconcentration method has to be applied. On-channel preconcentration by the opposing flow focusing injection of large sample volumes is the standard method in asymmetrical FlFFF and is easily modified in symmetrical FlFFF. The method utilizes the FlFFF channel as an ultrafiltration cell in a step just prior to elution. For Sedimentation FFF, external preconcentration methods are more practical even though examples of large volume injections have been shown.

Laser-Induced Fluorescence Detection in CE

Huan-Tsung Chang
Tai-Chia Chiu
Chih-Ching Huang
Department of Chemistry, National Taiwan University, Taipei, Taiwan

INTRODUCTION

Separations of small solutes and macromolecules by capillary electrophoresis (CE) have been widely accepted by the scientific community, mainly due to its inherent advantages such as high resolution, compatibility with smaller samples, consumption of less buffer, rapidity, and ease of automation. Some of these advantages stem from the use of capillaries with inner diameters of 1–100 μm. With such small diameters, injection volumes are typically 0.1–10 nl, leading to a difficulty of detection. For detecting an analyte present at 1 n*M* concentration, with a 0.1-nl injection volume, extremely sensitive detection systems, providing a detection limit below 100 zmol for the analyte, are needed. Over the past 20 years, a number of nanoscale detectors, based on mass spectrometry, amperometry, chemiluminescence, raidochemistry, and fluorescence, have been developed to meet the extraordinary sensitivity challenges posed by CE. Of these, laser-induced fluorescence (LIF) has been the most successful and has been applied to single-cell analysis, DNA sequencing and separations, protein analysis, single-molecule detection, etc. One good example is that LIF, in conjunction with capillary array electrophoresis (CAE), has been successfully used for DNA sequencing, which has considerably assisted in the rapid progress of the Human Genome Project.

FLUORESCENCE

Fluorescence is the process of emission of light after absorption; its intensity is generally small, which depends on the extinction coefficient and quantum efficiency of the analyte, optical length, power of the light source, and light collection efficiency. In fluorescence measurements, one molecule can be reexcited thousands of times during the measurement to generate sufficient numbers of photons for detection. Thus it is essential to minimize the stray light from the optics and Rayleigh and Raman scattering of the solvent molecules. Once stray light and background signals are under control, a laser can be used to increase the excitation intensity, leading to larger signals and improved limit of detection (LOD) in fluorescence. To prevent photobleaching of analytes and damages of capillaries, lasers with 1–10 mW power are commonly used in CE; some are listed in Table 1.

Instrumentation

Since the first successful use of LIF for CE by Gassmann et al.,[1] several designs have been tested, including cross-beam excitation, epi-illumination, axial-beam excitation, and sheath-flow cuvette. Of these, the design of cross-beam excitation has been most commonly adopted in CE. Because laser light is well collimated, it can be focused to a beam diameter smaller than any practical capillaries used in CE. Thus the maximum photon flux can be delivered to the interior of a capillary to allow efficient excitation of analytes and to reduce the scattering from the capillary wall. With the capillary tilted at an angle to the laser beam, and the emitted fluorescence collected in a direction perpendicular to the plane of the capillary and excitation beam, the background from refracted light is minimized after appropriate spatial and spectral filtering. One basic instrumental setup of CE/LIF is shown in Fig. 1. With such a simple system, Tseng et al. were able to detect 11.1 n*M* human serum albumin labeled with albumin blue 580, using a low-cost He–Ne laser.[2]

A novel LIF detector, which uses a sheath flow cuvette developed by Wu and Dovichi, provides better sensitivity than the design of cross-beam excitation.[3] For example, LOD values as low as 1.7 zmol for fluorescein derivatives of amino acids have been achieved when injecting a 1.3 nl sample. Briefly, a sheath flow cuvette uses a flowing jacket of refractive index-matching buffer to hydrodynamically focus solutes as they exit from the capillary, leading to a thin stream in the center of the flow chamber. Thus it is easy to excite fluorophores migrating in such a thin stream by a focused laser beam, with a minimum Rayleigh scattering from the capillary wall and Raman scattering from water.

Fluorescence Signal

Compared to absorption, fluorescence is highly selective and sensitive. However, only very few solutes of interest have excellent photophysical properties, including high molar absorptivity, quantum yield, and photostability. Some solutes that can be detected by laser-induced native

Table 1 Lasers commonly used in CE/LIF.

Wavelength (nm)	Type	Representative applications	Derivitizing agent	Comments
248	KrF	Proteins and DNA	none	pulsed, KrF gas used

488	Ar^+	Proteins and amino acids	FITC	continuous
543.6	He–Ne	DNA	YOYO-1	cheap, stable, low power

PAHs: polycyclic aromatic hydrocarbons. FITC: fluorescein isothiocyanate. DNS: dansyl halide. OPA: *O*-phthaldialdehyde. NBD: 4-clair-7-nitrobenz-2-oxa-1,3-diazole. YOYO-1: benzoxazolium-4-quinolinium dimer. NAD^+: nicotinamide adenine dinucleotide.

fluorescence (LINF) in CE, using mid- to deep-UV lasers, include proteins, nucleic acids, polycyclic aromatic hydrocarbons, and catecholamines. Most commonly used UV lasers include a continuous frequency-doubled Ar^+ laser as well as pulsed excimer lasers and quadruplet Nd:YAG laser. Although the analyses of proteins within single human erythrocytes and enzyme activity in cancer cells have been demonstrated by using a continuous UV laser,[4] high costs and maintenance of the laser are problematic.

For those without native fluorescence, two common approaches have been employed, namely, derivatization and indirect fluorescence. Derivatizing agents should be pure, low fluorescent, and stable, as well as react quickly and uniquely with the analytes and, thus, formed compounds should be strongly fluorescent and stable. These include dansyl chloride, fluorescamine, 4-clair-7-nitrobenz-2-oxa-1,3-diazole (NBD), *O*-phthaldialdehyde (OPA), fluorescein isothiocyanate (FITC), and naphthalene-2,3-dicarboxaldehyde (NDA), which have been used for the analyses of amino acids, peptides, proteins, thiols, and sugars with LOD in 1–100 n*M* range. Compared to LINF, approaches based on derivatization provide the

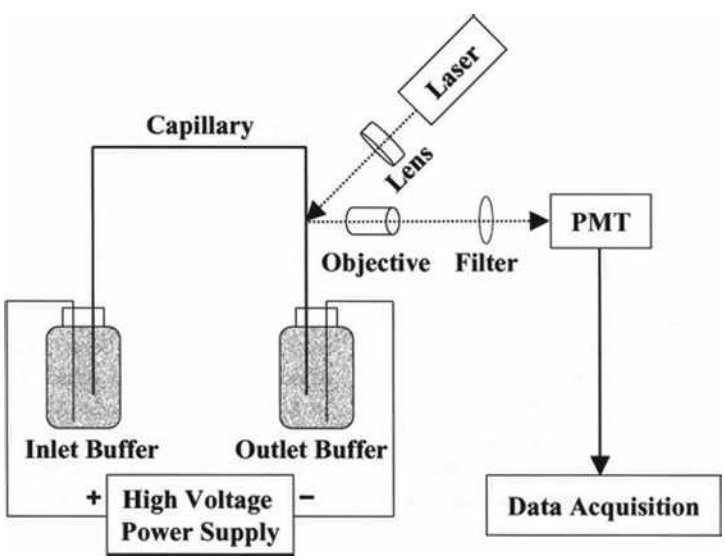

Fig. 1 Instrumental setup of CE-LIF.

advantages of relatively low cost and versatility in instrumentation, but they may suffer from contamination and loss of temporal information.

Indirect LIF (ILIF), in conjunction with CE, has been widely used for the analysis of ionic solutes, including organic acids, inorganic anions, carbohydrates, amino acids, and metal ions.[5] To optimize sensitivity, the use of an ionic dye with a greater fluorescent quantum yield and a very stable laser is essential, according to Eq. 1:

$$C_{\mathrm{LOD}} = C_{\mathrm{m}}/(\mathrm{DR} \times \mathrm{TR}) \quad (1)$$

where C_{LOD} is the concentration limit of detection; C_{m} is the concentration of relevant mobile-phase components; DR is the ability to measure a small change on top of a large signal and is equal to a signal-to-noise ratio (*S*/*N*) of the background signal; and TR refers to transfer ratio, which is the degree of displacement of the probe (co-ion) by the analyte. A system providing a high TR is also required for optimum sensitivity, as shown in Eq. 1, which can be realized by the use of fluorophores with a high charge density and a comparable mobility with analytes. By carefully controlling these factors, an LOD down to submicromolar for an analyte is easily achieved. As a result, the analysis of metal ions in single human erythrocytes by ILIF-CE has been demonstrated,[6] but its use for macromolecules such as proteins and DNA has been limited. Owing to the use of low ionic-strength buffers for achieving a high TR, matrix interference is a common problem.

APPLICATIONS

With high resolution, rapidity, and sensitivity, CE/LIF has become one of the most important separation tools in many fields. Most exciting research goals target at DNA sequencing, analysis of polymerase chain reaction products, single-cell analysis, single-molecule analysis, monitoring trace peptides and proteins in clinical analysis, determination of toxic chemicals, enantiospecific analyses in the fields of pharmaceutical drug research and production, etc. Herein we show some examples focusing on the analyses of DNA, proteins, and single cells.

DNA Sequencing and Separation

Although CE-LINF, using a UV Ar^+ laser, has been applied to the analysis of DNA, the majority has been performed by using visible lasers such as Ar^+ at 488 nm and He–Ne laser at 543.6 nm. These visible lasers are employed to excite DNA labeled covalently with fluorophores, such as modified fluorescein and rhodamine or intercalated DNA complexes. Some intercalating dyes, such as ethidium bromide (EtBr), benzothiazolium-4-quinolinium dimer (TOTO-1), benzoxazolium-4-quinolinium dimer (YOYO-1), and quinolinium-4-[(3-methyl-2(3*H*)-benzothiazolylidene)methyl]-1-[3-(trimethylammonio)-propyl]-diodide (TOPRO-1), have been developed that fluoresce weakly unless they insert inside a DNA strand, resulting in a low background and strong fluorescence. Detection limits in the level of zeptomole for these intercalated complexes have been demonstrated. Owing to high quantum yields, greater stability of these intercalated complexes, and multiple labeled capability, single-molecule detection for large DNA molecules has been achieved.[7] Moreover, some novel single-molecule-detection techniques have been developed and used to monitor the changes in DNA conformation (U-J-I) when migrating through gel matrices at applied electric fields.

Although DNA separation in CE relies on a sieving mechanism, like that in slab gel electrophoresis, polymer solutions prepared from linear polymers, such as linear polyacrylamide, poly(ethylene oxide), and cellulose derivatives, are commonly used, simply because they are of relatively low viscosity and are replaceable between runs. Polymer solutions can be filled into capillaries either under the influence of pressure prior to analysis in the absence of electro-osmotic flow (EOF), or by electrokinetic means during analysis in the presence of EOF. By taking advantage of EOF, Huang et al. have demonstrated gradient CE techniques for optimizing resolution, sensitivity, and speed in the analysis of DNA,[8] and online concentration techniques for DNA analysis with more than 400-fold improvement in the sensitivity, as shown in Fig. 2.[9] One should note that the migration order is the reverse of that observed in conventional CE methods (in the absence of EOF), because of DNA migrating against EOF.

The speed of CE is excellent compared to slab gel electrophoresis, but it is not throughput comparable to DNA sequencing. To overcome this disadvantage, the concept of high-throughput DNA analyzers, using an array of capillaries, has been realized and tested for DNA sequencing. One representative example is shown in Fig. 3.[10] Parallel separations result in significant challenges, such as reproducibility among capillaries, detecting DNA migrating through as many as 1000 capillaries at one time, cross talk between capillaries, and signal procession. So far, some novel CAE systems utilizing multiple sheath flow, line focus illumination, confocal fluorescence scanner, rotary confocal fluorescence scanner, fiber optic array illumination, together with charged coupled device (CCD) detection, have been developed and tested for DNA sequencing, forensic short tandem repeats, and genotyping.

Single-Cell Analysis

Generally, capillaries with inner diameters of 5–25 μm are used to inject and analyze single cells in CE. With such small capillaries, several features can be achieved, including low risk of injection of more than one cell at a time, low dilution factors after cell lysis, high resolving power, and

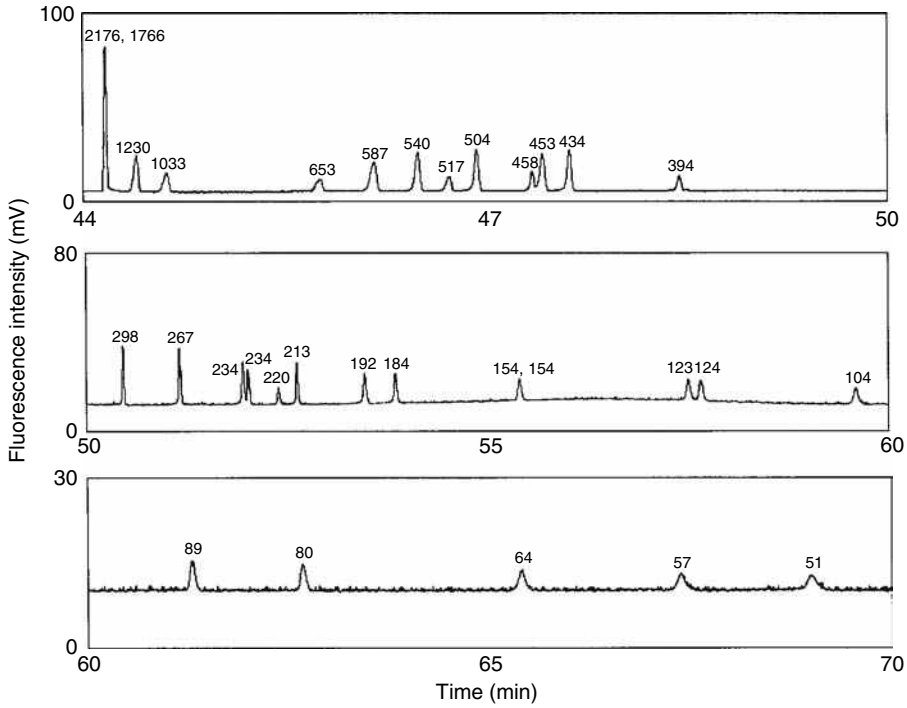

Fig. 2 Separation of 5 μl 0.1 μg/ml DNA markers V and VI prepared in 10 mm Tris-Borate (TB), pH 10.0, containing 2.5 mm NaCl at 444 V/cm for 30 min and, subsequently, at 222 V/cm for the rest using 2.5% PEO prepared in 200 mm TB, pH 9.0. Capillary: 45 cm in total length, 35 cm in effective length, 150 μm I.D., filled with 400 mm TB, pH 10.0.
Source: From Maximization of injection volumes for DNA analysis in capillary electrophoresis, in Electrophoresis.[9]

rapidity at high electric field strengths. It is important to keep a very small dilution factor, as the amounts of important markers in single cells are extremely low, mostly in the range of atomole–yoctomole. Besides, high resolving power is needed in order to separate a number of markers from a complicated cell environment. Although CE, in conjunction with mass spectrometry or amperometry, has been tested for single-cell analysis, most successful examples were conducted by CE/LIF. After injection of a cell into a capillary by pressure or electrokinetic means, lysis by osmosis, detergents, high voltage, or light takes place. When CE/LINF, using an Ar^+ laser at 275 nm is applied to detect proteins in erythrocytes, insulin contents in single islet cells, or catecholamines in adrenal medullary cells, the lysis components are directly subject to separation and detection. The success of these methods relies on the high sensitivity of LINF, with LOD values for proteins and catecholamines lower than nanomolar. For example, the determination of epinephrine and norepinephrine in individual bovine adrenal medullary cells, under acidic conditions, has been demonstrated.[11] Using a 285 groove/mm holographic grating and a CCD camera for detection, identification of ~ 30 compounds within single-neuron cells has been demonstrated using a frequency-doubled Ar^+ laser at 257 nm. When derivatization is required, background electrolytes containing suitable derivatizing agents are commonly used to perform on-column reaction. Compared to off-column derivatization, on-column reaction provides the advantages of low risk of contamination, low dilution factors, simplicity, and rapidity. One example is the use of naphthalene-2,3-dicarboxaldehyde and CN^- for the determination of dopamine and five amino acids in individual rat pheochromocytoma cells.[12] To increase the sensitivity and specificity, capillary affinity electrophoresis, in conjunction with immunoassay using antibody-fluorescein, has been developed for the determination of insulin in single islet cells.[13] In addition, the application of online enzyme assay, using an Ar^+ laser at 366 nm, has been demonstrated in the comparison of the activity of lactate dehydrogenase (LDH) in lymphoblastic cells and leukemia cells. With a high turnover number and low LOD for NADH, the same strategy has also been applied to the determination of the activity of single LDH molecules.

Protein Analysis

Proteomics is becoming increasingly important following the human genome era because proteins are the main catalysts, structural elements, signaling messengers, and molecular machines of biological tissues. A proteome represents the protein pattern of an organism, a cell, an organelle, or even a body fluid determined quantitatively at a certain time under precisely defined conditions. With high sensitivity and resolution, CE/LIF has shown high potential for quantification of proteins and exploration of their localization, modification, interaction, activity, and, ultimately, their function. In addition to separations based on a sieving mechanism, capillary zone electrophoresis using fused-silica capillary at low pH, high pH, or in high-conductivity background electrolytes, or using coated capillaries under mild conditions has been applied to the analysis of proteins. Besides, isotachophoresis and

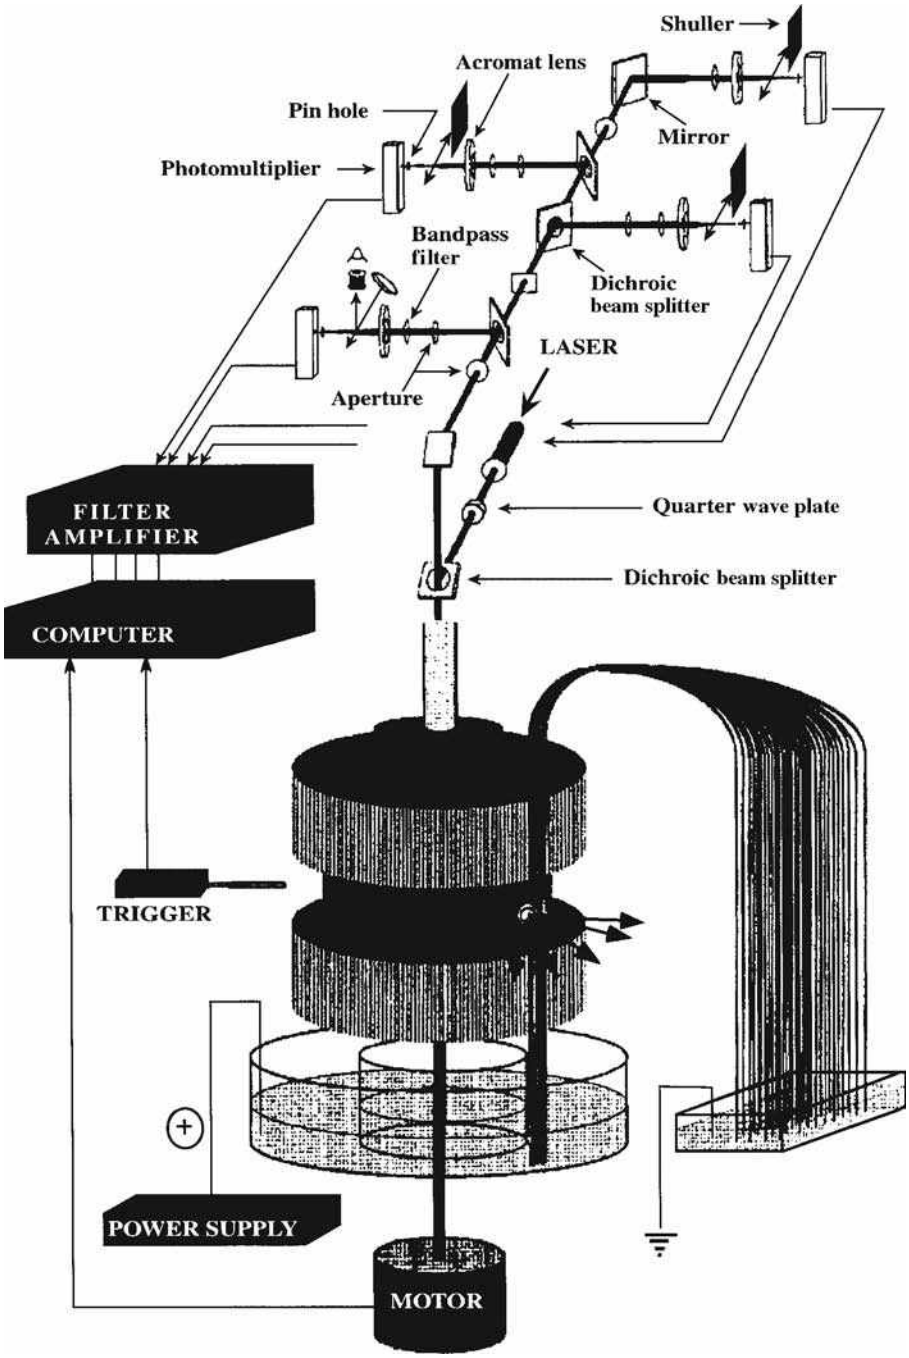

Fig. 3 Schematic representation of a 1000-capillary rotary scanner and a four-color confocal fluorescence detection system.

Source: From Ultra-high throughput rotary capillary array electrophoresis scanner for fluorescent DNA sequencing and analysis, in Electrophoresis.[10]

isoelectric focusing in capillaries have shown to be useful for separation of proteins. Although an Ar^+ laser at 275 nm and Kr^+ laser at 280 nm have been commonly used for protein analysis in CE/LINF, relatively inexpensive Nd:YAG pulsed laser at 266 nm and KrF excimer laser at 248 nm have also been employed. Generally speaking, pulsed lasers provide about 10 times higher LOD than continuous laser sources (former case). In spite of this, the LOD values down to picomolar for proteins have been achieved using a Nd:YAG laser when applying an online concentration technique.[14] When performing CE/LINF for protein analysis, a great effort must be made to minimize interferences, photobleaching, and quenching that may occur at low pH, high pH, high salt concentrations, and the existence of detergents. On the other hand, these problems can be minimized or prevented by careful selection of visible lasers, such as He–Ne lasers and dyes such as 3-(2-furoyl)quinoline-2-carboxaldehyde (FQ), NDA, Sypro Red, and Nile Red. Lee et al. have demonstrated protein analysis by on-column reaction using FQ, with a LOD of picomolar when excited with Ar^+ laser at 488 nm.[15] One drawback of performing derivatization is that multiple derivatization and byproducts might occur, leading to difficulty of separation.

CONCLUSIONS

With high sensitivity, rapidity, and high efficiency, CE/LIF has proved to be a powerful tool in the analysis of DNA, proteins, amino acids, glycoproteins, and single cells. To prevent photobleaching, as well as to reduce autofluorescence background and the cost of lasers, the use of diode lasers in the near-infrared region, together with suitable dyes, as well as sensitive detectors such as avalanche photodiode, has attracted much interest, which has been demonstrated in DNA sequencing and single-molecule detection. As the analyses of a single DNA molecule and single enzyme activity by CE/LIF have been demonstrated, its role in disease diagnosis and fundamental research, such as the interactions between DNA and proteins, will soon be recognized in many realms, such as in the life sciences. Recently, micrototal-analysis systems with LIF have become increasingly important in modern science and have been applied to the analysis of polymerase chain reaction (PCR) products or enzyme activity in a chip. Thus it is our belief that, despite LIF, some other laser techniques such as thermal lens absorption and Raman scattering spectroscopy will continue to play a strong role in the life sciences.

INTRODUCTION

In the few years that have passed since the first version of this entry, the field of liquid chromatography/mass spectrometry (LC/MS) has changed dramatically. We had quoted then that "The coupling of liquid chromatography and mass spectrometry (LC–MS) was initially considered impossible and actually is still characterized as a hyphenated technique." The situation now looks very different due to the remarkable increase of the magnitude of this subject and the massive expansion of the application of LC/MS, which are now driven by life sciences. The finalization of the human genome project (where the "shotgun approach" and hyphenated technologies were central) shifted the interest of a massive research and development sector toward the analysis and identification of macromolecules (genes, proteins, polysaccharides, etc.) in biological samples. These new needs are practically approached by a few rapidly evolving methodologies such as array techniques, LC/MS, and matrix-assisted laser desorption ionization/surface-enhanced laser desorption ionisation (MALDI/SELDI/MS). In addition, revolutionary developments in instrumentation (linear ion traps, quadrupole time-of-flight/MS, TOF/TOF/MS) continue to push instrument features and application possibilities even further. As a result, it is no surprise that LC/MS is now adapted by many different disciplines, and a greater scope of the technique's applicability and overall turnover is thus projected. In fact, in recognition of his innovative contributions for the coupling of LC with MS (electrospray technique), Prof. John Fenn was awarded a part of the Nobel Prize for Chemistry for the year 2002.

LC/MS

The coupling of LC with MS requires an appropriate interface due to the incompatibilities of the two methods. In order to introduce a conventional LC flow (0.5–1.5 ml/min) into the mass spectrometer, one should evaporate it, producing a vapor with a volume far beyond the capacity of the mass spectrometer pump systems. The selection of the interface is the key decision and a limiting factor in the utilization of the instrument. Some years ago, LC/MS systems were state-of-the-art, space-occupying machines, accessible only to specialists. In the last years, evolution in technology and electronics, together with stronger cooperation of LC with MS manufacturers (often in the form of company acquisition or merging and strategic alliances), brought to the market bench top, low price, dedicated systems that require less handling and are often used for routine analysis.

The advantages of an online LC/MS approach are many. Both techniques show high separation power and their on line combination is a powerful tool for identification purposes and quantitative studies. Many detectors are available for high-performance liquid chromatography (HPLC): ultraviolet (UV), conductivity, electrochemical, fluorescence, refractometer, etc. Unfortunately, most of them lack specificity, selectivity, and sensitivity. Hence, identification of unknown compounds is actually impossible.

An ideal detector for HPLC should combine optimum sensitivity with maximum identification capability. It should also respond to all the solutes and increase its signal linearly with the amount of the solute, but at the same time be unaffected by changes in the mobile phase. Finally, it should be reliable and robust and should not contribute to extracolumn peak broadening. Of the detectors used with HPLC, the mass spectrometer is the closest to these above requirements. A mass spectrometer offers many attractive features as a chromatographic detector. Low detection limits down to picogram range can be accomplished in optimized configurations. Mass spectrometry offers high specificity and mass distinction according to nominal mass (low-resolution MS). The specificity is much more increased in high-resolution MS where mass distinction is made according to accurate mass. This enables the resolution of compounds with the same nominal mass but with different elemental composition. Mass spectrometry provides compound specific information by fragmentation obtained either by hard ionization or by tandem MS. Fragmentation patterns greatly increase identification power in the analysis of unknown compounds in complex matrices. Finally, a mass spectrometer is potentially a universal detector.

A diagram of a typical mass spectrometer scheme is depicted in Fig. 1. The simplest form of an MS system should perform the following fundamental tasks:

1. Vaporize compounds of varying volatility. This is accomplished in the inlet system. Introduction of

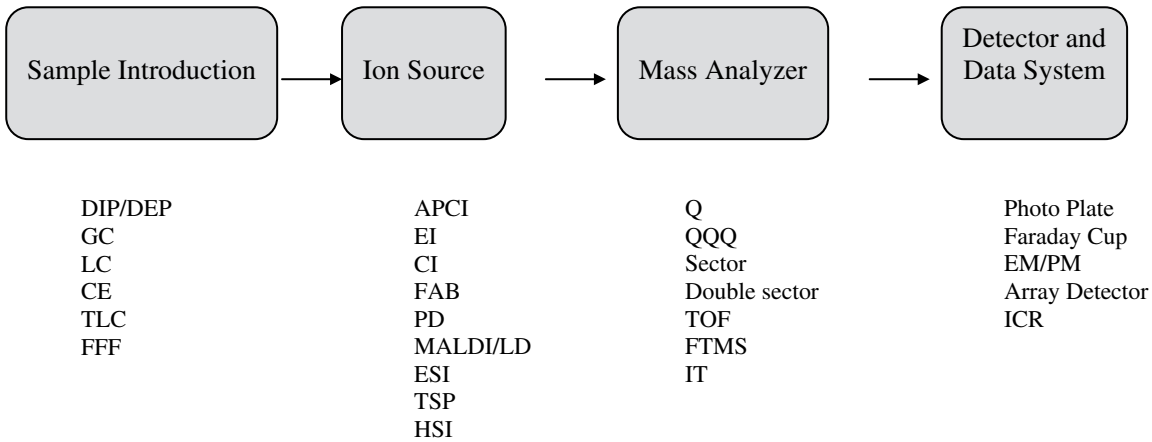

Fig. 1 Schematic representation of a mass spectrometer depicting its main components and the different modes used. DIP: direct insertion probe, DEP: direct exposure probe, CE: capillary chromatography, FFF: field flow fractionation, APCI: atmospheric pressure ionization, EI: electron impact, CI: chemical ionization, FAB: fast atom bombardment, PD: plasma desorption, MALDI: matrix-assisted laser desorption ionization, LD: laser desorption, TSP: thermospray, ESI: electron spray ionization, HSI: hyperthermal surface ionization, Q: quadrupole, QQQ: triple quadrupole, TOF: time-of-flight, FTMS: Fourier transform mass spectrometer, IT: ion trap, EM: electron multiplier, PM: photo multiplier, ICR: ion cyclotron resonance.

the sample is done by direct insertion probe, reservoir inlet, or following a separation step (GC, HPLC, or capillary electrophoresis (CE)). In the latter case to introduce on line the LC/CE flow to the mass spectrometer, one needs an appropriate interface. Development of appropriate interfaces was utmost for evolution of the LC/MS coupling.

2. Produce ions from neutral molecules in the vapor phase. This occurs in the ion source. As seen in Fig. 1, there are several modes of ion sources. Of those, the most used in LC/MS are: electrospray ionization (ESI), chemical ionization (CI), thermospray ionization (TSP), fast atom bombardment (FAB) and electron impact (EI).
3. Separate the formed ions according to their mass-to-charge ratio (m/z ratio). This takes place in the mass analyzer. By far the most used analyzer is the quadrupole either as single or as triple quadrupole combined with a soft ionization technique. In the latter configuration, tandem MS can be accomplished. The magnetic sector is also coupled to LC when there is a need for higher-resolution power or higher sensitivity.
4. Detect and record the separated ions. Multipliers are the most common detectors used in LC/MS instruments. Proper fully computerized data manipulation systems are required to handle the massive information flux from the detector.

Interfacing

Interfacing LC and MS benefits both techniques. An obvious question could be why does one need such a seemingly unorthodox coupling, when other robust and well-established techniques (GC/MS) are already available. The great potential of the LC/MS approach is its applicability in the analysis of thermolabile or non-volatile compounds; this is of enormous interest in bioanalysis. Despite its high-resolution power, GC is actually suitable only for the analysis of volatile compounds of low molecular mass. LC/MS analysis gave a real boost to bioanalysis enabling the positive identification and low level detection of peptides, proteins, carbohydrates, polar analytes, and many other types of synthetic or naturally occurring compounds. Lately, it has been stated by eminent mass spectrometrists that MS alone can handle most samples and provide adequate information (both qualitative and quantitative). Claims were made that chromatography could be disregarded since the mass spectrometer could operate as a perfect powerful separator and detector. This could be true in ideal situations or in pure "academic samples." The truth is that in real samples and most importantly in life sciences' applications, the separation power of chromatographic or electrophoretic techniques is still necessary. A big obstacle for the direct introduction of complex samples in MS is ion suppression: In such a case, the presence of interfering sample components would dominate the MS spectra and also hinder the ionization of important target analytes (in the ion source), which thus could not be seen by the analyzer. Due to such reasons, efficient methods for sample fractionation and analyte purification and enrichment are sought. As a result, more and more research groups are focused on the development of multidimensional separation modes. Hence, the future of LC and also LC/MS should not be regarded as vague. In contrast, in our opinion, LC/MS seems to dominate several routine analysis fields. LC/MS will hold a stronger grip in several fields such as forensic analysis, metabolite identification, or lead

Table 1 General features and applicability of various LC/MS interfaces.

Type	Solvent	Flow rate (μl/min)	Ionization	Analyte type
MB	NP	<2000	EI, CI, FAB	Non/slightly polar
	RP (< 50% H_2O)	<500	EI, CI, FAB	RV
DLI	RP (< 50% H_2O)	<50	Solvent-CI	Non/medium polar, MV
PB	RP, NP	100–500	EI, CI, FAB	Non/medium polar, MV
TSP	RP, NP	500–2000	TSP, solvent-CI	Non-polar to polar, V to RIV
ESI	RP, NP	1–1000	IE, API	Polar, IV
ISP	RP, NP	10–1000	IE, API	Polar, IV
HNI	RP, NP	1–2000	APCI	Non/medium polar, RV
cfFAB	RP, NP	<20	FAB	Polar, IV

MB: moving belt, DLI: direct liquid introduction, ISP: ionspray, HNI: heated nebulizer interface, cfFAB: continuous flow FAB, RP: reversed phase, NP: normal phase, IE: ion evaporation, API: atmospheric pressure ionization. RV: relatively volatile, RIV: relatively involatile, IV: involatile. The rest of the abbreviations as in Fig. 1.

finding and will continue to lead the proteome–genome–metabolome research.

Numerous types of LC/MS interfaces have been developed. Early attempts were focused on methods of overcoming the incompatibility of the liquid flow rate and maintenance of the MS high vacuum. Recent approaches pay more attention to the practical use of ionization techniques that do not require sample volatilization. The main approaches to overcome incompatibilities are:

1. Splitting of the flow. A high proportion of the sample is wasted this way.
2. Increasing the source housing pump speed, usually with the addition of a cryo-pump.
3. Miniaturizing the LC dimensions.
4. Removal of the solvent prior to the introduction in the MS. This approach is used in transport interfaces (MB) and PB.
5. Attaching additional pump to the ion source, which can then accept higher flow rates. This approach is used in TSP.
6. Atmosphere pressure ionization (ESI, APCI, ISP).

The main features of LC/MS interfaces are illustrated in Table 1.

The first commercially available LC/MS system (Finnigan 1976) used a moving belt interface. This was a straightforward approach based on the 1960s instrument design of moving wires and cords. An endless continuous moving belt transports the analytes from the LC system to the MS. The LC flow is deposited on a polyimide belt, and the mobile phase is removed by heating and subsequent evaporation in two consecutive vacuum chambers. Next, the analyte is desorbed from the belt and is introduced into the ion source. On the return path, the belt passes over a clean-up heater to remove residual solvent and sample and finally through a waterbath to remove any involatile material.

More robust, sensitive, and user-friendly devices soon replaced the first type of interfaces (MB and DLI). During the 1980s, a lot of effort was put on the development of TSP and PB. Since the last decade, ESI has been by far the most used interface for LC/MS, with APCI ranking second in applicability. Recently the two modes have been combined in a single interfacing device that can alternate from ESI to APCI eliminating the need for ion source replacement.

In ESI, the column effluent is passed through a small jet maintained at high voltage (kV range). Due to electronic charging, the liquid is broken into very small droplets. Desolvation of the droplets increases the electric field strength at the surface and leads to the ejection of charged compounds by ion evaporation (Fig. 2).

ESI demonstrates three major advantages:

1. It is a gentle technique and leads to less thermal degradation compared to other techniques.
2. Since it is an atmospheric pressure ionization technique, up to 100% ionization can be achieved, thus enhancing method sensitivity.
3. Multiple ions (sometimes up to 70–100 charges) are often formed, thus lowering the m/z ratio and permitting the analysis of high molecular weight compounds.

Despite its great advantages, LC/MS has also a number of limitations, apart from the interfacing need:

1. Incompatibility with some of the non-volatile buffers and other mobile phase additives. Hence, phosphates, ion pairing agents, and amine modifiers are replaced by ammonium acetate, ammonium formate, etc.
2. Special care has to be taken to ensure that no connection will introduce peak broadening.
3. Interfaces are not compatible with all the ionization modes, and, in general, although the MS is a universal detector, the fact remains that not all compounds can be analyzed with any configuration.
4. Instrument price still remains high (i.e., compared to GC/MS and MS/MS).

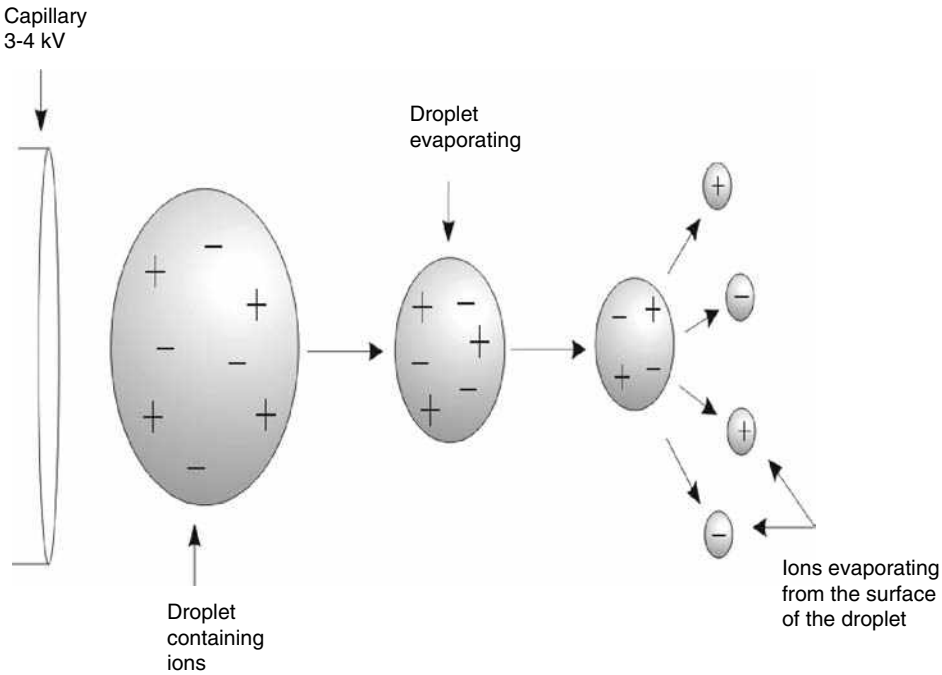

Fig. 2 Ion evaporation in the ESI mode.

ADVANCEMENTS

In the last years following the nanotechnology trend, great efforts have been put towards miniaturization and the developments of nano-LC. This is actually mandated from the end needs of the MS detection in genome–proteome research: Tiny amounts of the biomacromolecule are present in complex samples of limited volume and availability. Thus, miniaturization is a one-way road in proteomics, and microbore/capillary LC has become more popular. It is also believed that new bioanalytical LC/MS methods will be developed aiming at capillary or nano-LC dimensions. New, truly nano-LC pumps have now been commercialized to cover the niche. However, this has not yet passed into the bulk of the LC/MS reported works, where conventional LC columns still dominate the field. Reversed-phase (RP) LC is still by far the method of choice in LC/MS schemes, but more and more multidimensional schemes are reported employing size exclusion, ion exchange, or affinity modes and RP (Table 2).

The immense interest and the increasing needs for the application of LC/MS in various life science riddles motivated and pushed developments in mass analyzing technologies. Notable recent developments from the coupling and MS perspective include the development of interfaces for LC/MALDI/MS coupling, the LC/qTOF schemes, the expansion of LC/ion trap MS, and developments toward linear ion traps, Fourier transform ion cyclotron resonance MS, and TOF/TOF/MS schemes. Such developments result in enhanced versatility and dynamic span in method development. For example, LC/MALDI/MS schemes enable the simultaneous analysis (separation, identification, and quantitation) of a large number of very high molecular compounds (more than a 1,000,000 Da), and at the same time they improve detection sensitivity and scanning speed. The combination of LC with MALDI/MS is accomplished off-line as described at the end of this entry. The LC/TOF combination is practically realized via an APCI/ESI LC interface, introduction to a quadrupole MS, and subsequent orthogonal introduction to TOF/MS. Recent enhancement in the resolution power of TOF analyzers (reaching resolution values of 20,000 and 5–10 ppm mass accuracy) rendered LC/qTOF schemes as an attractive alternative of the bulky high-resolution

Table 2 Characteristics of various LC modes.

LC mode	I.D.	Injection volume	Flow rate
Conventional	3–6 mm	10–50 μl	0.5–2 ml/min
Microbore	0.5–2 mm	0.5–2 μl	10–300 μl/min
Packed microcapillary	0.2–0.5 mm	0.1 μl	1–10 μl/min
Drawn packed capillary	50–200 μm	10 nl	<0.1 μl/min
Open tubular	5–25 μm	1 nl	<0.1 μl/min

double/triple sector configurations. The LC/TOF/MS, when combined with ion traps or quadrupoles, provides also MS/MS capabilities with very high mass accuracy, improved resolution power, and wide dynamic range. LC/linear ion trap MS utilizes a quadrupole functioning as a linear trap (often in a triple quadrupole configuration). This scheme results in the accumulation of a higher number of ions, thus providing high-sensitivity full-scan MS and simultaneously improving MS/MS possibilities and time throughput.

APPLICATIONS

The application area of LC/MS is rapidly growing. LC/MS is now regularly used for the analysis of many different types of compounds: drugs and metabolites, herbicides–pesticides and metabolites, surfactants, dyes, saccharides, lipids–phospholipids, steroids, and many others. Obviously, the area that profits more from the development of LC/MS is life sciences: genomics and proteome research, bioanalysis, therapeutic drug monitoring, lead finding, natural products, and many other sectors rely on the unparalleled separation and identification possibilities of LC/MS. This is the field where a rapid expansion is progressing now and an even greater expansion is projected for the future. Needs in life sciences for the recognition of key elements (disease biomarkers, inherent compounds or metabolites and also drug metabolites) push more and more researchers to adopt LC/MS or MALDI/MS schemes in their protocols. Perhaps no tool has been more instrumental to proteomics revolution than the mass spectrometer. Due to its capacity to deconvolute highly complex matrices, MS instruments facilitate the identification and quantitation of proteins. Apart from the cartography of the proteome (estimates are from 300,000 to several millions of proteins in the human body), MS and LC/MS methods are the key elements in determining the dynamic state of proteins. In contrast to the more or less static genome, proteins are subject to several post-translational modifications, protein–protein interactions (including oligomerization and polymerization) and cell localization. In addition, many proteins exist in minute amounts and no multiplication tool is at hand. Thus, MS detection is absolutely necessary for both unambiguous identification and determination of proteins or peptides. Finally, peptide/protein sequencing is a broad field where again MS machines are instrumental.

LC/MS is penetrating many other scientific research sectors and is becoming widely used by various scientists: toxicologists, physicians, environmental scientists, veterinary scientists, and so forth. This becomes more evident in fields where unambiguous identification of banned or toxic substances is required. In clinical and forensic toxicology, LC/MS "competes" with GC/MS, the working horse of the field. Identification and quantitation of several drugs of abuse, pharmaceuticals, and doping agents is now performed with LC/MS or LC/MS/MS with equal or better specificity and sensitivity than GC/MS. Functional utilities used in GC/MS such as the MS libraries (obtained by electron impact ionization) are not at hand for LC/MS. Despite the developments and the ongoing efforts, reaching such high levels of validation and assurance in LC/MS seems a very difficult target.

The overwhelming amount of data generated and collected, produces what is now perceived as the bottleneck: the information manipulation. New software (bioinformatics) tools are being produced to cope with these rapidly expanding needs. In our opinion, this is the field where critical progress should be expected. The best software tools, which could rapidly and precisely identify minor amounts of complex peptide fragments in real samples or enable faster gene/protein identification, will probably be key elements in decision making.

Finally, an aspect that should not be left out of consideration is the off-line combination of LC with MS. A great advantage of the online methods is the integration of the evaluation systems used. In online LC/MS systems, identification of not completely resolved peaks is easily and unambiguously accomplished, taking advantage of the mass spectrometer separation power. In contrast in off-line LC/MS, complete resolution of the peaks is essential. Moreover, fraction collection, evaporation, and sample introduction may result in sample loss or contamination. However, off-line LC/MS can still be of great value, for preparative purposes or in cases where a special MS technique is required. For example, characterization of biopolymers or proteins by MALDI/TOF cannot be performed on line with a chromatographic separation method due to the nature of the two techniques (LC is a continuous flow technique whereas MALDI/MS is a pulsed technique). In this case, off-line LC/MS is the method of choice, and new interfaces have been recently produced. The LC effluent is robotically deposited onto precoated MALDI targets ("peak parking"). One by one, the spots on the target are subsequently shot by laser to ionize the molecules and introduce them to the MS. This orthogonal scheme has its own advantages as species can be selected to be analyzed again, whereas in online flow through modes this is not possible and a second LC/MS run is necessary.

CONCLUSIONS

In the past years, LC/MS has progressed and spread immensely and evolved from a high-end technology to a mature, indispensable technique applied both to research and routine analysis. The field continues to change dynamically as it remains in the forefront of contemporary research and development. Remarkable advancements have been made in both the LC field and the MS analyzing field; however, the interfacing principles and technologies

remain more or less more concentrated on the ESI/APCI schemes that have been developed more than a decade ago. It should be pointed out that new advancements and technologies seem to be driven by the pharmaceutical industry, which has invested heavily on hyphenated techniques (LC/NMR, LC/MS, and so forth) for bioanalytical purposes and the identification of disease biomarkers. Hence, important developments may not be disclosed for propriety purposes, whereas at the same time we see small instrumentation companies producing novel tools to cover interfacing niches mostly aiming at a higher throughput (multi-ESI needles). It should be expected that the chromatographic-separation element of several LC/MS methods and schemes will be significantly altered in the coming years. But we strongly believe that chromatography cannot and will not be displaced. In contrast, further expansion of the LC/MS can be expected: Miniaturization of both modes (LC and MS) will remain a major goal. Sample purification needs in proteome research render LC an integral part in the analysis of proteins. The absence of a multiplication method for proteins (as PCR functions for the genes) necessitates analyte separation and enrichment prior to the introduction to the MS for peptide identification and/or sequencing. The coupling is certainly a win–win situation from both perspectives and methods, and practitioners may greatly benefit by understanding and taking advantage of the additional features of the coupled methodology. LC/MS continues to be an exciting field, and now it is at the service of an ever-expanding number of scientists.

LC/NMR and LC/MS/NMR

Maria Victoria Silva Elipe
Analytical Research and Development Department, AMGEN, Thousand Oaks, California, U.S.A.

Abstract
A general overview of the recent technological advancements and applications of nuclear magnetic resonance (NMR) hyphenated with other analytical techniques is given from a practical point of view. Details of the pros and cons of the hyphenation of NMR with liquid chromatography (LC) as LC/NMR and also with mass spectrometry (MS) as LC/MS/NMR are demonstrated with two examples. Current developments of NMR and MS/NMR with other analytical separation techniques are discussed, especially with solid-phase extraction (SPE) as SPE/NMR and SPE/NMR/MS and capillary liquid chromatography (capLC) as capLC/NMR.

INTRODUCTION

During the last decade, hyphenated analytical techniques have grown rapidly to solve complex analytical problems. The combination of separation technologies with spectroscopic techniques is extremely powerful in carrying out qualitative and quantitative analysis of unknown compounds in complex matrices. High-performance liquid chromatography (HPLC) is the most widely used analytical separation technique for the qualitative and quantitative determination of compounds in solution. Mass spectrometry (MS) and nuclear magnetic resonance (NMR) are the primary analytical techniques that provide structural information for the analytes. The physical connection of HPLC and MS (LC/MS) or NMR (LC/NMR) increases the capability of analysts to solve structural problems of mixtures of unknown compounds. LC/MS has been the more extensively applied hyphenated technique because MS has higher sensitivity than NMR.[1–3] Advances in NMR, LC/NMR, and even LC/MS/NMR have enabled these techniques to become routine analytical tools in many laboratories. This entry provides an updated overview for the LC/NMR and LC/MS/NMR (or LC/NMR/MS) techniques with a description of their limitations, together with an example for LC/NMR and another for LC/MS/NMR to illustrate the data generated by these hyphenated techniques. This entry is not meant to imply that LC/MS/NMR will replace LC/MS, LC/NMR, or NMR techniques for structural elucidation of compounds. LC/MS/NMR, together with LC/MS, LC/NMR, and NMR, are techniques that should be available and applied to appropriate cases based on their advantages and limitations.

PRACTICAL ISSUES OF LC/NMR

NMR is one of the most powerful techniques for elucidating the structures of organic compounds. Before undertaking the NMR analysis of a complex mixture, separation of the individual components by chromatography is required. LC/MS is routinely used to analyze mixtures without prior isolation of their components. In many cases, however, NMR is needed for the identification of ambiguous structures. Although hyphenated LC/NMR has been known since the late 1970s,[4–6] it has not been widely implemented until the last decade.[7–11] The major technical considerations of LC/NMR are NMR sensitivity, NMR and chromatographically compatible solvents, solvent suppression, NMR flow-probe design, and compatibility of the volume of the chromatographic peak with the volume of the NMR flow cell.

NMR is a less sensitive technique compared to MS and hence requires much larger samples for analysis. MS analysis is routinely carried out in the picogram range. Modern high-field NMR spectrometers (400 MHz and higher) can detect proton signals from pure demonstration samples well into the nanogram range (MW 300 Da). For real world samples, however, purity problems become more intrusive with diminishing sample size and can be overwhelming in the submicrogram domain. This places a practical lower limit for most structural elucidation by NMR, which is estimated by the author to be close to 500 ng (MW 300 Da).

Although several other important nuclides can be detected by NMR, proton (^{1}H) NMR remains the most widely used because of its high sensitivity, high isotopic natural abundance (99.985%), and its ubiquitous presence in organic compounds. Of comparable importance

is carbon (^{13}C), with 1.108% abundance, which, because of substantial improvements in instrument sensitivity, is now utilized as routinely as proton. Fluorine (^{19}F) with 100% abundance is used less often because it is present in only about 10% of pharmaceutical compounds. Another consequence of the intrinsic low sensitivity of NMR is that virtually all samples require signal averaging to reach an acceptable signal-to-noise level. Depending on the sample size, signal averaging may range anywhere from several minutes to several days. For metabolites in the 1–10 μg range, overnight experiments are generally necessary.

Liquid NMR requires the use of deuterated solvents. Conventionally, the sample is analyzed as a solution using a 5 or 3 mm NMR tube depending on the NMR probe, which requires ~500 or 150 μl, respectively, of deuterated solvents. The increased solvent requirement for LC/NMR makes this technique highly expensive. Deuterium oxide (D_2O) is the most readily available, reasonably priced solvent (over $300/L). The price of deuterated acetonitrile (CD_3CN) is dropping and varies depending on the percentage of included D_2O, but still exceeds $1000/L. Deuterated methanol (CD_3OD) is even more expensive. Deuterated solvents for normal-phase columns are not readily available, but those that are available have even more prohibitive price tags. This necessitates the use of reversed-phase columns. Another factor that raises concern is the compatibility of the HPLC gradient–solvent system with NMR operations. An HPLC gradient–solvent system greater than 2–3%/min causes problems in optimizing the magnetic field homogeneity (shimming) because of solvent mixing in the flow cell.

During the LC/NMR run, the solvent signal in the chromatographic peak is much larger than those of the sample and needs to be suppressed. Even with deuterated solvents, the residual proton solvent signals need to be suppressed. In the case of acetonitrile, the two ^{13}C satellite peaks of either the protonated or residual protonated methyl group for CH_3CN or CD_3CN need to be suppressed because they are typically much larger than signals from the sample. In 1995, Smallcombe et al.[12] optimized the WET (water suppression enhanced through T1 effects) solvent suppression technique, which greatly improves the quality of spectra generated during LC/NMR. One disadvantage of suppressing the solvent lines is that any nearby analyte signal will also be suppressed, resulting in loss of structural information.

Conventional NMR flow cells have an active volume of 60 μl (i.e., corresponds to the length of the receiver coil) and a total volume of 120 μl. This means that NMR will only "see" 60 μl of the chromatographic peak. If the flow rate in the HPLC system is 1 ml/min, when 4.6 mm columns are used, only 3.6 sec of the chromatographic peak will be "seen" by NMR. Chromatographic peaks are generally much wider than 4 sec, indicating that less than half of the chromatographic peak will be detected. This is one of the disadvantages of LC/NMR compared with conventional 3 mm NMR probes where the amount of sample "seen" by NMR receiver coil is independent of the width of the chromatographic peak. There are other sizes commercially available for the NMR flow cells with active volume of 10, 30, 60, and 120 μl. For applications using solid-phase extraction (SPE) as SPE/NMR, the more appropriate sizes are 10 or 30 μl flow cells. Microcoil NMR flow cells for capillary LC/NMR (capLC/NMR) or microflow NMR have a flow cell with an active volume of 1.5 μl, which is appropriate for applications with samples in low concentrations.

Because NMR is a low-sensitivity technique that requires samples in the order of several micrograms, analytical HPLC columns have to be saturated when injecting samples in that range. This will affect the chromatographic resolution and separation because resolution is often degraded when sample injection is scaled up to that level. Another factor that can affect chromatographic performance is the use of deuterated solvents. In many cases, analytes show different retention times from non-deuterated solvents, resulting in occasional peak broadening. When this occurs, more study is required in order to obtain reasonable resolution. Decreasing the flow rate to less than 1 ml/min will increase the LC/NMR sensitivity, and a greater portion of the chromatographic peak will be "seen" by NMR. However, it requires an accurate LC pump for flow rates lower than 1 ml/min. For the SPE/NMR application, the LC/NMR sensitivity is increased by concentrating the chromatographic peak into the SPE cartridge when injecting the sample several times. In the case of capLC/NMR or microflow NMR, the LC/NMR sensitivity is improved by concentrating the sample to 5 μl volume.

There are many examples in the literature of LC/NMR applications in natural products,[13–19] food analysis,[20,21] metabolites,[22–29] degradation products,[30–32] drug impurities,[33–35] and drug discovery.[36–38]

Other chromatographic techniques have been coupled online to NMR for additional applications, such as size-exclusion chromatography (SEC), as SEC/NMR;[39] capillary electrophoresis (CE), as CE/NMR;[40,41] capillary electrochromatography (CEC), as CEC/NMR;[42–45] capillary zone electrophoresis (CZE), as CZE/NMR;[42,45] gel-permeation chromatography (GPC), as GPC/NMR;[46] and supercritical fluid chromatography (SFC), as SFC/NMR.[46] CE/NMR, CEC/NMR, and CZE/NMR are techniques that work with very small-volume NMR probes, with capillary separations. SPE/NMR has become a common technique for trace analysis.[47] In SPE/NMR, the chromatographic peaks are trapped into cartridges through multiple injections to concentrate the analytes of interest. The cartridges are dried with nitrogen to remove any residual solvent and the analyte(s) in each cartridge is flushed to the NMR flow cell with deuterated solvents, creating a sharp eluting band (25–30 μl eluting volume) appropriate for small NMR flow cells, such as 10 or 30 μl flow cells.[48,49] Recently,

more developments have been carried out to hyphenate capillary-based HPLC with NMR (capLC/NMR) and the use of commercial microcoil NMR probes.[50–52] With microcoil NMR probes, the range of sample used in capLC/NMR could reach the nanogram level (low nanogram level only for detection limit, but not for structural analysis).[50,51] With this technique, the volume of the chromatographic peak is comparable with the volume of the microcoil NMR flow cell.

OPERATIONAL MODES OF LC/NMR

HPLC is connected by red polyether ether ketone (PEEK) tubing to the NMR flow cell, which is inside the magnet. With shielded cryomagnets, the HPLC can be as close as 30–50 cm to the magnet as compared to 1.5–2 m with conventional magnets. Normally, a UV detector is used in the HPLC system to monitor the chromatographic run. Radioactivity or fluorescent detectors can also be used to trigger the chromatographic peak of interest.[10,11,26]

There are four general modes of operation for LC/NMR: on-flow, stop-flow, time-sliced, and loop collection.

On-flow or continuous-flow experiments require more sample to analyze "on the fly," because the resident time in the NMR flow cell is very short (3.6 sec at 1 ml/min) during the chromatographic run.

Stop-flow requires the calibration of the delay time, which is the time required by the sample to travel from the UV detector to the NMR flow cell, which depends, in turn, on the flow rate and the length of the tubing connecting HPLC with NMR. Because the chromatographic run is automatically stopped when the chromatographic peak of interest is in the flow cell, the amount of sample required for the analysis can be reduced and 2-D NMR experiments, such as correlation spectroscopy (COSY), total correlation spectroscopy (TOCSY), and others can be obtained because the sample can remain inside the flow cell for days. It is possible to obtain NMR data on a number of chromatographic peaks in a series of stops during the chromatographic run without on-column diffusion that causes loss of resolution, but only if the NMR data for each chromatographic peak can be acquired in a short time (30 min or less).

"Time-sliced" operation involves a series of stops during the elution of a chromatographic peak of interest. Time-sliced is used when two analytes elute together or have close retention times, or when the separation is poor.

Loop collection can be used when there is more than one chromatographic peak of interest. Chromatographic peaks are stored in loops for later off-line NMR study. In this case, the analytes must be stable inside the loops during the extended period of the analysis. Capillary tubing should be used to avoid peak broadening with concomitant loss of analyte "seen" by the NMR spectrometer.

Stop-flow is the preferred mode of operation to analyze the structure of metabolites when the chromatography is reasonable or the metabolite is unstable or volatile. The following example illustrates the application of LC/NMR for a volatile metabolite with a small molecular weight.[26] Conventional NMR was not doable because the radioactivity of the fraction containing the metabolite of interest was lost during evaporation to dryness prior the NMR analysis. In this case

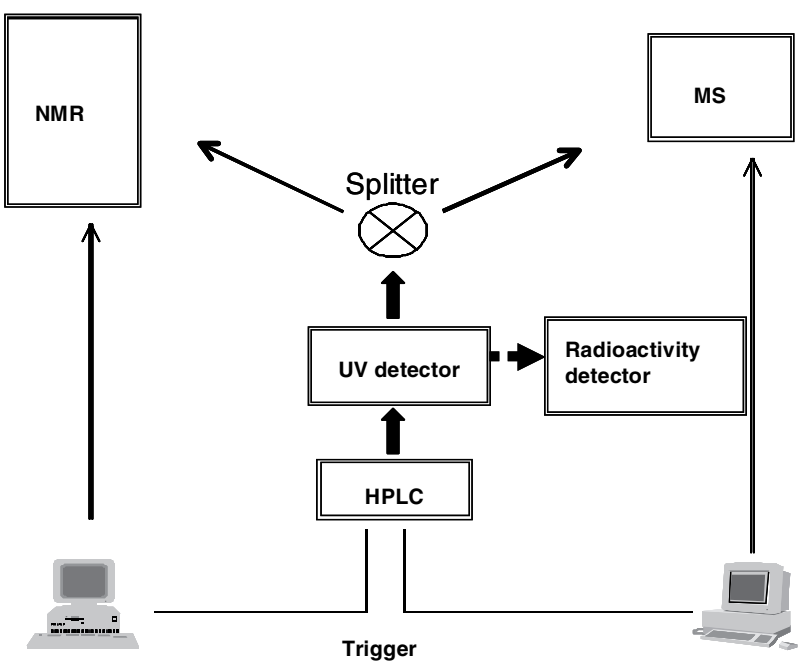

Fig. 1 Schematic setup for the LC/MS/NMR system.

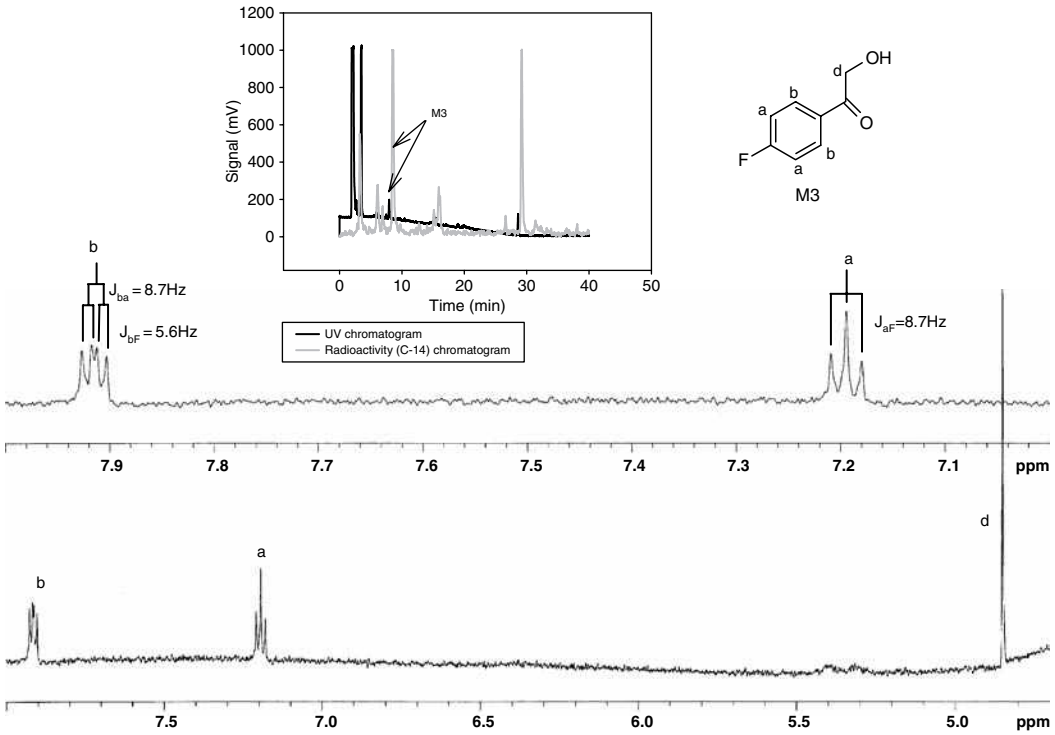

Fig. 2 UV and radioactive (C-14) chromatograms of the fraction containing the metabolite M3 (top), and the aromatic section (from 7.0 to 8.0 ppm) (middle) and the expanded section (from 4.7 to 8.0 ppm) (bottom) of the ^{1}H NMR spectrum of the metabolite M3.

LC/MS was not informative, suggesting a molecular weight less than 200 Da. LC/NMR was the alternative to solve the structural problem. A radioactive detector equipped with a liquid scintillation cell (Radiomatic C150TR, Packard, Meriden, Connecticut, U.S.A.) was connected online to the LC/UV system of the LC/NMR to identify the UV chromatographic peak corresponding to the radioactive metabolite, as shown in Fig. 1. For an initial identification of the metabolite of interest, small injections were carried out to identify the UV chromatographic peak associated with the radioactive peak of the metabolite prior the stop-flow experiment (Fig. 2). Because of the shorter transfer delay from the UV to the NMR than from the radioactive to the NMR because of the thicker tubing in the scintillation cell, UV was used to trigger the stop-flow experiments. ^{1}H NMR spectrum showed the presence of the *p*-fluorophenyl ring, with its characteristic splitting pattern indicating that the compound was drug related. The downfield shift of the *ortho* protons (δ 7.91 ppm) suggested the presence of a carbonyl substituent (Fig. 2). The presence of a singlet (δ 4.85 ppm) that integrated for approximately two protons was consistent with a methylene flanked by the carbonyl and a hydroxyl group (Fig. 2). The structure of *p*-fluoro-α-hydroxyacetophenone for the M3 metabolite was proposed based on these features (Fig. 2).

PRACTICAL ISSUES OF LC/MS/NMR (OR LC/NMR/MS)

NMR and MS data for the same analyte are crucial for structural elucidation. When different isolates are analyzed by NMR and MS, one cannot always be certain that the NMR and the MS data apply to the same analyte. To avoid this ambiguity, LC/MS and LC/NMR are combined. MS data should be obtained initially because with NMR, data collection in the stop-flow mode can take hours or days, depending on the complexity of the structure and the amount of sample. This is why it is preferable to designate this operation as LC/MS/NMR rather than LC/NMR/MS.

Because MS is considerably more sensitive than NMR, a splitter is incorporated after the HPLC to direct the sample to the MS and NMR units separately. In the example below, the MS used in these studies is an LCQ Classic instrument (ThermoFinnigan, California, U.S.A.). A custom-made splitter was used with a splitting ratio of 1:100 (Acurate^{TM}, LC Packings, California, U.S.A.). It was designed to deliver 1% of the sample initially to the MS and the balance 20 sec later to the NMR. With a flow rate of 1 ml/min, the final flow rate going to the NMR will be 0.990 ml/min and to the MS will be 0.010 ml/min. Electrospray is the only source of ionization that will work

with such a low flow rate (10 μl/min) in LCQ. Fig. 1 depicts the scheme of our LC/MS/NMR system.[10,11]

Another consideration for the LC/MS/NMR is the use of deuterated solvents needed for NMR. Analytes with exchangeable or "active" hydrogens can exchange (i.e., equilibrate) with deuterium (^{2}H) at different rates. The analyst should be alerted to this possibility because it could result in the appearance of several closely spaced molecular ions.

There are examples in the literature for the application of LC/MS/NMR in natural products,[53–55] drug metabolism,[55–63] combinatorial chemistry,[64] pharmaceutical research,[8,65] drug discovery,[66] degradation products,[67] and food analysis.[68,69] LC/NMR/MS (or LC/MS/NMR as described in this entry) has also been integrated with SPE as LC/SPE/NMR/MS combined with cryogenic NMR probes in the areas of natural products[70] and drug metabolism.[71]

OPERATIONAL MODES OF LC/MS/NMR (OR LC/NMR/MS)

As mentioned in the section "Operational Modes of LC/NMR," with the use of shielded cryomagnets the location of the MS instrument will follow the same rule as for the HPLC. The most common modes of operation for LC/MS/NMR are on-flow and stop-flow. With stop-flow, the MS instrument can also be used to stop the flow on the

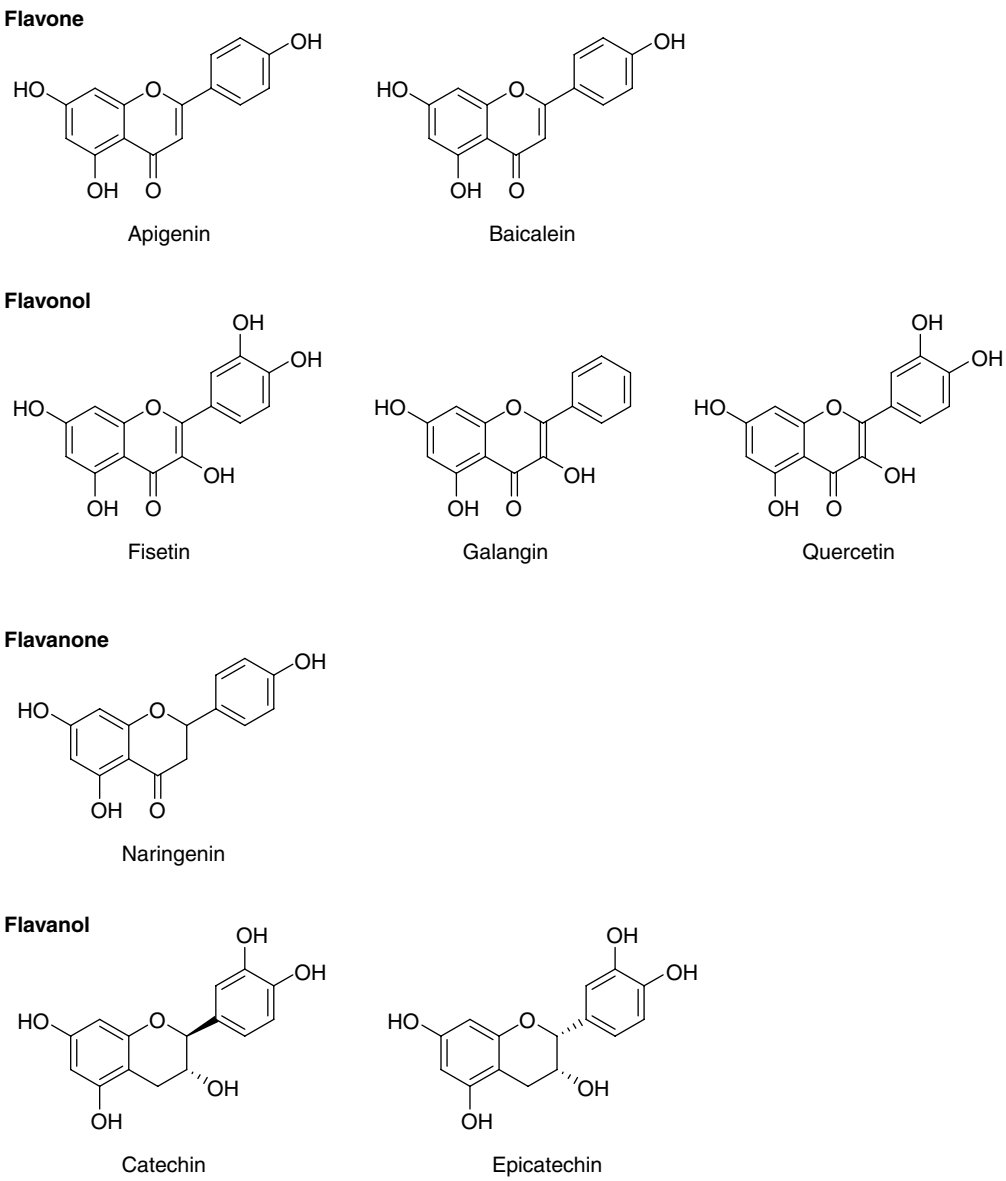

Fig. 3 Structures of eight flavonoids used for the LC/MS/NMR technology development studies.

chromatographic peak of interest that is to be analyzed by NMR.

In the last few years, there have been relatively few more examples in the literature that deal with the application of LC/MS/NMR. We have been interested in evaluating this technology to determine the pros and cons and to decide which cases are suitable for this application. To illustrate these modes of operation, a group of flavonoids was chosen. These compounds have simple structures with primarily aromatic protons; some have low-field aliphatic protons, which would not be hidden under the NMR solvent peaks. Phenolic protons exchange fast enough with D_2O so that each compound will only show one molecular ion. Flavonoids are natural products with important biological functions, acting as antioxidants, free-radical scavengers, and metal chelators, and are related to the food industry. Fig. 3 shows the group of eight flavonoids chosen for these studies.

The chromatographic conditions used for these studies were as follows: 35–50% B 0–10 min, 50–80% B 10–15 min; A: D_2O, B: acetonitrile (ACN), 1 ml/min, 287 nm, Discovery C18 column 15 × 4.6 cm, 5 μm. Stock solutions of each compound were prepared at 1 μg/μl in ACN/MeOH (1:1).

A Varian Unity Inova 600 MHz NMR instrument (Palo Alto, California, U.S.A.) equipped with a $^{1}H[^{13}C/^{15}N]$ pulse field gradient triple resonance microflow NMR probe (flow cell 60 μl; 3 mm O.D.) was used. Reversed-phase HPLC of the samples was carried out with a Varian modular HPLC system (a 9012 pump and a 9065 photodiode array UV detector). The Varian HPLC software was also equipped with the capability for programmable stop-flow experiments based on UV peak detection. An LCQ

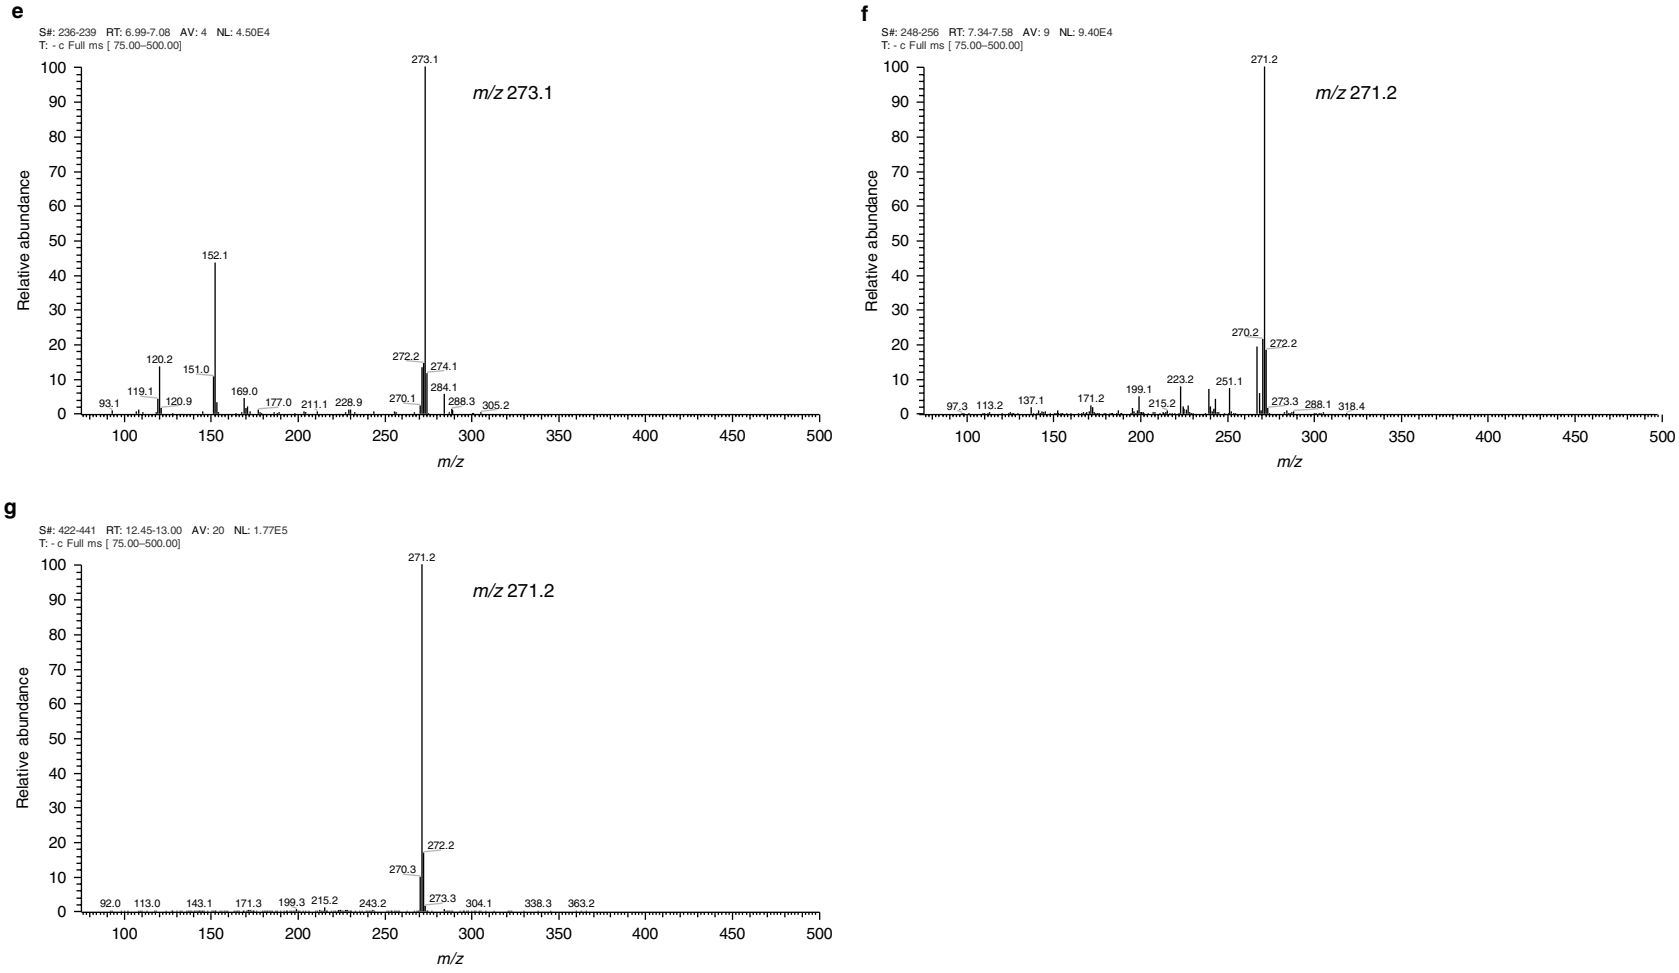

Fig. 5 (*Continued*)

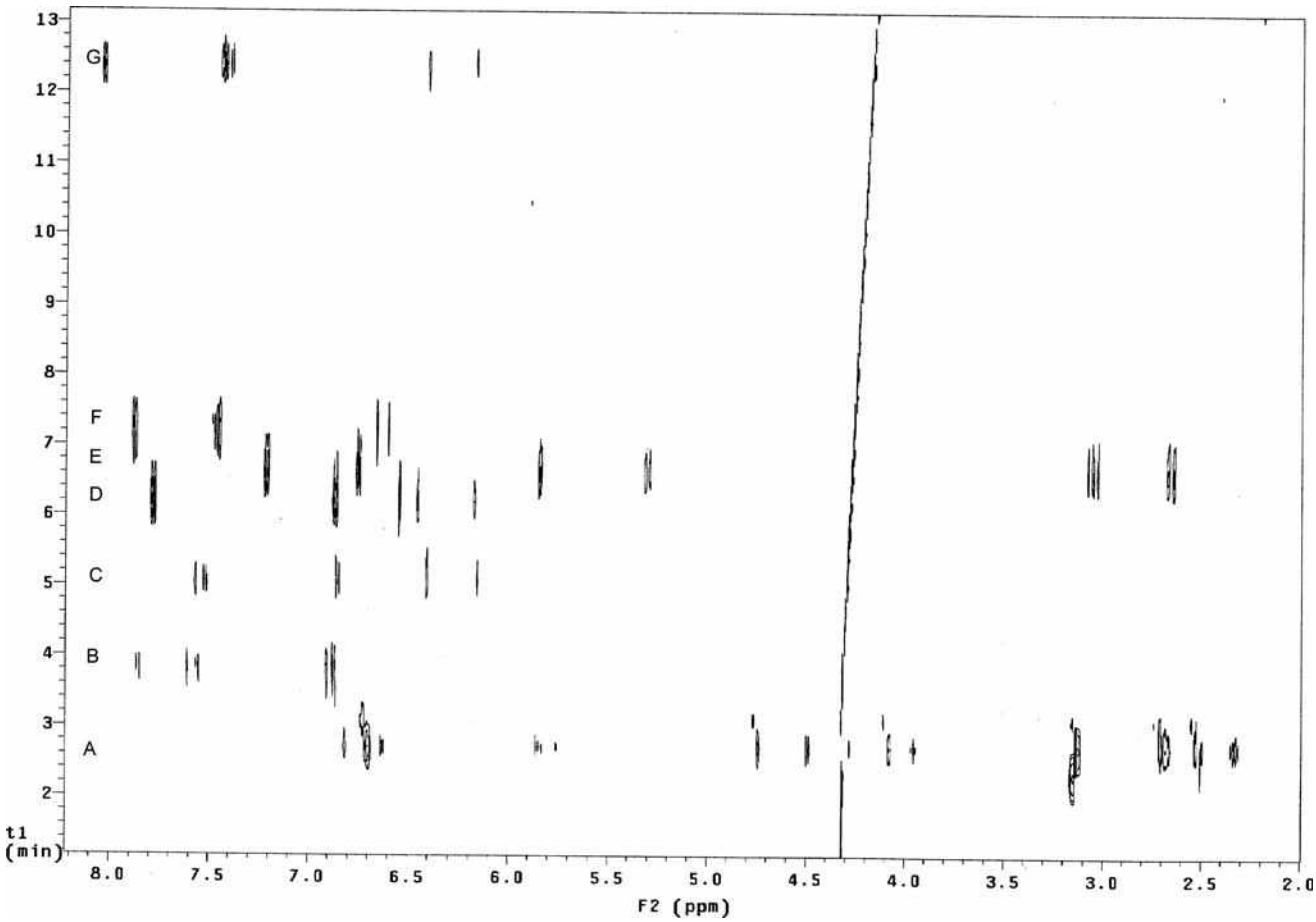

Fig. 6 2-D data set (time vs. chemical shift) for the on-flow experiment injecting a mixture of eight flavonoids: A, catechin + epicatechin; B, fisetin; C, quercetin; D, apigenin; E, naringenin; F, baicalein; G, galangin.

classic MS instrument, mentioned in the previous section, was connected online to the HPLC/UV system of the LC/NMR by contact closure. The ^{2}H resonance of the D_2O was used for field-frequency lock and the spectra were centered on the ACN methyl resonance. Suppression of resonances from HOD (the residual protonated signal of D_2O) and the methyl of ACN and its two ^{13}C satellites was accomplished by means of a train of four selective WET pulses, each followed by a B_0 gradient pulse and a composite 90° read pulse.[12]

The on-flow experiment was carried out on a mixture of eight flavonoids (20 μg each) (Fig. 3). MS and NMR data were obtained during this on-flow experiment. The UV chromatogram is depicted in Fig. 4. Table 1 and Fig. 5 show the pseudo-molecular ion information $[M\text{-}^{2}H]^{-}$ (where M is the molecular weight with all the hydroxyl protons deuterated, in negative mode) for the eight flavonoids obtained in this on-flow experiment. Fig. 6 is the 2-D data set (time vs. chemical shift) where each ^{1}H NMR spectrum was acquired for 16 scans and decreasing the delays (total time per spectrum of 20 sec). Fig. 7 depicts the ^{1}H NMR traces of each flavonoid extracted from the 2-D data set. It is notable that catechin and epicatechin coelute under these conditions (peak A of the UV chromatogram of Fig. 4). Distinguishing these diastereomers by MS alone is not feasible. Differences in the NMR spectra would be expected, and are in fact observed. The ability of LC/MS/NMR to distinguish signals from individual diastereomers is illustrated in Figs. 6 and 7A.

Two stop-flow experiments were carried out on apigenin (10 μg) (Fig. 3) by using, independently, the UV peak maximum or the molecular ion chromatographic peak seen in the MS instrument to trigger the stop-flow. The Varian software triggers the stop-flow automatically with the UV peak, so this mode was used as a reference point. When the MS was used to trigger the stop-flow, it was carried out manually with a chronometer while the molecular ion of apigenin was being monitored in negative mode (*m/z* 271). After peak detection in the UV or MS and a time delay of about 52 or 20 sec, respectively, the HPLC pump was stopped, trapping the peak of interest in the LC/NMR microprobe. ^{1}H NMR stop-flow spectra were acquired using an acquisition time of 1.5 sec, a delay between the successive pulses of 0.5 sec, a spectral width of 9000 Hz, and 32 K time-domain data points. The

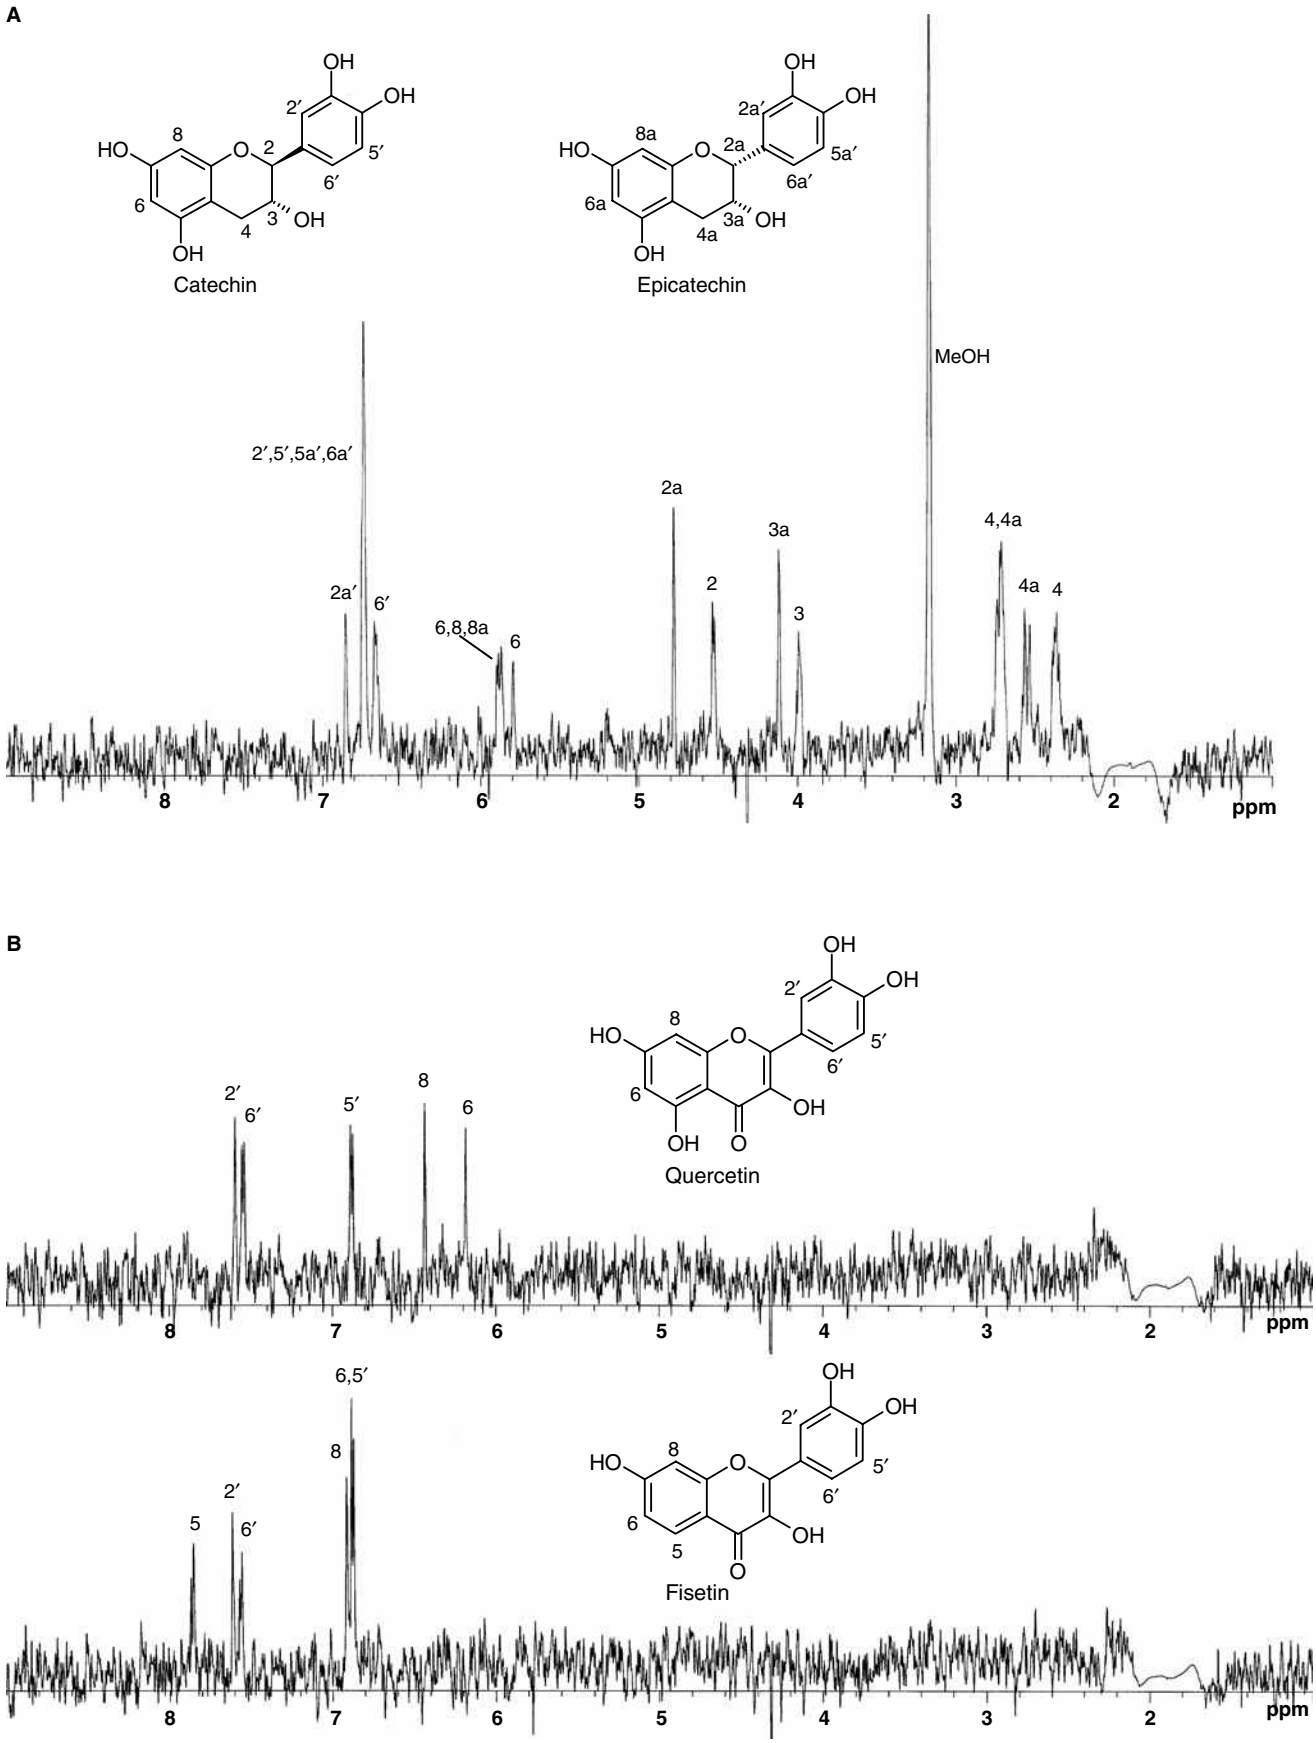

Fig. 7 ^{1}H NMR spectra from the 2-D data set of the on-flow experiment of (A) catechin and epicatechin, (B) quercetin (top) and fisetin (bottom), (C) naringenin (top) and apigenin (bottom), and (D) galangin (top) and baicalein (bottom).

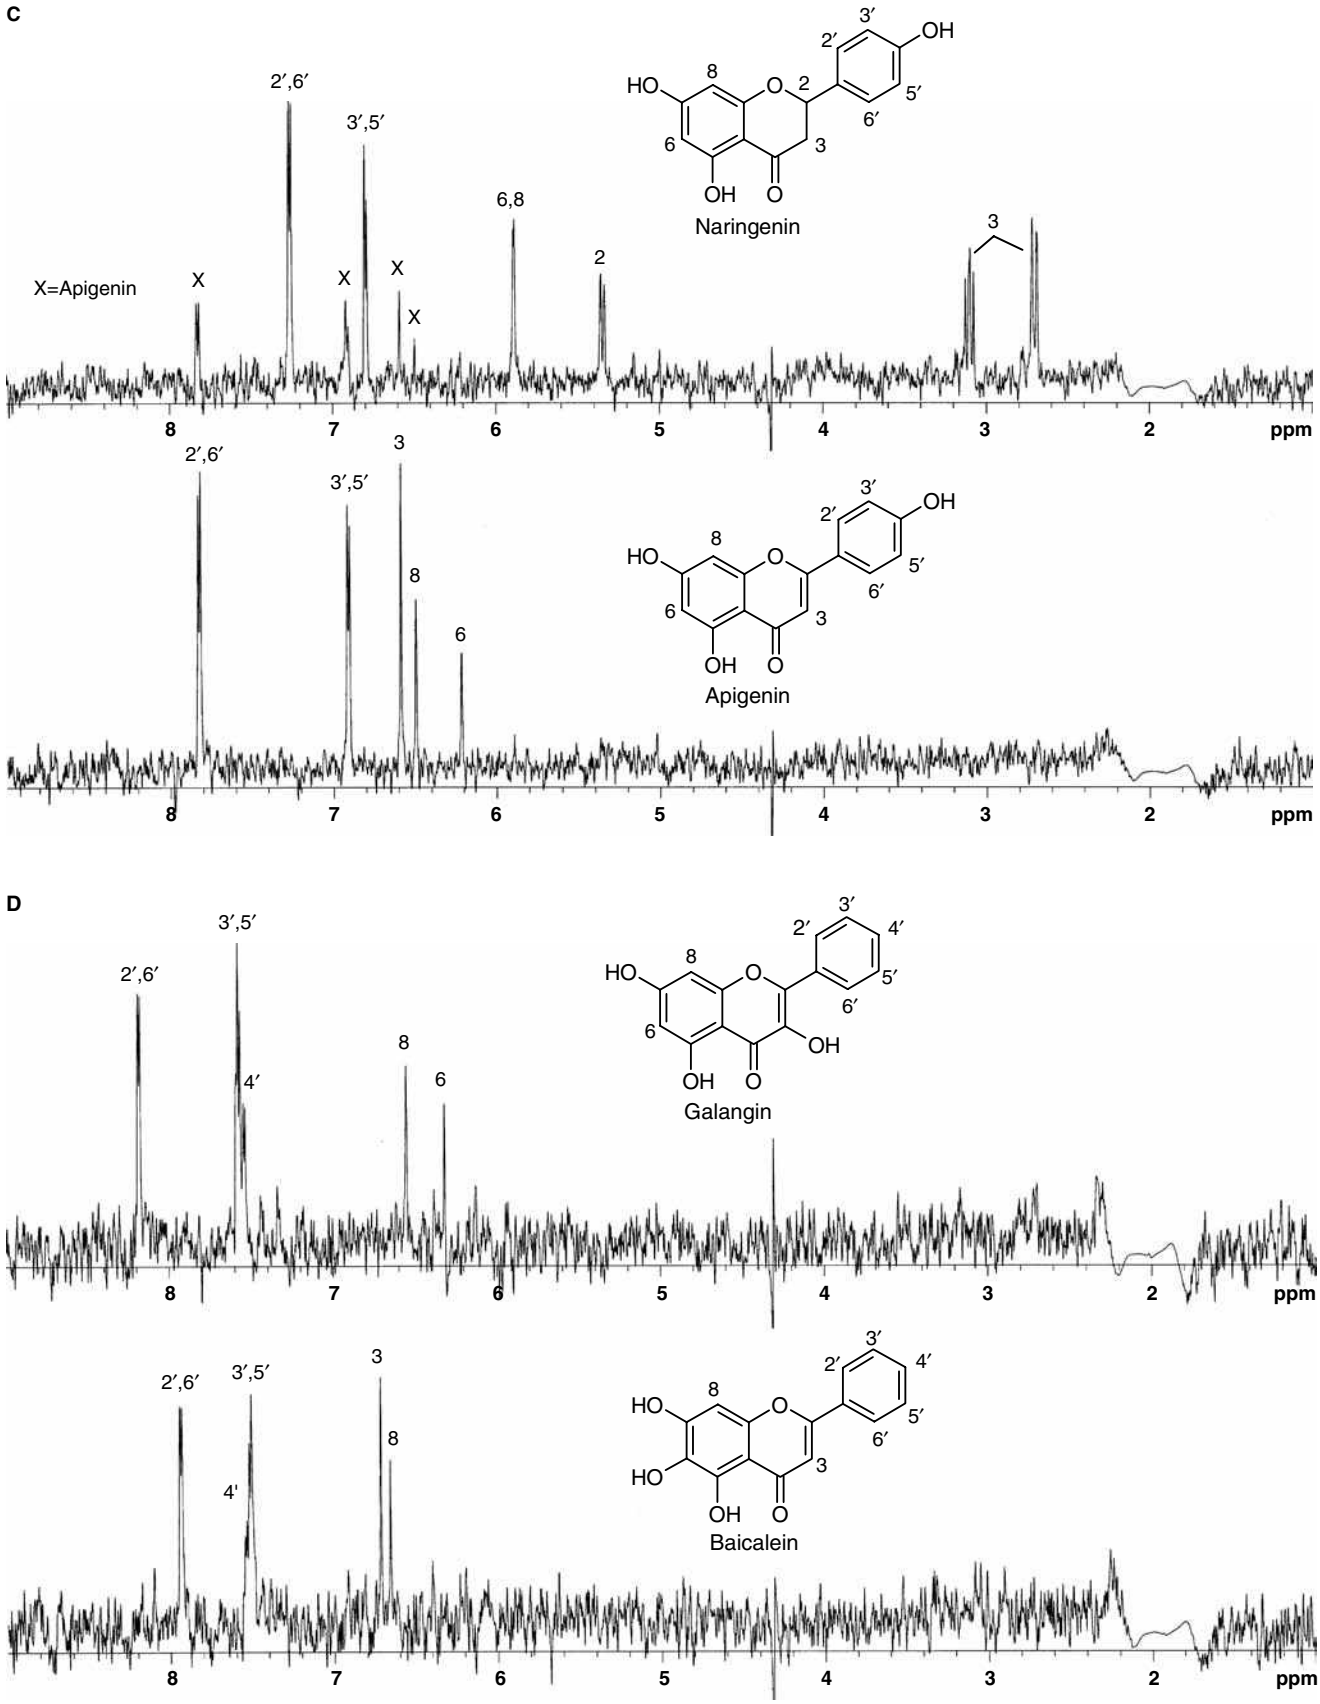

Fig. 7 (*Continued*)

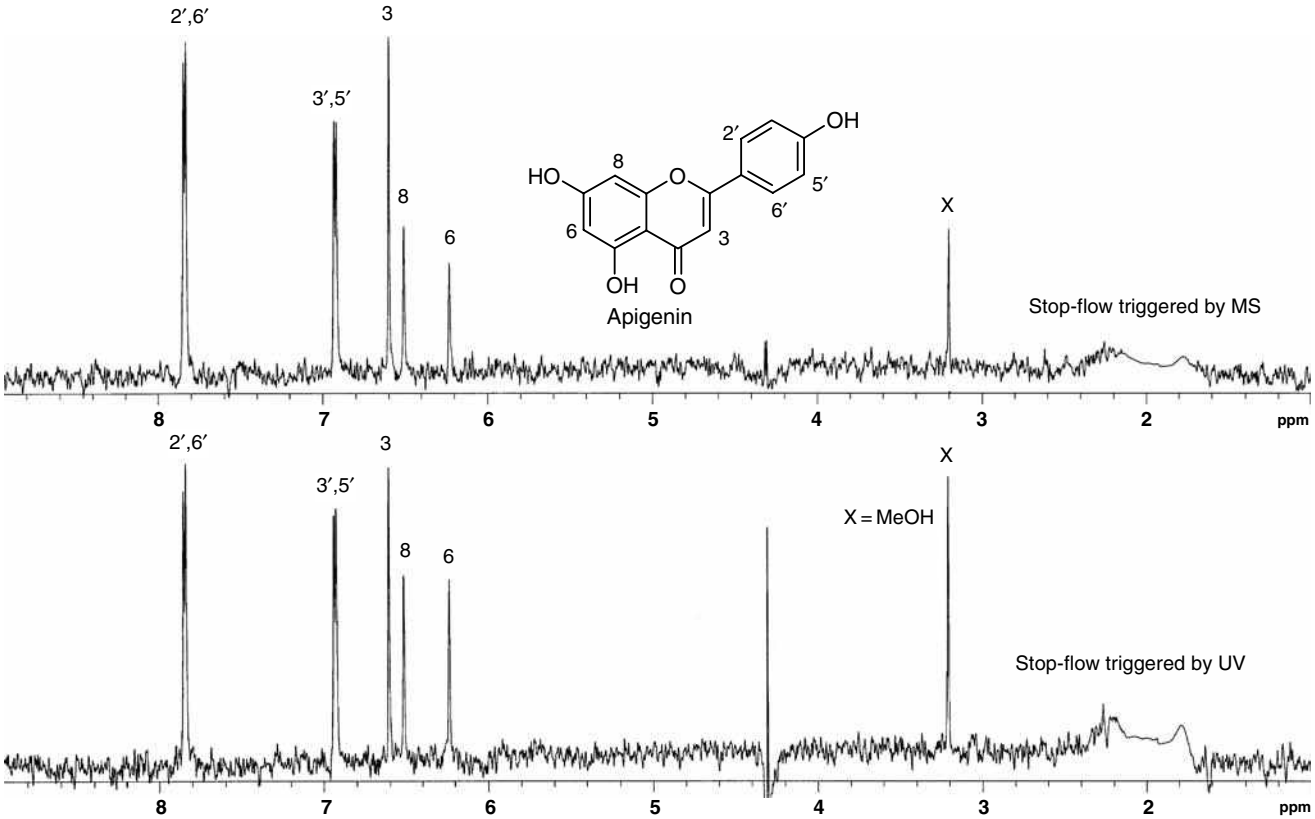

Fig. 8 ^{1}H NMR spectra of apigenin triggering the stop-flow by MS (top) and by UV (bottom).

methyl resonance of ACN was referenced to 1.94 ppm. These two experiments were carried out by injecting 10 μg of apigenin and acquiring ^{1}H NMR spectra for approximately 4.5 min (128 scans), giving rise to the same quality of ^{1}H NMR spectra of apigenin (Fig. 8).

These experiments indicate that for sample mixtures, the on-flow mode of LC/MS/NMR is useful in obtaining structural information for the major components. If a more detailed analysis is required, or the amount of sample is small and the compound(s) cannot be isolated because of instability, stop-flow is the mode of choice. LC/MS and LC/NMR chromatographic conditions must be compatible; in addition, prior evaluation of the LC conditions on the LC/MS/NMR system needs to be carried out to ensure consistency with the chromatographic resolution needed in the LC/NMR part of the system. The sample must ionize well by electrospray to obtain MS data. To use MS to trigger halting the flow in the stop-flow mode, prior MS information of the chromatographic peak(s) of interest in deuterated solvent(s) is needed to evaluate the suitability of the system in providing structural information.

CONCLUSIONS

Hyphenated analytical and spectroscopic techniques have enhanced the ability of analysts to solve structural problems. Until the advent of recent developments in NMR, LC/MS had been the only hyphenated technique for qualitative analysis of structures on mixtures. NMR could only be applied to reasonably pure compounds until the last decade. LC/NMR has expanded the capability of solving structural problems in complex mixtures. LC/NMR, however, is not comparable to LC/MS because of its lower sensitivity, the need of expensive deuterated solvents, the need of solvent suppression of the residual protonated solvents, and the compatibility of the volume of the chromatographic peak with the volume of the NMR flow cell. To overcome some of these problems, more development has led to the hyphenation of capillary HPLC (capLC) and NMR (capLC/NMR), where the amount of solvent used is minimal and the volume of the chromatographic peak is comparable to the volume of the NMR flow cell, but the suppression of the residual protonated solvents must still be carried out. SPE/NMR has been demonstrated to be another option for the analysis of minor components by concentrating them into cartridges through numerous injections and flush them to the NMR flow cell with deuterated solvents, and so minimum solvent suppression is required.

Within the last decade, hyphenated LC/MS, LC/NMR, and LC/MS/NMR (or LC/NMR/MS) techniques have become available. Because MS is destructive (in contrast to NMR) and requires far less sample than NMR, a splitter

is incorporated online, to direct the bulk of the sample to the less sensitive technique. In addition to the advantage of having MS and NMR information for the same chromatographic peak, the combination of these two techniques with different sensitivities must deal with other issues, such as the effect of deuterated solvents on the MS, the limitation of source of ionization on the MS compatible with low flow rates, and the timing that depends on the slower NMR technique. SPE/NMR/MS has been developed to analyze low-concentrated analytes. However, there is still room for improvement for LC/MS/NMR (or LC/NMR/MS) and the next decade will define the areas where this hyphenated technique is best suited.

LC/MS/NMR cannot replace LC/MS, LC/NMR, or even NMR techniques for the structural elucidation of compounds. There will always be cases where purification of the analyte(s) is required when the structural problem is too complex or the separation of the chromatographic peak is not suitable. LC/MS/NMR (or LC/NMR/MS), LC/MS, LC/NMR, and NMR have to be available so that the analyst can choose the appropriate technique for each structural problem. The success rate of problem solution will depend on choosing the right technique, depending on the difficulty and nature of the problem. Each technique has its own advantages and limitations.

Lewis Base-Modified Zirconia as Stationary Phases for HPLC

Y.-L. Hu
Y.-Q. Feng
S.-L. Da
Department of Chemistry, Wuhan University, Wuhan, China

INTRODUCTION

The developments of the Lewis base-modified zirconia and mixed-oxide containing zirconia as stationary phases for high-performance liquid chromatography (HPLC) are reviewed. In this context, the preparation methods of porous spherical zirconia, and zirconia supports for HPLC based on modification with fluoride, phosphate, phosphonate, carboxylic acid, phenols, and protein, as well as cyclodextrin derivative, are covered. The application of modified-zirconia in capillary electrochromatography (CEC) is also discussed.

ALTERNATIVES TO SILICA AS HPLC SUPPORTS

Over the past few years, there has been considerable interest expressed in materials that can serve as alternatives to silica as the basis of supports in different mode of HPLC. Zirconia is chemically and mechanically stable relative to silica and polymeric phases. It is resistant to chemical degradation from pH 1 to pH 14. The material's thermal stability is excellent over any liquid chromatographically accessible temperature, leading to increased flexibility when designing separation.[1]

However, the surface of zirconia is much more complex than silica. A number of distinct classes of sites exist which can significantly contribute to the retention of a given solute. These sites include Brönsted acid sites, Brönsted base sites, and Lewis acid sites. Among these, the most chromatographically troublesome sites on the zirconia surface are the Lewis acid sites. These sites arise from the surface discontinuity in bonding between metal and oxygen atoms. They can form coordinate complexes with a number of Lewis bases and are responsible for the irreversible adsorption for proteins and other solutes. However, these sites can be blocked by adsorption with competing Lewis bases. This can be compared to adding amines to the mobile phase when silica-based stationary phases are used to decrease peak tailing due to silanophilic interaction. The effective candidates for modification of the zirconia surface are those species that interact strongly with these hard surface Lewis acid sites, such as fluoride, inorganic phosphate, organic phosphonate, and carboxylic acid. When the surface of zirconia was modified by these species, they exhibited quicker kinetics in the chromatographic process, as well as different selectivity and separation mechanism. This review will cover some aspects of Lewis base-modified zirconia as stationary phases for HPLC.

Preparation of Porous Zirconia Spheres for HPLC

The preparation of porous zirconia with narrow particle size distribution is the foundation for further Lewis base modification. There are several methods reported for the preparation of spherical zirconia. Among these, an oil emulsion method is most widely used in several laboratories for its simplicity and good reproducibility.[2–4] The method involves mechanically dispersing micrometer-scale droplets of an aqueous zirconia sol in an oil phase, in the presence of surfactants. Simultaneous gelation of the colloids within the droplets and extraction of water from the droplets yields zirconia aggregates that are further strengthened by sintering. The oil emulsion method has also been successfully applied for the synthesis of zirconia-containing mixed oxides in our laboratory.[5–7] Sun et al.[8] and Reeder et al.[9] developed another promising method referred as the polymerization-induced colloid aggregation (PICA) for the preparation of spherical, porous zirconia. In this method, an aqueous zirconia sol is mixed with urea and formaldehyde, which are polymerized by the acidic sol. The oligomer so formed adsorbs on the surface of colloids, causing the colloids to aggregate. Zirconia prepared by the PICA method usually has a relatively narrow particle size distribution. Techniques based on a spray-drying process have also been used for the preparation of porous zirconia.[2,10] In this process, a zirconia sol, which may contain a reactive binder, is forced through a nozzle. Droplets of zirconia solution are dried to yield rigid particles. Zirconia spheres prepared by this method usually have a broad size distribution; so size classification is necessary to make them useful for HPLC.

Fluoride-Modified Zirconia as a Biocompatible Stationary Phase

Because fluoride ion forms some of its strongest coordination compounds with zirconium ion in solution, it should be a very powerful displacing agent toward any Lewis base

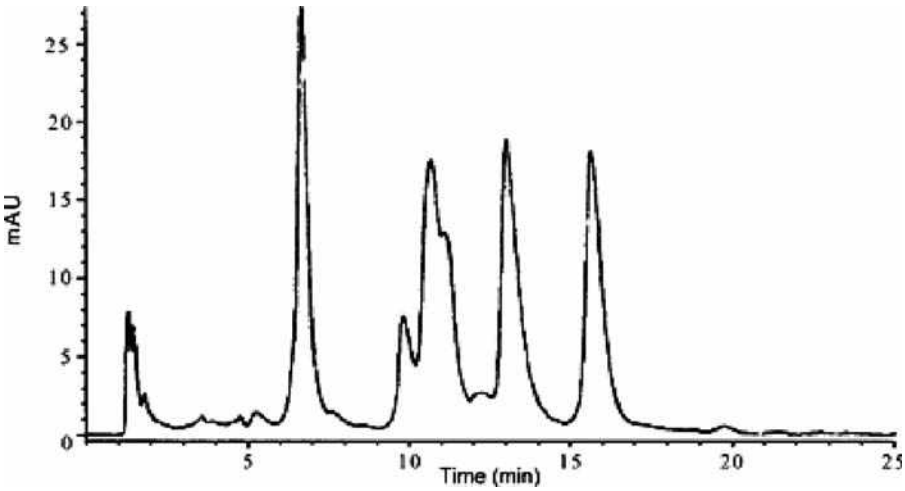

Fig. 1 Protein separation on fluoride modified zirconium oxide. A linear gradient of 0–0.75 *M* Na_2SO_4 in 100 m*M* NaF and 20 m*M* MES at pH 5.5 was used. Flow-rate was 0.5 ml/min at 35. Protein loadings were 4.4 μg lysozyme, 15.4 μg α-chymotrypsin, 13.6 μg myoglobin and 15.4 μg cytochrome *c*.
Source: From Fluoride-modified zirconium-oxide as a biocompatible stationary phase for high-performance liquid-chromatography, in J. Chromatogr.[12]

on a zirconium oxide surface. Blackwell and Carr[11] have studied the fluoride adsorption characteristics of porous zirconium oxide. They found that the composition of fluoride coordinated to the surface of zirconia is pH and ionic strength dependent. At low pH, the fluoride was more easily adsorbed onto the surface, due to less effective competition from hydroxide ion. Washing the zirconia particles with 0.1 M sodium hydroxide quantitatively desorbs bound fluoride. To maintain chromatographic reproducibility, a small amount of fluoride is added to the mobile phase for separation of proteins.[12] The fluoride-modified zirconia is very biocompatible. The unique overall retention properties of this material are operationally analogous to those of calcium hydroxyapatite. However, the system does not have the chemical and physical weaknesses that limit the use of hydroxyapatite. Fig. 1 shows that very efficient separation can be implemented in any of the number of elution schemes.[12] In addition, the substantial base stability allows sterilization of the packing material and stripping of irreversibly bound proteins with sodium hydroxide solution.

Inorganic Phosphate and Organic Phosphonate as Modifiers

The Lewis acid of zirconia can be blocked by other than fluoride. The effectiveness of the blocking of the Lewis acid sites should be related to the strength of the interaction between the Lewis base used and the zirconium ion coordination site. Blackwell and Carr[13] have developed the relative eluotropic strength of a number of Lewis bases in terms of their ability to elute a wide variety of benzoic acid derivatives. Phosphate ranks at the top of the elution series. It brought about elution of the benzoic acid derivatives in the column dead volume. This proves that phosphate binds strongly to the surface of zirconia. The strong affinity of zirconia for phosphate suggested that a phosphate modification of the surface should be a reasonable approach. Schafer et al.[14] used several spectroscopic techniques to characterize the surface species on phosphate-modified zirconia particles. Their results show that phosphate merely adsorbs on the surface of zirconia under the "mildest" phosphate concentration, i.e., neutral pH, room temperature, and short contact times. However, at acidic pH and higher temperatures, esterification of the phosphate with surface hydroxyls takes place as the kinetic barriers are overcome. The solid ^{31}P NMR studies clearly show the presence of covalently bound phosphate. This phosphate modification effectively blocks the sites responsible for the strong interaction of certain Lewis bases with the zirconia surface, resulting in a more biocompatible stationary phase.[15] Unlike fluoride-modified zirconia, phosphate-modified zirconia behaves as a classic cation exchanger and not as a mixed-mode medium analogous to hydroxyapatite, despite spectroscopic evidence of zirconium phosphate formation on the surface. This limits the applicability of the supports, as most proteins and enzymes are anionic at neutral pH. Nevertheless, its ability to separate proteins with high p*I* values still deserves much attention. The preparative-scale separation of murine IgGs from a fermentation broth demonstrates the utility of the supports for solutes that are retained.

Porous zirconia particles were also treated with polyphosphates of chain lengths between 3 and 100 for affinity chromatography of nucleic acids and proteins.[16] The affinity matrix was stable in the pH range of 3 to 11 during a 120 hr incubation period. It is demonstrated that polyphosphate-modified zirconia not only is a useful support for the separation of cationic proteins as is phosphate-modified zirconia, but also can be used for the binding of neutral proteins (e.g., DNase I) and anionic proteins (e.g., alkaline phosphatase). Applying both HPLC and batch procedures can perform protein separation on this packing. The polyphosphate-modified zirconia can also be used in the effective purification of nucleic acids. It was found that 1) double-stranded DNA does not bind to the zirconia

either in the absence or presence of Mg^{2+} ions, and 2) single-stranded DNA and RNA, in the absence of Mg^{2+} ions, also does not bind to the matrix; however, after addition of Mg^{2+} or other divalent cations, they bind strongly to the matrix. Elution of DNA and RNA can be performed with ethylenediaminetetraacetic acid (EDTA).

Based on the successful utility of phosphate-modified zirconia for protein separation, Clausen and Carr[17] have extended their investigation to include the study of ethylenediamine-*N*,*N*′-tetramethylphosphonic acid (EDTPA), a phosphonate analog of EDTA, as a surface modifier for zirconia. They compared EDTPA-modified zirconia (PEZ) with inorganic phosphate-modified zirconia ($ZrPO_4$). Similar to $ZrPO_4$, cation-exchange is the dominant mechanism of protein retention on zirconia. However, PEZ showed increased efficiency, as well as unique selectivity for chromatography of proteins on the chelator-modified surface. Fig. 2[17] shows the chromatogram of the protein mixture on the PEZ and the $ZrPO_4$ phases using the same elution conditions. It can be seen that PEZ is less retentive for all proteins but lysozyme relative to the $ZrPO_4$ phase, but PEZ is able to better resolve proteins especially for α-chymotrypsin and ribonuclease A. This can be accounted for by a mix of lower surface coverage of EDTPA and a change in the chemical nature of the modifier ligand. The presence of ionizable nitrogens in EDTPA should render the zirconia surface less negatively charged than orthophosphate-modified zirconia, resulting in the decrease in retention for all proteins other than lysozyme, as well as to serve, in part, to change the selectivity. It is important, as with $ZrPO_4$, to maintain a small concentration of EDTPA in the mobile phase to keep the stability. Subramanian et al.[18] have used the spray-dried zirconia microsphere (20–30 μm) modified with EDTPA for the isolation of monoclonal antibodies (MAbs) from cell culture supernatant. The selectivity between MAb and bovine serum albumin (BSA), which are the main constituents in the sample matrix, is very high. Analysis by enzyme-linked immunosorbent assay (ELISA) and gel electrophoresis demonstrates that MAbs can be recovered from a cell culture supernatant at high yield (92–98%) and high purity (95%) in a single chromatographic step.

As reversed-phase HPLC is the most common mode of HPLC, many efforts have been made by chromatographers to introduce hydrophobic moieties on the zirconia surface. Polybutadiene-coated zirconia (PBD-ZrO_2) was proven to be an excellent reversed-phase packing material.[19] PBD-ZrO_2 has excellent pH and thermal stability and is efficient for the separation of some small molecules. However, the separation of peptides and proteins on PBD-ZrO_2 has not been successful, due to irreversible adsorption. The addition of phosphate to the mobile phase can alleviate interaction between the Lewis acid sites on zirconia and carboxyl groups on proteins.[20] The phosphate-modified PBD-ZrO_2 phase has both reversed-phase and cation-exchange characteristics under acidic mobile-phase conditions. The PBD

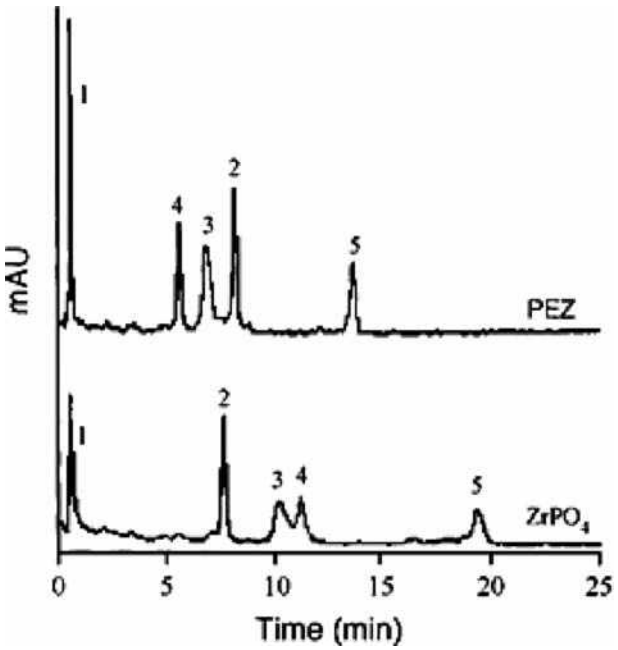

Fig. 2 Chromatographic comparison of protein elution profiles from PEZ and $ZrPO_4$ phases. Particles (4.5 μm) were packed in 50 mm times; 4.6 mm I.D. columns. Mobile phase: 30 min linear gradient from 50 to 500 m*M* potassium phosphate dibasic, pH 7.0; 0.5 ml/min; ambient temperature; detection at 280 nm. Peaks: 1—myoglobin, 2—lysozyme, 3—R-chymotrypsin, 4—ribonuclease A, 5—cytochrome *c*.

coating provides hydrophobic moieties, and the phosphate ions adsorbed on zirconia's surface provide cation-exchange sites. The phosphate-modified PBD-ZrO_2 performs satisfactorily for both hydrophobic peptides and positively charged peptides. The limitation of the phase is the reduced efficiency due to secondary equilibrium in the mixed-mode retention mechanism. As an alternative to adding Lewis bases to the eluent, Trammell et al.[21] also studied the effect of permanently modifying PBD-ZrO_2 by covalently attaching vinylphosphonic acid (VPA) to PBD which was predeposited in the pores of zirconia. The resultant stationary phase allows catechol and carboxylates to elute with 100% recovery, without the use of mobile-phase additives. Although this is a tremendous improvement over previous PBD-ZrO_2 phases, a mobile-phase Lewis base additive is still required to provide acceptable peak shapes and plate counts. Evaluation of the cation exchange characteristic of VPA-PBD-ZrO_2 shows that it is significantly more negatively charged than is PBD-ZrO_2 in the presence of phosphate or phosphonate eluent additive. A tremendous improvement in the separation of peptides is achieved when ultralow-pH eluents are used.

Particle pore characteristics are crucial factors for chromatographic performance. Recently, other metal oxides,

such as magnesia and ceria, were introduced into zirconia for improvement of its physicochemical properties in our laboratory.[5–7] The mixed-oxides demonstrate higher specific surface area, large specific pore volume, and better pore connectivity than pure zirconia. Increased surface basicity was also observed on magnesia–zirconia and ceria–zirconia, but especially on magnesia–zirconia, which led to stronger affinity toward Lewis base solutes. In the consequent study, alkylphosphonate with 15 carbons, which was synthesized in our laboratory, was adopted to modify magnesia–zirconia[22] and ceria–zirconia.[23] The new materials illustrated satisfactory pH stability, even in the absence of alkylphosphonic acid in the mobile phase. Alkylphosphonic acid–modified magnesia–zirconia is very stable against extreme pH conditions, e.g., from pH 2 to pH 11.[22] This might be ascribed to be the existence of magnesia on the surface of magnesia–zirconia. The chromatographic performance of the new materials was studied by using polycyclic aromatic hydrocarbons (PAHs) and basic compounds as probes. PAHs were retained on alkylphosphonic acid–modified mixed oxides by typical reversed-phase mechanism in the entire pH range studied. Basic solutes were retarded on stationary phases, mainly by hydrophobic interaction at higher pH, whereas they also showed cation-exchange interaction with the stationary phase at relatively lower pH conditions.[24] It is found that the alkylphosphonic acid–modified magnesia–zirconia and ceria–zirconia are more viable supports for reversed-phase chromatography of basic solutes, relative to silica-based hydrophobic stationary phases, for less peak tailing of these solutes.[22–25] The separations of PAHs and basic solutes on alkylphosphonic acid–modified magnesia–zirconia are illustrated in Fig. 3[26] and Fig. 4,[25] respectively. Application of this material to the separation of nucleosides and nucleobases was also confirmed successful.[27] However, acidic compounds still exhibit strong interaction with alkylphosphonic acid–modified magnesia–zirconia and ceria–zirconia using a typical reversed-phase mobile phase.

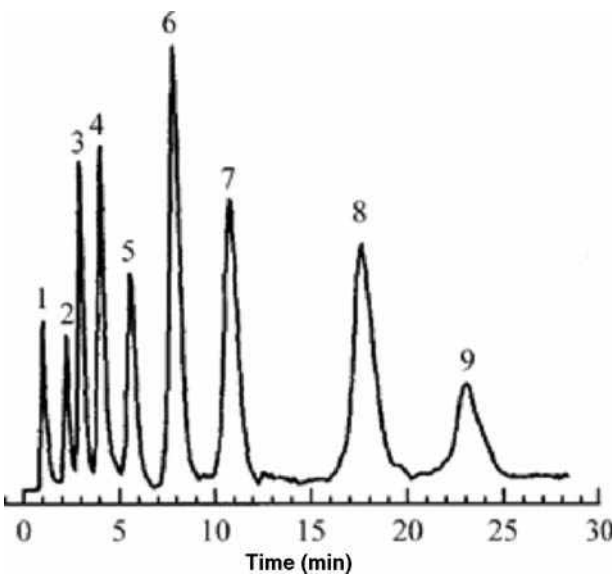

Fig. 3 PAHs separation on alkylphosphonate-modified magnesia–zirconia composite (4–6 μm, 150 mm × 4.6 mm I.D. column). Mobile phase: methanol-water (75 : 25, v/v). 1—Solvent; 2—Benzene; 3—Toluene; 4—Naphthalene; 5—Biphenyl; 6—Fluorene; 7—*O*-terphenyl; 8—*M*-terphenyl; 9—*P*-terphenyl.

Stearic Acid-Modified Zirconia and Ceria–Zirconia for RP-HPLC

Octadecyl-silica stationary phases (ODS) are among the most widely used packing materials in all modalities of

HPLC, owing to their applicability to the separation of solutes of very different polarity, molecular weight, and chemical functionality. Yu and Rassi[28] have investigated the expansion of chemical bonding octadecylsiliane on the zirconia's surface. The resulting octadecyl-zirconia was quite useful in the separation of PAHs, alkylbenzenes, alkylalcohol homologous series, oligosaccharides, and peptides. However, this method has its limitation for lower stability of Zr–O–Si–R relative to Si–O–Si–R bonds. As zirconia and zirconia-containing mixed-oxides have strong affinity toward carboxyl acid derivatives, we[7,29] developed a simple method to dynamically modify zirconia and ceria–zirconia with stearic acid, a fatty acid with 18 carbons, and comparable to octadecylsilane. Stearic acid–modified ceria–zirconia illustrates better chromatographic properties than stearic acid–modified zirconia, owing to its improved column efficiency and hydrophobicity. PAHs and basic compounds are well resolved on the material. Better selectivity of basic compounds was obtained on stearic acid–modified ceria–zirconia than on an ODS column. However, the stability of the stationary phases is worse than for alkylphosphonic acid–modified mixed-oxides in higher pH eluents. This is predictable, since phosphates are stronger Lewis bases than carboxyl acids.

Zirconia-Containing Mixed-Oxides Modified with Phenol Derivatives for Separation of Fullerene Compounds

Chromatographic separation of fullerene compounds has been of great interest during the past few years. Silica-based stationary phases were the most widely used materials for fullerene purification. As synthesis of new silica bonded stationary phase is always time-consuming, we have recently attempted to prepare a useful stationary phase for fullerene separation by a simple method. As mentioned previously, Lewis bases, including some phenol derivatives, strongly adsorb onto the surface of zirconia-containing mixed-oxides. Although these phenol derivatives can be gradually stripped from the matrix in polar solvents, they exhibit high stability while exposed to non-polar solvents which are commonly used as the mobile phase for fullerene separation. Therefore, zirconia-containing mixed-oxides were modified with various phenolic compounds to test their ability for separation of fullerene compounds.[30] A consequence of the retention behavior of fullerene compounds on these stationary phases was that charge–transfer interaction was the main retention mechanism. Based on the results of a column loading capacity test, 2,4,6-trinitrophenol-modified ceria–zirconia and alumina–zirconia are considered as a potential material for the separation of C_{60} and C_{70} in large amounts.[31] Fig. 5 illustrated their separation under the overloaded condition on an analytical column.

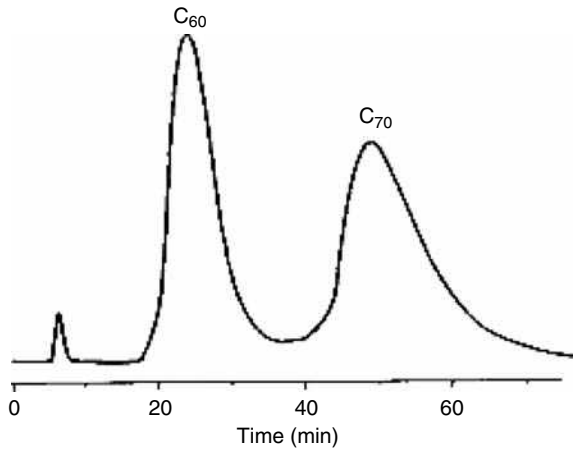

Fig. 5 Separation of C_{60} and C_{70} on 2,4,6-trinitrophenol-modified zirconia–ceria stationary phase (4–6 μm, 150 mm × 4.6 mm I.D. column). Mobile phase: toluene–cyclohexane (30 : 70, v/v). Sample: 11.4 mg/ml of C_{60}, C_{70} mixture in toluene. Injection volume: 0.8 ml. Flow rate: 0.25 ml/min. UV detection at 380 nm.

Other Lewis Bases as Modifier

The results of Blackwell and Carr's study show that the chromatographic properties of the zirconia surface in aqueous media are highly dependent upon the chemical composition of the eluent.[32] They investigated the retention of various small solutes in the presence of glycolic acid, malic acid, succinic acid, citrate, or borate, and concluded that these Lewis base eluent components act to control retention in two ways. They modify the net ligand exchange contribution to retention, and they serve as sites for secondary interactions, such as hydrogen bonding and hydrophobic interaction between solutes and the dynamic stationary phase.

Whitman et al.[33] also evaluated the effect of pretreatments of zirconia with a number of Lewis bases on normal phase selectivity. Chemometric methodology was used to characterize the similarities and differences between the "acid"- and "base"-washed supports. Hydrogen bonding interactions are quite pronounced for the Lewis base-modified zirconia, the extent of which differs greatly among the various Lewis bases used to modify the zirconia.

The irreversible binding of many proteins to bare zirconia can be modulated by addition of some weaker Lewis bases other than phosphate and fluoride.[34] Phosphate and fluoride are able to bring about elution of nearly all proteins, as they are the strongest Lewis bases. On the other hand, there is not much leeway for modulating the strength of the competitive ligand exchange interaction through adjustments of their concentrations for the ease of saturation of their adsorption isotherm. In contrast, weaker Lewis bases such as borate, sulfate, and bromide are able to elute only those proteins retained primarily by ionic interaction. Proteins that contain a large number of accessible Lewis base sites cannot be eluted from zirconia in weak eluents.

Blackwell and Carr investigated the ligand exchange chromatography of free amino acids on copper-loaded zirconia.[35,36] It was shown that the use of Lewis base buffers in this system improved the operating efficiency. Acetate, sulfate, fluoride, and phosphate are the effective competing ions.

Park et al.[37] reported a method to modify zirconia by adsorption with BSA and, subsequently, crosslinked by glutaraldehyde. The BSA-zirconia showed good enantioselectivity for some enantiomers and could be used for RPLC separation in mobile phases of alkaline pH. They also developed a carboxymethyl-β-cyclodextrin-coated zirconia stationary phase for the separation of racemic 2,4-dinitrophenyl amino acids.[38]

Lewis Base-Modified Zirconia–Magnesia in Capillary Electrochromatography (CEC)

Capillary electrochromatography (CEC) is a relatively new technique for chemical analysis. It brings together the advantages of the capillary electrophoresis (CE) and HPLC. CEC can be performed in open tubes or packed structures. To date, the most commonly used packing materials for CEC are the silica-based stationary phases. Recently, zirconia and zirconia–magnesia were successfully utilized as packing or coating material for CEC in our laboratory.[39–41] As mentioned above, alkylphosphonic acid–modified zirconia–magnesia has exhibited excellent chromatographic properties in HPLC. In the subsequent study, Xia et al.[39] demonstrated its usefulness as packing material in CEC. The alkylphosphonic acid–modified zirconia–magnesia shows distinct electro-osmotic flow (EOF), compared with the unmodified zirconia–magnesia for its negative surface at lower pH. Successful separation of polycylic aromatic hydrocarbons can be obtained within a shorter time in the CEC mode than in the HPLC mode, due to the higher column efficiency in CEC. A zirconia–magnesia coating was also fabricated inside fused-silica capillaries for open tubular capillary electrochromatography (OTCE).[40] The capillaries coated with zirconia–magnesia exhibited switchable EOF at pH 5.2. Then, its surface was further modified with SO_4^{2-} and alkylphosphonic acid, respectively, and the isoelectric point of the capillary shifted accordingly. The capillary coated by SO_4^{2-} modified zirconia–magnesia shows better chromatography toward basic compounds than unmodified zirconia–magnesia, with less peak tailing; the alkylphosphonate-modified magnesia–zirconia coated capillary can separate six PAHs within 13 min.

Lignins and Derivatives: GPC/SEC Analysis

Wenshan Zhuang
Taro Pharmaceuticals, Inc., Brampton, Ontario, Canada

INTRODUCTION

Lignins are a group of naturally occurring organic polymers that are present in all dry-land arborescent and herbaceous plants as one of three major structural materials of cell walls (the other two are cellulose and hemicelluloses). Among all biopolymers, lignins are second only to cellulose in abundance; they are readily available in massive quantities from chemical pulping processes, which convert wood chips into cellulosic fibers (pulps) by removing lignins. Presently, these byproducts are consumed mostly as fuel. Intensive research is underway, worldwide, for the full utilization of this valuable resource for polymeric materials. Such materials have a clear advantage in terms of environmental management over the widely used synthetic plastics such as polyethylene, polypropylene, and polystyrene; if suitably formulated, they are completely biodegradable.

LIGNINS

Molecular weight distribution (MWD) and average molecular weights are important macromolecular properties of lignins. In this regard, size-exclusion chromatography (SEC) has been the most convenient and widely used technique for lignin determination. The technique was originally termed differently in different scientific branches; some examples are gel filtration chromatography (GFC) for separating water-soluble biopolymers and gel permeation chromatography (GPC) for determining the average molecular weights and MWDs of synthetic polymers, which are mostly soluble in organic solvents; the latter term is still commonly used today. Although SEC has other applications in lignin research, such as purification, desalting, and kinetic studies, this entry focuses on its usage for the determination of MWD and average molecular weights, with a brief introduction to the chemical structures, preparations, and associative properties of lignins, which is necessary knowledge for understanding and practicing SEC of these compounds.

Structures of Native Lignins

Lignins are phenylpropane-type polymers, formed by enzyme-catalyzed dehygrogenative polymerization of one to three types of monolignols, viz., coniferyl, sinapyl, and *p*-coumaryl alcohols (Fig. 1). The corresponding building blocks in the resulting lignin molecular structure are often referred to as guaiacylpropane (G), syringylpropane (S), and *p*-hydroxyphenylpropane (H) units, respectively. The proportion of these three types of units is dependent on the plant species. As a rule of thumb, gymnosperm (softwood) lignins are almost exclusively built from G units; angiosperm (hardwood) lignins are composed of both G and S units, while lignins of Gramineae (grasses) contain all three types of units. The three-carbon side chain of the units is essentially of the glycerol type if the interunit linkages are ignored. The structural elements comprising lignins are linked by both ether and carbon–carbon bonds, mainly β–O–4 (around 50–65%), α–O–4, 4–O–5, β–5, 5–5, β–1, and β–β. These linkages are denoted by the positions involved in creating the bonds between the phenylpropane units in question. Thus, lignins are basically copolymers, not only in terms of monomers (in the case of hardwood and grass lignins), but also because of interunit linkages (for all three types of lignins). It should be pointed out that lignins, even within a plant species, exhibit considerable variations in their monomer composition and frequency of interunit linkages with age, cell type, and morphological region of the cell wall.

Although the basic concepts of lignin structure described above have been firmly established, many structural details are still vague and remain to be revealed, such as the nature and extent of chain branching and/or cross-linking, and the sequence of building units. Consensus has not been reached on the most fundamental question—whether the native biopolymers possess random or regular structures.

Lignin Preparations

Even though many techniques have been invented for isolating lignins, it has not been possible to obtain intact lignins from source materials, where lignins coexist with carbohydrates, not only in physical proximity, but also through chemical bonding. For structural study, lignins are usually isolated as milled wood lignins (MWLs), with a yield of about 50% of total lignins. The preparation involves extensive milling of wood meals followed by extraction with a neutral organic solvent, typically aqueous dioxane. Milling increases the yield, but causes rupture of some covalent bonds. Nevertheless, MWL has

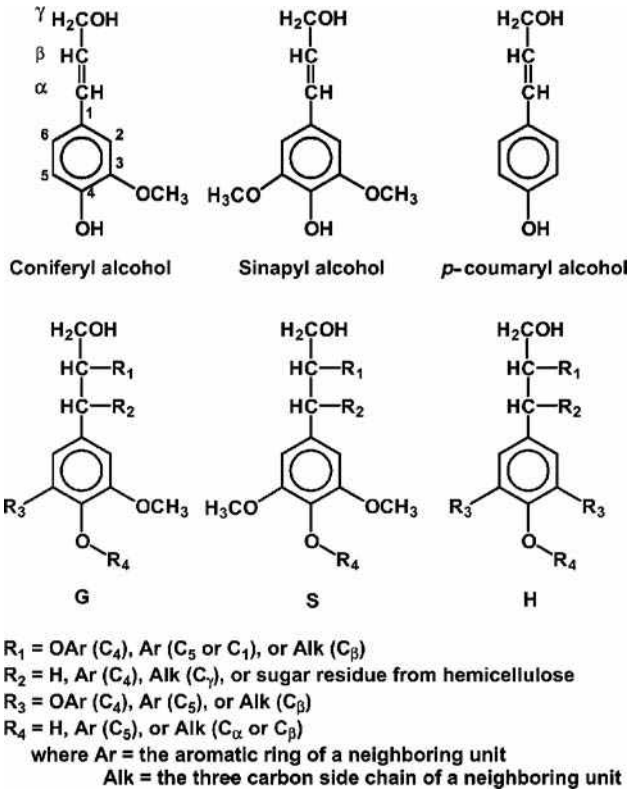

Fig. 1 Three *p*-hydroxycinnamyl alcohols (lignin precursors) and corresponding structural units in lignin molecular structure.

been frequently touted as being most closely related to the native biopolymer.

Isolated lignins available in the largest quantity are those derived from pulp production as byproducts, i.e., kraft lignins from kraft pulping (approximately 45 million metric tons each year globally) and lignosulfonates from sulfite pulping (2 million metric tons per annum). In pulping processes, nucleophilic reagents (OH^- and HS^- in kraft pulping or HSO_3^- in sulfite pulping) react with native lignins in wood chips at high temperature, resulting in the cleavage of some interunit alkyl aryl ether bonds with concomitant generation of hydrophilic groups (phenolic hydroxyl group and sulfhydryl or sulfonic group) in the resultant lignin fragments, which are thus made soluble in the aqueous pulping liquor. The yield of soluble lignins is about 70–90% of the total lignins in wood chips. These industrial lignins are characterized by decreased average molecular weights, decreased frequency of interunit ether bonds with correspondingly increased phenolic hydroxyl content, increased interunit carbon–carbon linkages, and the presence of some functional groups that are absent in the native macromolecules from which they are derived.

It is still a mystery as to what the true molecular weights and polydispersities of native lignins are. Isolated lignins have molecular weights ranging from hundreds to millions, with varying polydispersities, depending on the plant species and the isolation method. Despite significant differences in their chemical structures and molecular sizes, native lignins, isolated lignins and lignin derivatives, are often indiscriminately referred to as "lignins" or simply "lignin."

Non-covalent Intermolecular Interaction

One of the difficulties encountered in the measurement of MWDs and average molecular weights of lignin samples is that lignin components generally exhibit a strong tendency to form associated complexes in solution. Before this associative phenomenon was recognized in the field, people were often frustrated by their inconsistent and irreproducible results when determining average molecular weights and MWDs of lignin preparations. It has now become quite clear that there are two distinct mechanisms responsible for intermolecular lignin associations, i.e., non-covalent interactions, presumably between the aromatic rings, and hydrogen bonding. Which mechanism prevails in the system is dependent on solution conditions such as pH and the type of solvent.[1]

For example, in aqueous alkaline solutions, kraft lignin preparations with concentrations greater than 100 g/L readily undergo a slow, but well-defined, associative process; conversely, dissociation occurs in diluted preparations (< 1 g/L).[1] Fig. 2 illustrates the

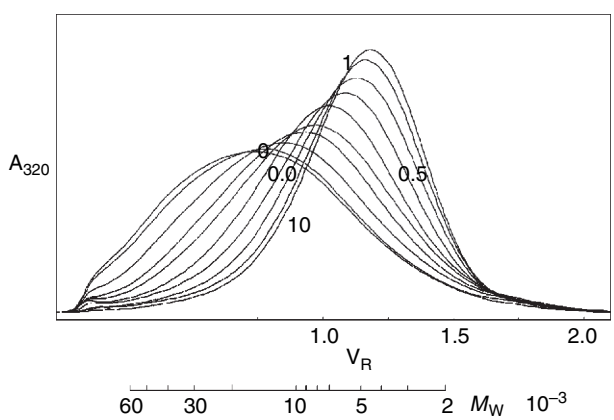

Fig. 2 Apparent MWDs representing homologous series of an aspen kraft lignin preparation secured by fractionation/desalting through Sephadex LH-20 in aqueous 35% dioxane after incubation of parent preparation at 203 g/L in 1.0 *M* ionic strength aqueous 0.40 *M* NaOH for (1) 7215 hr, (2) 4600 hr, (3) 1930 hr, (4) 1116 hr, (5) 542 hr, and (6) 252 hr, and at 0.10 g/L in aqueous 0.10 *M* NaOH for (7) 74 hr, (8) 382 hr, (9) 1167 hr, and (10) 2728 hr. Sephadex G-100/aqueous 0.10 *M* NaOH elution profiles monitored at 320 nm.
Source: From Hardwood kraft lignin: Molecular weight dependent structural properties and non-covalent interactions between constituent species, in M.S. Thesis; University of Minnesota.[2]

dependence of degree of association of a lignin sample on the lignin concentration and incubation time. It is presumed that intermolecular non-bonded orbital interactions, dominated by those of the HOMO–LUMO type involving the π-orbitals of the aromatic moieties, govern the underlying mechanism of these processes. The reported findings suggest that association/dissociation is a reversible process, involving at least two kinetically distinguishable steps.[1] Two coupled steps have been identified as a rapid equilibrium between associated complexes and dissociated components, and a slow (and thus rate determining) equilibrium between the conformation of a (dissociated) discrete species which is ready to associate with complementary complexes and that of one for which association is not directly accessible:[1]

$$\begin{array}{c}\text{Associated complex with } n \text{ components}\\ \uparrow\downarrow \text{ fast}\\ \text{Associated complex with } n-1 \text{ components}\\ +\ \text{Conformationally compatible component}\\ \uparrow\downarrow \text{ slow}\\ \text{Discrete component}\end{array}$$

On the other hand, the rapid and extensive association facilitated by protonation of kraft lignin phenoxide moieties as the pH of the aqueous solution is lowered, or when they are present in non-aqueous solvents, is presumably mediated by hydrogen bonding and/or dipolar interactions, with non-bonded orbital interactions remaining the primary intermolecular forces. It has been shown that the absolute molecular weights of associated kraft lignin complexes encountered in *N*,*N*-dimethylformamide (DMF) could exceed values 1000 times larger than those observed in aqueous alkaline solutions.[3]

Therefore, precaution should be taken in interpretation of the average molecular weights and MWDs reported in the literature. Depending on the sample history (e.g., isolation method, solution conditions, and storage/incubation time) and SEC conditions, the reported measurements may represent those of totally discrete lignin components or those of mixtures of discrete components and complexes with varying degrees of association.

SEC OF LIGNINS AND THEIR DERIVATIVES

Unlike other forms of chromatography that are driven by enthalpy terms in thermodynamic equilibrium, SEC is an entropy-controlled chromatographic separation technique that is, under ideal conditions, based solely on solute size. Although SEC is a relatively rapid and simple method for determining the MWDs and average molecular weights of macromolecular lignins, there are some strict requirements that must be met for proper use of this technique.

Column Packing Material/Eluent

The "ideal conditions" for lignin SEC are those under which energetic interactions between the solute and the column packing material (typically adsorption) and between solute species (mainly association) are negligible. Thus, the selection of appropriate eluting solvent and column packing material for the SEC of lignins is a critical step, and, in practice, it is the most difficult task. From a chromatographic point of view, the main selection criteria for eluent are: high solubility for lignins, inactivity toward lignin solute, packing materials, and other components of the chromatograph, hindrance of solute–matrix and solute–solute interactions, and suitability for the chosen detector type. The choice of column packing materials is based largely on the nature of the eluting solvent and lignin solute. A literature survey shows that solvents popularly used for eluting lignins and their derivatives are tetrahydrofuran (THF), DMF, dimethylsulfoxide (DMSO), and aqueous alkaline solutions. Frequently used packing materials are cross-linked polysaccharides and poly(styrene–divinylbenzene) (PSDVB). Some typical examples are shown in Table 1. Polysaccharide-based gels, such as the Sephadex G series, function very well in aqueous SEC, i.e., in those SEC systems that, as the term suggests, use aqueous solvent as the mobile phase. Conversely, PSDVB columns can be used only in non-aqueous SEC. When THF, a relatively non-polar solvent, is employed as the eluent, lignin samples usually have to be derivatized, typically by silylation, methylation, and/or acetylation, since most underivatized lignins are sparsely soluble in this solvent. On the other hand, both DMF and DMSO dissolve most underivatized lignin preparations, but they tend to elicit pronounced association between lignin components. A common solution is to add LiCl or LiBr, as it is generally believed that lithium halide can interfere with the molecular association by shielding dipoles in individual molecules or by blocking proton uptake from solution, which presumably occurs before anionic lignin molecules undergo association—the negative charge density on the resulting complexes would otherwise be prohibitively large.[1] The effect of LiCl is observable only when its concentration is above 0.1 m*M*, and a concentration of 0.1 *M* is needed for effectively defeating molecular association.[1] However, absolute molecular weight determinations have not been carried out to clarify whether the effect of lithium halides arises really from promotion of dissociation of the macromolecular lignin complexes or largely from enhancement of reversible adsorption to the column packing material.[23,24] Serious adsorption onto the packing material was noted in several SEC systems; for instance, it was reported that the recovery of acetylated lignin samples from PSDVB columns was

Table 1 Typical packings/eluents used in the SEC of lignins and derivatives.

Packing material	Brand name	Eluent	Sample	Refs.
Dextran cross-linked with epichlorohydrin	Sephadex G	Aqueous 0.1 *M* or 0.5 *M* NaOH	Kraft lignin	[1,4]
		Dioxane/H_2O (1 : 1, v/v)	MWL	[5]
		DMSO	MWL	[6,7]
Hydroxypropylated cross-linked dextran	Sephadex LH	Dioxane/H_2O (7 : 3, v/v)	Low-MW lignin in bleachery effluent	[8]
		DMF/0.1 *M* LiCl	Kraft lignin	[1]
Agarose cross-linked with 2,3-dibromopropanol	Sepharose CL	DMF/0.1 *M* LiCl	Kraft lignin	[1]
		Aqueous 50% DMSO/0.1 *M* Tris buffer, pH 7.1	Kraft lignin	[9]
Highly cross-linked agarose	Superose	Aqueous 0.1 *M* NaOH	MWL	[10]
Methacrylate-based polymer	Ultrahydrogel	Aqueous 0.05 *M* NaOH	Lignin reaction products	[11]
Hydrophilic cross-linked polymer gel of $(–CH_2CHOHCH_2O–)_n$ with residual carboxylate functionality on packing surface	TSK-gel GMPW	Aqueous 0.1 *M* $NaNO_3$/CH_3CN (4 : 1, v/v)	Lignosulfonate	[12]
Silica gel chemically bonded with hydrophilic compounds that have primary alcohols on surface	TSK SW	Aqueous 0.2 *M*NaAc adjusted to pH 7 by HNO_3	Lignosulfonate	[13]
PSDVB gel with polar-bonded phase	DVB Glucose BR	DMSO/0.1 *M* LiCl	Lignins	[14]
Cross-linked PSDVB	Styragel	Dioxane/water (9 : 1)	Exploded lignin	[15]
	Styragel HR	*N,N*-Dimethylacetamide/0.1 *M* LiCl, DMF/0.1 *M* LiCl	Kraft lignin and its acetylated derivative	[6,17]
	Ultrastyragel	THF	Kraft lignin, and its acetylated and silylated derivatives	[18]
		DMF/0.1 *M* LiBr	Superfluid-extracted lignin	[19]
	μStyragel	THF or THF/0.05 *M* LiBr	Acetylated MWL and its fractions	[20,21]
	μSpherogel	THF	Acetylated MWL, organosolv lignin, etc.	[20,21]
	TSK HXL	THF/20 m*M* methyltrioctyl ammonium chloride	Kraft lignin, lignosulfonate, organosolv lignins	[22]
	TSK H	DMF	Acetylated methylated kraft lignin	[23,24]
	PLgel	DMF	Acetylated methylated kraft lignin	[23,24]
	PLgel MIXED	DMF/0.1 *M* LiCl	Kraft lignins	[25]
		THF	MWL, organosolv and alkaline lignins	[26]
	LiChrogel PS	THF	Organosolv lignin	[27]

incomplete in both THF and DMF (pure or containing dissolved electrolyte).[23,24]

It appears that SEC with the Sephadex G series/aqueous 0.1 *M* NaOH solution is remarkably reliable:[23,24] Lignin samples are totally recovered from the column, and fast associations through hydrogen bonding or dipolar interactions are completely defeated. However, more stable lignin complexes held by non-bonded orbital interactions can be disassembled completely in aqueous alkaline solution only after prolonged incubation at low concentrations, since the association/dissociation via this mechanism is a considerably slow process. It should be also noted that, with soft Sephadex G series gels, formed in the 30–80 μm particle size range, which are packed manually in open columns, resolution is inherently lower than that offered by high-resolution SEC columns, e.g., those packed with rigid PSDVB gels of smaller particle size. Thus, a continuing search for better column/eluent systems for the SEC of lignins is needed.

It is equally important to choose an appropriate sample concentration, injection or loading volume, flow rate, column temperature, pore size, particle size, and detection method in order to obtain MWDs with high fidelity and adequate resolution. The effects of these parameters are relatively straightforward, except for pore size and detection method, which are discussed later in "Error Analysis". The choices of those parameters are based on the same considerations as for commonly known polymers, which are discussed in several excellent monographs, one of which is listed in the Bibliography (Yau, Kirkland, and Bly).

Standardization of Elution Profiles

Raw elution profiles are expressed as detection response vs. elution volume. To facilitate comparison of elution profiles of various samples, elution profiles need to be normalized to a common area through rescaling of the *y*-axis.

When the SEC of lignins is performed on an open column packed with soft gels, such as Sephadex G, the elution volume of the same solute size varies slightly between runs due to small fluctuations in the flow rate and ambient temperature that may disturb the void volume and total permeation volume of the gel bed. Moreover, a new column has to be packed every three months for a Sephadex G gel/aqueous 0.1 *M* NaOH system because reproducible column performance can be maintained only for a finite period of time as a result of slow decomposition of the packing material. Thus, the variation in the elution volume between columns can be considerably large because of variation in the height of the gel bed from one column to another. To overcome uncertainty arising from these potential sources, the elution volume is often converted to a dimensionless variable prior to *y*-axis rescaling. This variable is termed the distribution function $K = (V - V_0)/(V_T - V_0)$, where V is the elution volume of the sample, and V_T and V_0 are the total permeation volume and the void volume, respectively. The value of K represents the fraction of the internal volume (the total volume of pores in the gel bed) accessible to a particular solute in a given column and, thus, is directly related to molecular size. The variable K is insensitive to the small changes in V_T and V_0 caused by fluctuations of pressure and temperature and to the bed height variation in columns packed with the same batch of gel if the packing technique is consistent.

The values of V_T and V_0 are usually determined by the respective standard markers. For example, in the Sephadex G-100/aqueous 0.1 *M* NaOH system, blue dextran (BD) and *p*-nitrophenol (*p*NP) are often used as standard markers for V_0 and V_T, respectively. In the standardized elution profiles depicted in Fig. 2, the elution volume has been converted to a slightly different dimensionless parameter, termed relative retention volume (V_R), which is operationally defined as $V_R = V_r \times$ scaling factor, where $V_r = (V - V_0)/V_0$. The V_0 is taken as the starting, rather than the apex position, of the BD peak.[23,24] The "scaling factor" normalizes V_r, which may vary slightly from run to run due to experimental background variations, by setting the V_R value of *p*NP to 2 (since the V_r value of *p*NP eluted from a 2.5 × 100 cm column packed with Sephadex G-100 with aqueous 0.1 *M* NaOH is close to 2). Thus, an equivalent expression is $V_R = 2 \times (V - V_0)/(V_{pNP} - V_0)$, where V_{pNP} is the elution volume of *p*NP.[23,24]

Determination of V_0 and V_T is not always straightforward. Since elution profiles of lignins often cover almost the whole elution volume range (between V_0 and V_T) a column can offer, V_0 and V_T standard markers added would coelute with sample components. Under this circumstance, the sample may be eluted twice, once with and once without markers. Corresponding points with respect to the shapes of both profiles can be found according to a constant concentration ratio. Since baseline fluctuations have relatively small effects at the maximum of the largest peak, due to high signal levels in that region, and since changes in the concentration in the vicinity of this position are relatively small, the ratio of the concentrations at the respective peak maxima in the two profiles can be conveniently used to find the corresponding points between them: The concentration ratio at each pair of corresponding points must always be the same.

Since the values of V_R at each pair of corresponding points between the two profiles must be the same, it follows that

$$\frac{V_i - V_0}{V_T - V_0} = \frac{V_i' - V_0'}{V_T' - V_0'} \quad (1)$$

Rearranging gives

$$V_i = \frac{V_T - V_0}{V_T' - V_0'} V_i' - \frac{V_T - V_0}{V_T' - V_0'} V_0' + V_0 \quad (2)$$

where $i = 1, 2, 3, \ldots$ for the pairs of corresponding points, and the prime ($'$) refers to the profile with standard markers. Hence, V_0 and V_T can be derived from the values of the slope and the intercept obtained by a linear regression for a plot of V_i vs. V_i':

$$\begin{aligned} V_0 &= \text{slope} \times V_0' + \text{intercept} \\ V_T &= \text{slope} \times (V_T' - V_0') + V_0 \end{aligned} \quad (3)$$

The validity of the pairing between both profiles can be evaluated by the ratios of calculated relative retention volume in the profile with markers, V_R', to the corresponding one in the profile without markers, V_R; they should be centered at unity and show no systematic changes with increasing retention volume (e.g., the 90% confidence interval of the slope should encompass zero).

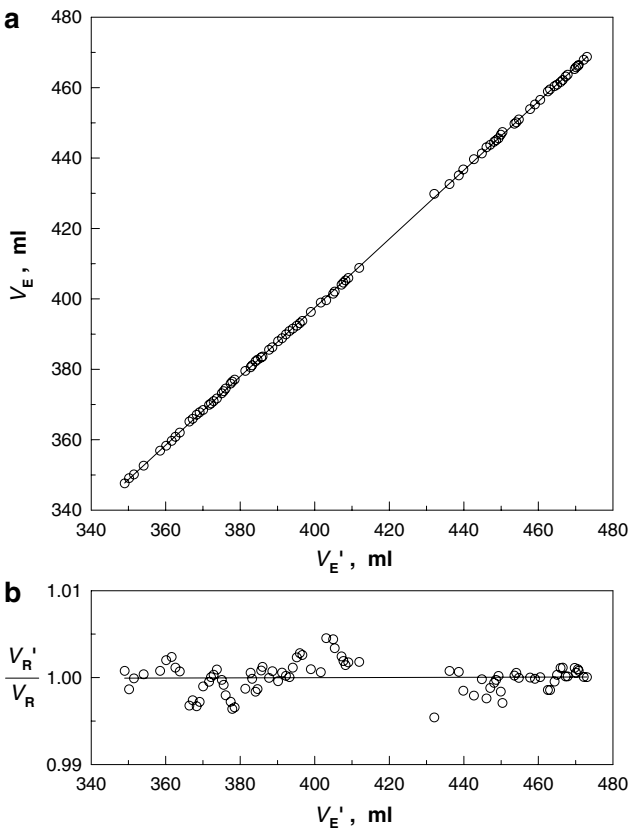

Fig. 3 Linear regression for (a) determination of V_0 and V_T and (b) evaluation of validity of calculated V_R in sample profile. Regression results: Plot A: slope $= 0.976 \pm 0.002$, intercept $= 7.0 \pm 0.6$, and $R^2 = 0.9999$; Plot B: slope $= 9 \times 10^{-7} \pm 8 \times 10^{-6}$, intercept $= 1.000 \pm 0.003$, and $R^2 = 0.0005$. Uncertainties following $\pm$ are calculated at 90% confidence level.
Source: From Hardwood kraft lignin: Molecular weight dependent structural properties and non-covalent interactions between constituent species, in M.S. Thesis; University of Minnesota.[2]

Taking a dissociated aspen kraft lignin preparation as an example, Fig. 3a shows a plot of V_i vs. V_i' with a linear regression line, and Fig. 3b illustrates a plot of V_R'/V_R vs. V_i' with a least-squares fit. Regression lines in both plots fit to the data very well. The V_R'/V_R values have an average of 1.0000 ± 0.0003 and the regression gives a slope of $9 \times 10^{-7} \pm 8 \times 10^{-6}$, indicating that corresponding points between the two profiles have been satisfactorily found.

CALIBRATION

Since the size-exclusion phenomenon depends not really on molecular weight but rather on hydrodynamic volume, calibration is needed for making reliable measurements of average molecular weights and for making meaningful comparisons of MWDs reported by different authors. The purpose of calibration is to correctly establish the quantitative relationship between elution volume and molecular weight for a particular SEC system and sample type under study. Several calibration methods can be used in the SEC of lignins.

Peak Position Calibration with Paucidisperse Standards

This is the most reliable method to obtain the true calibration curve and, thus, is frequently used in the lignin field. The standards should be conformationally close to lignins, preferably those narrow fractions collected from the elution profile of the lignin sample under study. The fractions should be characterized independently by an absolute method such as ultracentrifuge sedimentation equilibrium or velocity, light-scattering photometry, osmometry, or mass spectrometry with soft ionization (matrix-assisted laser desorption/ionization or electrospray ionization). Fig. 4 illustrates a molecular weight calibration curve for a Sephadex G-100 column with aqueous 0.1 *M* NaOH as the eluent for an aspen kraft lignin. The calibration curve was constructed using paucidisperse standards obtained by chromatographic fractionation of parent, associated, and dissociated lignin preparations. The relative elution volume of each standard was based on its peak position in the elution profile obtained from the SEC system being calibrated, and the weight-average molecular weight of each standard was determined by ultracentrifuge sedimentation equilibrium analysis. The standard having the highest molecular weight was collected near the void volume from the elution profile of the associated kraft lignin. The linear calibration curve was established by least-squares fitting to the data points of the remaining standards. The drawback of this type of calibration is that these absolute methods are time-consuming and expensive.

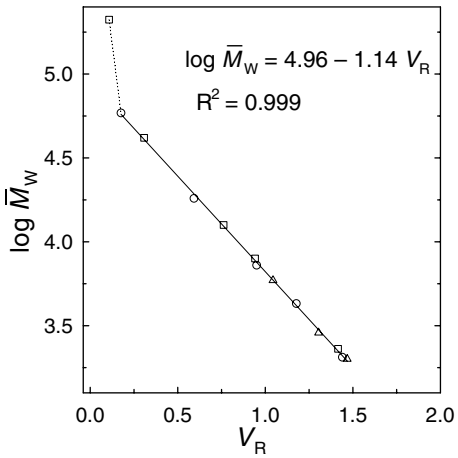

Fig. 4 Molecular weight calibration curve for Sephadex G-100/aqueous 0.10 *M* NaOH of aspen kraft lignins, constructed based on paucidisperse fractions of aspen kraft lignin samples differing in degree of association. ○ Parent preparation; □ associated sample obtained from a 7215 hr incubation of parent preparation at 200 g/L in 1.0 *M* ionic strength aqueous 0.40 *M* NaOH at room temperature; Δ dissociated sample obtained from ultrafiltration with water through Amicon YC05 membrane (to remove NaOH and to concentrate sample solution) following a 5640 hr incubation of parent preparation at 0.10 g/L in aqueous 0.10 *M* NaOH at ambient temperature. Data point with highest $\overline{M}_w$ value was excluded for least-squares linear regression.

Universal Calibration

The SEC of lignins reported in the past has been dominated by calibration with the commercially available well-characterized paucidisperse standards of polystyrene. However, the hydrodynamic volume of a lignin solute is generally not the same as that of polystyrene of the same molecular weight. Furthermore, when the solvent or temperature is changed, the extent to which the molecular size of a lignin solute changes is often different from that for polystyrene. Hence, the measurements based on conventional polystyrene calibration not only do not represent the true molecular weights of a lignin sample, but also depend on the given eluting solvent and temperature. An elegant solution to this difficulty is universal calibration. It was shown more than 30 years ago that the effective hydrodynamic specific volume of a molecule, expressed by the product $[\eta]M$, is uniquely related to the elution volume.[28] Thus, by measurement of the intrinsic viscosities of polystyrene standards and of selected sample fractions, or by the use of an online differential viscometer with SEC, a calibration curve constructed from a homologous series of polystyrene can be converted to a lignin calibration curve with little effort and simple equipment.

Calibration with One or More Polydisperse Standards

An effective calibration curve can be constructed based on any two known values of $\overline{M}_n$ and/or $\overline{M}_w$ of one or two polydisperse standards of the lignin of interest. A nonlinear regression method is used to find the two unknown coefficients in the linear calibration equation such that the calculated $\overline{M}_n$ and/or $\overline{M}_w$ of the broad chromatogram(s) based on this calibration curve agree with the known values, which have been obtained by independent methods such as osmometry and light-scattering photometry. Obviously, the accuracy of this type of calibration depends on the accuracy of the known values of $\overline{M}_n$ and $\overline{M}_w$ as well as the validity of the assumption that the molecular weights of all constituent species of the polydisperse standard are within the linearity ranges of the column being calibrated. In addition, significant deviation from the true calibration curve can occur unless a low-dispersion SEC column is employed or correction for column band dispersion is incorporated into the method.[29] This method is of practical convenience for routine calibration, though its application in the lignin field is only scarcely reported.

Online Calibration

A recent advance in the SEC of lignins is the online molecular weight measurement of macromolecules eluting from the column using molecular-weight-sensitive detectors such as differential viscometers and light-scattering photometers. Among several types of light-scattering detectors, the low-angle laser light-scattering (LALLS) photometer is favored for online measurement, since the incident laser beam is very intense to allow for measurement of very dilute eluate with reasonably good signal-to-noise ratios and can be focused extremely well to allow for reliable measurement of scattered light at an angle very close to zero (typically 2–7°), thus avoiding any uncertainty that arises from data extrapolation and fitting that would have to be performed in multiangle light-scattering detection to obtain the excess Rayleigh ratio at 0°.

ERROR ANALYSIS

Several factors may affect the accuracy of lignin elution profiles and, thus, that of the calculated average molecular weights. Some important sources of errors are discussed below.

Enthalpic Interactions

It is well understood that any kind of energetic interaction of the solute with the stationary phase would cause

non-SEC behaviors. The proper choice of mobile and stationary phases is critical to eliminate this type of error or reduce it to insignificant levels. An appropriate mobile phase is also needed to suppress instant association between lignin components, which often results in misleading SEC results.

Pore Size

Separation of solutes by SEC is regulated by the selection of the pore size of the packing material. Most lignin preparations have very wide ranges of molecular weights. It has been pointed out that the bimodal distributions reported in many cases were due to insufficient pore size of the packing material used, which resulted in a high-molecular-weight peak that merely represents the accumulation of all macromolecules of hydrodynamic volume greater than the total exclusion limit of the column.[6] Apparently, use of inappropriate pore size causes considerable error in molecular weight analysis. Any peak appearing at the void volume or at the total permeation volume is an alarming sign of this problem.

Detector Response to Heterogeneous Polymeric Solutes

Ideally, an SEC detector for measuring mass concentration should have a constant response factor (response per solute concentration) for all polymeric solutes so that the elution profile recorded represents the true concentration (or weight fraction) change with elution volume. This is true for homogeneous polymers, but not so for heterogeneous polymers, since the response factor generally changes with the chemical composition of eluate. For example, it is well known that the absorptivities of H, G, and S units at a given wavelength are considerably different and that some local structure features, such as the ionized phenolic hydroxyl group, have significant influence on the absorptivity. Notwithstanding this, the ultraviolet detector, being highly sensitive to aromatic structures and yet insensitive to temperature variation, is the most frequently used detector in the SEC of lignins and their derivatives. However, in publications dealing with lignin SEC, the absorptivity at a chosen detection wavelength has been commonly assumed to be the same for all lignin molecules in the sample. Thus, lignin elution profiles generally contain a certain degree of error. This may be especially true for hardwood and grass lignin preparations, which are built up from more than one type of structural unit. The second most frequently used concentration detector is the differential refractometer (though far less popular than the UV detector) for the SEC of lignins; however, it fares no better. Since the specific refractive index increment (dn/dc) is sensitive to the heterogeneous nature of lignin macromolecules, the response factor of this detector type is likely to fluctuate, to some degree, during the course of elution. Indeed, ideal concentration-sensitive detectors for lignins have yet to be found. Interestingly, SEC can be undertaken without any concentration detector, and thus free of the foregoing source of error, to determine number-average molecular weights. The method uses a universal calibration curve and needs only an online differential viscometer in the SEC system.[30–32] This measurement, however, is quite sensitive to baseline noise.

Compositional Local Polydispersity

For compositionally heterogeneous polymers, macromolecules of different molecular weights may possess the same hydrodynamic volume; thus, their SEC elution profile exhibits local polydispersity in the molecular weight at each elution volume where different molecular weights coelute. Since conventional interpretation of SEC elution profiles assumes no local polydispersity, the MWDs derived via column calibration can be misleading if significant coelution of different molecular weights occurs in the SEC of lignins. Conceivably, the problem is more serious for hardwood and grass lignins.

Column Axial Dispersion (Band Broadening)

Axial dispersion impairs the chromatographic resolving power, causing local polydispersity in molecular size (and thus, in molecular weight as well) at each elution volume, even for homogeneous polymers. As a result, the elution profile obtained is broader than it should be, calculated average molecular weights deviated from the true values, and polydispersity ($\overline{M}_w/\overline{M}_n$) is usually overestimated. Obviously, the error is more significant for low-resolution columns, which are often employed in aqueous SEC of lignins. Fortunately, band broadening can be assessed by the standard deviation of a narrow standard peak obtained under the same SEC conditions as for samples, and local polydispersity due to this source can be corrected for by published mathematical treatments.[29]

INTRODUCTION

We demonstrate the separation of human brain lipids by using toroidal-coil countercurrent chromatography (TC-CCC). It becomes possible to select the suitable two-phase solvent systems because retention of a stationary phase is much more stable in TC-CCC than in high-speed countercurrent chromatography (HS-CCC). Optimizing the solvent systems, we succeeded in separating major brain lipids. The two-phase solvent, consisting of chloroform/methanol/water (5:4:3), was suitable for the separation of acidic phospholipids (phosphatidic acid [PA], phosphatidylserine [PS], phosphatidylinositol [PI], lysophosphatidylinositol [lysoPI], and lysophosphatidylserine [lysoPS]). By using hexane/ethylacetate/ethanol/0.1% aqueous ammonia (5:5:5:4), neutral phospholipids (phosphatidylcholine [PC], sphingomyelin [SPM], and lysophosphatidylcholine [lysoPC]) were separated. Nonpolar lipids (cholesterol, alkali-labile glycoglycerolipids, and cerebrosides [CS]) were separated by using the solvent of hexane/ethanol/water (10:15:4). Sphingomyelin (SPM), cerebrosides, and phosphatidylcholine are each reported to have more than 100 molecular species, which are derived from variations of the hydrophobic tail group in mammalian tissues. For this reason, SPM was further separated into two groups (SPM-I and SPM-II). Cerebrosides were separated into several groups by using hexane/ethanol/water (5:4:3). It was clearly shown that synthesized PC (distearoyl phosphatidylglycerol and dipalmitoyl phosphatidylglycerol) was completely separated. Because the partition behavior of molecules in the two-phase solvent system can be measured, TC-CCC could be useful not only for the separation, but also for the biological analysis of mammalian cell-membrane lipids.

COUNTERCURRENT CHROMATOGRAPHY

Phospholipids, glycolipids, and cholesterol are the major components of mammalian cell-membrane lipids. They play important roles in cell-signaling transduction and cell-to-cell recognition or modification of enzyme functions. All of these lipids have amphipathic properties, and contain hydrophobic and hydrophilic regions. In the cell membrane, the hydrophobic and hydrophilic residues and their behavior play an important role in cell functions. The amphipathic property disturbs the separation of these compounds via a countercurrent distribution method because the vigorous mixing of the two solvent phases causes the formation of an emulsion.

Countercurrent chromatography (CCC) is a liquid partition chromatographic technique which eliminates the use of a solid support.[1,2] CCC utilizes two immiscible solvent phases. The partition process takes place in an open column in which one phase (the stationary phase) is retained while the other phase (the mobile phase) is continuously equilibrating with the stationary phase. To retain the stationary phase in the column, the system uses various combinations of column configuration and force fields (gravitational and centrifugal). Countercurrent liquid partition chromatography is a system without a solid phase. Therefore it may become a useful method for analyzing the hydrophobicity and the behavior of lipids, avoiding the influence of a solid phase or spacers.

Previously, we showed that HS-CCC could separate alkali-labile glycolipids (ALGLs), which were isolated from the human brain, into several groups.[3] In that experiment, HS-CCC could finely separate the molecular species in the final step of purification. Nevertheless, the retention of a stationary phase is poor in HS-CCC. Therefore the available two-phase solvent systems have their limitations. Moreover, it was actually difficult to separate them from crude materials because of severe emulsification and the subsequent loss of the stationary phase from the column. To overcome this problem, we developed an analytical-scale TC-CCC, which has the advantage of using centrifugal force to retain the stationary phase.[4] In this system, a stable two-phase separation can be obtained by increasing the rotational speed (centrifugal force) and/or decreasing the flow rate to avoid emulsification. We can use most of the two-phase solvent systems for this TC-CCC.

In this study, the TC-CCC system was applied to solve the problem of emulsification, and satisfactory stationary phase retention was obtained. Human brain lipids could then be separated. We established the solvent systems that are used for the separation of most of the phospholipids, glycolipids, and less-polar lipids of the human brain. Furthermore, we demonstrated that molecular species, which are derived from variations of the hydrophobic tail group, were separated by optimizing the composition of the solvents. TC-CCC is available for analyzing the hydrophobicities of various lipid molecules in biomembranes.[5]

EXPERIMENTAL APPROACH

Apparatus

The present studies employ a commercial model of the toroidal coil centrifuge (TC-CCC 1000) purchased from Pharma-Tech Research (Baltimore, Maryland, U.S.A.). The apparatus is a compact tabletop unit measuring 30 × 630 × 640 cm. It is equipped with a flow-through device without the use of rotary seals, according to a previously described principle.[6] In this implement, rotation speed is continuously adjustable up to 3000 rpm, having a speed regulator equipped with a digital display. The toroidal coil separation column was prepared by winding a 0.4 mm I.D. 15–100 m polytetrafluoroethylene (PTFE) tubing (Zeus Industrial Products, Raritan, New Jersey, U.S.A.) onto a nylon pipe of 1.5 mm O.D. thus making a right-handed coil. Next, the coiled tube was affixed to the inner wall of the cylindrical centrifuge bowl (diameter: 12 cm and height: 5 cm), thus forming a doughnut-shaped configuration (toroidal coil) consisting of two to three coiled layers. The toroidal coil is about 6 m in length (made from 60 m-long PTFE tubing) and consists of 12,000 helical turns with a total capacity of about 8 ml. The inlet and outlet flow lines were made of thick-wall PTFE tubes (0.35 mm I.D.) to withstand constant flexing movements. A chromatographic metering pump (model 515 HPLC pump, Waters, U.S.A.) was used for pumping in the mobile phase, and a fraction collector (Ultrorac, LKB Instruments, Stockholm, Sweden) was used to collect the eluate into test tubes.

Reagents

Phospholipid standards (Phospholipid kit) were purchased from Funakoshi (Tokyo, Japan). Cerebroside (bovine), D-α-phosphatidylcholine dipalmitoyl, and D-α-phosphatidylcholine distearoyl were purchased from Sigma (St. Louis, Missouri, U.S.A.). Chloroform and methanol, both of glass-distilled chromatographic grades were purchased from Burdick and Jackson Labs. (Muskegon, Michigan, U.S.A.), and a reagent-grade glacial acetic acid, water, hexane, and ethyl acetate from Fisher Scientific (Fair Lawn, New Jersey, U.S.A.). Ethanol was purchased from Pharmaco Products (Brookfield, Connecticut, U.S.A.). Trifluoroacetic acid (TFA) was from Pierce Chemical (Rockford, Illinois, U.S.A.). Ammonium hydroxide was from J.T. Baker (Philipsburg, New Jersey, U.S.A.).

Lipid Extraction and Purification

Human brain tissue (200 g, wet weight) was homogenized, and the total lipids were successively extracted with 3 L each of mixtures composed of chloroform/methanol, 2:1, 1:1, and 1:2 (v/v). The lipid extracts were combined and evaporated to dryness in a rotary evaporator, then suspended and dialyzed against distilled water, and, finally, lyophilized. Unbound (neutral) lipids and bound (acidic) lipid fractions were separated with a column packed with DEAE Sephadex A-25 (Pharmacia LKB Biotechnology, Uppsala, Sweden) (bed volume, 200 ml).

Preparation of Two-Phase Solvent System and Sample Solution

Each solvent system was thoroughly equilibrated in a funnel at room temperature. The sample solution was prepared by dissolving 1–5 mg of lipids in 0.05 ml each of the upper and lower phases.

CCC Procedure

In each separation, the toroidal coil was first entirely filled with a stationary phase (either the upper or the lower phase), and a sample solution was injected into the coil. Next, the mobile phase (organic phase) was pumped into the column while the column was rotated at the desired rate. The effluent from the outlet of the column was collected in test tubes at a rate of 0.2 ml/tube, and at a flow rate of 0.1 ml/min. After the desired peaks eluted, the centrifuge run was terminated and the column contents were fractionated into test tubes at 0.5 ml/tube by eluting the column with the solvent initially used as the stationary phase, at a flow rate of 0.25 ml/min.

High-Performance Thin-Layer Chromatography

The lipids were separated on a high-performance thin-layer chromatography (HPTLC) plate. The developing solvent was a mixture of chloroform, methanol, and 0.2% aqueous $CaCl_2$. Orcinol reagent[7] and Dittmer's reagent[8] were used to detect glycolipids and phospholipids.

RESULTS

Fig. 1A shows the procedure for acidic and neutral lipid preparation. Human brain tissue was homogenized and extracted by using a mixture of chloroform and methanol. Next, the lipid extract was dialyzed and applied to the

anion exchange column. Then, the binding fraction (acidic fraction) and the non-binding fraction (neutral fraction) were separated. Cholesterol, phospholipids, and glycolipids were the main components of these fractions. The general structures of these lipids are summarized in Fig. 1B. There are two types of glycolipids and phospholipids. One is a sphingo type and the other is a glycero type. In humans, sphingomyelin is only one sphingo type of phospholipid. In glycosphingolipids, X represents various carbohydrates. The carbohydrate containing sialic acid is called a ganglioside, which is eluted as a binding fraction by using anion-exchange column chromatography. We tried various solvent systems and various compositions for each solvent system. We then determined that the following conditions are the most appropriate for the separation of the lipids.

Separation of Acidic Fraction

A chloroform/methanol/water system is appropriate for the separation of an acidic fraction. If the solvent compositions are not optimized, the phospholipids and glycolipids are eluted at the solvent front or in the column contents. When we chose a suitable solvent, acidic phospholipids (phosphatidic acid, phosphatidylserine, phosphatidylinositol, lysophosphatidyl-inositol, and lysophosphatidylserine) were satisfactorily separated between the solvent front and the column contents (Fig. 2A). Samples (2 mg each) of the acidic fraction of human brain lipids was applied to TC-CCC by using the chloroform/methanol/water (5:4:3) solvent system. Aliquots of each fraction were spotted and developed by HPTLC.

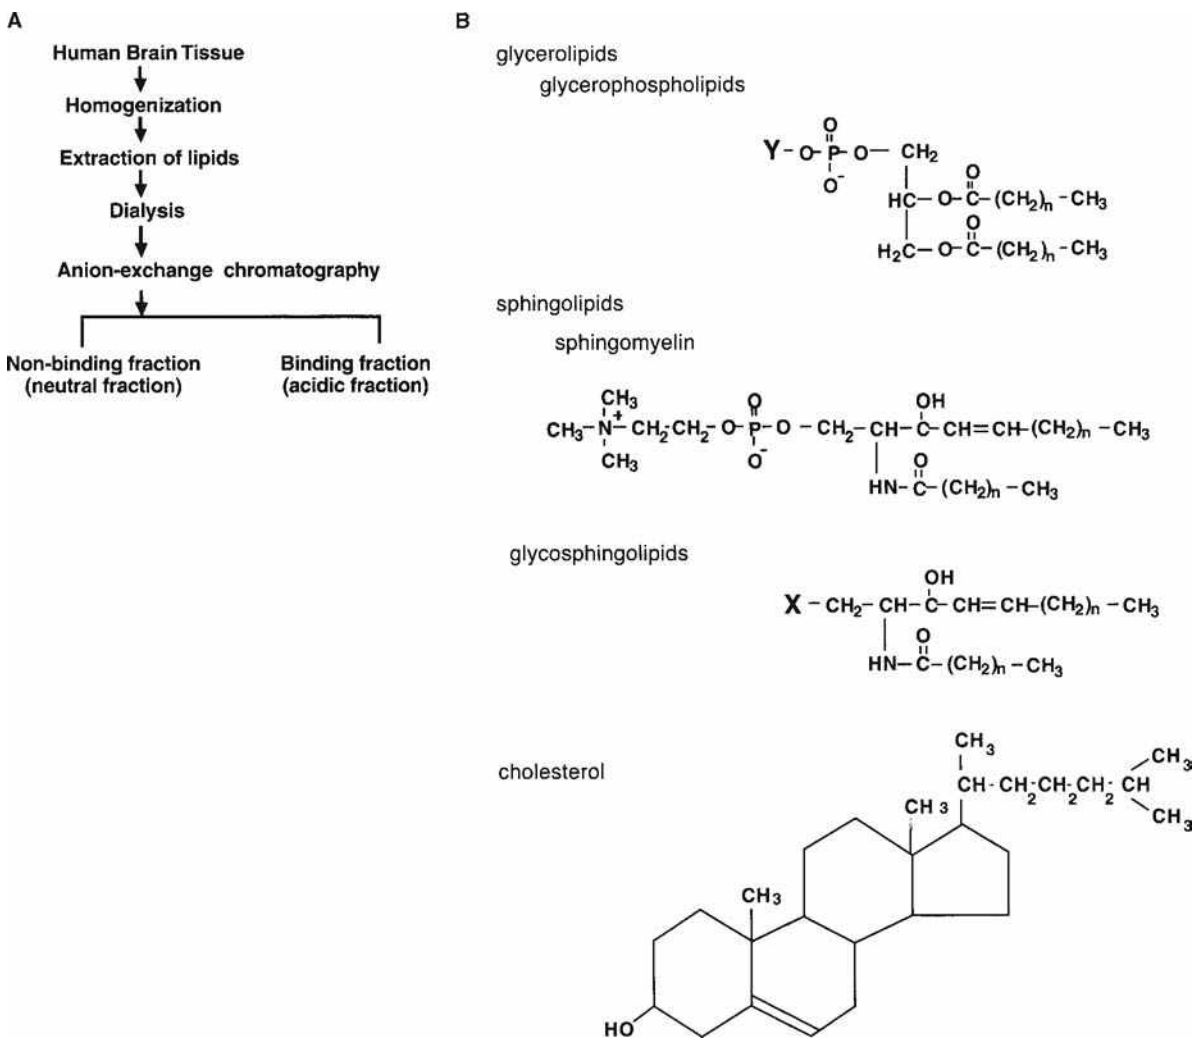

Fig. 1 A, Procedure to obtain acidic and neutral fractions; B, General structures of lipids analyzed in this study. Glycosphingolipid is composed of a ceramide (a hydrophobic-tail group) and a carbohydrate (X). X represents various sugar chains. If the X contains sialic acid, it is called a ganglioside. The gangliosides are eluted as acidic fraction in anion-exchange column chromatography. A glycerophospholipid is composed of diacylglycerol (a hydrophobic-tail group) and Y. Y is a hydrophilic head group. Phospholipid classes show differences in Y residue as follows: –H, PA; $–CH_2CH_2NH_3$, PE; $–CH_2CHN(CH3)_3$, PC; $–CH_2CHNH_3 + COO–$, PS; myo-inositol, PI.

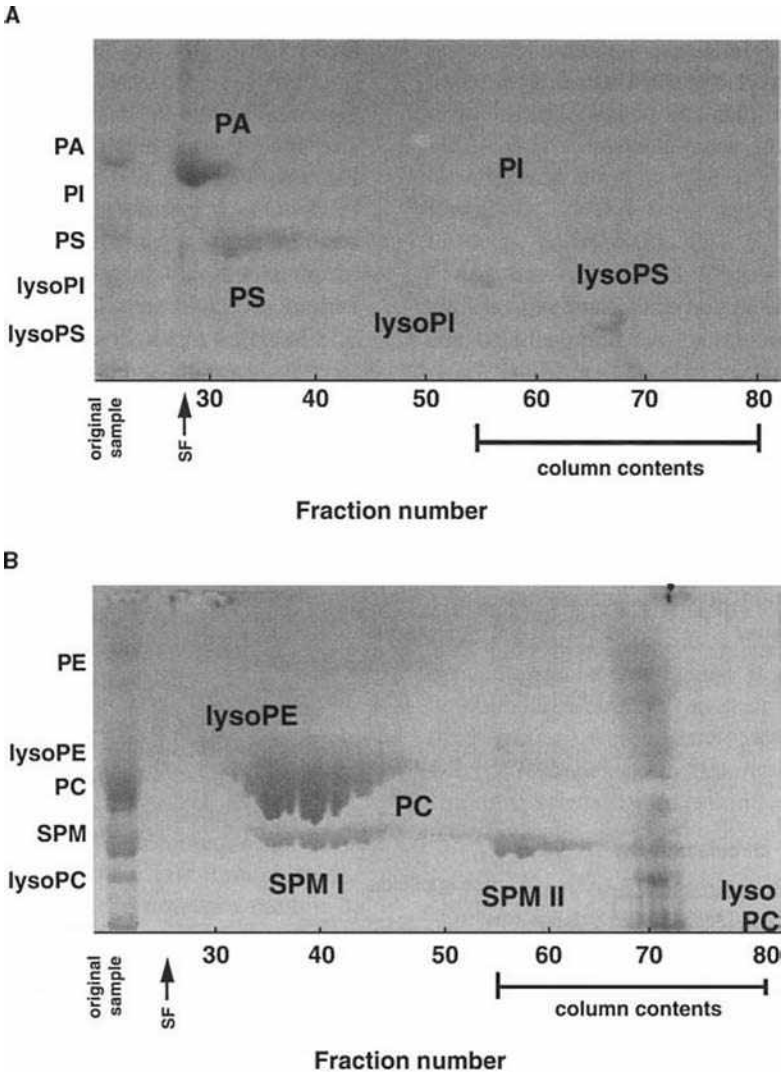

Fig. 2 Separation of acidic phospholipids in the human brain. A, The solvent system used for TC-CCC was chloroform/methanol/water (5:4:3). The lower phase (organic phase) was mobile. The revolution speed was maintained at 1500–700 rpm. The highest column pressure was 350 psi. A 2 mg portion of the acidic fraction of human brain lipids was loaded. Each fraction was spotted and developed on the HPTLC using chloroform/methanol/0.2% $CaCl_2$ (60:32:4). Phospholipids were stained with Dittmer's reagent. PA, phosphatidic acid; PS, phosphatidylserine; PI, phosphatidylinositol; lysoPI, phosphatidylinositol; lysoPS, lyso phosphatidylserine. SF, solvent front. (B) Separation of neural phospholipids in the human brain. The solvent system used for the TC-CCC was hexane/ethyl acetate/ethanol/0.1% aqueous ammonia (5:5:5:4). The upper phase (organic phase) was mobile. The revolution speed was controlled to run from 1500 to 700 rpm. The highest column pressure was 350 psi. A total of 5 mg of a neutral fraction of human brain lipids was loaded. Each fraction was spotted and developed on the HPTLC sing chloroform/methanol/0.2% $CaCl_2$ (60:32:4). Phospholipids were stained with Dittmer's reagent. PC, phosphatidylcholine; SPM, sphingomyelin; PE, phosphatidylethanolamine; lysoPE, lysophosphatidylethanolamine; lysoPC, lysophosphatidylcholine. SF, solvent front.

Phospholipids were visualized as blue-colored bands by using Dittmer's reagent, which specifically stains phospholipids. Phosphatidylinositol is completely separated from phosphatidic acid (PA) and phosphatidylserine (PS). The PA, which is the most hydrophobic phospholipid in this solvent system, eluted first, followed by PS, PI, lysoPI, and lysoPS. These phospholipids were identified by using phospholipid standards. The minor phospholipid components (fr. 65–68) may either be phosphatidylinositol phosphate (PIP) or phosphatidylinositol bisphosphate (PIP2). Each phospholipid (e.g., PS or PI) was further separated into some groups, because each phospholipid has various molecular species, which are derived from variations of hydrophobic tails (ceramide or diacylglycerol). Glycolipids were visualized as pink- or purple-colored bands by using orcinol reagent (data not shown). Sulfatides (fractions [frs.] 40–64) and gangliosides (GM1, GD1a, and GD1b) (frs. 68–70) were eluted. The abbreviations for gangliosides (GM1, GD1a, and GD1b) are according to Svennerholm's nomenclature. The sulfatides and phospholipids were eluted in the same fraction by TC-CCC.

Separation of the Neutral Fraction

Most of the lipids of the neutral fraction were eluted at the solvent front when the chloroform/methanol/water solvent system, which is suitable for the separation of the acidic fraction, was used. We then tried solvent systems which can separate more hydrophobic lipids. Using the hexane/ethyl acetate/ethanol/0.1% aqueous ammonia solvent system, we could separate phospholipids (Fig. 2B) and glycolipids (data not shown). A 5 mg amount of a neutral fraction from human brain lipids was applied to TC-CCC by using hexane/ethyl acetate/ethanol/0.1% aqueous ammonia (5:5:5:4). Phosphatidylcholine (PC), sphingomyelin (SPM), and lysophosphatidylcholine (lysoPC) were successively eluted. Phosphatidylethanolamine (PE) and lysophosphatidylethanolamine (lysoPE) and other minor phospholipid components were retained as the column contents with this solvent system. Cerebroside (fr. 28/36) and some other neutral glycolipids (frs. 35–43 and 55–63) were visualized on HPTLC when we used orcinol staining (data not shown). Cholesterol (Chol) is eluted at the solvent front (frs. 28–32)

and non-specifically stained (a brown color). It should be noted that SPM, which is usually difficult to separate into two groups with a silica bead column, is completely separated into two groups (SPM I and SPM II) (Fig. 2).

Separation of Less-Polar Neutral Lipids

Cholesterol and cerebrosides were difficult to separate via the hexane/ethyl acetate/ethanol/0.1% aqueous ammonia system. Therefore we used another solvent system to separate less hydrophobic lipids. A 5 mg amount of a neutral fraction from human brain lipids was applied to TC-CCC by using hexane/ethanol/water at a volume ratio of 10:15:4 (Fig. 3). In Fig. 3, the orcinol staining shows the specific purple color for cerebroside (CS) and ALGLs,[3] and a non-specific brown color for other lipids (not identified). Most of the phospholipids and glycolipids were retained in the column contents. Cholesterol was isolated from other lipids (frs. 38–43) (Fig. 3A). Cerebroside is eluted at frs. 60–72.

We changed the composition of the solvent system to determine whether TC-CCC could separate molecular species of CS. Fig. 3B shows the result when we used hexane/ethanol/water at a volume ratio of 5:4:3. It has been reported that CS is composed of more than 100 molecular species. The difference in intensity in the two bands represents the different molecular species. To show more clearly that TC-CCC can separate molecular species, the following studies were carried out.

Separation of Molecular Species

To assess the ability of the TC-CCC molecular species, two molecular species of phosphatidylcholine, which weresynthesized, were subjected to TC-CCC. Dipalmitoyl phosphatidylcholine (PC C16:0) and distearoyl phosphatidylcholine (PC C18:0), two of the major molecular species of phosphatidylcholine, were completely separated as shown in Fig. 4. Distearoyl phosphatidylcholine contains 2 mol of esterified stearic acids and dipalmitoyl phosphatidylcholine contains 2 mol of esterified palmitic acid. The structures of these compounds are shown in Fig. 4. These two compounds were completely separated. This result indicates that the TC-CCC system can separate molecular species in both phospholipids and glycolipids categories.

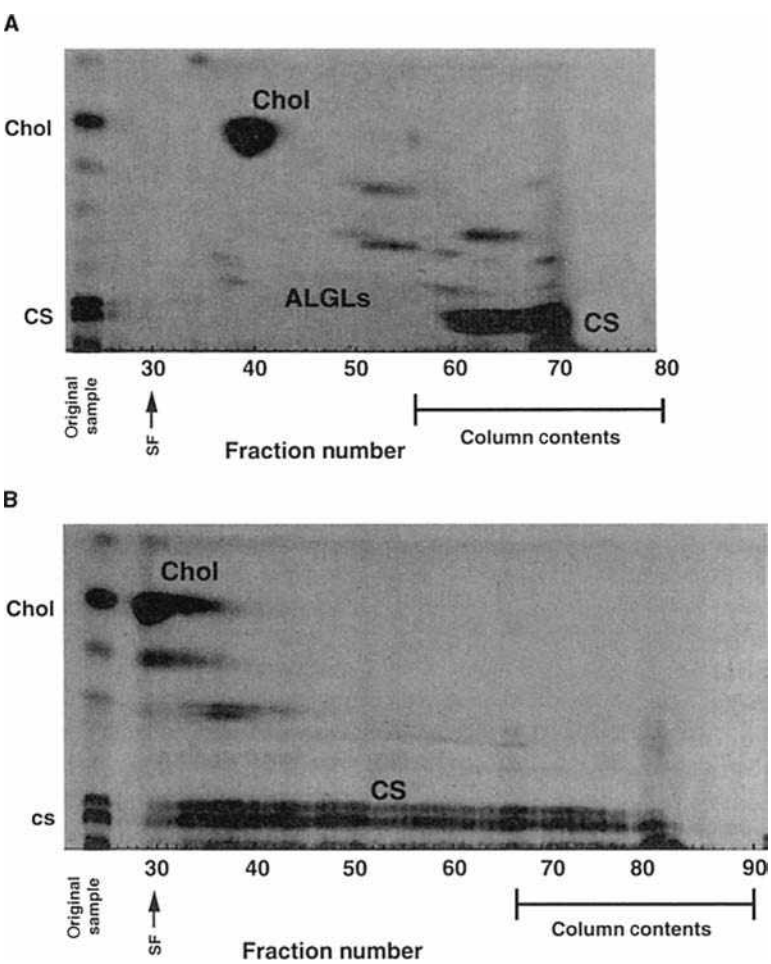

Fig. 3 Separation of highly non-polar neutral glycolipids in the human brain. The solvent system used for the TC-CCC was hexane/ethanol/water (10:15:4) (A) and (5:4:3) (B). The upper phase (organic phase) was mobile. The revolution speed was controlled to run from 1500 to 700 rpm. The highest column pressure was 350 psi. A total of 5 mg of a neutral fraction of human brain lipids was loaded. Each fraction was spotted and developed on the HPTLC using chloroform/methanol/0.2% $CaCl_2$ (90:12:1). Chol, cholesterol; CS, cerebroside. SF, solvent front.

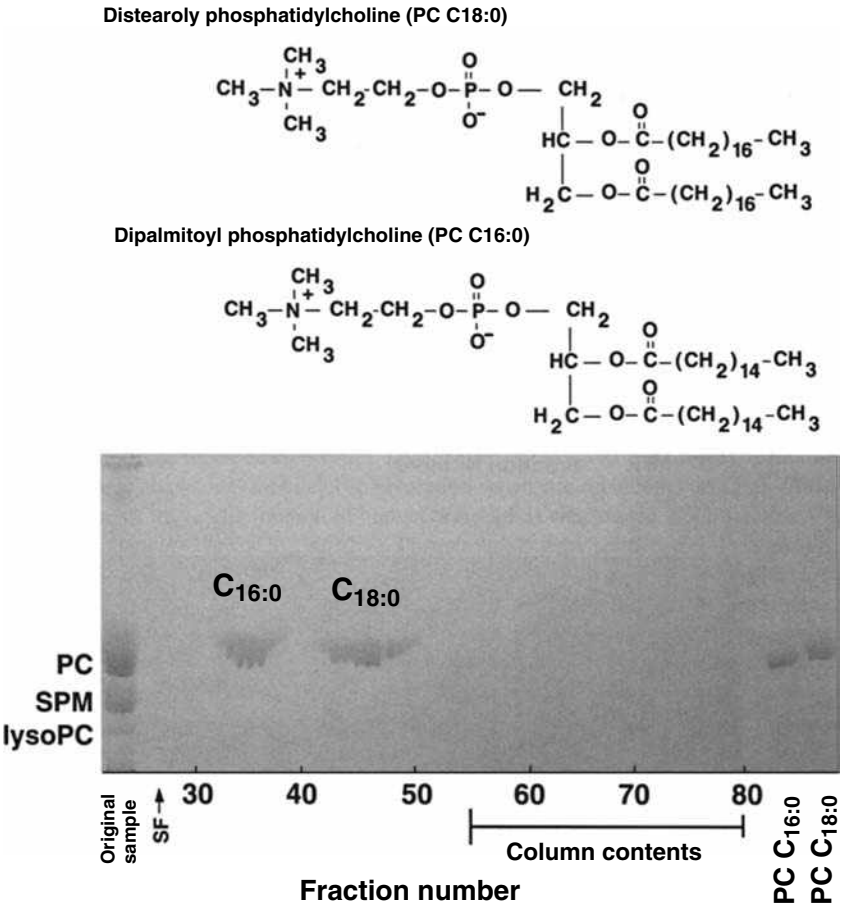

Fig. 4 Separation of dipalmitoyl phosphatidylcholine and distearoyl phosphatidylcholine. The solvent system used for the TC-CCC was hexane/ethyl acetate/ethanol/1% trifluoroacetic acid (5:5:5:4). The upper phase (organic phase) was mobile. The rotational speed was maintained at 1500–700 rpm. The highest column pressure was 360 psi. Amounts (100 μg each) of phosphatidylcholine dipalmitoyl and phosphatidylcholine distearoyl were loaded. Each fraction was spotted and developed on the HPTLC using chloroform/methanol/0.2% $CaCl_2$ (60:32:4). Distearoyl phosphatidylcholine contains 2 mol of esterified stearic acids and dipalmitoyl phosphatidylcholine contains 2 mol of esterified palmitic acids. PC C16:0, dipalmitoyl phosphatidylcholine; PC C18:0, distearoyl phosphatidylcholine. SF, solvent front.

DISCUSSION

Advantages of TC-CCC

Applications of countercurrent distribution to lipid purification were already reported in the 1950s. These included the isolation of PC, SPM, or cerebrosides from brain tissue,[9,10] or the placenta.[11] It was then mentioned that lipids easily emulsify, and this adversely affects the ability to separate them. Therefore these methods were only used for crude separation. The method also requires a long time for phase separation before each phase transfer, and this procedure needs to be repeated 500–3000 times. Otsuka and Yamakawa[12] reported the application of droplet CCC to the purification of phospholipids and glycolipids. Because the stationary phase retention is much more stable in TC-CCC than with HS-CCC, it has become possible to select appropriate two-phase solvent systems. In this study, we showed the successful separation of human brain lipids by using TC-CCC. Additionally, if an isolated band can be observed on HPTLC, the lipid can be purified by using silica column chromatography after TC-CCC crude separation.

Reverse-phase column chromatography using HPLC can be used to separate these compounds according to their hydrophobicities. However, the reported solvent systems contain salt. The TC-CCC system has an advantage in that lipids can be separated without the use of salted buffer. We plan to monitor the eluted lipids from TC-CCC by using a mass spectrometer, and this can be achieved employing salted, buffer-free solvent systems.

Separation of Molecular Species

In this paper, we have shown that this system can separate molecular species. One example is shown for cerebrosides (Fig. 3B). Human phospholipids and glycolipids have many forms (molecular species) because of the variation in fatty acids or ceramides. Phosphatidylcholine, sphingomyelin, and cerebroside are each reported to consist of more than 100 molecular species.[13] As shown in Fig. 4, it is possible to obtain better resolution by changing the flow rate and the volumes of the fractions. Furthermore, better conditions can be optimized by changing the composition of the solvents to target one lipid, as shown.

It should be emphasized that the SPM was completely separated into at least two groups (SPM I and SPM II). It was reported that there are two forms of dihydrosphingomyelin (DHS) and sphingomyelin (SPM) in commercially available bovine brain SPM;[14] SPM I and SPM II may correspond to these. TC-CCC is still in the prototype stage because there

are many factors that still need to be improved, e.g., the flow volume, the flow rate, and the tube length, as previously described. In addition, the injection system and the detection system could be improved. If these elements can be enhanced, resolution may dramatically improve.

Applications for Biological Analysis

There is a possibility that TC-CCC can be useful not only for the separation of lipids, but also as an instrument for showing the hydrophobic behavior of lipids in cell membranes. Both phospholipids and glycolipids are important components of cell membranes, in which molecular interactions between hydrophilic or hydrophobic molecules play an important role in a cell's physiology. Avoiding the effects of hydrophobicity in a solid phase system, we are able to study molecular interactions between lipids and hydrophobic molecules. The advantage of the present system is that the net partition behavior of molecules in the two-phase solvent system can be measured by monitoring the retention volumes of eluted molecules. As a result, we can obtain the partition coefficient (K) of molecules in the two-phase solvent system. This may provide a method for measuring the lipid–protein interaction in a cell membrane. This method may be useful for purifying and analyzing of caveolae, lipoprotein, or such hydrophobic microdomains in biomembranes.

Next, we determined appropriate solvent systems, and showed the hydrophobicity of lipids. In other words, most of the major human brain lipids were mapped with HPTLC using TC-CCC. Calcium plays an important role in a biomembrane. It is interesting to note that calcium improves the separation of lipids by the HPTLC.[15] In this system, it is possible to see the effect of either calcium or pH on the elution profiles of lipids.

CONCLUSIONS

Phospholipids, glycolipids, and cholesterol are the major components of mamalian cell-membrane lipids. They play important roles in cell-signaling transduction and cell-to-cell recognition or modification of enzyme functions. In this study, the TC-CCC system was applied to solve the problem of emulsification, and satisfactory stationary phase retention was obtained. Human brain lipids could then be separated. We established the solvent systems that are used for the separation of most of the phospholipids, glycolipids, and less-polar lipids of the human brain. Furthermore, we demonstrated that molecular species, which are derived from variations of the hydrophobic tail group, were separated by optimizing the composition of the solvents. TC-CCC is available for analyzing the hydrophobicities of various lipid molecules in biomembranes.

ACKNOWLEDGMENT

The authors thank Dr. Henry M. Fales of the National Institutes of Health for editing the manuscript with valuable suggestions.

Lipids: HPLC Analysis

Jahangir Emrani
Department of Civil and Environmental Engineering, North Carolina A & T State University, Greensboro, North Carolina, U.S.A.

INTRODUCTION

Lipids are mixtures of fatty molecules that contain polar and non-polar groups. Polar lipids include phospholipids and glycolipids, whereas non-polar lipids include fatty acids and their esters, cholesterol and its esters, essential oils, wax esters, and squalene. Lipids are important ingredients in the production of modern food and play key roles in physiological systems. The role of lipids in certain cardiovascular and dermotological conditions has been established. Understanding the roles of lipids in cellular and physiological systems have been the driving force behind recent developments in lipid analysis. Historically, thin-layer chromatography (TLC) and gas chromatography (GC) have been used for the analysis of lipids. Due to the limitations of these techniques and the advances in high-performance liquid chromatography (HPLC) detection technology, HPLC is gaining popularity for lipid analysis. The high temperatures used in the GC causes degradation of some molecules, whereas many fat molecules are not volatile enough to go through the GC. On the other hand, detection of fats on TLC is somewhat cumbersome.

Today, HPLC is the dominant analytical technique used for the analysis of most classes of compounds. The analyses can be carried out at room temperature and the collection of fractions for reanalysis or further manipulation is straightforward. The main reason for the slow acceptance of the HPLC technique for lipid analysis has been the detection system. Traditionally, HPLC used ultraviolet/visible (UV/Vis) detection, which requires the presence of a chromophore in the analyte. Most lipid molecules do not contain chromophores and therefore would not be detected by UV/Vis. Modern HPLC detection techniques, such as the use of a mass spectrometer as the detector, derivatization techniques to introduce chromophores, and the availability of pure solvents to reduce interference, have allowed HPLC to compete with and/or complement GC and other traditional methods of lipid analysis. In addition to analytical HPLC, preparative HPLC has been used extensively to collect pure samples of the lipids for the derivatization or synthesis of new compounds.

MODES OF SEPARATION OF LIPIDS BY HPLC

The mode of separation in the HPLC depends on the selection of the stationary and mobile phases. In HPLC of lipids, normal- and reversed-phase modes are primarily used, with the reverse phase being more common than the normal phase. Separation in the reversed-phase mode is mainly by partition chromatography, whereas separation in the normal phase mode is primarily by adsorption chromatography. Normal-phase HPLC is used for the separation of the lipids into classes of lipids.[1] Reversed-phase HPLC (RP-HPLC), on the other hand, is mainly used to separate each lipid class into individual species.[2,B1] For example, several triglycerides were separated from each other via non-aqueous reversed-phase HPLC, involving an octadecyl (ODS) column and a non-polar (non-aqueous) mobile phase. RP-HPLC alone can be used to separate the fat molecules into classes and species.[2,B1]

In reversed-phase chromatography of lipids,[B2] the lipophilic interaction between the octadecyl chains of the column and the fatty molecules of the analyte determines the retention. For this reason, the retention times of the lipid molecules depend on the stationary-phase chain length and number of double bonds in each lipid structure. In general, the retention time increases as the number of double bonds decrease. Glycerides with the shortest acyl chain length and highest number of double bonds elute first. This general rule applies if the column contains a stationary phase. Using such a general correlation and knowing the relative retention time of a reference compound such as a phospholipid on ODS columns, the retention time of other phospholipids can be calculated.[B1]

In addition to normal- and reversed-phase chromatography, silver ion HPLC, RP ion-pair HPLC, chiral separation, and supercritical fluid chromatography (SFC) have been used for analysis of lipids.[3] In silver-ion HPLC, the counterion of an ion-exchange column such as sulfonate is exchanged with silver ions. Only the degree of unsaturation in the lipid molecule determines retention. In RP ion-pair HPLC, different ion-pairing agents, such as alkylamonium phosphates, are added to the ODS column for molecular species separation. In SFC, which is used in combination with flame ionization detection (FID), solubility of lipids in carbon dioxide allows the separation to be performed. This mode of analysis is not widely used.

SELECTION OF THE STATIONARY PHASE

The type of packing in the HPLC column is the most important factor affecting the HPLC separation. Silica is

the most common packing material for normal-phase chromatography because it is stable under pressure and has a neutral pH. Silica-bonded and on the other hand, are the most common packing materials for RP chromatography because they are stable to pressure and low pH. Diol-bonded phases are also used as polar column packing.[4] In cases where gradient elution is necessary, diol-bonded stationary phases are more suitable than silica. For lipid classes found in plants, chemically bonded phases have produced better resolution than silica gel.[5] Cyanopropyl, amino, and other stationary phases have all been used. Aminopropyl phases are suitable for acidic and non-polar lipids. These columns are compatible with commonly used solvents and modifiers. Florisil is another stationary phase used for the separation of lipids; however, irreversible retention may occur.

The method of stationary-phase preparation has a major effect on the resolution, column stability, retention time, reproducibility, and peak shape. When preparing or for example, it is important that the residual silanol groups are capped to prevent peak tailing. The extent of capping must be consistently maintained between different batches of the stationary phase for reproducible results.

In terms of particle size and column dimensions, stationary phases with particle sizes of 5–10 μmm in 250×4.6 mm analytical columns are most common. HPLC columns with smaller particle sizes (2–3 mm) have also been prepared and used. Such columns have the advantages of higher efficiency, better resolution, and shorter analysis times. For example, the triglycerides of cocoa butter were baseline separated with columns that contained 2–3 mm particles. Research and development of columns with smaller particles is very active.

SELECTION OF THE MOBILE PHASE

The mobile phase consists of one or more solvents that are pumped through the chromatographic system, resulting in the separation of analytes. Mobile phases may also contain modifiers. Examples of frequently used solvents include hexane, methanol, 2-propanol, acetonitrile (ACN), and water. Examples of modifiers include tri-fluoroacetic acid, acetic acid, or formic acid. In general, the composition of the mobile phase should be kept simple. Factors that influence the choice of mobile phase include the solubility of the sample in the mobile phase, the polarity of the mobile phase, ultraviolet absorption wavelength, refractive index, and viscosity of the solvents. The purity of the solvents in the mobile phase is also important because the region of UV that is used for the detection of lipids (200–215 nm) must be free of interferences. For phospholipids, the most popular solvent systems are transparent to UV in the range of 200–215 nm; they include hexane–2-propanol–water and acetonitrile–methanol–water. Variations include hexane–methanol–isopropanol or water–methanol. The ratios of these solvents in the mobile phase depends on the nature of the lipid substances being separated. Several examples of mobile phases commonly used in the analysis of lipids are listed in the general references.

In order to separate the molecular species of lipids that have very close characteristics, small differences such as the number of double bonds in each molecule can occasionally be used as a guide to devise a solvent system to separate the molecules. This method is not always successful and may have to be further optimized for a good separation.

DETECTION

No single HPLC detector has all the characteristics of a good detector, which include sensitivity, specificity, detectability, linearity, repeatability, and dependability. Detection by UV/Vis is widely used for the analysis of lipids; it is simple, concentration sensitive, and non-destructive. However, the analyte to be monitored by UV/Vis absorption must contain a chromophore, and because many fat molecules do not contain a chromophore, this detection system cannot be used in many cases. Fortunately, in cases where no chromophore is present in the molecule, a chromophore can be introduced through derivatization. If the derivatization is done before the analyte enters the column, it is called precolumn derivatization, whereas if it is done after the elution of analyte, it is called postcolumn derivatization.

For the detection of phospholipids, UV/Vis at 205 nm is often used. In cases where the molecules contain several lipid groups, UV detection in the range of 205–215 nm has been used. Vitamin E, α-, β-, δ-, and γ-tocopherols have been analyzed by RP-HPLC using UV at 215[B1] and 280 nm. In other cases, UV diode-array detection at 190–350 nm or 200–400 nm has been used. Tocopherols and triglycerides from vegetable oils and human lipoproteins were analyzed by RP-HPLC using a UV/Vis diode-array detector. With diode-array detection, UV spectra of the peaks can be collected during the analysis. In many analyses, the UV absorption of the lipid analyte is due to the carbonyl group in the actyl group of the molecules.

More recently, a less sensitive detection technique, refractive index (RI) detection, has been used. The disadvantage of RI is that one is limited to isocratic elution, because RI detection is affected by changes in the pressure and temperature of the mobile phase. On the other hand, infrared (IR) detection can be used when the solvents in the mobile phase do not absorb infrared light, which can create interference. Because of these limitations, RI and IR have not been used as widely as UV detection.

In contrast, newer techniques such as FID and evaporative light-scattering detection (ELSD, "Universal Detector") are more sensitive and have been used for the analysis of many lipids, including the polar and neutral lipid classes.[6] For preparative scale separations, if the UV absorbance is more than what the detector can handle, an ELSD is used.[B2]

Fluorescence (FL) detection is another selective and sensitive technique. Vitamin E, α-, β-, δ-, and γ-tocopherols have been analyzed by RP-HPLC using FL as well as UV detection. In addition, a newer technique, electrochemical detection, has been reported in the analysis of phenolic compounds of olive oil.[7]

Finally, the detection by liquid chromatography/mass spectrometry (LC/MS), which has been largely dependent on the price, mode of ionization, and ease of operation of the mass spectrometer, is becoming popular.[8] It is predicted that LC/MS will become the method of choice for lipid analysis in coming years.

DERIVATIZATION

Samples of lipids may be derivatized either before they are injected into the HPLC or after they emerge from the HPLC column. The purpose of derivatization is either to make the lipid molecules detectable or to improve peak shape during the analysis. The addition of functional groups, such as phenyl, 2,4-dinitrophenyl, or anisyl to the molecule enhances the detectability by changing the absorption wavelength of a lipid molecule. On the other hand, making derivatives such as acetates or methyl esters help to improve the peak shape. To make the lipid molecules fluorescent, groups such as anthroyl, 7-methoxycoumaryl, naproxen, and naphthyl[B1] are added to the lipid molecules. The reactions are carried out postcolumn and the derivatized molecules can be detected by both excitation and emission. For the detection of fatty acids, they are derivatized by reacting with either *p*-bromophenacylbromide, 9-anthryldiazomethane, or bromomethyl-methoxy-cumarin. These derivatizations also make the molecules UV absorbers. Fatty acids have also been analyzed directly without derivatization using conductivity for detection (Fig. 1).[9] Many examples of derivatization techniques have been tabulated in Ref.[B1] Phosphatidilic acids, which result from the enzymatic reaction of phospholipase D with phospholipids, are derivatized to the methyl ester by treatment with diazomethane. In the reaction, the phosphate salt is converted to a neutral organophosphate, thereby changing its chromatographic behavior without affecting UV absorption of the lipid. Several commercially available phosphatidylethanolamines (PEs) have been derivatized for HPLC analysis as dansyl, pyrenesulphonyl, and fluoresceinthiocarbomoyl derivatives. Diacylglycerol acetates, from bovine brain ethanol-amineglycerophospholipid (EGP), were separated into molecular species using an ODS column. The chromatograms of derivatized phospholipids showed better resolution when compared with the chromatograms of underivatized phospholipids.

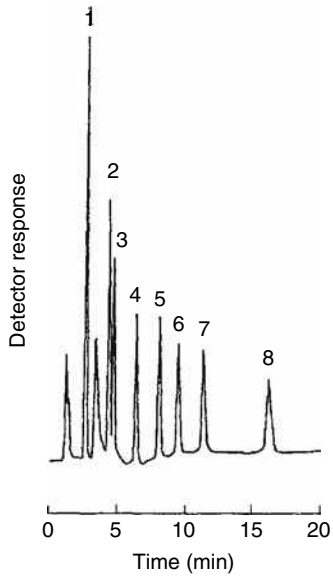

Fig. 1 Separation of free fatty acids by HPLC with conductivity detection. Mobile phase is methanol–5 m*M* tetrabutylammonium salt (75:25, v/v; pH 7.5) at a flow rate of 0.8 ml/min. Peaks: 1, lauric (12:0); 2, myristic (14:0); 3, linolenic (18:3); 4, linoleic (18:2); 5, palmitic (16:0); 6, oleic (18:1); 7, margaric (17:0); 8, stearic acids (18:0).

SAMPLE CLEANUP

Before analysis, lipids are extracted from biological matrices with either a single organic solvent or a mixture of several organic solvents, such as chloroform–methanol or 2-propanol–hexane. Some lipids that contain several double bonds are easily oxidized by air during extraction. To prevent oxidation of such lipids, it is best to perform the extraction in an atmosphere of nitrogen and/or at low temperature. Prior to extraction, an antioxidant, such as BHT, may be added to inhibit oxidation. After the extraction, the extracts are cleaned up by solid-phase extraction (e.g., aminopropyl), column chromatography, or TLC.[10] Then, one-dimensional or two-dimensional TLC is used to separate the lipids. The separated lipids are eluted from the silica gel by scraping the zones of interest from the plate and extracting the lipids with a solvent.

In many cases, HPLC can replace TLC in this step. HPLC has the advantage that, during the analysis, oxygen-sensitive lipids are not exposed to air and autoxidation is limited. After the cleanup steps, samples are analyzed by GC or HPLC. Analysis of triglycerides often involves saponification before the HPLC analysis. Because samples of lipids may originate from a variety of different sources,

the specific cleanup steps prior to analysis depend largely on the sample and the original sample matrix. For analysis of cholesterol in blood plasma, a sample of plasma was mixed with isopropanol and centrifuged. After centrifugation, the supernatant was directly analyzed by HPLC.[10] For analysis of monoglycerides in emulsifiers, the sample was dissolved in hexane–2-propanol (90:10), diluted, and injected into the HPLC. For analysis of vegetable oils, a dilute solution of oil in hexane–2-propanol is prepared and analyzed.

For quantitation of cholesterol and its derivatives in muscle and liver tissues, the extracts of the tissue homogenates are evaporated, dissolved in a mobile phase such as hexane–isopropanol, and injected onto a normal-phase column. For analysis of soybean oil by reversed-phase HPLC, after extraction with chloroform–methanol (9:1), the neutral lipids, chlorophyls, and the phospholipids are separated by TLC. The lipids recovered from the TLC are analyzed by HPLC.

EXAMPLES OF LIPID ANALYSIS BY HPLC

For examples of separation of lipids see general references. For tabulated examples, see Ref.[B1] for separation of molecular species of phospholipids by HPLC, Ref.[I] for separation of lipids in food by HPLC, Ref.[H] for HPLC of phosphatidic acid, and Ref.[B2] for preparative HPLC of lipids.

For separation of intact polar lipids by HPLC and detection by mass spectrometer, see Ref.[8] For triglycerides and fatty acids, see Ref.[B4] For separation of neutral lipids into classes and species, see Ref.[2]

INTRODUCTION

In recent years, solid-phase extraction (SPE) has emerged as an important tool for the purification of compounds in various fields of chemistry and biochemistry. This technique is taking place with others such as thin-layer chromatography (TLC) and high-performance liquid chromatography (HPLC) in the wide range of preparative tools available to the analyst. SPE technology is relatively new, as the first applications were published during the past two decades, and its real development occurred only in the nineties. The advantages of SPE, as compared to other methods, makes it an attractive method of choice for purification of molecules. Among these advantages are less time and lower solvent consumption when compared to classical liquid–liquid extraction, low cost, and excellent reproducibility of SPE products. Moreover, SPE is easily automated, so that numerous samples can be processed at the same time. SPE is frequently used in lipid chemistry and biochemistry for the isolation of particular compounds or groups of molecules for analytical or preparative purposes.[1–3] Here, we will focus on the applications of SPE in the field of lipid biochemistry, and, primarily, on the use of the aminopropyl-bonded silica gel matrix for lipid fractionation.

GENERAL PRINCIPLES AND METHODOLOGY OF SPE

SPE is a technique which is used for concentration and purification of analytes from solution by adsorption onto a disposable solid-phase-containing cartridge, disk, or syringe barrel, followed by elution of analytes with an appropriate solvent. From a general point of view, the principles of SPE are the same as conventional LC and HPLC, so that the retention and elution depend on interactions of the analyte with the stationary solid and mobile liquid phases. Retention mechanisms include normal and reversed phases and ion exchange. The SPE procedure begins by sorbent conditioning to remove cartridge impurities and to wet the functional groups at the surface of the matrix. Then, the sample is loaded onto the SPE matrix and the sorbent is rinsed to remove the components which are not desired. In a final step, the analytes are eluted from the SPE matrix and recovered in an appropriate solvent for further analysis. A wide variety of solid phases are available. Most applications are performed on the silica gel solid phase, which can be bonded with the same substituents used for HPLC or conventional LC columns. SPE principles are described in detail in adhoc reviews or books.[1,4] This method (as with all chromatographic methods) requires an accurate determination of the conditions of column preparation, sample loading, and stepwise elution. Hence, incomplete elution or analyte breakthrough can occur if optimal conditioning or elution parameters are not well defined. A good choice of solid sorbent must be made according to the nature of the analytes that are to be recovered. The choice of solvents and their volumes, as well as flow rates, must also be carefully determined to ensure optimal recovery of analytes. An understanding of the interactions between sorbent and analytes is needed to develop and optimize SPE procedures.[4]

Its advantages and ease of use have made SPE an appropriate method for concentration and fractionation of lipid classes.[2,3] Many different solid-phase types have been used in lipid fractionation on silica, alumina, porous carbon, and ion-exchange resins. Various bonded phases have been used, particularly with the silica gel matrix.

SEPARATION OF LIPID CLASSES BY REVERSED-PHASE SPE

The reversed-phase procedure has been applied in some cases for the isolation of lipid classes on SPE columns. This procedure is mainly suitable for the isolation of lipids dissolved in polar solvents, such as aqueous samples. The mechanism involves partitioning of organic solutes from the polar mobile phase to a non-polar sorbent phase, which can be C_2, C_4, C_8, and C_{18} aliphatic chains, or cyclohexyl and phenyl groups. Elution of analytes is accomplished by choosing a solvent that will disrupt the van der Waals forces retaining the molecules on the matrix. Methanol, ethyl acetate, and acetonitrile are often used for this purpose, as they can overcome van der Waals forces and they succeed in bonding to free silanol groups of the column and dissolve residual water coming from the aqueous matrix sample. Reversed-phase separations are not as common as

normal-phase separation of lipids by SPE. C_{18} SPE tubes have been often used in the isolation of phosphatidylcholine, cerebrosides, sulfatides, and gangliosides from water-soluble compounds (Figlewicz et al. 1985, quoted in Ref.[2]). C_{18} has been shown to be an efficient tool for the purification of these lipids and is easier to use than other liquid–liquid methods. Reversed-phase SPE columns have also been used for the isolation of short- and long-chain fatty acids from distilled water and seawater (Pempkoviak 1983, quoted in Ref.[2]). For more information on the use of SPE in the reverse phase, references cited at the end of this entry should be consulted.

SEPARATION OF LIPID CLASSES BY NORMAL-PHASE SPE

Most of applications deal with silica gel sorbent and with aminopropyl-bonded silica sorbents. Silica is a sorbent of choice for lipid fractionation, because these analytes are first recovered in non-polar solvents as chloroform. The polar silanol groups present at the surface of the silica sorbent will more strongly adsorb polar compounds such as phospholipids, rather than neutral lipids such as sterols and triglycerides. The retention of analytes and their elution will depend on solvent polarity. The mildly acidic nature of silica can also interfere with the separation mechanism by ion-exchange effects. Silica matrix solid-phase extraction has been used to purify some individual lipid classes, such as phosphatidylcholine (PC) or phosphatidylethanolamine (PE) from total lipids. More complex separations are also possible with silica SPE columns. Hence, a procedure for isolating cholesterol esters, triglycerides, free fatty acids (FFAs), cholesterol, acidic phospholipids such as phosphatidylinositol (PI) and phosphatidylethanolamine (PE) from a neutral phospholipid fraction containing PC, lyso-PC, and sphingomyelin (SPH) has been described.[5] This procedure was modified and adapted for further isolation of specific classes of molecules such as the choline phospholipid platelet-activating factor (PAF).

Numerous chemically bonded stationary phases can be formed by reacting the silanol groups of silica with various organic reagents. These can be successfully used for the isolation of specific lipid classes, because the bonded phases will have greater bonding potential for some specific molecules according to their functional groups. This is the case for aminopropyl-bonded phases whose primary amine group can develop a strong interaction by hydrogen-bonding with molecules having functional groups such as hydroxyl. The amino group can also be used to separate molecules on the basis of an ion-exchange mechanism, because it can also have weak anion-exchange properties.[2]

As with silica gel sorbent, neutral lipids will be poorly retained as compared to polar lipids such as phospholipids or glycosphingolipids. Aminopropyl-bonded silica gel SPE sorbent can be used according to its chemical properties, compared to an unbonded silica matrix. Surprisingly, relatively few procedures have been described for lipid fractionation and purification using aminopropyl-bonded silica SPE columns. Kaluzny et al.[6] first described a detailed procedure which allows the fractionation of neutral lipids into different classes. In this procedure, all neutral lipids were eluted from the column with a mixture of chloroform–methanol (2:1, v/v) and transferred for further fractionation onto a second column to obtain cholesterol esters, triacylglycerols, cholesterol, diacylglycerols, and monoacylglycerols to separate fractions, with good yields. With such elution, FFAs and phospholipids still bind to the column. They are then eluted in a stepwise manner by washing this column with 2% acetic acid in diethyl ether (FFA) followed by methanol to elute neutral phospholipids such as PC and SPH. Aminopropyl columns show, here, some advantage compared to unbonded silica matrix to isolate FFA, since these molecules are firmly bound to the amino group of the column and with relative selectivity compared to other neutral lipids. In the case of an unbonded silica matrix, FFAs would have been eluted before monoacylglycerols, with the other neutral lipids.

Elution of FFAs from the aminopropyl-bonded column requires a change in pH of the elution solvent to weaken the interaction between the FFA carboxyl and the column's amino groups. This is achieved by washing the column with diethyl ether containing 2% acetic acid. This example shows the advantage which can be realized by adapting the nature of the solid phase to the kind of molecule to be recovered. This is particularly useful with molecules which tend to elute together on an unbonded silica sorbent. This is often the case with free ceramides and FFAs, which will tend to migrate close to each other on a silica gel matrix; thus, it can sometimes be difficult to individually purify these compounds, particularly when high levels of FFAs are present in the sample. By choosing aminopropyl SPE tubes, this problem can be avoided, as FFA will be firmly retained, allowing further efficient elution and purification of these compounds.

However, Hamilton and Comai described a procedure which allows good recovery and separation of the neutral lipids from FFA on a silica SPE matrix.[5] Separation of the different phospholipids can be also achieved on an aminopropyl column. These polar compounds are tightly bound to the matrix, so they are retained while eluting neutral lipids and FFAs. Then, the different phospholipids can be washed from the column by changing the pH and the ionic strength of the solvent. Stepwise elution of phospholipids was obtained (PC, PE, PS, and PI) by increasing, progressively, the polarity of the solvent and its pH.[7]

Suzuki et al. also separated phospholipids by using a combination of aminopropyl-bonded silica and an unbonded silica SPE to recover PC, PE, cardiolipin, phosphatidylglycerol, and phosphatidylserine. Phospholipids

were recovered with good purity and high yields.[8] The present procedure allows the optimized use of the advantages of each kind of column. Such a combination of two SPE tubes with different matrices was already successfully used by Prietto et al. (1992, in Ref.[2]). Steryl esters, TGs, FFAs, diglycerides, monoglycerides, monogalactosylmonoglycerides, and monogalactosyldiglycerides and their digalactosyl derivatives were separated from PC and lyso-PC onto a silica gel SPE tube by different solvents of increasing polarity. Then, phosphatidylethanolamine and its lyso derivatives, which were coeluting from the silica tube, were separated on an aminopropyl-bonded SPE.

Recovery of phospholipids, as well as the various neutral lipids, is obtained with good yields on aminopropyl tubes. Hence, Kaluzny's procedure was shown to recover up to 100% of all the lipid classes studied, giving better results than the TLC procedure.[6] This latter procedure has been extensively used by many workers to separate lipid mixtures from different origins. It has been slightly modified and adapted for particular use with poorer fractionation of lipid samples.[2] This SPE procedure has been used to achieve partial fractionation of phospholipids by various researchers[2] and, particularly, to recover acidic phospholipids, which can only be eluted from an aminopropyl matrix by changing the ionic strength of the solvent.

Surprisingly, the development of SPE procedures for fractionation of lipid samples has attracted relatively little attention as compared to conventional methods, such as TLC. However, because of its qualities and advantages, it promises to be applied much more in the future. The development of such separation methods is still in progress, as new sorbents and enhanced quality of packing will become available in the near future, from the more than 50 manufacturers currently making SPE products.[9]

Lipids: TLC Analysis

Boryana Nikolova-Damyanova
Institute of Organic Chemistry, Bulgarian Academy of Sciences, Sofia, Bulgaria

INTRODUCTION

The term lipids in this entry is restricted (according to Christie) to esters and amides of the long-chain aliphatic monocarboxylic acids, the fatty acids, and to their biosynthetically or functionally related compounds. The most abundant lipids are the esters of fatty acids with glycerol (1,2,3-trihydroxypropane), which are denoted as glycerolipids. Lipids are classified according to the number of hydrolytic products per mol.

Simple (or *neutral*) lipids release two types of products, e.g., fatty acids and glycerol. The most abundant simple lipids are the triacylglycerols.

Complex (or *polar*) lipids give three or more products, such as fatty acids, glycerol, phosphoric acid, and an organic base. Typical complex lipids include the glycerophospholipids (phospholipids), glycoglycerolipids (galactolipids), and the sphingolipids. A natural lipid mixture comprises different types (denoted as lipid classes) of simple and complex lipids.

LIPIDS

Lipids are important constituents of all living organisms. Thus, for example, triacylglycerols serve as an energy reserve while complex lipids are structural components of the cell membranes with substantial role in cell functions. Lipids are also important components of the human and animal diet. Disturbances in the lipid metabolism of the organism leads to various disorders and malfunctions. In humans, these are unambiguously related to the development of cardiovascular disease.

The complexity of natural lipids requires relevant methods for examination. Adequate approaches for separation and isolation of lipid components are mandatory and, among these, the chromatographic techniques are of primary importance. Among the different chromatographic methods, thin-layer chromatography (TLC) occupies a special place, being one of the first separation methods applied to lipid analysis. Most of the present basic knowledge on the structure and biological role of lipids has been achieved by using various TLC techniques.

The first description of TLC goes back to 1938, but Kirchner (in the fifties) and later Stahl (1965) were those who converted the idea into a full-scale analytical technique. In the early 1960s, Kaufmann and coworkers in Germany and the group of Privet in the United States introduced TLC to lipid analysis.

TLC is a powerful tool in the analysis of lipids.[1–7] It is easy to perform, versatile, and relatively cheap, and it allows for direct quantitative measurements of the separated compounds via scanning densitometry. An important feature is that the analyst obtains a full picture of the examined sample.

The General TLC Technique for Lipids

TLC is a separation technique in which the components of a lipid mixture are differentially distributed between a solid stationary phase, spread as a thin layer on a plate made of inert material, and a solvent mobile phase. Depending on their type, the components are retained with different strengths on the layer to give distinctive spots or bands. The migration of a band is presented quantitatively by the corresponding R_f value. The stronger the retention, the lower the R_f value becomes.

Three modifications of TLC are in use for lipid analysis: 1) separation on unmodified silica gel layer, silica gel TLC; 2) separation on a layer impregnated with silver ions, silver ion-TLC (Ag-TLC); and 3) separation on a layer modified with silanes or long-chain hydrocarbons to give a nonpolar stationary phase, reverse-phase TLC (RP-TLC).

The universal TLC facilities are utilized: plates, adsorbents, microcapillaries, or micropipettes for sample application, development tanks, detection spray reagents, devices for spraying, and densitometers for quantification. Plates are either commercially precoated or handmade. Silica gel G (G, for gypsum as a binding substance), silica gel H (no binding substance) and, rarely, alumina and kieselguhr, form the thin-layer stationary phases. Complete sets of devices necessary for the preparation of handmade plates are commercially available. After the silica gel slurry is spread on the plates, they are left to dry in the air for at least 24 hr and shortly in an oven at 110°C. The plates are then ready for either direct use or for modification of the layer. From the great variety of precoated plates, which are commercially available and preferred nowadays, silica gel plates and plates with layers modified with carbon chains from C_2 to C_{18} are of interest in lipid analysis. Understandably, precoated plates for Ag-TLC are not commercially available. Preparative TLC is performed mostly on 20×20 cm plates with layer thickness of

1 mm. Analytical separations are usually performed on 5 × 20 cm plates with layer thickness of 0.2 mm.

The preparation of a lipid sample includes extraction of the lipid material from the examined object (seeds, tissues, food, etc.) and choosing which among the several widely accepted procedures should be used. Extraction with chloroform–methanol, 2 : 1 (the Folch extraction) is the most popular. A solution of known concentration in hexane or dichloroethane is prepared and a suitable aliquot is applied onto the plate as a small spot or, better yet, as a narrow band. Two, three, or more solvents, mixed in different proportions, comprise the mobile phase. Development is performed in common tanks (Desaga-type, for example), in the ascending mode. For fine separations, cylindrical or sandwich-type tanks provide better results.

In preparative TLC, detection is performed by spraying the plate with 2,7-dichlorofluorescein and viewing the plate under UV light. The spraying reagent does not affect the lipid and it can be easily removed during the isolation process, if necessary. Non-specific destructive reagents are used in analytical TLC. The most widely used of these are the alcoholic solutions of sulfuric (up to 50%) or phosphomolybdic (5%) acid, applied as spraying reagents. They are equally suitable for non-modified, as well as for modified layers. Reliable results are also obtained by saturating the layer with vapors of sulfuryl chloride (for silica gel TLC and Ag-TLC only). To visualize the separated components, the plate is heated at 180–220°C. The substances carbonize to give intensively stained spots, contrasting well with the background. The concentration of the lipid substance in the spots can be directly measured on the plate by using scanning densitometry.

Separation by Silica Gel TLC

Silica gel TLC is used for the identification of lipid classes in the sample (analytical TLC) and for isolation of a given lipid class for further examination (preparative TLC). Silica gel TLC is a good aid in checking both the identity and purity of individual components and different derivatives.

Separation is based on the interaction (hydrogen bonding, van der Waals forces, and ionic bonding) between the lipid molecules and the silica gel. Lipid classes with free hydroxyl-, keto-, and carboxyl groups are held stronger than those containing only fatty acid residues.

Mobile phases of hexane or light petroleum ether as main components and acetone or diethyl ether as polar modifiers are used for the separation of simple lipids. Acetic or formic acid is often added to keep the free fatty acids in the fully protonated form. The retention of simple lipids increases in the order: waxes, sterol esters, methyl esters, triacylglycerols, free fatty acids, sterols, diacylglyerols, monoacylglycerols (Fig. 1A). If no acid is present in the mobile phase, the free fatty acids migrate between diacylglyerols and monoacylglycerols. Complex lipids remain at the starting point. Retention of phospholipids depends on the nature of the polar "head" and increases in the order: cardiolipin, phosphathidylethanolamine, phosphathidylserine, phosphatidylinositol, phosphatidylcholine [silica gel H, mobile-phase chloroform–methanol–acetic acid–water, 25 : 15 : 4 : 2 (v/v/v/v)]. Galactolipids can be separated with the same solvent system after the solvent proportions are changed to increase the polarity. Predictably, monogalactosyl diacylglycerols migrate ahead of digalactosyl diacylglycerols.

Identification of the lipid components is easily performed by applying a standard lipid mixture on the same plate prior to the development.

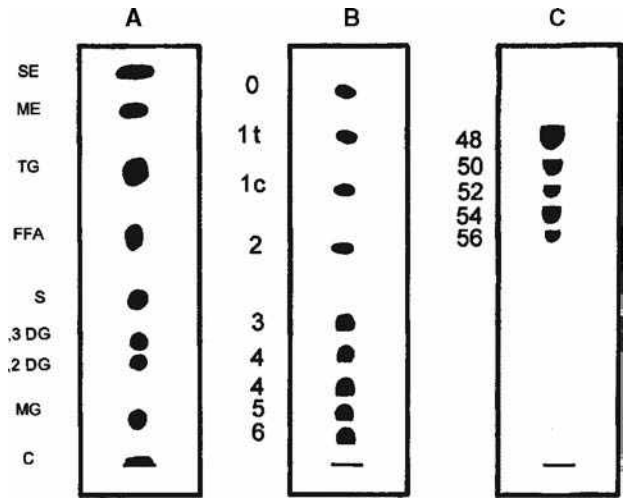

Fig. 1 Schematic presentation of lipid separation by TLC. (A) Reference mixture of simple lipid classes, silica gel TLC, mobile phase: hexane–ethyl ether–acetic acid, 80 : 20 : 2 (v/v/v); SE, sterol esters; ME, fatty acid methyl esters; TG, triacylglycerols; FFA, free fatty acids; S, sterols; 1,3-DG, 1,3-diacylglycerols; 1,2-DG, 1,2-diacylglycerols; MG, monoacylglycerols; C, complex lipids; detection by spraying with 5% ethanolic phosphomolibdic acid and heating for several minutes at 180°C. (B) Reference mixture of fatty acid methyl esters, Ag-TLC on silica gel layer impregnated with 0.5% methanolic solution of silver nitrate, mobile phase 5 ml of light petroleum ether–acetone–formic acid, 92 : 2 : 1 (v/v/v), development in open cylindrical tank; detection by treatment for 30 min with sulfurylchloride vapors and heating for 5 min at 180°C; the figures denote the number of double bonds, t, for a *trans* double bond, c, for a *cis* double bond. (C) triacylglycerols of the 001 class (0 for zero and 1 for one double bond in the molecule), RP-TLC on kieselguhr layer silanized by treatment with dimethyldichlorosilane vapors, mobile phase acetone–acetonitrile–water, 70 : 30 : 12 (v/v/v), detection by spraying with 50% ethanolic sulfuric acid and heating at 220°C for 10 min; the figures denote the partition number of the triacylglycerol species.

Separation by Ag-TLC

Ag-TLC is the modification with the most important impact on the development of lipid chemistry and has been of immense importance for the understanding of

lipid structure. The separation is based on the ability of unsaturated fatty acid residues in lipid molecules to form weak, reversible charge-transfer complexes with silver ions. Thus Ag-TLC separates lipid classes into molecular types depending on the number, configuration, and occasionally, on the position of the double bonds in the fatty acid residues.

The impregnation of the layer is performed by immersing the plate in a solution of the silver salt in methanol, acetone, or acetonitrile, or by spraying the plate with one of these solutions. Preparative plates are usually treated with 1–20% silver nitrate solutions. For analytical Ag-TLC, the concentration of silver nitrate varies in the range 0.5–10%. The impregnation procedures must be standardized to provide reproducible separation. Plates are left in the air for the solvent to evaporate and are usually activated prior to use (between 5 min and 1 hr depending on the purpose) by heating at 110°C.

The separation is affected by the dimensions of the tank, the volume of the mobile phase, the development mode (covered or "open" tanks, with or without saturation of the atmosphere, respectively), the atmospheric humidity, and the temperature. Ag-TLC plates are normally developed at ambient temperature.

Hexane or light petroleum ether, chloroform, benzene, and toluene are most often the major components of the mobile phase, while smaller proportions of diethyl ether, acetone, methanol, ethanol, or acetic acid are added as modifiers. Chloroform–methanol and hexane–acetone mobile phases reportedly provide very good separations. Often, more than one development is required for reliable resolution. The separation starts with the most polar phase and proceeds, after drying between runs, with mobile phases of gradually decreasing polarity. Highly unsaturated components are resolved first and do not move further with subsequent developments when the more saturated components are separated.

In general, the migration order of any lipid class is determined by the overall number of double bonds in the molecule. Thus the retention of common fatty acids (chain lengths of 16–22 carbon atoms, methylene interrupted double bonds) increases with increasing number of double bonds from 0 to 6 (Fig. 1B). For the triacylglycerols, which contain the above type of acyl residues, the order of increasing retention is: 000, 001, 011, 002, 111, 012, 112, 003, 112, 013, 113, 222, 023, 123, 223, 133, 233, 333 (the figures indicate the number of double bonds in the fatty acid residue but not the position in the glycerol backbone). The same order of retention is valid for complex lipids but, because of different technical difficulties, Ag-TLC is only rarely applied in the analysis of these lipids. Species with *cis*-double bonds are held stronger than those with *trans*-double bonds, and this differentiation is of great practical importance. Ag-TLC is capable, under specific conditions, of differentiating fatty acids and triacylglycerols according to the position of the double bond in the carbon chain.

Both handmade and precoated plates provide reliable separation of fatty acids. Successful separation of triacylglycerols has been achieved on handmade plates only.

Ag-TLC offers an effective means of fractionation of lipid mixtures into distinct fractions differing in the number of double bonds, thus ensuring unambiguous results by further chromatographic and spectral characterization. Ag-TLC serves also as an enrichment procedure for minor components and allows for a more accurate identification and quantification. Quantitative procedures have been developed for the determination of fatty acids and triacylglycerols by using Ag-TLC and densitometry.

Separation by RP-TLC

RP-TLC is less popular and has been applied, so far, only for the resolution of fatty acids and triacylglycerols. It is based on the distribution of lipid molecules between a non-polar stationary phase and a relatively polar mobile phase. Lipids are, therefore, separated according to their overall polarity, expressed by the Partition Number (PN). PN relates the migration of a component to the total number of carbon atoms, CN (in the acyl residues only) and the total number of double bonds, n, so that $PN = CN - n$; the higher is the PN, the stronger the component is retained in the non-polar layer (the lower the R_f value becomes).

RP-TLC also uses the common supporting facilities. In the laboratory, the non-polar stationary phase can be produced by impregnating the layer (kieselguhr G or silica gel G) with long-chain hydrocarbons or liquid paraffin or by treatment with dimethyldichlorosilane (DMCS). Although commercial RP-TLC plates are available, so far, experiments have only employed C_{18} plates.

Mobile phases that provide good separation for triacylglycerols include: 1) acetone–acetonitrile water, 70 : 30 : X (v/v/v, the water proportion, X, increases with the increasing unsaturation of the lipid class), which is suitable for handmade kieselguhr layers, treated with DMCS; and 2) acetonitrile-2-butanone-chloroform, 50 : 35 : 15 (by volume), which is suitable for precoated C_{18} plates.

At present, RP-TLC finds application only as a quantitative technique, complementary to the analytical and preparative Ag-TLC of triacylglycerols. The triacylglycerol mixture is first fractionated into classes according to the unsaturation, and then each class is subjected to RP-TLC to give a series of species with different PN. An example is shown in Fig. 1C.

Quantification

The most widely applied procedure is indirect quantification by extracting the fractions from the adsorbent layer in the presence of an internal standard, transmethylating, and

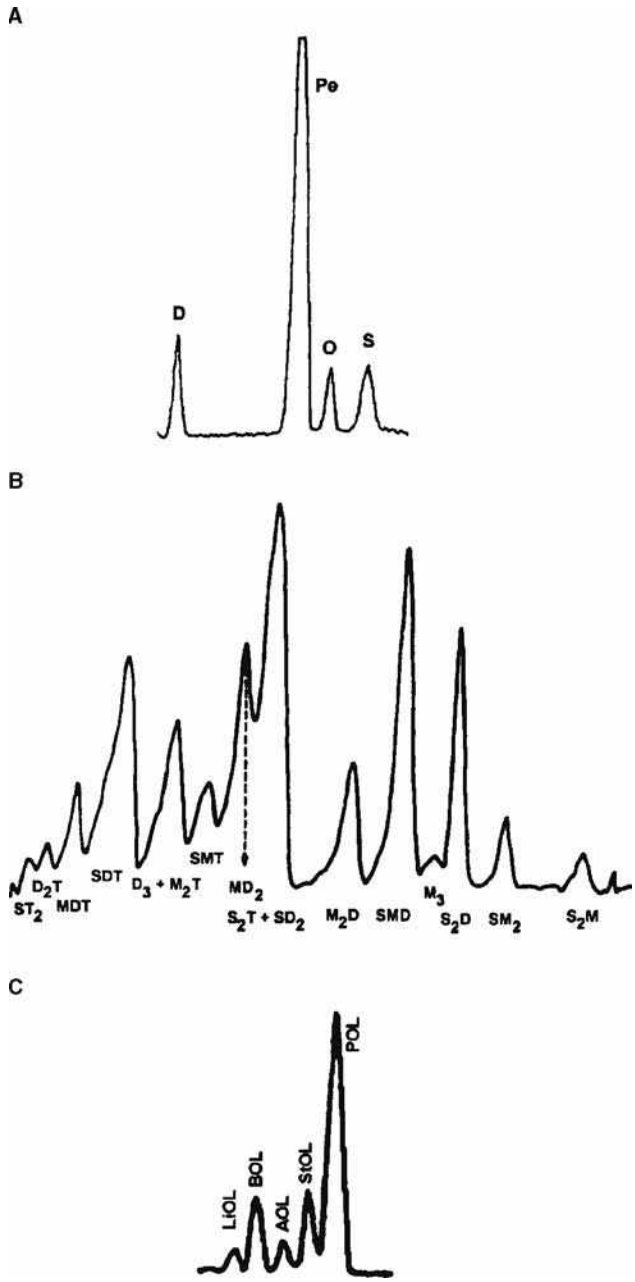

Fig. 2 Densitograms for quantitative determination of fatty acid and triacylglycerol in lipid samples produced on Shimadzu CS-930 scanner in zigzag reflection mode at 450 nm, beam slit varies depending on the sample. A) Determination of fatty acids, as phenacyl esters, in *Petroselinum sativum* seed oil by Ag-TLC, 4 × 19 cm glass plate covered with 0.2 mm thick silica gel layer; layer was impregnated by dipping with 1.0% methanolic silver nitrate and the plate was developed twice in closed cylindrical tank with 3 ml of chloroform–acetone, 100 : 0.25 (v/v); visualization by successive treatment with bromine (30 min) and sulfuryl chloride (30 min) vapors and heating on a hot plate at 180–200°C; scanning with beam slit 0.4 × 0.4 mm; S, saturated, O, oleic, Pe, petroselinic, D, dienoic fatty acid. B) Determination of lemon seed oil triacylglycerols by Ag-TLC, TLC plate as in panel A, impregnated by dipping with 0.5% methanolic silver nitrate and developed with 8 ml petroleum ether–acetone, 100 : 6 (v/v) in open cylindrical tank; visualization by successive treatment with bromine (30 min) and sulfuryl chloride (30 min) vapors and heating on a hot plate at 180–200°C; scanning with beam slit 1.2 × 1.2 mm; S, saturated, M, monenoic, D, dienoic, T, trienoic acyl residues. C) Determination of triacylglycerols by RP-TLC on kieselguhr layer silanized by treatment with dimethyldichlorosilane vapours, mobile phase acetone–acetonitrile–water, 70 : 30 : 18 (v/v/v), visualization by spraying with 50% ethanolic sulfuric acid and heating at 220°C for 10 min; P, palmitic, St, stearic, A, arachidic, B, behenic, Li, lignoceric, O, oleic, L, linoleic acyl residues.

subjecting the methyl esters of the fatty acids to GC analysis. Information is simultaneously obtained on the composition of the fractions and their absolute amounts. In practice, the sample is resolved on a preparative plate, each distinct zone is carefully scraped off, a standard solution of the internal standard (usually an odd-chain fatty acid methyl ester) is added, and the material is extracted with a suitable polar solvent such as diethyl ether or a chloroform–methanol mixture. More complicated extraction procedures are sometimes needed for polar complex lipids. Fatty acid methyl esters are directly subjected to GC while triacylglycerols and other lipids are usually transmethylated with the internal standard before analysis by GC. Indirect quantification is the method of choice in the determination of lipid classes.

Direct, in situ, quantification by scanning photodensitometry (a technique developed especially for TLC) is more advantageous. Densitometric measurements are based on the difference in optical response between the blank part of the plate and regions where the analytes are present. Nowadays, excellent instrumentation is available and the problems that arise are rarely a function of the densitometer and depend mainly on the properties of the chromatogram. A uniform layer, a clean background, well-resolved, distinct, and evenly stained zones, and good contrast between spots and background are required. Zigzag (or flying spot) scanning is greatly superior to linear scanning and should be preferred. Modern instruments are fully computerized and quantify the peaks in the most accurate, reproducible, and convenient manner.

The problem in applying scanning photodensitometry is that lipids do not possess any chromogenic groups and are usually visualized for direct quantification by charring and carbonization. Although charring is a sensitive detection procedure, all steps, including treatment of the plate with the charring reagent, and the temperature and duration of heating must be standardized as far as possible to obtain reproducible results. In most instances, the charring procedure is therefore the critical step. However, efforts to replace charring by another visualization procedure have not led to satisfactory results. An important requirement is that the charring reagent should react in an equal manner with all components, and in particular, staining should not be influenced by the different degree of unsaturation of the separated species. Spraying of the layer with charring reagents (50–70% aqueous, methanolic, or ethanolic solutions of sulfuric acid) or treatment with vapors of such charring reagents such as sulfuryl chloride have been tested, and which one to choose depends on the specific application of TLC.

The recommended procedure for densitometric quantification of fatty acid esters and triacylglycerol separated by Ag-TLC is the successive treatment of the plate with bromine and sulfuryl chloride vapors, followed by heating at 180–200°C (Fig. 2a and b). Correction factors are not required because the quantitative results do not depend on the unsaturation. Spraying with a 50% ethanolic solution of sulfuric acid is suitable for densitometric quantification of triacylglycerols separated by RP-TLC (Fig. 2c).

Lipid analysts have often been skeptical about the possibilities for quantification offered by densitometry, their opinions generally being formed by earlier experience when the instrumentation was quite primitive. Today, however, the situation is greatly changed and laboratories whose staff are well trained in silver ion TLC methods can successfully apply densitometry. It can be claimed that the overall procedure is cheaper and more suitable for routine analysis of large numbers of samples compared to any alternative technique, while providing results of the same range of accuracy and reproducibility.

Lipophilic Vitamins: TLC Analysis

Alina Pyka
Department of Analytical Chemistry, Medical University of Silesia, Sosnowiec, Poland

INTRODUCTION

Vitamins are organic compounds that have biochemical and physiological proprieties. Because of these qualities, they have been the subject of numerous scientific investigations. Vitamins are classified according to their solubility in water and in fats. Lipophilic (hydrophobic) vitamins are vitamins A, D, E, and K. Chromatography is useful in the identification and determination of vitamins in pharmaceutical preparations, the identification and determination of vitamins and related substances in natural materials and foodstuffs, and the chemical and biochemical determination of vitamins and their metabolites in fats and tissues.

Vitamins that are soluble in fat (lipophilic vitamins) are the subject of wide investigations because of their biological proprieties. High-performance liquid chromatography (HPLC), thin-layer chromatography (TLC), and gas chromatography (GC) are the principal techniques used for qualitative and quantitative investigations of lipophilic vitamins. Analysis of lipophilic vitamins by liquid chromatography (LC) (TLC and HPLC) is the subject of many scientific publications.

Generally, TLC is useful for the investigation of a wide range of lipophilic vitamin applications, i.e., purification of samples, qualitative detection, quantitative determination, and the use of new visualizing agents, and also for separation of some optical isomers.[1,2]

The aim of this entry is to present selected works that describe the analytical separation of lipophilic vitamins by means of TLC.

VITAMIN A

Physiological forms of vitamin A include retinol (vitamin A_1) and its esters, 3-dehydroretinol (vitamin A_2) and its esters, retinal (retinene, vitamin A aldehyde), 3-dehydroretinal (retine-2), retinoic acid, neovitamin A, and neo-β-vitamin A_1. Active analogs and related compounds known as vitamin A are α-, β-, and γ-carotene, neo-β-carotene B, cryptoxanthine, myxoxanthine, torularhodin, aphanicin, and echinenone. Kitol, xanthophyll, and others are inactive analogs and related compounds of vitamin A. Vitamin A supports the formation of the cells of the skin and is essential for vision. It is involved in the viability of the reproductive system by acting as a hormone and regulating the expression of specific genes. Good sources of vitamin A are fish liver oil from cod, salmon, halibut, and shark, chicken, eggs, milk, cheese, butter, and liver. Vitamin A occurs as retinyl esters in foods of animal origin. Vitamin A_1 is susceptible to oxidation and degradation. Therefore, control of the vitamin A level in foodstuffs is recommended. Foods of plant origin do not contain vitamin A, but are rich sources of previtamin A. About 50 of the 500 known carotenoids may be converted to vitamin A. β-Carotene is the most important of the carotenoids that occur in nature. β-Carotene (provitamin A), precursor of vitamin A, is found in plants. Good sources are yellow-orange fruits and vegetables, and green leafy vegetables (carrots, apricots, collard green, sweet potatoes, spinach, mangoes, mustard greens, turnip, and sweet red peppers). Both vitamin A and carotenoids with and without provitamin A activity appear to show anticancer effects. Vitamin A plays an essential role in protecting the body from infection.

Sliwiok, Podgorny, and Siwek[3] used TLC and HPLC to compare the hydrophobicity of vitamin A derivatives. TLC was performed on RP-2 F_{254} and Kieselguhr F_{254} (impregnated with 10% paraffin oil in cyclohexane) with methanol–water (95 : 5, v/v). R_M values were –0.60, –0.51, –0.37, and 0.09 on RP-2F_{254} plates and –1.59, –0.84, –0.22, and 1.18 on paraffin oil-impregnated Kieselguhr for all-*trans*-retinic acid, all-*trans*-retinal, vitamin A acetate, and vitamin A palmitate, respectively. The separations of the vitamin A derivatives on the paraffin oil-impregnated plates were better than those on the RP-2 plates. The log *P* values calculated from fragmental constants by Rekker for all-*trans*-retinic acid, all-*trans*-retinal, vitamin A acetate, and vitamin A palmitate are 4.85, 6.48, 7.92, and 15.30. The relationship obtained by the authors on the basis of R_M and log *P* values confirms the following sequence of increasing hydrophobicity: all-*trans*-retinic acid < all-*trans*-retinal < vitamin A acetate < vitamin A palmitate.

Two separate methods all-*trans*- and 13-*cis*-retinoic acids, one for gel and one for cream samples, were described by De Paolis.[4] A methanol extract of the gel formulation may be analyzed directly on high-performance TLC (HPTLC) silica gel plates eluted with diethyl ether–cyclohexane–acetone–glacial acetic acid (40 : 60 : 2 : 1, v/v/v/v). This method gives fast and complete resolution of the two isomers with a detection limit

of about 20 ng for each of them. Methanol extracts of the cream samples contain interfering excipients, which require cleaning prior to chromatography. This was accomplished conveniently on a reversed-phase C_{18} and normal-phase silica gel, two-dimensional TLC plate. The C_{18} reversed phase separated the cream excipients from the isomers of retinoic acid using ethanol–distilled water (80 : 20, v/v) as mobile phase. The normal phase on silica gel resolved both isomers all-*trans*- (R_F 0.34) and 13-*cis*-retinoic acid (R_F 0.39). This two-dimensional separation of all-*trans*- and 13-*cis*-retinoic acid is shown in Fig. 1.[4]

Recent publications concern the qualitative and the quantitative determination of β-carotene by TLC. Isomerization of α- and β-carotene was catalyzed by iodine according to the method of Zechmeister.[5] Fig. 2A illustrates typically developed TLC plates for a mixture of α- and β-carotene isomers.[5] Two-dimensional TLC was done on calcium hydroxide plates with 1.2% acetone in petroleum ether as mobile phase. Expected isomers from the iodine-catalyzed reaction are neoisomers U and B for β-carotene and neoisomers U, W, and B for α-carotene.[5] Photoisomerization of all-*trans*-α- and β-carotene solutions was also conducted by Nyambaka and Ryley.[6] This photoisomerization of individual all-*trans*-α- and β-carotene solutions produced several isomers each. Nyambaka and Ryley[6] applied the separation TLC method, which was done by Schwartz and Patroni-Killam,[5] to isolate and collect major isomers of β-carotene (13-*cis*-, all-*trans*-, 9-*cis*-, and 7-*cis*-). Fig. 2B illustrates a typical plate obtained by Nymbaka and Ryley[6] for β-carotene isomers from iodine-catalyzed photoisomerization. After extraction of the zones by TLC, the isomers were identified by their behavior in UV–Vis absorbance spectra. This method was applied to dark green leafy vegetables (Italian spinach, sprig cabbage, and cowpea leaves).

The carotenoid composition, including β-carotene, of *Rosa canina* fruits was determined by TLC with densitometric analyses and also by HPLC. The peaks of the extracts obtained from TLC densitograms were identified as β-carotene, lycopene, β-cryptoxanthin, rubixanthin, and zeaxanthin mixed with lutein (R_F 0.96, 0.90, 0.62, 0.53, and 0.32, respectively) on silica gel with 15% (v/v) acetone in petroleum ether. The distribution of these compounds was reproducible by TLC as well as by HPLC.[7]

Small amounts of intensely colored pigments can be detected in UV light and also in visible light; the limit of detection is 0.01 μg of the carotenoids. Retinal (0.02–0.03 μg) can be detected after spraying rhodamine (orange-red spot of retinal). Many vitamin A compounds fluoresce yellow-green in light at 365 nm (limit of detection 0.05 μg). Vitamin A compounds can be detected with antimony(III) chloride (Carr–Price reagent) and antimony(V) chloride (blue spots), with concentrated sulfuric acid (blue color of spot),[4,8] with molybdophosphoric

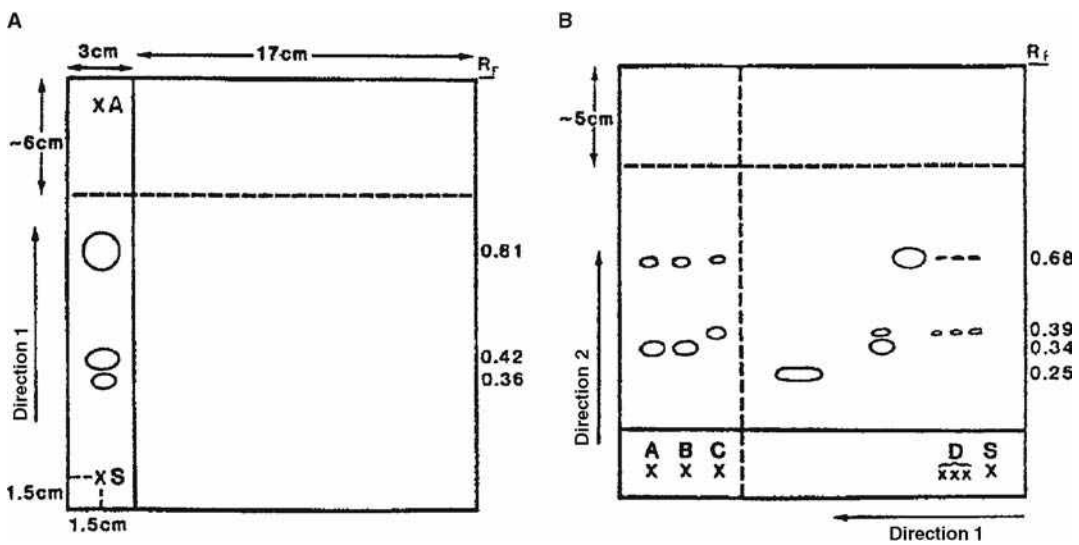

Fig. 1 Typical chromatograms of (A) the cream sample on the Multi-K CS5 TLC plate after development in solvent system B (80% ethanol in water), and (B) the cream sample and standards, tretinoin and 13-*cis*-retinoic acid (13-*cis*-Ra), after development in solvent system A (diethyl ether–cyclohexane–acetone–glacial acetic acid, 40 : 60 : 2 : 1). The spotting areas are designated as follows: S = sample; A and B = tretinoin standard stock solution at the beginning of analysis and just before development in direction 2, respectively; C and D = 13-*cis*-RA standard test solutions. The broken lines represent solvent fronts. The R_F values in (A) are 0.81 for plar excipients, 0.42 for tretinoin and 13-*cis*-RA, and 0.36 for butylated hydroxytoluene (bHT). In (B), the R_F values are 0.25 for polar excipients, 0.34 for tretinoin, 0.39 for 13-*cis*-RA, and 0.68 for BHT.

acid (green-blue spots), and with potassium dichromate in sulfuric acid (limits of detection 0.1–0.3 μg). The limit of detection of retinol isomers converted to 2,4-dinitrophenylhydrazones of retinals is 1 μg.[1,2,8] Bromophenol blue was also used for detection of vitamin A (3 μg) after adsorption TLC.[9]

VITAMIN D

Physiological forms of vitamin D include vitamin D_2 (calciferol, ergocalciferol), vitamin D_3 (cholecalciferol), phosphate esters of D_2, D_3, 25-hydroxycholecalciferol, 1,25-dihydroxycholecalciferol, and 5,25-dihydroxycholecalciferol. Vitamins D_2 and D_3 are 9,10-secosteroids, which differ structurally in the degree of saturation of an isoprenoid side chain. The biological activity of vitamin D_3 is greater than that of vitamin D_2. Vitamin D_2 is of vegetable origin, whereas D_3 is formed in the skin of humans and animals. From the chemical standpoint, ergocalciferol (vitamin D_2) is a relatively stable vitamin. Active analogs and related compounds known as vitamin D include 22-dihydroergosterol (vitamin D_4), 2-dehydrostigmasterol (vitamin D_6), and 7-dehydrositosterol (vitamin D_5). Lumisterol, tachysterol, ergosterol, and 7-dehydrocholesterol are inactive analogs and related compounds of vitamin D. Vitamins D_2 and D_3 are photochemically derived from their precursors ergosterol (provitamin D) and 7-dehydrocholesterol, respectively. Vitamins D_2 and D_3 are precursors of hormones. Vitamin D_3, which has little biological activity is converted into biologically active metabolites by oxidation.

Kocjan and Śliwiok[10] determined the hydrophobicity of vitamins D_2 and D_3 by RPTLC, thin-layer adsorption chromatography, and IR spectrometry. Partition TLC separations of vitamins D_2 and D_3 were done on TLC plates precoated with Kieselguhr F_{254} (E. Merck) impregnated with 10% paraffin oil in benzene and developed to 10 cm with binary mixtures of methanol–water (9.5 : 0.5, v/v; R_F values 0.56 and 0.48, respectively) and acetonitrile–water (9.5 : 0.5, v/v; R_F values 0.50 and 0.41, respectively). Adsorption TLC was done on glass plates precoated with activated silica gel 60 F_{254} (E. Merck), with a mobile phase of benzene–methanol (9 : 1, v/v). Measurement of the surface of chromatographic spots (141.0 and 99.5 mm^2 for vitamins D_2 and D_3, respectively) obtained by adsorption TLC gave hydrophobicity coefficients (h_f values are 6.09 and 9.05 for vitamins D_2 and D_3, respectively). The results indicate that the hydrophobicity of vitamin D_3 is greater than that of vitamin D_2. This conclusion was proved by the lower R_F values for vitamin D_3 obtained by partition chromatography, the higher values of the respective hydrophobicity coefficients, and by the greater relative decreases in the ratio of free to bonded OH groups (obtained by spectrometry measurement). It was apparent from the literature that the biological activity of vitamin D_3 is greater than that of vitamin D_2. The authors concluded that the molar weight of vitamin D_2 is greater than that of vitamin D_3; the double bond in the hydrocarbon chain of vitamin D_2 results in its lower hydrophobicity.[10]

Justova and Starka[11] described TLC separations of vitamin D_3 and its hydroxymetabolites. They tested three stationary phases [Kieselgel 60F_{254} (E. Merck), Silufol UV 254 (Kavalier, Sávaza, Czech Republic), and silica gel 6061 (Eastman-Kodak, Rochester, U.S.A.)] and one relatively polar mobile phase (chloroform–ethanol–water, 183 : 16 : 1, v/v/v). The optimal separation was achieved on Kieselgel 60F_{254} foils produced by E. Merck; the R_F values were 0.69, 0.35, 0.56, 0.20, 0.41, and 0.30 for D_3, 1-OH-D_3, 25-OH-D_3, 1,25-$(OH)_2$-D_3, 24,25-$(OH)_2$-D_3, and 25,26-$(OH)_2$-D_3, respectively.[11] In biological samples, the vitamin D_3 hydroxymetabolite contents are at nanogram levels, which is below the limit of sensitivity of the applied visualization methods (UV light and the anisaldehyde reagent). Therefore, the

hydroxycholecalciferols were localized with corresponding metabolites used as markers. The vitamin D_3 metabolites were then scraped off and extracted with ethanol, and eluates were examined for radioactivity. The complete chromatographic procedure on the accuracy and precision of the determination was presented. The recovery of the markers in five replicate determinations was 97.8 ± 2.9% for vitamin D_3 and 98.7 ± 1.5% for 25-OH-D_3.

Thierry-Palmer and Kenney-Gray[12] compared HPTLC and TLC methods for the analysis of vitamin D_3 as well as the mono- and dihydroxylated metabolites of vitamin D_3. TLC was performed on silica gel HPTLC-HLF and GHLF plates (Analtech, Newark, Delaware, U.S.A.) without previous activation. The mixtures dichloromethane–isopropanol (90 : 10, v/v), hexane–isopropanol (85 : 15, v/v), and chloroform–ethyl acetate (50 : 50, v/v) were applied as mobile phases. Migration distances were 7 cm for HPTLC plates and 14 cm for the conventional TLC plates. Generally, the effectiveness of separation by conventional TLC was very similar to that by HPTLC (Table 1).[12] 23,25-Dihydroxyvitamin D_3 and 24,25-dihydroxyvitamin D_3 separate faintly using dichloromethane–isopropanol (90 : 10, v/v) and HPTLC and conventional TLC plates as well as using chloroform–ethyl acetate (50 : 50, v/v) and conventional TLC plates. Therefore, the system of choice would depend on the metabolite of interest. However, the separations by HPTLC were faster (developing times were 11–12 min) than those by conventional TLC (developing times were 35–45 min).[12]

Spots of vitamin D derivatives can be inspected in short-wavelength UV light (limit of detection 0.025–0.5 μg). The mono- and dihydroxycholecalciferols can be visualized under UV light at 254 nm or by spraying the foil with a solution of anisaldehyde in sulfuric acid (2%, w/v) mixed with glacial acid (1 : 10, v/v) at 40°C. Vitamins D_2 and D_3 can be detected with antimony(III) chloride (Carr–Price reagent) and antimony(V) chloride (gray-blue and orange-red spots, respectively; limit of detection 0.025–0.3 μg), with concentrated sulfuric acid (brown and green spots, respectively, of vitamins D_2 and D_3; limit of detection 30 μg), with tungstophosphoric acid (gray-brown spots; limit of detection 0.2 μg), with molybdophosphoric acid (gray-blue spots; limit of detection 0.3 μg), and with trichloroacetic and trifluoroacetic acids (limit of detection 0.1–0.2 μg).[1,2,8] Vitamins D_2 and D_3 separated by adsorption TLC were visualized with 0.005% aqueous new fuchsine solution.[10] A densitogram of vitamin D_3 after a spraying of antimony(III) chloride (Carr–Price reagent) is given by Jork et al.[8] Vitamin D_3 was also detected with sodium hydroxide (yellow and orange spots in visible and UV light, respectively; limit of detection 1–8 μg), with iron(III) chloride (brown-red spot in visible light; limit of detection 8 μg), with iodoplatinate (black and brown spots in visible and UV light, respectively; limit of detection 1–8 μg), and with phosphomolybdate (pinkish brown spot in visible light; limit of detection 8 μg).[13] Bromocresol green, bromothymol blue, and helasol green can be used for detection of vitamins D_2 and D_3 after adsorption TLC (limit of detection 5 μg) and partition TLC (limit of detection 50 μg), respectively.[9]

VITAMIN E

The known physiological forms of vitamin E are D-α-tocopherol, tocopheronolactone, and their phosphate esters. Active analogs and related compounds known as vitamin E are DL-α-tocopherol, L-α-tocopherol, esters (succinate, acetate, phosphate), β, ζ_1, and ζ_2-tocopherols. δ-, ε-, and η-Tocopherols are inactive analogs and related to vitamin E.[1,2] In nature, vitamin E occurs in eight different forms (α-, β-, γ-, and δ-tocopherols and α-, β-, γ- and δ-tocotrienols) with varying biological activities. The biological properties of α-tocopherol are of particular importance. Of these eight compounds, α-tocopherol has the highest biological activity. Tocopherol possesses three asymmetric carbon atoms, and there are eight possible stereoisomeric tocopherols. Natural α-tocopherol occurs as the enantiomer about the configuration 2*R*, 4′*R*, 8′*R*.

Table 1 Comparison of separations of the hydroxylated metabolites of vitamin D_3 and vitamin D_3 by HPTLC and TLC methods.

	R_F values

Semisynthetic α-tocopherol is a mixture of the diasteroisomers about configuration 2*R*/*S*, 4′*R*, and 8′*R*. The antioxidative effect of the different tocopherols may not be identical. It has been shown in antioxidation tests with foodstuffs that the antioxidative activity of the tocopherols increases in the order γ-, δ-, β-, and α-tocopherol. Vitamin E occurs principally in wheat germ, vegetable oil, and vegetables.

α-, β-, γ-, and δ-Tocopherols were separated (R_M values 0.438, 0.037, 0.008, and –0.275, respectively) on Kieselguhr G plates impregnated with a 10% solution of paraffin oil in hexane and a mobile phase of methanol–water (9.5 : 0.5, v/v) by Sliwiok and Kocjan.[14] They correlated their results with those of quantum-mechanical calculations and respective steric effects. Hydrophobic constants h_f were determined by adsorption TLC and partition coefficient by Rekker as well as the sum of the net electron charges ($\sum$ NEC) on the tocopherols' –C–O–H groups were calculated for the investigated tocopherols (Table 2).[14] It was established that the investigated tocopherols can be arranged with respect to their lipophilic properties in the order α-tocopherol > β-tocopherol > γ-tocopherol > δ-tocopherol. But, enantiomers of DL-α-tocopherol were separated on Chiralplates (Machery-Nagel, Germany) with 2-propanol–water–methanol (17 : 2 : 1, v/v/v) as mobile phase.[15] Under these conditions, two bands were generated with R_F values of 0.72 and 0.62.

α-, β-, γ-, and δ-Tocopherols were also separated by reversed-phase high-performance TLC (RP-C18-HPTLC), normal-phase HPLC, reversed-phase HPLC (RP-C18-HPLC), and GC.[16] R_M values of the α-, β-, γ- and δ-tocopherols investigated by RP-18-HPTLC and ethanol–water as mobile phase are shown in Table 2.[16] The chromatographic conditions can be used to allow for the separation of the four tocopherols in various biological samples. The selected topological indices based on connectivity–adjacency matrix (M^{ν}, $^1\chi^{\nu}$), on distance matrix (W, ^0B, MTI) and on information theory (I_{AC}, $\bar{I}_{AC}$) were calculated for these tocopherols. The observed chromatographic separations of investigated tocopherols were compared. The comparison indicated that RP-C18-HPTLC, HPLC, and GC are the best techniques for the separation of these tocopherols. Topological index ^0B was the most significant. A definite dependence between the numerical values of the topological index ^0B and the chromatographic separation of the investigated tocopherols was obtained.[16] α-, β-, γ-, and δ-Tocopherols were also separated by RP-TLC on C_{18} plates using seven different mobile phases (methanol, ethanol, *n*-propanol, and mixtures containing ethanol and water, and *n*-propanol and water in the volume proportions 9.5 : 0.5, and 9 : 1, v/v).[17] The R_M values obtained are presented in Table 2.[17] The R_M values of the compounds were correlated with the numerical values of the topological indexes, the sum of the net electron charge ($\sum$ NEC) on the tocopherols' –C–O–H groups, the moment dipoles (μ_{mph}), and the permittivities (ε_{mph}) of the mobile phases. Most accurate prediction of the R_M values of the tocopherols in all the mobile phases investigated was achieved by the use of two parametric equations employing the dipole moments of the mobile phases, and one topological index from among the topological indexes $^2\chi^{\nu}$, ^0B, C, or the sum of the net electron charge ($\sum$ NEC).[17] For example:

$$R_{M(all)} = -25.3626(\pm 2.4142) + 11.1984(\pm 0.5350)\mu_{mph} + 3.1933(\pm 1.0329)^0B \quad (1)$$

($n = 28$; $R^2 = 94.70\,\%$ $F = 223.5$; $s = 0.114$; $P < 0.0001$.)

Ruggeri et al.[18] investigated DL-α-, DL-γ-, and DL-δ-tocopherol, DL-α-tocotrienol, and DL-tocol by TLC and HPLC. TLC was performed on silica gel GF plates (Analtech, Newark, Delaware, U.S.A.) using hexane–isopropyl ether (85 : 15, and 80 : 20, v/v) as mobile phase, and a scanning densitometer operating at 350 nm. Fig. 3 illustrates the chromatogram obtained by Ruggeri et al.[18] for analysis of the

standard compounds. The HPLC system used a Varian MCH 10 C18 Micropak column (30 cm × 4 mm), methanol–water (95 : 5, v/v) as mobile phase (2 ml/min), and detection at 296 nm. The two systems (TLC and HPLC) were considered comparable in sensitivity, reproducibility, recovery (~ 91%), and ease of application.[18]

Olejnik, Gogolewski, and Nogala-Kałucka[19] have determined α- and γ-tocopherols and plastochromanol-8 in linseed oil. TLC was applied for purification of unsaponifiable fraction of linseed oil. TLC was carried out on silica gel G. Chromatograms were developed by means of chloroform, which separated PC-8 and α-tocopherol from γ-tocopherol (Fig. 4A).[19] After reapplication, hexane–diethyl ether (19 : 1, v/v) separated PC-8 from α-tocopherol (Fig. 4B).[19]

Vitamin E compounds can be detected (about 20 μg) as dark spots in UV light. They appear violet, and detection is more sensitive (0.02 μg) on layers that contain 0.02% Na-fluorescein. Moreover, these are visible in daylight as red spots (limit of detection 2 μg). Spraying with fluorescein or dichlorofluorescein reagent produces the same effect. Non-specific visualization procedures for tocopherols and tocotrienols are based on spraying with sulfuric acid, molybdophosphoric acid, antimony(V) chloride, dipyridyliron reagent, nitric acid, copper(II) sulfate–phosphoric acid, and bathophenanthroline. α-Tocopherol was also visualized by a coupled redox–complexation reaction with iron (III), phenanthroline, and bromophenol blue.[1,2,8] Aniline blue, alkaline blue, and bromothymol blue can be also used for detection of vitamin E (1 μg)

after adsorption TLC.[9] When β-carotene was used as a TLC spray reagent, tocopherols (10 μg) appeared as yellow spots against a white background.[1,2,8] The densitogram of D-α-tocopherol after spraying dipyridyliron reagent was given by Jork et al.[8]

VITAMIN K

Physiological forms of vitamin K are vitamin K_1 (phylloquinone, phytonadione) and vitamin K_2 (farnoquinone). Active analogs and related compounds known as vitamin K are menadiol diphosphate, menadione (vitamin K_3), menadione bisulfite, phthiocol, synkayvite, menadiol (vitamin K_4), menaquinone-*n* (MK-*n*), ubiquinone (Q-*n*), and plastoquinone (PQ-*n*). Reduced vitamin K is an inactive analog. Dicoumarol, sulfonamides, antibiotics, α-tocopherol quinone, dihydroxystearic acid glycide, salicylates, iodinin, and warfarin are antagonists of vitamin K. Vertebrates and some bacteria (intestinal bacteria in humans) are exogenous sources of vitamin K. Endogenous sources of vitamin K are plants, bacteria, and all other organisms that require it. Phylloquinone (K_1), and menaquinone-4 (MK-4) are natural K vitamins and are often used as medicine to prevent intracranial hemorrhage in the newborn. Vitamin K contributes to the formation and regulation of numerous proteins in the body, but most significantly to prothrombin, a protein essential for blood clotting. Vitamin K is also necessary for converting prothrombin to thrombin, which is also required for blood clotting. Vitamin K is a key factor in the creation of many important nutrients and proteins necessary for essential body functions.

Argentation TLC (on silver nitrate-impregnated silica gel plates) and hexane–ethyl acetate–diisopropyl ether (2 : 2 : 1, v/v/v) as mobile phase were used to separate vitamins K_1, K_2, K_3, ubiquinone-6, ubiquinone-9, and ubiquinone-10 (R_F values 0.71, 0.63, 0.57, 0.42, 0.21, and 0.28, respectively).[20]

Hachuła[21] developed a sensitive spectrophotometric method for determination of vitamin K_4 in drugs (Styptobion, E. Merck) after chromatographic separation on silica gel with benzene–acetone (9 : 1, v/v) as mobile phase. Beer's law was obeyed for 0.3–1 μg/ml vitamin K_4 ($\varepsilon = 196{,}000$). No detection limit was given. The results obtained from proposed analytical procedure were in accordance with those expected and the precision of the measurement was satisfactory. The proposed method is rapid and has rather low analysis costs. Pharmaceutical preparations, including tablets, coated tablets, and injection solution, containing vitamin K_1 (I), vitamin K_3 (II), or vitamin K_4 (III), were analyzed by TLC/spectrophotometry.[22] TLC was done on silica gel HF_{254} (E. Merck) with the following mobile phases: benzene–ethyl acetate (97 : 3, v/v) for K_1, cyclohexane–chloroform–methanol–glacial acetic acid (2 : 15 : 3 : 1, v/v/v/v) for K_2, and benzene–acetone lpar;9 : 1, v/v) for K_3. The spots, located with 254-nm radiation, were scraped off, extracted with ethanol (for I), water (for II) or methanol (for III), and the vitamins were determined at 251, 234, or 225 nm, respectively, by using suitable calibration graphs.[22]

All lipoquinones at levels of 0.5 μg or more are visible as dark spots on layers containing inorganic fluorescent material when illuminated with UV light, after adding Na-fluorescein or rhodamine B or 6G to the adsorbent or by spraying the chromatographed layer with fluorescein or dichlorofluorescein reagents. These compounds can be detected in daylight and, with high sensitivity, in UV light. Vitamin K compounds can be detected with iodine vapor (brown spots), with concentrated sulfuric acid followed by heating (violet spots, limit of detection 3 μg), with molybdophosphoric acid (gray-blue spots, limit of detection 0.5 μg), and with potassium hexaiodoplatinate reagent. Long and shortwave UV light were used to detect vitamin K; under shortwave UV light, vitamin K showed an intense purple color. Vitamin K_1 was also detected with antimony(III)chloride (pink spots in visible light, limit of detection 8 μg), with iron(III) chloride (blue spot in visible light; limit of detection 8 μg), with sulfuric acid (green-brown spot in visible light; limit of detection 8 μg), with iodoplatinate (yellow and brown spots in visible and UV light, respectively; limit of detection 1–8 μg), and with phosphomolybdate (black spot in visible light; limit of detection 8 μg).[1,2,8]

SEPARATION OF MIXTURES OF LIPOPHILIC VITAMINS AND OF LIPOPHILIC VITAMINS FROM OTHER COMPOUNDS

Chromatographic systems have been developed for the reversed-phase TLC separation of lipophilic vitamins on RP-18 as stationary phase.[23] A mixture of lipophilic vitamins (A acetate, E, E-acetate, and D_3) was separated using acetonitrile–benzene–chloroform (10 : 10 : 1, v/v) as mobile phase (Table 3).[23] The applied chromatographic conditions do not permit the separation of vitamin E and vitamin E-acetate. Derivative spectrometry was used to determine vitamin A acetate in mixtures of other lipophilic or water-soluble vitamins. Spectrophotometric analysis of lipophilic vitamins enables determination of vitamin A-acetate in the presence of vitamins E, E-acetate, and D_3 and also C, B_1, and nicotinamide.

The satisfactory separation of D-α-, D-β-, D-γ-, and D-δ-tocopherol, and vitamin A acetate (R_F values 0.362, 0.287, 0.255, 0.165, and 0.635, respectively) was obtained on silica gel G using cyclohexane–*n*-hexane–isopropyl ether–ammonium hydroxide (40 : 40 : 20 : 2, v/v/v/v) as mobile phase.[24]

Perisic-Janjic, Petrovic, and Hadzić[25] described a method for the quantitative analysis of lipophilic vitamins

Table 3 R_F values of hydrophobic vitamins separated on various supports.

Support Vitamin	RP-18	Starch	Cellulose	Talc

K_3	—	0.45[c]	0.57[c]	0.60[c]
K_4	—	0.84[c]	0.77[c]	0.47[c]
K_5	—	0.26[c]	0.18[c]	0.09[c]

[a]Mobile phase: acetonitrile–benzene–chloroform (10 : 10 : 1, v/v/v).
[b]Mobile phase: acetone–concentrated acetic acid (3 : 2, v/v); stationary phase impregnated with paraffin oil.
[c]Mobile phase: water–dioxane–acetone–formaldehyde (85 : 20 : 15 : 25, v/v/v/v).
Adapted from Baranowska & Kadziolka[23] and Perisic-Janjic, Petrovic, & Hadzić.[25]

by TLC on starch, cellulose, and talc impregnated with paraffin oil. Vitamin A acetate, A palmitate, K_1, DL-α-tocopherol, DL-α-tocopherol acetate, D_2, and D_3 were separated with acetone–concentrated acetic acid (3 : 2, v/v), while vitamins K_3, K_4, and K_5 migrate to the front (Table 3).[25] Vitamins K_3, K_4, and K_5 can be separated on starch, cellulose, and talc using mixture of water–dioxane–acetone–formaldehyde (85 : 20 : 15 : 25, v/v/v/v) as mobile phase (Table 3).[25] Differences between the R_F values were satisfactory (except vitamins A-acetate, D_2, and D_3) and allowed for accurate identification. However, identification was still possible. Vitamin A-acetate gives blue color with $SbCl_5$ indicator, while vitamins D_2 and D_3 give reddish brown color seen as two connected spots of different colors.[25]

Most of the prenyllipids, such as chlorophylls, carotenoids, and prenylquinones, as well as tocopherols and vitamin K_1, which occur in plant lipid extracts, can be separated by TLC using silica gel plates or special mixtures of silica gel with other adsorbents.[20] But the compounds with one double bond per isoprene and others with a partially or fully unsaturated isoprenoid chain can be separated efficiently by argentation TLC. The R_F values of selected lipophilic vitamins, their provitamins, and related compounds separated by argentation TLC using different mobile phases are listed in Table 4.[20]

Wardas and Pyka[9] separated vitamins D_2, D_3, acid of vitamin A, and DL-α-tocopherol by NP-TLC and RP-TLC. Vitamins D_2 and D_3 could not be separated by NP-TLC and RP-TLC. Eleven visualizing reagents were used for detection of vitamins on TLC plates. It was found that more advantageous visualizing effects for all investigated vitamins were

obtained on adsorption TLC compared with partition TLC. In adsorption TLC, the limits of detection found for the vitamins followed the pattern DL-α-tocopherol > acid of vitamin A > vitamin D_2 and D_3. After separation using adsorption TLC, the best results were obtained with aniline blue, alkaline blue, phenol red, bromocresol green, and brilliant-cresyl blue, and bromophenol blue. After separation using partition TLC, the best results were obtained with bromothymol blue and helasol green. The R_F values and color formation of vitamins D_2, D_3, acid of vitamin A, DL-α-tocopherol with selected visualizing reagents are listed in Table 5.[9]

On silica gel plates (LK6DF Linear-K silica gel), diphacinone, pindone, valone, warfarin, bromadiolone, vitamins K_1 and D_3 were separated with three tested mobile phases (1,2-dichloroethane–methanol–glacial acetic acid, 90 : 8 : 2, v/v/v; chloroform–methanol, 97 : 3, v/v; and cyclohexane–1,2-dichloroethane–glacial acetic acid (75 : 25 : 0.6, v/v/v). No single phase used could separate all seven compounds. However, vitamins

[c]Mobile phase: chloroform—methanol, 97 : 3, v/v.
Adapted from Wardas & Pyka[9] and Opong-Mensah & Porter.[13]

K_1 and D_3 were separated with a mixture of 1,2-dichloromethane–methanol–glacial acetic acid (90 : 8 : 2, v/v/v), and with a mixture of chloroform–methanol (97 : 3, v/v).[13] The R_F values obtained using chloroform–methanol (97 : 3, v/v) and color formation of vitamins D_3, and K_1 with spay reagents are listed in Table 5.[13]

Densitometrical analysis is the most important method of detection of organic compounds including lipophilic vitamins. Jork et al.[8] investigated vitamin D_3 and D-α-tocopherol on HPTLC Kieselgel 60 (Merck) plates using cyclohexane–diethylether (40 : 20, v/v) and toluene–chloroform (10 : 10, v/v), respectively. Fluorescence scan of a chromatogram track with 50 ng vitamin D_3 per chromatogram zone is presented in Fig. 5A.[8] Reflectance scan of a chromatogram track with 200 ng D-α-tocopherol per chromatogram zone is presented in Fig. 5A.[8]

CONCLUSIONS

In the present entry, TLC in the investigation of lipophilic vitamins was shown. It was shown that TLC as the separation method assures qualitative and quantitative investigation of lipophilic vitamins. Considering the development of densitometry and spectrodensitometry, the analysis of these vitamins is becoming more common. The application of TLC techniques, together with a densitometric scanning apparatus, now allows precise and sensitive quantification of vitamins A, D, E, and K compounds on TLC plates. The application of TLC to the separation of mixtures of fatty vitamins as well as their derivatives was introduced simultaneously. Generally, we can say that TLC stands up as the important investigative technique in relation to different chromatographic techniques. The presented data indicate that TLC can be further developed to investigate lipophilic vitamins.

Lipophilicity: Assessment by RP/TLC and HPLC

Anna Tsantili-Kakoulidou
Department of Pharmaceutical Chemistry, University of Athens, Athens, Greece

INTRODUCTION

The purpose of this review is to summarize the conditions used to derive chromatographic lipophilicity indices, to appraise associated difficulties, and to provide an overview of their relation with octanol–water partition coefficients. In this aspect, both techniques will be discussed in parallel.

LIPOPHILICITY

The major importance of lipophilicity in drug design has been well established since the pioneering work of Hansch in the 1960s. Penetration across biological membranes during drug transport, hydrophobic interactions with receptors, as well as toxic aspects of drug actions are governed, to a great extent, by this property.[1,2] The most widely accepted measure of lipophilicity is the octanol–water partition coefficient, which is expressed in its logarithmic form as log P. A variety of experimental protocols for the determination of log P are reported in the literature.[3,4] The classical shaking flask method, via direct partition experiments, is tedious and time-consuming, while presenting limitations concerning the log P range, which can be reliably measured. Partition chromatographic techniques, in particular high-performance liquid chromatography (HPLC) and reversed-phase thin-layer chromatography (RP-TLC), permit an easy and rapid measurement of various indices that provide information on the lipophilic behavior of chemicals and offer a popular alternative, combining the possibility of automation, high dynamic range, and low sensitivity to impurities, while being compound-sparing.[5,6] Extrapolated capacity factors to pure water as mobile phase, expressed as log k_w and R_{Mw}, are considered as more representative lipophilicity indices compared to isocratic log k and R_M.[5–8] Literature is rich in research articles investigating similarities/dissimilarities between octanol–water partitioning and chromatographic retention. The selection of either technique is associated with the state of the art concerning their technology. Moreover, all assumptions dealing with the complex nature of lipophilicity as the outcome of intermolecular and intramolecular interactions, involving electronic, steric, or conformational effects, embrace chromatographic retention as well.[9,10]

STATIONARY PHASES IN PARTITION CHROMATOGRAPHY

In RP-TLC, silica gel plates impregnated with a strong hydrophobic agent (paraffin oil or silicone oil, usually 5%) have been extensively used in the past as non-polar stationary phases. Nowadays, plates covered with octadecyl-silanized (ODS) silica gel are available. In this material, the silanol groups are etherified with alkyls containing 8 (C_8) or 18 (C_{18}) carbon atoms. The low wettability of high-pressure TLC (HPTLC) plates coated with highly etherified silica gel poses limitations in the water content of the mobile phase. This problem is circumvented by the use of RP-C_{18} plates with 50% etherification. However, the presence of free silanol groups may lead to undesirable silanophilic interactions, especially with low water content in the mobile phase.[11]

ODS silica gel is, in most cases, the filling material in HPLC columns. Because the columns in HPLC are not disposable, one should take into account the pH limitations of this material (i.e., outside the pH range 2–7.5). The second problem is associated with the presence of free silanol groups, which may be responsible for silanophilic interactions, as already mentioned.[5,12–14] Nowadays, end-capped BDS or ABZ columns are available, which are treated with secondary silanization using small alkyls or zwitterionic fragments to bind the free silanol groups, thus suppressing their contribution to retention.[13]

Octadecyl–polyvinylalcohol copolymer gel, ODP, offers an alternative as a non-polar stationary phase in HPLC.[12,13] With this material, no silanophilic interactions take place and there are no pH limitations. Drawbacks of ODP columns are the large retention times observed and the longer equilibration time required.

Octanol-coated ODS columns have also been used in an effort to better simulate octanol–water partitioning. However, retention times were less reproducible due to instability and column bleeding.[13]

Recently, immobilized artificial membrane (IAM) tationary phases are becoming more popular for membrane simulation.[15] In IAM columns, silica gel is chemically bonded to phospholipids. There are various types of IAM columns. Among them, the most frequently used is IAMPC, which contains phosphatidylcholine.

MOBILE PHASES USED IN PARTITION CHROMATOGRAPHY

The mobile phases in RP-TLC and HPLC are mixtures of water or buffer with organic modifiers. With an octanol-coated stationary phase, no organic modifier is added to the mobile phase, whereas in IAM chromatography, the organic modifier is necessary only in the case of highly retained solutes.[13,15]

The most common organic modifiers are methanol, acetonitrile, and tetrahydrofuran. Acetonitrile may not be suitable for use with an ODP stationary phase,[12] whereas this solvent is the modifier of choice in IAM chromatography.[15]

The buffer composition of the aqueous component may affect the retention of ionizable solutes. Some authors suggest the use of morpholinepropanesulfonic acid (MOPS). The zwitterionic nature of this buffer offers the advantage that it does not lead to any interactions with the solutes.[12,13]

The addition of a masking agent to the mobile phase may be necessary when silanophilic interactions interfere with the partition mechanism. Silanophilic interactions are important in the case of protonated amines, or with solutes containing strong hydrogen bond acceptor groups, especially when mobile phases poor in water content are used.[12,14] Hydrophobic amines (e.g., *n*-decylamine) are suitable masking agents; however, their addition to the mobile phase adds an extra component to chromatographic conditions.

CAPACITY FACTORS AS LIPOPHILICITY INDICES

The lipophilicity indices measured by RP-TLC and HPLC are derived from the retardation factor R_f and the retention time t_r, respectively. R_f and t_r are converted to the logarithm of the capacity factor (R_M/log k') via Eqs. 1 and 2:

$$R_M = \log(1/R_f - 1) \quad (1)$$

$$\log k = [\log(t_r - t_o)/t_o] \quad (2)$$

where t_o is the retention time of an unretained compound, usually the solvent front or an inorganic salt such as potassium bichromate.

The less polar a solute is, the stronger will be its interaction with the stationary phase, which is expressed by decreasing R_f values and increasing R_M values in RP-TLC and by increasing retention times and log k' values in HPLC. Thus R_M and log k' values are directly correlated to octanol–water log P via Collander-type equations:

$$\log P = aR_M + b \quad (3)$$

$$\log P = a' \log k' + b' \quad (4)$$

where the coefficients a,b and a',b' are derived by regression analysis. The quality of the equations depends on the chromatographic conditions and the solutes.

For lipophilicity assessment, calibration equations with types similar to Eqs. 3 and 4 should be constructed using compounds with known log P values. These calibration equations are applied for further log P calculations. According to the author, it is recommended to measure more than one set of isocratic R_M or log k' values to construct the corresponding calibration equations and to calculate the average log P.[16]

Instead of isocratic capacity factors derived for a selected mobile phase composition, one can use extrapolated R_{Mw} and log k_w' values, which correspond to 100% aqueous mobile phase.[5–8,11–13]

Eqs. 5 and 6 describe the relationship between retention and fraction φ of the organic modifier present in the mobile phase:

$$R_M = A\varphi^2 - B\varphi + C \quad (5)$$

$$\log k' = A'\varphi^2 - B'\varphi + C' \quad (6)$$

The intercepts C and C' correspond to R_{Mw} and log k_w', respectively.

For a certain φ range, the quadratic term in Eqs. 5 and 6 may not be significant. In that case, R_{Mw} and log k_w' are obtained by linear extrapolation according to Eqs. 7 and 8:

$$R_M = -S\varphi + R_{Mw} \quad (7)$$

$$\log k' = -S'\varphi + \log k_w' \quad (8)$$

Linearly extrapolated capacity factors should be preferred because quadratic extrapolation may lead to erroneous overestimated values. The linearity range depends on the organic modifier as well as on the solutes. Methanol does not disrupt, substantially, the hydrogen bonding network of water and, usually, a wide linearity range is achieved relative to acetonitrile or tetrahydrofuran.

However, in the case of protonated amines, quadratic relationships were obtained with MeOH.[17] In general, for polar solutes, linearity holds within a limited range using mobile phases rich in aqueous component. In contrast, for more hydrophobic solutes, linear extrapolation is still possible with mobile phases rich in organic modifier. It has been suggested that linearity holds better for modifier concentrations that produce $0 < \log k' < 1$.[18]

ISOCRATIC VS. EXTRAPOLATED CAPACITY FACTORS

Extrapolated capacity factors, R_{Mw} and log k_w', are in the same order as the octanol–water log P values and are

considered as more general lipophilicity indices. Because the slopes in Eqs. 7 and 8 may vary considerably, the extrapolation lines may intersect each other, thereby leading to an inversion of lipophilicity in a higher percentage of organic modifiers (Fig. 1). In this aspect, a proper expression of the lipophilicity actually is found only at 100% aqueous phase composition. However, some authors argue that extrapolated capacity factors can predict log P only for compounds that do not contain strong hydrogen bond acceptor substituents.[19] Nevertheless, the problem of non-hydrophobic interactions can be faced by the proper selection of the stationary phase and the protection of the silanophilic sites.

However, extrapolated capacity factors may be affected by the nature of the organic modifier. In a study concerning the measurement of lipophilicity indices for monosubstituted benzenes by HPLC, the log k_w' values of the more polar derivatives appeared to be lower when methanol was used as an organic modifier, compared to the log k_w values obtained with acetonitrile.[12] In contrast, for non-polar derivatives, acetonitrile led to lower log k_w' values. An analogous decrease in the log k_w values for a series of lipophilic 9*H*-xanthene and 9*H*-thioxanthene derivatives was observed when tetrahydrofuran was used instead of methanol.[20] The differences in the extrapolated capacity factors described above may be attributed to changes in the hydrophobic character of the stationary phase caused by organic modifiers and water molecules dragged onto the reversed-phase material during equilibration.

It is the opinion of the author that the best simulation of the octanol–water system is achieved with (end-capped) silanized octadecylsilica gel stationary phase, methanol as the organic modifier, and a masking agent, if necessary. Depending on the structure of the solutes, in many such cases, a good correlation between the chromatographic data and log P is obtained with the coefficients a,a' and b,b' close to 1 and 0, respectively.

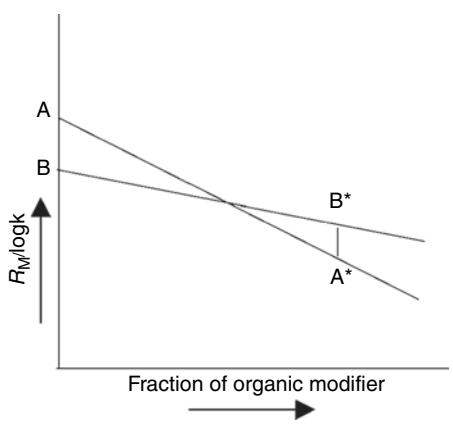

Fig. 1 Plot of R_M/log k vs. fraction of organic modifier. Inversion of lipophilicity occurs for organic modifier concentrations higher than the intersection point of the lines.

$$\log P = aR_{Mw} + b \quad (9)$$

$$\log P = a' \log k_w' + b' \quad (10)$$

Far from being a general rule, Eqs. 11–13 represent three examples of 1 : 1 correlation between log P and extrapolated capacity factors obtained under the above-recommended conditions:

$$R_{Mw} = 0.959(\pm 0.011) \log P + 0.067(\pm 0.147) \quad (11)$$

[$n = 121$, $r = 0.967$, $s = 0.353$, $F = 1703$ (RP-18 plates; from Ref.[11])]

$$\log P = 1.01(\pm 0.08) \log k_w - 0.43(\pm 0.25) \quad (12)$$

[$n = 19$, $r = 0.947$ (ABZ column; from Ref.[13])]

$$\log P = 0.91(\pm 0.03) \log k_w + 0.18(\pm 0.12) \quad (13)$$

[$n = 28$, $r = 0.983$, $s = 0.181$, $F = 763$ (ODS column + n-decylamine as masking agent; from Ref.[12])].

EFFECT OF IONIZATION ON RETENTION

To correct capacity factors for ionization, the same equations are used as for the corresponding correction of the apparent partition coefficients. Thus for monoprotic acids and bases, Eqs. 13 and 14 are suggested for extrapolated, as well as isocratic, capacity factors derived from HPLC and RP-TLC:

$$\log k_w = \log k_{w(app)} + \log(1 + 10^{pH - pK_a}) \quad \text{acids} \quad (14)$$

$$\log k_w = \log k_{w(app)} + \log(1 + 10^{pK_a - pH}) \quad \text{bases} \quad (15)$$

However, whether the effects of ionization in the octanol–water partition systems in HPLC and TLC are similar remains to be clarified. The stationary phase material and, especially the presence of the acidic silanol sites, may have an active role. Moreover, concerning the two chromatographic techniques, even in the case of identical stationary phases, an essential difference between HPLC and TLC is the fact that, in HPLC, the column is equilibrated with the mobile phase before runs are conducted. Thus the stationary phase is adjusted to the mobile phase pH, whereas on a TLC plate, a pH gradient is formed.

EFFECT OF CONFORMATION IN RETENTION

Conformational effects in lipophilicity have been well established.[9] Analogous effects, although not necessarily to the same extent, may be expected in retention. In such

cases, differences in the partitioning behavior in the octanol–water system and the chromatographic system may be manifested, thus affecting the quality of equations.

OTHER CHROMATOGRAPHIC DATA AS LIPOPHILICITY-RELEVANT EXPRESSIONS

The slope S of the regression curve used to obtain $\log k_w'$ or R_{Mw} (Eqs. 7 and 8) is considered to encode significant information on the lipophilic behavior of the solute. In a simplified aspect, the slope is thought to express, mainly, the solute/solvent interactions, whereas the intercept value is rather associated with solute stationary phase interactions. Some authors relate the slope S to the specific hydrophobic surface area.[21] Basically, the retention mechanism consists of two components: the size of the solute (reflected by its volume or surface area), and its hydrogen-bonding capacity. If there are no considerable differences in hydrogen-bonding capacity within a series of compounds, a good relationship between the slope and the intercept is anticipated:

$$S = aR_{Mw} + b$$

$$S' = a' \log k_w + b'$$

Thus slope analysis may unravel differences in hydrogen bonding within a series of compounds.[13]

The organic modifier concentration φ_o, which produces an equal molar distribution between the stationary phase and the mobile phase, leading to $\log k = 0$, has also been proposed as a measure to rank lipophilicity.[22] φ_o indices have been mainly developed for HPLC. They correspond to the quotient:

$$\varphi_o = \log k_w / S$$

Based on the φ_o concept, a fast gradient method RP-HPLC has been proposed to determine the chromatographic hydrophobicity index (CHI) as a high-throughput alternative to other lipophilicity measures.[23] For this purpose, gradient retention times (t_g) are measured and converted to CHI values by means of a calibration equation, derived by a set of standards with well-determined CHI (φ_o) values:

$$\text{CHI} = \text{slope} \times t_g + \text{intercept}$$

The absolute magnitude of the CHI parameter depends on the values assigned to the set of standards. The method has the advantage that, once the calibration equation has been established, the retention parameter is obtained from a single fast gradient run, thus saving time and solvents. The CHI parameter has been reported to correlate satisfactorily with log P.

CONCLUSIONS

RP-TLC and HPLC provide a variety of descriptors that can be used as lipophilicity indices. Among them, extrapolated capacity factors often lead to 1 : 1 correlation with octanol–water log P. On the other hand, isocratic capacity factors need fewer experiments to be determined; however, they depend strongly on chromatographic conditions. The CHI combines easy and rapid measurements with a uniform lipophilicity scale. However, both lipophilicity and reversed-phase chromatographic retention are composite phenomena and, consequently, their resemblance cannot always be anticipated. Because standard reference sets cannot be available for all structurally diverse compounds, a comparison between chromatographic indices and octanol–water log P within the series of the investigated compounds is still indispensable.

Abstract
High-density, low-density, and very-low-density lipoproteins (HDLs, LDLs, and VLDLs) were purified from human serum by the combined use of countercurrent chromatography (CCC) and hydroxyapatite chromatography. Polymer-phase CCC of human serum using the cross-axis coil-planet centrifuge (cross-axis CPC) yielded two lipoprotein fractions, one containing HDLs and LDLs and the other VLDLs and serum proteins. Each fraction was concentrated and subjected to hydroxyapatite chromatography to obtain three lipoprotein fractions, all free from serum proteins. Each lipoprotein was confirmed by agarose gel electrophoresis.

INTRODUCTION

Polymer phase systems were first introduced by Albertsson[1] in the 1950s for partitioning macromolecules and cell particles. One of these two-phase solvent systems consists of one polymeric component, such as polyethylene glycol (PEG), and a high concentration of a salt such as potassium phosphate in water. Being free from any organic solvents, the system can preserve a natural structure of proteins if the pH of the system is kept within physiological range. In the past, polymer phase systems composed of PEG and potassium phosphate were most successfully used for protein separations. In these systems, proteins are distributed according to their partition coefficients; this forms the basis for their purification. For example, relatively hydrophobic proteins distribute more into the PEG-rich upper phase and hydrophilic proteins into the phosphate-rich lower phase.

Chromatographic partitioning of proteins using polymer phase systems can be performed by countercurrent chromatography (CCC)[2] using a centrifugal device: the cross-axis coil-planet centrifuge (cross-axis CPC) is mainly used for preparative-scale separations. Because of the protective effects of high polymer-salt concentrations, proteins can maintain their integrity at room temperature for a relatively long period of time, and, usually, the purification can be performed without cooling the column or collecting fractions. Combined with liquid chromatography (LC), this method has been successfully applied to separation of lipoproteins directly from human serum, as described below.[3]

APPARATUS

A photograph of the cross-axis CPC is shown in Fig. 1. The apparatus consists of a pair of horizontal rotary shafts, symmetrically mounted, one on each side of the rotary frame, at a distance of 10 cm from the centrifuge axis. A spool-shaped column holder is mounted on each rotary shaft at an off-center position 10 cm from its midpoint. The large multilayer coil separation column was prepared from polytetrafluoroethylene (PTFE) tubing with 2.6 mm I.D. by winding it on a 15.2 cm diameter holder hub, forming a single layer of left-handed coils between a pair of flanges spaced 5 cm apart. The pair of columns mounted on the rotary frame are connected in series using a flow tube to give a total capacity of 60 ml. Both inflow and outflow tubes exit together at the center of the top plate of the centrifuge case where they are tightly supported by a pair of clamps equipped with silicone rubber pads. The speed of the apparatus is regulated at 500 rpm using a speed control unit.

PARTITION COEFFICIENTS OF LIPOPROTEINS AND SERUM PROTEINS

CCC is a two-phase procedure where the separation is based on the difference in partition coefficients of solutes

Encyclopedia of Chromatography, Third Edition DOI: 10.1081/E-ECHR3-120045285

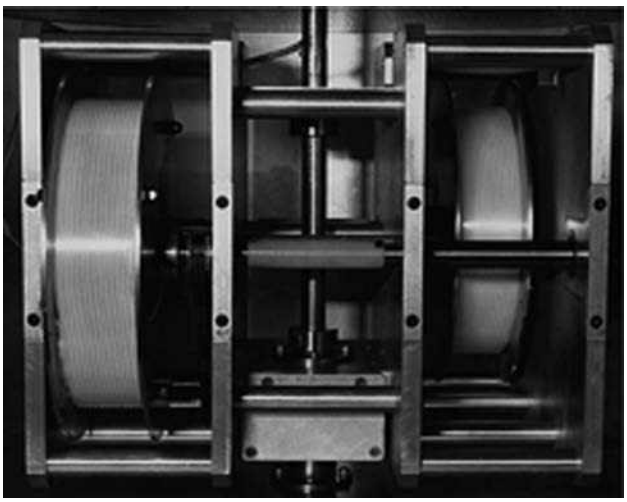

Fig. 1 Photograph of the type XL cross-axis coil-planet centrifuge.

within the phases. To achieve efficient separation of lipoproteins from human serum, it is essential to optimize the partition coefficient of each component by selecting an appropriate pH for the polymer phase system.

Fig. 2 shows the partition coefficients of three lipoproteins and three serum proteins plotted on a logarithmic scale against the pH of 16% PEG 1000–12.5% potassium phosphate buffer. The partition coefficients of serum proteins and very-low-density lipoprotein (VLDL) show an increase from 6.8 to 9.2 with increased pH, while those of high-density lipoprotein (HDL) and low-density lipoprotein (LDL) display quite different trends, i.e., they become less than 1.0 at pH 9.2, indicating that these lipoproteins are mainly distributed in the potassium phosphate-rich lower phase at high pH.

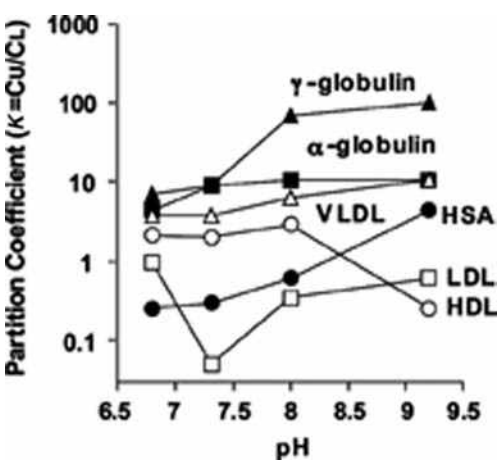

Fig. 2 Partition coefficients (K) of HDLs, LDLs, VLDLs, and serum proteins in polymer phase systems composed of 16% PEG 1000 and 12.5% potassium phosphate buffers.

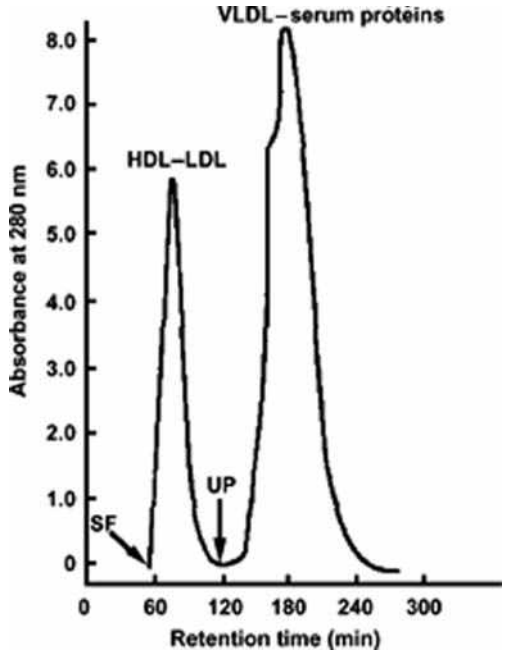

Fig. 3 CCC separation of HDL–LDL and VLDL–serum protein fractions from human serum with an aqueous polymer phase system. Column: 2.6 mm I.D. PTFE single-layer coil (×2) with 60 ml capacity; sample: 4 ml of human serum; solvent system: 16% PEG 1000–12.5% dibasic potassium phosphate at pH 9.2; mobile phase: lower phase; flow rate: 0.5 ml/min; revolution speed: 500 rpm. SF = solvent front, UP = starting point of the reversed elution mode with the upper phase.

CCC OF HUMAN SERUM

Two lipoprotein fractions (HDL–LDL and VLDL–serum proteins) from human serum were obtained using the cross-axis CPC equipped with a small-capacity column (60 ml). Fig. 3 shows a chromatogram of human serum (4 ml) obtained with the cross-axis CPC using 16% PEG 1000–12.5% potassium phosphate buffer (pH 9.2). The separation was performed at 500 rpm and at a flow rate of 0.5 ml/min using the lower phase as the mobile phase where HDLs and LDLs were eluted together near the solvent front (SF), while other proteins were retained in the column for a much longer period of time. After collecting the HDL–LDL fraction, VLDL was eluted together with serum proteins (VLDL–serum proteins fraction) by pumping the upper phase in the reverse direction (marked "UP" in Fig. 3). The separation was completed within 4.5 hr. The lipoprotein in each peak fraction was confirmed by agarose gel electrophoresis with Oil Red 7B staining, and the serum proteins were also detected by SDS–PAGE with Coomassie Brilliant Blue protein staining. The first peak contained HDLs and LDLs but no serum proteins, and the second peak contained VLDLs mixed with serum proteins.

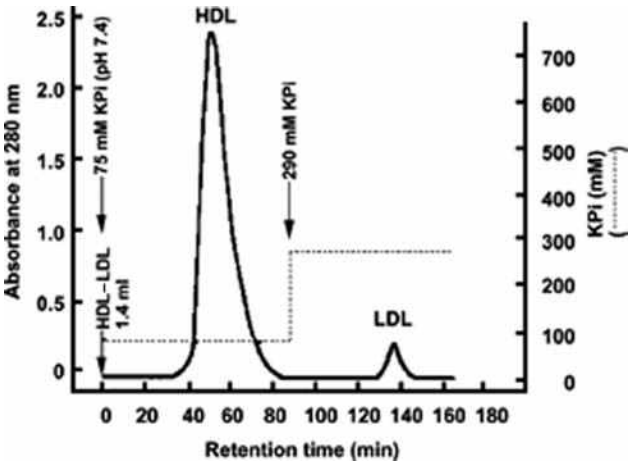

Fig. 4 Stepwise elution profile of HDLs and LDLs by hydroxyapatite chromatography. Column: Biogel HTP DNA-grade hydroxyapatite (5.0 × 2.5 cm I.D.); eluents: 75 and 290 m*M* potassium phosphate buffers at pH 7.4; flow rate: 1.0 ml/min; sample: 1.4 ml concentrated HDL–LDL CCC fraction.

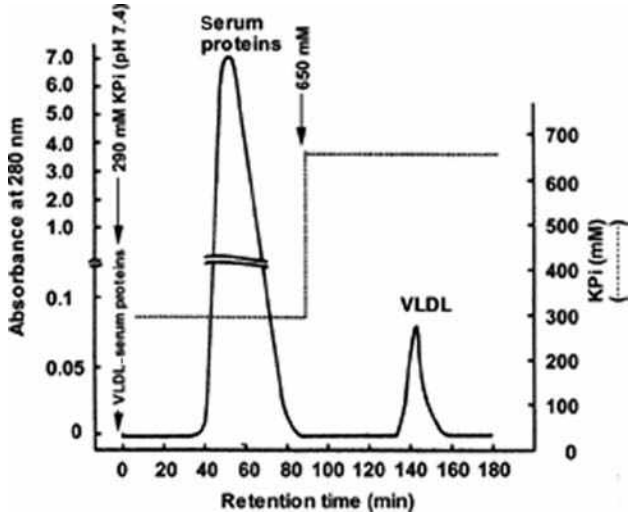

Fig. 5 Stepwise elution profile of serum proteins and VLDLs by hydroxyapatite chromatography. Column: Biogel HTP DNA-grade hydroxyapatite (5.0 × 2.5 cm I.D.); eluents: 290 and 650 m*M* potassium phosphate buffers at pH 7.4; flow rate: 1.0 ml/min; sample: 1.5 ml concentrated VLDL–serum protein CCC fraction.

HYDROXYAPATITE CHROMATOGRAPHY OF CCC FRACTIONS

The CCC fractions, HDL–LDL and VLDL–serum proteins, were each separately dialyzed against distilled water until the concentration of potassium phosphate was decreased to the level in the starting buffer used for the hydroxyapatite chromatography. These two fractions were concentrated separately by ultrafiltration. The concentrates of both fractions were chromatographed on the hydroxyapatite column. Fig. 4 shows the elution profile on hydroxyapatite obtained from the HDL–LDL fraction. A 1.4 ml volume of the concentrate was loaded onto a Biogel HTP DNA-grade column (5.0 × 2.5 cm I.D.) and eluted at 1.0 ml/min with 75 and 290 m*M* potassium phosphate buffer at pH 7.4. Two lipoprotein peaks were eluted: the first peak contained HDLs and the second peak contained LDLs.

The concentrate (1.5 ml) of the VLDL–serum proteins fraction was similarly chromatographed (Fig. 5). The separation was performed in a two-step elution process with 290 and 650 m*M* potassium phosphate buffer at pH 7.4. Most of the serum proteins, including albumin and globulins, were eluted with 290 m*M* potassium phosphate buffer at pH 7.4. The VLDLs, on the other hand, were retained in the column for a much longer period of time and were eluted with a 650 m*M* potassium phosphate buffer. Lipoproteins in the hydroxyapatite chromatographic fractions were confirmed by agarose gel electrophoresis.

CONCLUSIONS

CCC is a very useful technique for the separation and fractionation of human serum lipoproteins. The HDL–LDL and VLDL–serum protein fractions were directly obtained from human serum using a solvent system composed of 16% PEG 1000–12.5% potassium phosphate at pH 9.2. The separated HDL–LDL and VLDL–serum protein fractions were loaded onto hydroxyapatite columns and separated into HDLs, LDLs, VLDLs, and serum proteins, respectively. The combination of CCC and hydroxyapatite chromatography is a useful method for the separation of the three main classes of lipoproteins from human serum, without prior ultracentrifugation.

Liquid Crystal GC Phases

Zygfryd Witkiewicz
Jerzy Oszczudlowski
Institute of Chemistry, Jan Kochanowski University, Kielce, Poland

INTRODUCTION

The search for new and highly selective stationary phases is one of the trends in gas chromatography (GC) development. Among them are chiral phases, cyclodextrins, and liquid crystals. Liquid crystals are materials with anisotropic properties. While being liquids, they maintain an ordered state of molecules, characteristic of crystals within the range of melting and clarifying points. Among several types of liquid crystals of primary importance are rod-like and thermotropic liquid crystals whose occurrence and properties depend on temperature. These liquid crystals are mainly used in displays, but as solvents with anisotropic properties they are also used for syntheses of certain chemical compounds and as chromatographic stationary phases.

The use of liquid crystals as stationary phases in gas chromatography has been described in the literature.[1,2] A survey of uses of liquid crystal applications as stationary phases in gas chromatography has been given in Refs.,[3–7] whereas a survey of uses of analytical liquid crystals as stationary phases in liquid chromatography has been presented in Refs.[8,9] The use of side-chain liquid-crystalline polymers as stationary phases in GC, high-performance liquid chromatography (HPLC), and supercritical fluid chromatography (SFC) has been described by Chain-Shu-Hsu.[10]

CHARACTERISTICS OF LIQUID CRYSTALS

The molecular structure of thermotropic, rod-like liquid-crystalline substances can be shown as a scheme:

$$\text{Substituent}_1 - [\text{Cyclic system-joining bridge}]_n - \text{Cyclic system} - \text{Substituent}_2$$

Alkyl, acyl, ester, etheric, cholesteryl, nitrile, nitro, rhodanate, and halogen groups are substituents. Terminal substituents affect the polarities of the mesophase and thermotropic properties of a liquid crystal. The cyclic system consists of aromatic, cycloalkane, and heterocyclic rings. Such groups of chemical compounds as olefin and Schiff's base and those that contain groups like nitro, azo, azoxo, and ester make the central group (the joining bridge).

Liquid crystals are substances which attain the mesomorphic state, called the mesophase, after melting. This state is maintained within a certain range of temperatures, from the melting to the clarifying points, where ordinary isotropic liquid is formed. The mesophase can range from a few degrees to about 200°C.

According to the character and the degree of the ordering of molecules in the mesophase, liquid crystals are divided into nematics, smectics, and cholesterics (Figs. 1–3). Smectics are the most ordered phases, whereas nematics are the least ordered ones.

The ordering of rod-like molecules of liquid crystals affects the various ways in which chemical compounds, whose molecules are different in shape, dissolve in them. This was employed in chromatography using liquid crystals as stationary phases.

EXAMPLES OF LIQUID-CRYSTALLINE STATIONARY PHASES

About 60,000 liquid crystals are known, and over 250 have been investigated as stationary phases in gas chromatography, high-pressure liquid chromatography, and supercritical chromatography.

In gas chromatography, thermotropic liquid crystals belonging to such groups of chemical compounds as Schiff's base, azo- and azoxy-compounds, esters, derivatives of biphenyls and terphenyls, organic complexes with transition metals, and organic polymers are used. Siloxane polymers of liquid-crystalline properties are stable within the wide range of temperatures from 50°C to 300°C.

As conventional stationary phases, liquid-crystalline stationary phases (LCSPs) are used in columns packed after depositing onto supports or, more widely, in capillary columns generally used with temperature programming. In columns of this type, a high stability of liquid-crystalline stationary phases is required within the wide temperature range where the mesophase should occur. Among such LCSPs are monomeric liquid crystals of high molecular weight and liquid-crystalline polymers.

Monomeric liquid crystals of low-molecular weight and low-melting temperatures are successfully employed to

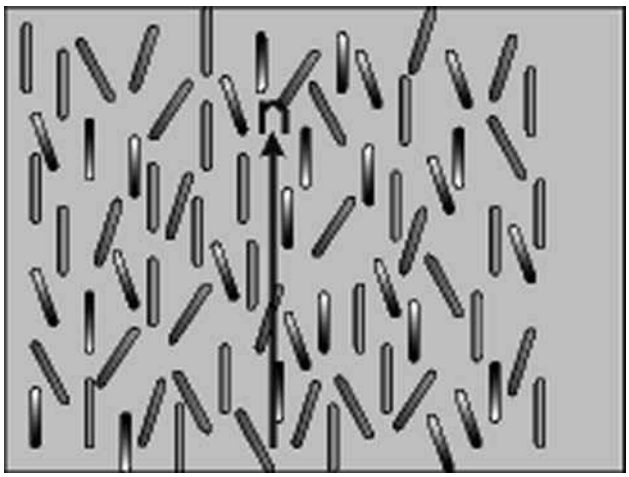

Fig. 1 Molecules are oriented parallel in average to an axis called director in the nematic phase.

separate volatile organic compounds, including their isomers (e.g., alkanes, and derivatives of benzene and naphthalene). Liquid-crystalline stationary phases of high-molecular weight and polymeric liquid crystals are employed to separate high-boiling compounds (e.g., polycyclic aromatic hydrocarbons, polychlorinated biphenyls, polychlorinated dibenzodioxines, and polychlorinated dibenzofuranes).

Examples of Polymeric Liquid-Crystalline Phases

4. TBBA with temperature of phase transition: crystalline; 113.0°C, smectic G; 144.5°C, smectic A; 199.0°C, nematic; 235.0°C, isotropic (Scheme 5).
5. Liquid-crystalline complex with transition metal ion [e.g., Cu(II)] (Scheme 6).

MECHANISM OF SEPARATION ON LIQUID-CRYSTALLINE STATIONARY PHASES

The chromatographic separation of components of mixtures, using most of the conventional stationary phases, is associated with the polarities of these phases, and with the polarities and polarizabilities of chromatographed substances as well as with subsequent intermolecular interactions.

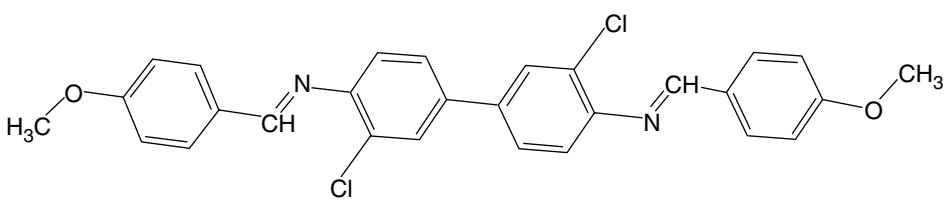
The mechanism of chromatographic separation on LCSPs is mainly connected with the differentiation of the structures of molecules of chromatographed substances with the so-called stereoselectivity or stereospecificity. The differentiation of the structures of molecules of the chromatographed substances results from the ordering of the liquid crystal structure and depends on the type of mesophase and on thermodynamic effects of dissolving components of the chromatographed mixture in LCSP.[11] The effect of the separation of components of mixtures on LCSPs is associated with the different energies of the interactions of components of these mixtures with liquid crystals.

On the basis of the dependence of the selectivity coefficients (α) of the tested substances on temperature: $\ln \alpha = f(1/T)$, it is possible to determine the selectivities of liquid crystals in relation to the substances of molecules that are different in shape. However, on the basis of the dependence: $\ln \alpha = -\Delta(\Delta G_{a,b})/(RT)$, it is possible to determine, quantitatively, the differences of partial molar free energies of the substances a and b that are chromatographed on liquid crystals.

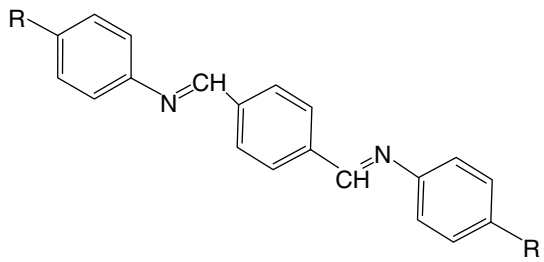
Liquid-crystalline stationary phases are particularly useful to separate isomers. Isomers that are more elongated in shape (e.g., *p*-xylene) are retained in a column filled with LCSPs longer than isomers that are less elongated in shape (e.g., *m*-xylene). The retention of isomers of chromatographed substances considerably depends on the type of the mesophase of the liquid-crystalline stationary phase. This results from the fact that the type of mesophase affects the dissolution and diffusion of isomers of the chromatographed substance to a different degree. On the whole, nematic liquid crystals show the best separation properties in relation to isomers but, in some cases, very good separation can be obtained on smectic and cholesteric stationary phases.

Diffusion and dissolution of substances chromatographed on stationary phases are determined by the mass transfer resistance, which affects the efficiencies of chromatographic columns. Efficiencies of columns with LCSPs are generally lower than those of columns with conventional stationary phases. Therefore, mixtures of LCSPs with conventional stationary phases can be advantageous. The mixture of a liquid crystal with a conventional stationary phase increases the efficiency of a column by improving the homogeneity of the stationary phase film on the wall of a capillary column. The mixture of two liquid crystals can also prove advantageous. The properties of combined stationary phases are described elsewhere.[12]

Some monomeric LCSPs of high-molecular weight have been found to separate high-boiling chemical compounds at temperatures corresponding to the solid of a liquid



Scheme 3



Scheme 5

crystal.[13] In such conditions, a good separation is obtained in a shorter time than during the separation in the mesophase range. This phenomenon can probably be accounted for by the local transition of a liquid crystal to liquid under the influence of the chromatographed substance interacting with it.

With a view to obtaining stationary phases of the wide temperature range of the mesophase, of high stability in columns, and of good separation properties, more attention is paid to polymeric liquid crystals, including those in the form of complexes with transition metal ions [e.g., Cu(II), Zn(II), and Ni(II)]. The separation ability of the latter is considered to be connected with both their ordered structures and the possibility of exchanging organic ligands of a liquid crystal with organic substances.[14] The separation on these LCSPs is complex and, in the case of mixtures whose components can interact with LCSPs according to both mechanisms, the separations obtained can be very good.

While investigating interdependences between general physico-chemical properties of liquid crystals and their separation ability, apart from traditional methods of physico-chemical investigations, methods of inverse gas chromatography are also used.[15]

APPLICATION EXAMPLES

Liquid-crystalline stationary phases are used to analyze a great number of chemical compounds such as polycyclic aromatic hydrocarbons, polychlorinated biphenyls, polychlorinated dibenzodioxins, polychlorinated dibenzofurans, polychlorinated naphthalenes, terpenes, steroids, pesticides, pheromones, etc.

On the monomeric LCSP called 4,4′-biphenylene-bis (4-*n*-butyloxy-benzoate) placed in a capillary column, 12 polynuclear aromatic hydrocarbon (PAHs) were separated in the mixture derived from coal tar (Fig. 4). The chromatogram of selected PAHs on metallomesogen stationary phase is presented in Fig. 5. Chromatograms of selected volatile aromatics compounds on monomeric stationary phases are presented in Figs. 6 and 7.

CONCLUSIONS

It is possible to achieve good separation of drugs, environmental pollutants, and components of biological liquids having electron donor properties on liquid-crystalline complexes with ions of transition metals. In recent years, remarkable progress in research on the use of liquid-crystalline compounds as stationary phases, in both gas

chromatography and liquid chromatography, has been observed. However, it is noteworthy that the commercialization of research achievements is still of little importance, and liquid-crystalline stationary phases are not so popular

Liquid–Liquid Partition Chromatography

Anant Vailaya
Merck Research Laboratories, Rahway, New Jersey, U.S.A.

INTRODUCTION

Liquid–liquid partition chromatography (LLPC), employing an organic–aqueous two-phase solvent system and a silica support to separate amino acids, was pioneered by Martin and Synge,[1] for which they received the Nobel Prize. Its invention presented a significant advancement over conventional adsorption-based chromatographic processes that were rather unfavorable, due to the energetic heterogeneity of the adsorbent surface. By replacing the solid surface with a layer of an immiscible liquid to retain the solutes, much higher separation efficiencies could be obtained with LLPC. Its scope was later expanded to resolve water-insoluble sample mixtures as well as to isolate biopolymers by introducing organic–organic and aqueous–aqueous two-phase systems, respectively, and by extending the range of supports to include cellulose, dextran, and polymerbased supports.

The rapid development of hydrocarbonaceous bonded phases (non-polar stationary phases with hydrocarbon chains covalently attached to the silica support) in the 1970s and 1980s for the popular reversed-phase chromatographic (RPC) technique has, however, eclipsed this technique somewhat, lately. Nevertheless, LLPC has become one of the most powerful separation techniques for the isolation of natural products and biopolymers.

FUNDAMENTAL PRINCIPLES AND THEORETICAL BACKGROUND

Martin and Synge provided the first theoretical treatment of LLPC by adapting the concept of theoretical plates which had been developed, mainly, for distillation and countercurrent extraction. According to the theory, a chromatographic column is considered to consist of a number of theoretical plates, within each of which perfect equilibrium occurs between the mobile and the stationary phases. Unlike in RPC employing hydrocarbonaceous bonded stationary phases where the retention mechanism is still the subject of controversy,[2] three distribution processes contributing to the total retention of the solute may be clearly identified in LLPC systems. They are (a) partitioning between the two bulk liquid phases, (b) adsorption at the surface of the support, and (c) adsorption at the liquid–liquid interface. Assuming an inert support with large pores that minimize solute adsorption at the support surface and weak adsorption at the liquid–liquid interface, solute retention associated with undesirable adsorption effects may be neglected. Thus, separation in LLPC may be visualized as a multistep partition process, similar to countercurrent distribution, in which the differential migrations of various sample constituents are governed by their partition coefficients and by the volume ratio of the two phases. Then, the magnitude of solute retention in LLPC, measured under isocratic condition by the retention factor, k', is given by

$$k' = \frac{KV_s}{V_m} \tag{1}$$

where K is the partition coefficient of the solute in the two-phase system employed, V_m is the volume of the mobile phase, measured by an inert tracer and V_s is the volume of the stationary phase.The retention factor is evaluated directly from the chromatogram as

$$k' = \frac{V_r - V_m}{V_m} \tag{2}$$

where is the retention volume of the solute.

Shake-flask measurements are often employed to design a suitable LLPC system for a given sample mixture by assisting in the selection of the two phases in which the compound of interest shows a partition coefficient sufficiently different from those of the impurities. One of the two phases is then immobilized on a suitable support that is packed into the column, and the second phase is used as the mobile phase. In general, partition coefficients of solutes obtained from static experiments compare favorably with those obtained from chromatographic experiments.[3] A comprehensive thermodynamic treatment of LLPC can be found in Ref.,[4] and the prediction and control of zone migration is discussed extensively in Ref.[5] Liquid–liquid partition chromatography systems have been used with or without stationary-phase support. Support-free LLPC has been classified as countercurrent chromatography (CCC). High-speed CCC techniques, based on planetary motion and coaxial orientation of the coiled column, have been developed that achieve both high partition efficiency and excellent retention of the stationary phase, thus circumventing the need for stationary-phase supports.[6]

Encyclopedia of Chromatography, Third Edition DOI: 10.1081/E-ECHR3-120040039

Liquid–liquid partition chromatography systems employing stationary-phase supports have been applied in both paper and column chromatographic modes. Paper strips impregnated with the liquid stationary phase are employed as supports for paper chromatography.[5] Column supports for LLPC bind the liquid stationary phase selectively enough to immobilize it and thus prevent its bleeding by the mobile phase. The support surface is homogeneously coated with the stationary phase and is sufficiently large to generate an interface for solute partitioning. Given these considerations, macroporous supports of average pore diameter greater than 50 nm are most suitable as column packings. Supports with smaller pores might contribute to retention by adsorption of solutes. In principle, both organic- and inorganic-based column packings can be employed in LLPC. Soft packings, such as cellulose, dextran, polymers, and diatomaceous earth, which do not withstand high pressures, are preferably used as larger particles at low pressures. On the other hand, microparticulate and bonded silicas are the supports of choice in the high-performance mode.

In the separation of large biopolymers, such as proteins and nucleic acids, specific supports characterized by large pores and bonded structure have been developed for LLPC employing poly(ethylene glycol) (PEG)–dextran two-phase aqueous–aqueous system. Bonded silica [e.g., LiChrospher® Diol (typically 1000 Å pore size and 10 μm particle size)] or a hydrophilic methacrylate polymer (e.g., Fractogel®) are chemically modified to form polyacrylamide chains of defined lengths that facilitate the selective binding of a dextran-rich aqueous phase. Polymer-based materials serve frequently as phase supports insensitive to high pH systems.

Columns for LLPC are prepared by using solvent evaporation, direct coating, precipitation, or a dynamic coating technique.[3] In the solvent-evaporation technique, the non-volatile liquid stationary phase is dissolved in a volatile solvent and mixed with the dry support. Then, the solvent is slowly removed by rotating the suspension in a rotary evaporator until the coated support remains as a dry, free-flowing powder. In the direct coating technique, the liquid stationary phase is pumped through the column, and then the excess is displaced by elution with a mobile phase saturated with the stationary phase. In the precipitation technique, the liquid stationary phase precipitates in the support pores when a solvent, which is not miscible with the liquid stationary phase, is pumped through the column. Finally, the liquid-mobile phase saturated with a liquid stationary phase is pumped through the prepacked column in the dynamic coating technique. The liquid stationary phase is adsorbed at the surface of the support until it builds a multilayer and completely fills the pore volume.

LIQUID–LIQUID SYSTEMS

Binary and sometimes ternary systems employing phases of different polarity, which is characterized by Hildebrand's solubility parameter[7] or Snyder's polarity index,[8] are used for LLPC separations. Applying the solubility parameter concept, various organic–organic, organic–aqueous, and aqueous–aqueous LLPC systems have been utilized to modulate solute retention. Based on polarity differences, LLPC can be operated in both normal phase (polar stationary phase, non-polar mobile phase) and reversed-phase (polar mobile phase and non-polar stationary phase) modes. Mobile phases typically used in the normal-phase mode are aliphatic hydrocarbons such as hexane, heptane and isooctane, alcohols, tetrahydrofuran (THF), methylene chloride, dioxane, and aromatic solvents. Stationary phases in the normal-phase mode include water, formamide, glycerol, and glycols. In the reversed-phase mode, hydro-organic mixtures such as acetonitrile–water and methanol–water are employed as mobile phases, whereas non-polar solvents such as squalane, octanol, and aliphatic hydrocarbons are used as stationary phases. For the separation of large biopolymers based on aqueous–aqueous LLPC systems, a PEG-rich aqueous phase forms the mobile phase, and the dextran-rich aqueous phase is immobilized on the polyacrylamide support to form the stationary phase.

APPLICATIONS

A number of advantages of current LLPC systems make them attractive for widespread application in the separation and isolation of low-molecular-weight compounds as well as macromolecules. Among them are simple preparation of bulk liquid phases, high reproducibility of retention and selectivity under isothermal conditions and lesser contamination, higher efficiency, and longer lifetime compared to adsorbent columns. Some of the most common applications of LLPC are now described.

Small Molecules

Liquid–liquid partition chromatography employing organic–organic, organic–aqueous, and aqueous–organic binary systems with column support have been used to separate small molecules of wide polarity.[3] A majority of applications involve the use of LLPC systems in the normal-phase mode (e.g., the separation of polyaromatic hydrocarbons, alcohols, esters, alkylated and chlorinated aromatic derivatives, pesticides, herbicides, and steroids). Several nitrogen-containing compounds, radionuclides, derivatives of aromatic carboxylic acids, benzodiazepines, aromatic compounds, and naphthalenesulfonic acids have successfully been separated in the reversedphase mode. Many ternary LLPC systems in both the normal-phase and reversed-phase modes have also been employed in the separation of polyaromatic hydrocarbons, benzodiazepines, steroids, metal chelates, glycosides, metabolites, dansyl amino acids, herbicides, aliphatic carboxylic and dicarboxylic acids, sulfonic acids, nucleosides, barbiturates,

chlorinated phenols, and alkylbenzenes. Support-free high-speed CCC has been employed in the separation of dyes, rare earth and certain inorganic elements, as well as in the preparative and analytical applications of medicinal herbs and other natural products, such as alkaloids, tannins, flavonoids, marine compounds, and anthraquinones.[6]

Biopolymers

Classical LLPC using aqueous–aqueous polymer systems based on Albertsson's[9] PEG–dextran system has provided a versatile tool for the separation of proteins and nucleic acids, thus increasing the arsenal of biopolymer purification methods currently dominated by gel filtration, ion-exchange chromatography, and affinity chromatography RPC.The technique operates on the basis of the biopolymers partitioning between the top PEG-rich aqueous mobile phase and the bottom dextran-rich aqueous stationary.[10] Factors that depend on the nature of the protein, such as size, surface area, and hydrophobicity, determine their partition in the PEG–dextran systems. Other factors associated with the nature of the two-phase system that strongly influence protein retention in LLPC are the size of the phase-forming polymers, the pH of the system, and the presence of salts, zwitterions, detergents and organic solvents.

Liquid–liquid partition chromatography techniques based on aqueous–aqueous systems have successfully been employed in the fractionation of crude human serum, purification of steroid hormone-binding proteins from human serum, isolation of basic proteins from crude bacterial extracts, purification of immunoglobulins and monoclonal antibodies, DNA fractionations by size, topology and base sequence, as well as the isolation of soluble and ribosomal RNAs in preparative amounts from bulky mixtures.[10] High-speed CCC using PEG–dextran system has also been employed in the separation of proteins.[6]

Long-Chain Branching Macromolecules: SEC Analysis

Andre M. Striegel
Department of Chemistry, Florida State University, Tallahassee, Florida, U.S.A.

INTRODUCTION

Long-chain branching (LCB), generally thought of as when the length of the branch or branches is comparable to (or is a substantial fraction of) that of the main macromolecular backbone, can influence a variety of chemical, physical, processing, and end-use properties of polymers and polymer solutions. The multiplicity of end-groups that is created as a result of an increase in branches can affect the chemical reactivity of the molecule, while the changes that LCB brings about in space-filling physical properties affect the viscosity and elasticity of melts as well as the viscosity, sedimentation behavior, and angular distribution of scattered radiation of dilute polymer solutions.[1]

In an size-exclusion chromatography (SEC) also known as gel permeation chromatography (GPC) experiment, a branched macromolecule elutes from the column later than a linear macromolecule of equal chemistry and molar mass. As the branched polymer occupies a smaller solvodynamic volume in solution than does its linear counterpart, the former experiences a longer statistical path in its passage through the porous column packing than does the linear analyte.[2] This, of course, assumes that we are operating within the separation range of the column and that the separation proceeds by a strict size-exclusion mechanism (i.e., that the enthalpic contribution to the separation process is minimal).

In this chapter, the analysis of LCB in macromolecules using SEC with multiple detection is described.[3] While the qualitative information obtained from this type of analysis is mentioned, particular attention is paid to the requirements necessary for accurate, quantitative determination of LCB, of the long-chain branching distribution (LCBD), and of the fractal dimension (d_f) of macromolecules.

QUANTITATING THE MACROMOLECULAR LCBD BY SEC/MALS

Virtually every chromatographic method of quantifying the LCB of macromolecules harkens back to the classic 1949 publication by Zimm and Stockmayer.[4] There, the authors derived the root-mean-square (rms) radius of a polymer in a near-infinitely dilute solution, $\langle r^2 \rangle^{1/2}$, and showed how the ratio of the mean-square radius of a branched polymer, $\langle r^2 \rangle_B$, to that of a linear polymer, $\langle r^2 \rangle_L$, may be used as the basis for branching calculations. This ratio, termed the ratio of the mean-square radii, has been given the symbol g and is defined by Eq. 1, with the subscript M referring to values obtained for the same molar mass:

$$g = \left(\frac{\langle r^2 \rangle_B}{\langle r^2 \rangle_L} \right)_M \tag{1}$$

Strictly speaking, it is the z-average radii that are being compared, though, in the case of an SEC separation, it is usually assumed that each slice eluting from the column is monodisperse within the limits of experimental accuracy.

The assumptions inherent in the branching calculations were well-recognized at the time:[4] Only materials of equal chemistry should be compared, their molar mass distributions (MMDs) should overlap in the region of interest, and the type (functionality, f) of the branch points should remain uniform throughout the molecule. The calculations were shown to be invariant to changes in the length of the branches throughout the MMD. The number-average number of branch points (B_n) per molecule for a monodisperse system is given by Eq. 2 for the case of trifunctional ($f = 3$) branching and by Eq. 3 for the case of tetrafunctional ($f = 4$) branching. The weight-average number of branch points (B_w) for a trifunctionally branched polydisperse species is given by Eq. 4, while B_w for a tetrafunctionally branched polydisperse species is given by Eq. 5:

$$g = \left[\left(1 + \frac{B_{3n}}{7} \right)^{1/2} + \left(\frac{4B_{3n}}{9\pi} \right) \right]^{-1/2} \tag{2}$$

$$g = \left[\left(1 + \frac{B_{4n}}{6} \right)^{1/2} + \left(\frac{4B_{4n}}{3\pi} \right) \right]^{-1/2} \tag{3}$$

$$g = \frac{6}{B_{3w}} \left\{ \frac{1}{2} \left(\frac{2 + B_{3w}}{B_{3w}} \right)^{1/2} \times \ln \left[\frac{(2 + B_{3w})^{1/2} + {B_{3w}}^{1/2}}{(2 + B_{3w})^{1/2} - {B_{3w}}^{1/2}} \right] - 1 \right\} \tag{4}$$

$$g = \frac{\ln\,(1 + B_{4w})}{B_{4w}} \tag{5}$$

It should be noted that the symbols used here are those that have found favor in the literature over the years and

Encyclopedia of Chromatography, Third Edition DOI: 10.1081/E-ECHR3-120040040

that are presently being used; as such, they may differ from the symbols used in the original publication. It is also important to realize that, excluding the backbone, one branch emanates from each branch point when $f = 3$, whereas two branches emanate from each branch point when $f = 4$. Zimm and Stockmayer[4] and, later, Stockmayer and Fixman[5] showed how to calculate the number of arms (f) for various types of star polymers by first determining the g parameter.

The rms radius of the polymeric species in each slice eluting from the SEC column can be measured by using an online multiangle light-scattering (MALS) detector, in combination with a concentration-sensitive detector (most often, though not exclusively, a differential refractometer, here abbreviated DRI).[3] This combination also allows measurement of the weight-average molar mass (M_w) of the polymer in each eluting slice. Thus, combining the molar mass results for all the slices yields the MMD, while comparing the molar mass and radius data produces the so-called "conformation plot" of $\log \langle r^2 \rangle^{1/2}$ vs. $\log M$. Comparing the conformation plot of the branched species with that of its linear counterpart allows the determination of g at each molar mass slice and, thence, calculation of the number of branches as a continuous function of the molar mass of the branched macromolecule, the LCBD (these calculations necessitate an a priori knowledge of the branching functionality, f, as do the calculations using g' and the "mass method," both described below). One may also obtain the fractal dimension, d_f, of macromolecules from the conformation plot, as d_f is inversely related to the slope, α, of the plot ($d_f \equiv 1/\alpha$).[3,6] Changes in d_f across the MMD are normally related to architectural variations in the polymer, though they may also be caused by thermodynamic changes in the polymer solution, the latter being a less likely scenario.

Recently,[6] SEC/MALS measurements were used to obtain approximate measures of the average molar mass of a long-chain branch and of the average molar mass between branch points, both as a continuous function of the molar mass of the macromolecule. Though the particular experiments applied to the study of cross-link-induced branching well below the percolation threshold, the theory and measurements extend naturally to the study of "native" branching.

QUALITATIVE AND SEMIQUANTITATIVE DESCRIPTIONS OF THE LCBD BY SEC/VISC

If an online viscometer (VISC) is used instead of a MALS detector in SEC (again, in conjunction with a concentration-sensitive detector),[3] the ratio, g', of the intrinsic viscosities of the branched molecule ($[\eta]_B$) and of the linear standard ($[\eta]_L$), at the same molar mass (M), has been used for the branching calculations:[7,8]

$$g' = \left(\frac{[\eta]_B}{[\eta]_L}\right)_M \tag{6}$$

The relationship between g and g' is given by Eq. 7, where ε is known as the viscosity shielding ratio:

$$g' = g^{\varepsilon} \tag{7}$$

This ratio was defined by Debye and Bueche[9] as the distance within the hydrodynamic sphere occupied by the molecule in solution over which the flow of solvent decreases by a factor $1/e$ of that in the free solution, divided by the radius of said hydrodynamic sphere. It should be noted that even though this definition applied strictly to the Debye–Bueche linear-density pearl-string model of a polymer in solution, the authors demonstrated its suitability to the more accurate Kirkwood–Riseman Gaussian-density polymer model. The value of ε is dependent upon a number of factors, including solvent, temperature, and branching. ε has been found to fall in the range of 0.5–1.5, with the smaller value determined by Zimm and Kilb[10] to correspond to non-free draining, high molar mass, and regular stars, and the larger value determined by Berry[11] for comb-shaped polystyrenes in good solvents. (For a table of ε values, see Ref.[12]) ε can be determined, as a continuous function of molar mass, in a single SEC/DRI/MALS/VISC experiment. It is precisely this type of measurement that has shown the viscosity shielding ratio to be non-constant across the MMD of certain low-density polyethylenes.[13] As such, quantitation of the LCBD by SEC/VISC should be approached with extreme caution.

One may alternatively calculate g by what is known as the "mass method,"[14] by comparing the molar masses of the branched molecule (M_B) and of the linear standard (M_L) at the same elution volume (V), via

$$g = \left(\frac{M_L}{M_B}\right)_V^{(a+1)/\varepsilon} \tag{8}$$

Here, a is the exponent in the Mark–Houwink relationship ($[\eta] = KM^a$). As results from the mass method are also dependent upon the value of the viscosity shielding ratio, the same caveat expressed in the previous paragraph applies.

While generally less accurate than SEC/MALS measurements, SEC/VISC measurements are usually both more precise and extend to lower molar masses. The increased precision stems from the relatively higher signal-to-noise ratio in viscometric measurements than in dissymmetry experiments. The lack of sufficient angular dissymmetry for medium- to small-size polymers means that it is extremely difficult to determine their rms radius precisely, especially for the low molar mass species of a broad polydispersity sample; employing high concentrations is out of the question for these types of sample due to column overloading effects as well as to the possibility of

no longer operating in the dilute, non-entangled viscoelastic regime.[15] As a rule of thumb, an approximate cut-off in the determination of the rms radius occurs when $\langle r^2 \rangle^{1/2} \leq \lambda/20$, where $\lambda = \lambda_0/n$, and λ_0 is the vacuum wavelength of the incident radiation and n is the refractive index of the solvent.

An example of the type of qualitative comparison that SEC/VISC permits is shown in Fig. 1 for two polyolefin molecules, one linear and one branched.[7,8] In this overlay of Mark–Houwink plots, the slope of the plot of the linear polyethylene is constant as a function of increasing molar mass, reflecting the constancy in chain density at different sizes. At any given molar mass, the intrinsic viscosity of the branched polyethylene is lower than that of its linear counterpart, as a result of the more compact nature of the former with respect to the latter caused by LCB. Moreover, the slope of the Mark–Houwink plot of the branched polyethylene is seen to decrease with increasing molar mass, indicating an increase in LCB with increasing molar mass. It is important to realize that these types of qualitative assessments, as well as the quantitative measures obtained by SEC/MALS, are contingent upon the thermodynamics of the polymer solution remaining constant at different molar masses, i.e., it is assumed that the second virial coefficient does not change with molar mass.

Calculation of the fractal dimension is also possible from SEC/VISC measurements. Here, d_f is determined from[3,16]

$$d_f = \frac{3}{1+a} \tag{9}$$

where a, once again, is the exponent in the Mark–Houwink equation. This way of calculating d_f presupposes a constancy in the polymer draining (Φ) and coil interpenetration (Ψ^*) parameters across the MMD.[3,6,17]

BRANCHING AND SEC/QELS

In 1953, Stockmayer and Fixman[5] observed that the ratio, h, of hydrodynamic or Stokes radii (R_H) of the branched and linear macromolecules could also be used as a measure of branching. The relatively recent introduction of online quasielastic light scattering (QELS, also known as dynamic light scattering and as photon correlation spectroscopy) detectors for SEC[3,18] permits direct determination of h by

$$h = \left[\frac{(R_H)_B}{(R_H)_L}\right]_M \tag{10}$$

To date, this relation has not been used extensively in SEC/QELS to measure branching as a continuous function of molar mass, chiefly because it is not clear how to correlate measured values of h to calculations of B, the number of branch points. Nonetheless, the ratio of hydrodynamic to rms radii, ρ, and the distribution of ρ as a function of molar mass, has proven fruitful in demonstrating either constancy or changes in architecture across the MMD of polymers.[17,18]

CONCLUSIONS

The study of LCB in macromolecules by means of multi-detector SEC has been described. Calculations of LCB, of the LCBD, and of fractal dimensions are performed most

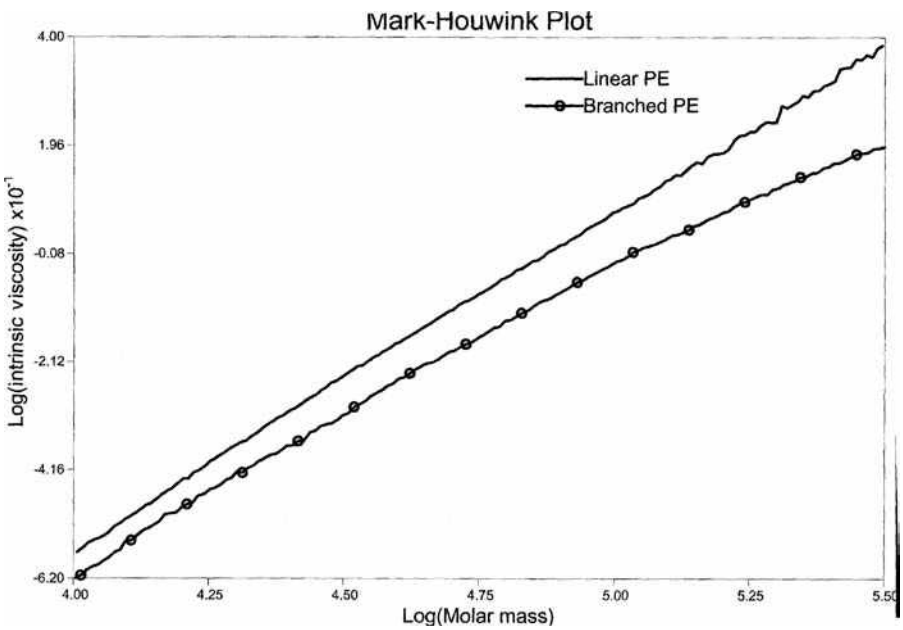

Fig. 1 Overlay of the Mark–Houwink plots of linear and branched polyethylene (PE) samples. See Ref.[7,8] for experimental details.
Adapted from Striegel & Krejsa.[7,8]

accurately using SEC/MALS, though SEC/VISC appears to provide higher precision, more distinct qualitative comparisons, and discrimination between branching levels to lower molar masses than does SEC/MALS. Large errors can result from the branching calculations based on Zimm–Stockmayer theory, however, if careful attention is not paid to a number of parameters.[7,8] Various metrics exist for gauging macromolecular branching and architecture, and an excellent way of determining these is by SEC/DRI/VISC/MALS/QELS, as demonstrated recently by Cotts.[18] As SEC detectors, VISC, QELS, and even nuclear magnetic resonance (NMR) spectroscopy all have the potential to determine the short-chain branching distribution (SCBD) in polymers.[3] Though not the topic of this entry, measurement of the SCBD is complementary to that of the LCBD. Currently, some of the most elegant work on measuring the SCBD in polyolefins is being performed using SEC coupled to Fourier-transform infrared spectroscopy detection (SEC/FT-IR).[19]

Additional support to the chromatographic determination of the LCBD in polymers can be provided by rheological experiments,[20] by a variety of computer modeling techniques,[21,22] and even by enzymology.[23]

Longitudinal Diffusion in LC

J.E. Haky
Department of Chemistry and Biochemistry, Florida Atlantic University, Boca Raton, Florida, U.S.A.

INTRODUCTION

Longitudinal diffusion refers to the natural spreading of a solute band from regions of high concentration to those of lower concentration as it passes through a chromatographic system.[1] It is a simple process which is dependent on the time that the solute spends on the chromatographic system, which, in turn, is related to the flow rate of the mobile phase.

DISCUSSION

As an extreme illustration of the longitudinal diffusion process, consider a situation in which a solute is put onto a liquid chromatographic column and the flow of the mobile phase is shut off prior to any of the solute eluting from the column. The column is then sealed. Under these conditions, the solute molecules in the column would begin to diffuse from a concentrated band outward to regions of lower concentrations in the column. Given enough time, this diffusion would continue until the solute concentration throughout the mobile phase in the sealed column is constant. Although this is an extreme example of band broadening caused by this phenomenon, such longitudinal diffusion occurs to a lesser extent even when the mobile phase is flowing.

The degree of band broadening of any chromatographic peak may be described in terms of the height equivalent to a theoretical plate, H, given by

$$H = \frac{L}{N} \tag{1}$$

where L is the length of the column (usually in cm) and N is the number of theoretical plates, which can be calculated from Eq. 2,

$$N = 16\left(\frac{t_R}{W}\right)^2 \tag{2}$$

where t_R and W are the retention time and width of the peak of interest, respectively. Because higher values of N correspond to lower degrees of band broadening and narrower peaks, the opposite is true for H. Therefore, the goal of any chromatographic separation is to obtain the lowest possible values for H.

The contribution of longitudinal diffusion and other factors to band broadening in liquid chromatography can be quantitatively described by the following equation, which relates the column plate height H to the linear velocity of the solute, μ:

$$H = A\mu^{0.33} + \frac{B}{\mu} + C\mu + D\mu \tag{3}$$

In this equation, A, B, C, and D are constants for a given column.[2] The linear velocity μ is related to the mobile-phase flow rate and is determined by

$$\mu = \frac{L}{t_0} \tag{4}$$

where t_0 (the so-called "dead time") is determined from the retention time of a solute which is known not to interact with the stationary phase of the column.

The second term in Eq. 3, B/μ, describes the contribution of longitudinal diffusion to band broadening of the solute as it passes through the chromatographic system. This is the only term in the equation inversely proportional to the linear velocity of the mobile phase; the other terms increase in value as the linear velocity increases. Giddings and others have also shown that this term is also directly proportional to the diffusion coefficient D_m of the solute in the mobile phase according to the following equation, where C_d is a constant:[3]

$$\frac{B}{\mu} = \frac{C_d D_m}{\mu}$$

Encyclopedia of Chromatography, Third Edition DOI: 10.1081/E-ECHR3-120040041

Fortunately, the mobile-phase flow rates used in most modern liquid chromatography (LC) separations are sufficiently high enough to minimize the effects of longitudinal diffusion on chromatographic band broadening under usual conditions. Other factors, such as solute mass transfer, are usually more important contributors to band broadening in LC. However, longitudinal diffusion can be an important factor in situations where the flow rate of the mobile phase is either stopped or significantly reduced during a chromatographic separation. Additionally, because it occurs throughout the path of a solute passing through a chromatographic system, efforts should be made to minimize longitudinal diffusion effects by minimizing open space ("extracolumn volume") in the chromatographic system before and after the column.

Abstract
The addition of magnetic force to the family of field-flow fractionation (FFF) and split-flow thin-channel (SPLITT) techniques expands their application to characterization and separation of magnetic nanoparticles, microparticles, and magnetizable particular matter, such as biological cells. A combination of the well-established analytical principles of FFF and information about the material properly of the particles subjected to analysis allows one to probe for the magnetic properties of particulate matter on a micro- and nanoscale. A highly regular SPLITT separation process provides the basis for a rational design of new magnetic separation for difficult separations, such as rare circulating tumor cells from blood. Well-established principles of FFF and SPLITT provide foundations for continuing development of better magnetic separation and microanalytical techniques.

INTRODUCTION

Magnetic field-flow fractionation (FFF) employs static or quasi-static magnetic fields and excludes electromagnetic fields. Electromagnetic fields having frequencies in the kilohertz to megahertz range are used in dielectrophoretic FFF. Static electric fields are used in electrical FFF (see *FFF Fundamentals*, p. 849). In this Chapter, a review of magnetic separation fundamentals is provided together with a selection of recent applications of magnetic FFF, SPLITT, and related techniques.

MAGNETOPHORETIC MOBILITY AND MAGNETIC FIELD ENERGY DENSITY GRADIENT

The magnetic field is described by two vectors: magnetic field strength, **H** and magnetic flux density (also called magnetic induction or simply magnetic field), **B**, described by Maxwell's equations. The magnetic field is solenoidal; that is, its sources are electric currents or magnetic dipoles (but not "magnetic charges").[1] The magnetic property of matter is described by its magnetic permeability, μ, which for an isotropic medium is a scalar. The difference between the external, applied field **H** and the induced field **B** is the magnetization of the matter, which is a vector quantity **M**. An external magnetic field always induces magnetization in matter and, in this sense, all matter is magnetic. (The microscopic basis of magnetization is provided by quantum physics and is beyond the scope of this entry.) For a large class of materials, magnetization is a linear function of the applied external magnetic field strength and it always consists of a diamagnetic contribution and, less often, a paramagnetic contribution. In the International System of Units, we have

$$\mathbf{B} = \mu\mu_0\mathbf{H},\ \mathbf{M} = \frac{1}{\mu_0}\mathbf{B} - \mathbf{H},\ \mathbf{M} = \chi\mathbf{H}$$

where **B** is measured in tesla (T), **H** is measured in A/m, $\mu_0 = 4\pi \times 10^{-7}$ Tm/A is a constant called the magnetic permeability of a vacuum, and χ is the volumetric susceptibility of the material (dimensionless). The vector quantities are indicated by boldface type, **B**, their magnitude by italics, **B**, etc. Note that $\mu = 1 + \chi$. Diamagnetic magnetization is antiparallel to the applied field ($\chi < 0$) and paramagnetic magnetization is parallel to the applied field ($\chi > 0$). Diamagnetic effects are very weak (with the notable exceptions of bismuth and graphite) and are dominated by much stronger paramagnetic effects.

Typical fluid media encountered in magnetic separation are diamagnetic (for water, $\chi = -9.05 \times 10^{-6}$). For certain metals, their alloys and oxides, the coordinated behavior of the neighboring atoms or molecules (the totality of which is referred to as a magnetic domain) gives rise to very strong magnetic effects known as ferromagnetism and ferrimagnetism.[2] For such material, magnetization increases very rapidly with the applied field strength H, and the value of the magnetization depends on the history of the material (hysteresis effect). In particular, the magnetization does not disappear with the removal of the external field (residual magnetization) and requires

application of an opposite field to be brought down to zero (coercive force). For convenience, diamagnetics and paramagnetics are characterized by their magnetic susceptibility, χ (typically, the absolute value of $\chi = 10^{-2}$–10^{-5}), whereas ferromagnetics are characterized by their magnetic permeability, μ (typically, $\mu = 10^5$). For particles having a size not larger than that of the magnetic domain, the hysteresis curve reduces to a straight line and such particles are referred to as superparamagnetic particles. Paramagnetic and superparamagnetic particles and colloids are used to tag (or label) weakly magnetic particles and biological cells for their selective separation.[3]

The fluid dynamic properties of continuous magnetic media, including liquid ferromagnetic media (ferrofluids), are described by the Navier–Stokes equations with the addition of terms describing the interaction with the magnetic field and are the subject of a considerable number of studies.[1] The motion of discrete magnetic particles in a very weakly magnetic ("non-magnetic") medium can be described by a combination of long-range magnetic body forces and local shear stresses due to the resulting motion through the viscous medium. In the case of colloidal particles for which inertial effects are much lower than the viscous effects (low-particle Reynolds number), and for laminar flows (low-channel Reynolds number), the equation of motion reduces to

$$0 = 6\pi\eta R\mathbf{v} - \Delta\chi V\nabla\left(\frac{B^2}{2\mu_0}\right)$$

from which

$$\mathbf{v} = \frac{\Delta\chi V}{6\pi\eta R}\nabla\left(\frac{B^2}{2\mu_0}\right)$$

where η is the viscosity of the medium, R is the particle radius, V is the particle volume, $\mathbf{v}$ is the particle linear velocity vector relative to the medium, and $\Delta\chi$ is the difference between the particle magnetic susceptibility and that of the medium. The operand acted on by the nabla operator (resulting in a gradient of scalar quantity), is the external magnetic field energy density, $B^2/2\mu_0$, in a non-magnetic medium. The expression for the field-induced velocity can be conveniently presented as a product of the particle magnetophoretic mobility, m, and the magnetic field energy density gradient, $\mathbf{S}_\mathrm{m}$,

$$\mathbf{v} = m \cdot \mathbf{S}_m$$

where

$$m \equiv \frac{\Delta\chi V}{6\pi\eta R} \text{ and } \mathbf{S}_m \equiv \nabla\left(\frac{B^2}{2\mu_0}\right)$$

For paramagnetic (and diamagnetic) particles in diamagnetic media, $\Delta\chi$ is independent of S_m and the magnetophoretic mobility depends entirely on the intrinsic properties of the particle and those of the continuous medium.[4] For a ferromagnetic particle, $\Delta\chi$ is, in general, a function of H, and therefore the magnetophoretic mobility depends on the properties of the particle, the medium, and the field strength.[5] Particle magnetophoretic mobility provides the basis of magnetic separation, and its role is analogous to the electric and sedimentation mobilities encountered in the electrical and sedimentation split-flow thin-channel (SPLITT) separations, respectively.

The order-of-magnitude analysis of the magnetophoretic mobility of weakly paramagnetic particles, 10 μm in diameter, acted on by the body forces available for the magnetic separation, returns the following numerical values: $\Delta\chi = 10^{-3}$, $V = 524\ \mu\mathrm{m}^3$, $\eta = 10^{-3}$ kg/ms, $R = 5$ μm, $B = 1$ T, gradient of $B = 200$ T/m, $m = 5.6 \times 10^{-15}$ (m/sec)/(N/m^3), and $S_\mathrm{m} = 1.6 \times 10^8$ N/m^3. It follows that the particle velocity induced by the magnetic field is $\nu = 9 \times 10^{-7}$ m/sec, or about 1 μm/sec.

Advantages of the magnetostatic or quasi-static field as compared to the oscillating electromagnetic fields in application to separation include the following: no interaction with the suspending fluid, which typically is diamagnetic or very weakly paramagnetic, and therefore no Joule heating, no convective effects and no need for a cooling system; no electro-osmotic effects; long range of the magnetic interactions (as compared to dielectrophoresis); the possibility of using permanent magnets for the magnetic field and thus no requirement for power supply; high specificity in targeting the separands by using magnetic labels as ligands to specific receptors; and no demonstrated biological effects in the practical range of magnetic fields and gradients. The limitations of the magnetic separation include a requirement for magnetic labels for non-magnetic separands and, generally, a complex geometry of the magnetic force field, which tends to make it difficult to control the separation process.

MAGNETIC FFF

The majority of publications concerning magnetic field-flow fractionation (magnetic FFF or MgFFF) describe different technical approaches for achieving a uniformly high magnetic field and gradient over the entire channel volume. In this sense, MgFFF has not achieved the level of maturity of other FFF techniques for which the field and flow geometries are well established. The separation mechanism of FFF requires a laminar fluid flow in a thin channel with a field or field gradient applied across the channel thickness, perpendicular to the direction of flow. The field or field gradient need not be constant across the channel thickness, but there should not be strongly localized forces on particles that might induce capture. As in chromatography, separation is achieved by differential rates of migration of the sample components along the

separation column (or channel, as it is referred to in FFF), leading to different elution times. Unlike in chromatography, there is no partition between phases in FFF and the different migration rates of the sample components depend on their different steady-state distributions across the fluid velocity profile.

The simplest approach to implementing magnetic FFF is to use a capillary tube as the separation channel. The tube may be coiled against the face of a circular pole piece as proposed by Vickrey and Garcia-Ramirez in 1980.[6] A similar approach was taken by Mori in 1986.[7] High field strengths may be generated in the tube, but field gradients tend to be small for this approach. Latham et al.[8] more recently wound a capillary tube along the edge of a circular magnet pole piece where the field gradient is highest and were able to obtain a separation between 6 nm Fe_2O_3 and 13 nm $CoFe_2O_4$ particles. Tubular channels with transverse fields or field gradients are far from ideal for achieving FFF separation,[9] although some continue their study.[10,11] Semenov and Kuznetsov[12] proposed in 1986 the mounting of a ferromagnetic wire on the axis of a tubular separation channel. The channel was to be placed perpendicular to a magnetic field that magnetized both the wire and the particles to be separated. They presented calculations that suggested retention of both paramagnetic and diamagnetic particles would be possible in such a system. However, the force on the particles may be expected to increase rapidly as they approach the wire and this may lead to particle capture. The small surface of the wire would also have to serve as the accumulation wall which would mean that the system would be susceptible to overloading effects.

In the same year (1986), Semenov[13] proposed a parallel plate magnetic FFF channel in which the field gradient was provided by an array of ferromagnetic wires embedded in one of the walls. The wires were to be magnetized by a magnetic field applied across the channel thickness. The channel geometry was much better suited to FFF, but the field gradient would still vary rapidly with distance from the magnetized wires. From 1994, Ohara et al.[14–21] have pursued an approach to magnetic FFF similar in concept to that proposed by Semenov.[13]

The magnitude of the quadrupole magnetic field is axisymmetric and increases in proportion to the radial distance from the axis. The gradient in field is therefore directed radially outward from the axis and is of constant magnitude within the aperture. This is a great advantage for the purposes of implementing magnetic FFF, as there is no strong variation in field gradient that can induce particle capture. A quadrupole field was considered by Takahashi et al.[10] but with a tubular FFF channel offset from the quadrupole axis. A better exploitation of the axisymmetric magnetic field gradient uses an annular FFF channel,[22] as for the magnetic SPLITT devices described below. A drawback of using an annular channel for achieving FFF separations is the requirement of very uniform mean fluid velocity around the full circumference. Very slight variation in annular thickness will strongly influence the fluid distribution. Also, the fluid must be distributed evenly around the circumference at the channel inlet and be collected uniformly around the outlet. The distribution and collection of fluid was accomplished using several inlet and outlet ports around the circumference. Any flow variation in the ports, including that caused by their partial or complete blockage, would also disturb the fluid flow uniformity. It must be pointed out that these disturbances to flow would greatly reduce the efficiency of separation by FFF, but are far less critical for continuous separation by SPLITT fractionation in an annular channel.

The disturbance to flow arising out of the use of multiple inlet and outlet ports can be avoided by using single inlet and outlet ports and making use of just a fraction of the annulus for the channel. A better approach is to use single inlet and outlet ports and a helical path for the channel in the annular space. The channel is machined into the surface of a polyoxymethylene rod (Delrin™ from DuPont) that fits tightly into an internally polished stainless steel tube.[23–25] The constant thickness of the channel is maintained by the tight fit of the rod within the steel tube. The helical path taken by the channel also exposes all of the migrating species to any slight variations in the magnetic field gradient around the circumference. In an annular channel, such variations would also contribute to loss of separation efficiency.

The FFF retention theory for quadrupole magnetic FFF (QMgFFF) is developed in an analogous way to that of the other FFF techniques. The magnetic force on a single particle due to its interaction with the magnetic field is given by

$$\mathbf{F}_m = V_m M \nabla B$$

where V_m is the volume of the magnetized component of the particle, M is the magnetization of this component, and ∇B is the gradient in magnetic field. It is common for magnetic nanoparticles used for cell labeling or for magnetic drug targeting to have a core of magnetite or some other magnetizable material and a hydrophilic coating to stabilize the particles in aqueous suspension. Other materials such as antibodies or drugs may also be included. The coating also reduces the particle magnetic dipole–dipole interaction between particles in a magnetic field and reduces the tendency for chaining and aggregation. To a good approximation, only the magnetic component has a significant response to the magnetic field. A steady-state concentration profile is quickly established in the thin FFF channel where the drift toward the outer channel wall and consequent buildup of concentration against the wall is countered by diffusion. As in other forms of FFF, the concentration c decays exponentially away from this wall according to the equation

$$c = c_0 \exp\left(-\frac{x}{l}\right) = c_0 \exp\left(-\frac{1}{\lambda}\frac{x}{w}\right)$$

where c_0 is the concentration at the outer wall (the so-called accumulation wall), x is the distance from the wall, l is the mean layer thickness of the steady-state particle zone, w is the channel thickness, and $\lambda = l/w$ is the FFF retention parameter. It may be shown that

$$\lambda = \frac{kT}{F_m w}$$

For a parallel plate channel and to a good approximation for a thin helical channel, the elution time for a monodisperse sample of particles is obtained from the equation

$$R = \frac{t^0}{t_r} = 6\lambda(\coth(1/2\lambda) - 2\lambda) \approx 6\lambda(1 - 2\lambda)$$

in which R is the so-called retention ratio, t^0 is the time for a non-retained material to pass through the channel, and t_r is the elution time for the retained particles. The elution time is therefore directly related to the volume of magnetic material in the particles.

The magnetic nanoparticles used for cell labeling and for magnetic drug targeting have been found to be polydisperse in terms of their magnetic content. Because of the relatively high selectivity of magnetic FFF (i.e., elution time increases with the cube of magnetic core diameter), it is necessary to carry out particle elution under conditions of magnetic field gradient decay. A quadrupole electromagnet with computer control of the current is required for this.[23–25] The quantitative relationship between the amount of magnetic material contained in the nanoparticles and their elution times, even under conditions of field gradient decay,[26] allow the characterization of a sample in terms of not only the mean magnetic content but also the distribution in the magnetic content of the particles.[25]

MAGNETIC SPLITT

The requirement of a highly regular field and flow geometries is even more stringent in SPLITT separations because they often rely on the transport, rather than the equilibrium, separation mechanism. The solenoidal character of the magnetic field requires modification of the usual rectangular geometry of the SPLITT channel. This has led to the design of an annular channel around an axisymmetric magnetic quadrupole field (similar to that used in quadrupole mass spectroscopy).[27] Quadrupole magnetic SPLITT offers the advantages of a highly regular S_m, which is a linear function of the distance from the axis of symmetry and directed along the radial position vector, and of an edgeless flow channel. The theory of the quadrupole magnetic SPLITT separation has been developed and its experimental verification in biological applications is ongoing.[28]

A SPLITT system based on a quadrupole magnetic field combined with annular channel geometry possesses an axial symmetry that lends itself to the mathematical description of the separation process. Given the magnetophoretic mobility of a paramagnetic particle, m, the magnetic field energy gradient in the annular channel, S_m, the system dimensions, and flow rates, it is possible to predict particle trajectory through the system as a function of starting position. It follows that it is possible to calculate the flow rate conditions required to continuously separate particles within a given window of the magnetophoretic mobilities. All particles having mobilities higher than a certain characteristic upper critical m value are collected at one channel outlet, and those having mobilities lower than a lower critical m value are collected at another outlet. The resolution of the fractionation increases with the increasing size of the mobility window separating the two outlet fractions. The volumetric throughput is inversely proportional to the separation resolution.

The availability of monoclonal antibodies conjugated to magnetic micro- and nanoparticles from commercial sources makes it possible to purify or isolate certain specific biological cell types using magnetic SPLITT.[28] These procedures are designed for applications in cancer treatment, cancer treatment prognosis, and various other cell therapies. Unlabeled biological cells tend to be only very weakly influenced by magnetic fields. Flow conditions may be selected so that when a mixture of labeled and unlabeled cells is passed through the magnetic SPLITT system, the labeled cells are selectively drawn toward the outer channel wall and are retained inside the channel (removed from the flow of cell suspension). An example of this type of separation is shown in Fig. 1. For that particular application, the SPLITT system was reduced to a single inlet-single outlet configuration.

The magnetophoretic mobility of a cell labeled with a monoclonal antibody–magnetic particle conjugate (or more generally, a magnetic ligand) is directly proportional to the number of magnetic particles attached to the cell. An important question in magnetic SPLITT is this: Given the upper and lower limit of the number of the antibody receptors on a cell and the size of the cell, how many different fractions may one separate the magnetically labeled cell sample into? For a simple model of a cell as a sphere of a diameter distributed normally in the cell sample population, the theoretical number of the magnetically fractionated subpopulations is given by

$$n = \ln\left(\frac{\alpha_n}{\alpha_0}\right)\left[\ln\left(\frac{1 + z\sigma}{1 - z\sigma}\right)\right]^{-1}, \; 0 < |z\sigma| < 1$$

where α_n and α_0 are the high and low values of the magnetic receptor density on a cell, respectively, and σ is the relative

standard deviation in the cell diameter. The parameter z is an independent variable of the standard normal distribution (with a mean of zero and a variance of one). The number z is chosen according to the desired confidence level of including cells of a given receptor density in a sorted fraction. For instance, at a level of 95.5%, the corresponding value of $z = 2$. As an example, assuming $\alpha_0 = 100$, $\alpha_n = 100{,}000$, and $\sigma = 0.3$ (representative of white blood cells) one obtains $n = 5$ at a confidence level of 95.5%. A more complete discussion of this relationship can be found in the work done by Chalmers et al.[29]

RELATED TECHNIQUES

There are significant advantages in miniaturizing channels and magnets used for magnetic FFF and magnetic SPLITT. These include the ability to generate high fields and high magnetic gradients at moderate magnet costs and an increased flexibility in testing various field and flow configurations.[30] The advances in channel microfabrication methods and permanent magnet material technologies led to an increasing number of publications on magnetophoretic separations in flowing suspensions during the past several years.[31–37] Although the field and flow configurations used for miniaturization rarely fit the narrow definition of the FFF and SPLITT geometries, they nevertheless share many important properties, in particular, the independence of solid phase (substrate) for accomplishing separation and the well-defined laminar flow conditions. It is likely that the basic concepts of the (magnetic) FFF and SPLITT such as, resolving power and the interdependence of the resolving power and throughput will be adapted with time to quantitative analysis of separations based on microfluidics and the micromagnetics.

Mark–Houwink Relationship

Oscar Chiantore
Department of Inorganic, Physical, and Material Chemistry, University of Torino, Torino, Italy

INTRODUCTION

The molecular weight of polymer molecules can be determined by the measurement of the viscosity of dilute polymer solutions.[1] The relationship used is the so-called Mark–Houwink (MH) empirical equation:

$$[\eta] = KM^a \tag{1}$$

where the intrinsic viscosity $[\eta]$, also called the limiting viscosity number, is proportional to the polymer molecular weight, M, through the constants K and a, valid for each polymer–solvent system at a given temperature.

APPLICATIONS

The constants of Eq. 1 are obtained by measuring the intrinsic viscosities, in the solvent and at the temperature of choice, of a series of polymer samples having different and known molecular weights.

For flexible macromolecules, the exponent a takes values between 0.5 and 0.8, whereas, for rigid chains, it can reach values higher than 1, up to 2.

The intrinsic viscosity of a polymer is obtained from the viscosities η and η_0 of solution and solvent, respectively, through the following transformations. The relative viscosity is the ratio $\eta_{rel} = \eta/\eta_0$. By assuming that the viscosity η of a dilute solution is given by the sum of viscosities from solvent and solute molecules, the specific viscosity, η_{sp}, represents the polymer contribution to viscosity:

$$\eta_{sp} = \frac{\eta - \eta_0}{\eta_0} = \eta_{rel} - 1 \tag{2}$$

and dividing by the concentration, c, the reduced viscosity η_{sp}/c is obtained. The intrinsic viscosity is the value of reduced viscosity at infinite dilution:

$$\eta = \lim_{c \to 0} \frac{\eta_{sp}}{c} \tag{3}$$

Experimentally, the viscosity of dilute polymer solutions is, in most cases, determined with glass capillary viscometers, making application of the Hagen–Poiseuille's law for laminar flow of liquids. The time required for a specific volume of a liquid to flow through a capillary of defined length and radius is proportional to the ratio of the viscosity by the density of the liquid itself. As the density of a dilute solution may be considered practically equal to that of the pure solvent, the ratio of efflux time of the solution, t, to that of solvent t_0, gives the relative viscosity:

$$\eta_{rel} = \frac{t}{t_0} = \frac{\eta}{\eta_0} \tag{4}$$

The relative viscosities of polymer solutions are measured at different concentrations and a plot of the reduced viscosity vs. concentration is made, in order to extrapolate to zero concentration. The concentration dependence of the viscosity of polymer solutions, in the dilute regime, may be expressed by several linear equations. For practical extrapolation to zero concentration, the most commonly employed are the Huggins equation:

$$\frac{\eta_{sp}}{c} = [\eta] + k_H[\eta]^2 c \tag{5}$$

and the Kraemer equation, where a new quantity, the inherent viscosity η_{inh}, is defined:

$$\eta_{inh} = \ln\left(\frac{\eta_{rel}}{c}\right) = [\eta] + k_K[\eta]^2 c \tag{6}$$

The constants of the two equations are connected by the relationships $k_K = k_H - 0.5$. Given that, for flexible polymers, the k_H values vary between 0.3 and 0.5, the slope of Kraemer equation is generally negative, with absolute values lower than the Huggins slope. This helps in the extrapolation procedure which is conveniently made, in order to reduce experimental uncertainties, by plotting in the same graph the viscosity data according to Eqs. 5 and 6, as shown in the example of Fig. 1.

The combination of Eqs. 5 and 6 with the assumption that $k_H + k_K = 0.5$ leads to the Solomon–Ciuta equation:

$$[\eta] = \frac{[2(\eta_{sp} - \ln \eta_{rel})]^{0.5}}{c} \tag{7}$$

which may be used to obtain intrinsic viscosity by a single measurement performed at reasonably low concentration. Eq. 7 finds application also in the evaluation of data from viscometer absolute detectors in gel permeation chromatography/size-exclusion chromatography (GPC/SEC).[2]

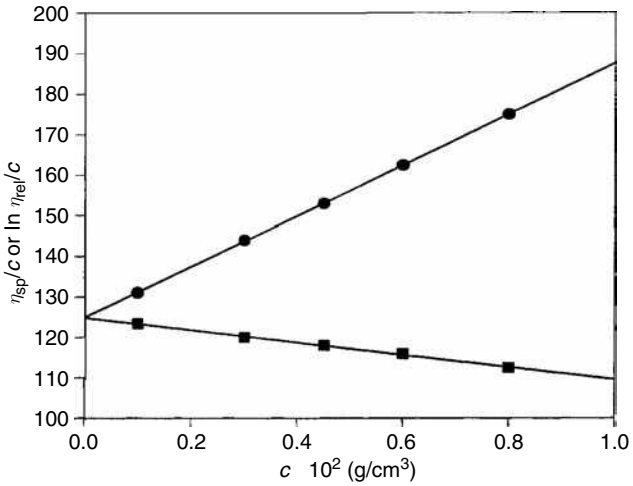

Fig. 1 Double extrapolation of viscometric data according to the Huggins and Kraemer equations: ●: reduced viscosity; ■: inherent viscosity.

In the case of polymers with different chain lengths, the molecular weight obtained from the Mark–Houwink equation is a viscosity-average molecular weight, M_v, whereas the intrinsic viscosity is the weight average. In fact, at infinite dilution, one may write

$$[\eta] = \Sigma\left(\frac{\eta_{sp,i}}{c_i}\right) = \Sigma\left(\frac{c_i[\eta]_i}{c_i}\right) = \Sigma\ w_i[\eta]_i = [\eta]_w \tag{8}$$

where $w_i = c_i/\Sigma\ c_i$ is the weight fraction of the ith component.

The expression for M_v is immediately derived by combining Eq. 8 with the Mark–Houwink relationship:

$$[\eta]_w = \Sigma\ w_i[\eta]_i = K\ \Sigma\ w_i M_i^{\ a} = KM_v^a \tag{9}$$

$$M_v = (\Sigma\ w_i M_i^{\ a})^{1/a} \tag{10}$$

The viscosity-average molecular weight is located between the number- and weight-average values but is, in any case, closer to the weight average. From Eq. 10, it may be seen that viscosity and weight averages coincide for $a = 1$. It is also worth noting that the M_v of a polymer is not a unique definite value because, depending on the exponent a, it varies with the solvent, where the polymer is dissolved.

Mark–Houwink relationships are also important for the application of the universal calibration procedure in GPC/SEC of polymer molecules, where the calibration curve is expressed in terms of the size of fractionated molecules against retention volumes. The intrinsic viscosity of a polymer (expressed in cm^3/g) is, in practice, a measure of the

volume occupied by a unit weight of the macromolecules in the solution. From the Flory–Fox equation for viscosity of flexible chain molecules and from the Einstein relationship for viscosity of a dispersion of spheres,[3] it turns out that the product $[\eta]M$ can be used to represent the dimension of polymer molecules in the solution:

$$[\eta]M = \phi'\alpha^3\langle s_0^2\rangle^{3/2} = 2.5N_AV_h \quad (11)$$

ϕ' is the so-called Flory's constant, α is the expansion factor of the polymer molecule, which depends from the thermodynamic quality of the solvent ($\alpha = 1$ in ideal solvent), $\langle s_0^2\rangle$ is the mean-square radius of gyration, N_A is Avogadro's number, and V_h is the volume of the equivalent hydrodynamic sphere.

In GPC/SEC with universal calibration, at each retention volume i of the chromatogram, a value of $[\eta]_i/M_i$ is read, and for molecular-weight and molecular-weight-distribution calculations the values of $[\eta]_i$ are needed. These are obtained, whenever the equation is known, from the Mark–Houwink constants of the polymer in the solvent and at the temperature of chromatographic elution.

A selection of literature values for Mark–Houwink constants K and a in tetrahydrofuran, which is the eluent most commonly used in size-exclusion chromatography, is collected in Table 1 for the principal polymer structures. An accurate, more extensive compilation of the same constants for homopolymers and copolymers may be found in Ref.[22]

Mass Transfer between Phases

J.E. Haky
D.A. Teifer
Department of Chemistry and Biochemistry, Florida Atlantic University, Boca Raton, Florida, U.S.A.

INTRODUCTION

Chromatography is a separation method which involves two phases—one stationary and one mobile. A mixture is introduced into the mobile phase and is carried through the system by it. At some point, the mobile phase passes over and through the stationary phase. The components of the mixture partition between the two phases, resulting in different migration rates through the system.[1] At any given point, an analyte molecule will either be moving along the mobile phase or be held immobile in the stationary phase. A separation results as the molecules emerge from the bed at different times, which are called retention times.

BACKGROUND INFORMATION

The retention time of a solute is partially controlled by how effectively it interacts with the stationary phase as it passes through the column. As a solute molecule moves through a chromatographic system, it is carried through the mobile phase to a new solution site in the stationary phase. Simultaneously, other solute molecules are moving from the stationary phase and are being conducted through the column by the mobile phase. In any separation of components of a mixture by, liquid chromatography (LC) the rate at which this repeated transfer of solutes between the stationary phase and the mobile phase is an important factor affecting retention, peak shape, and resolution.

Mass transfer in both the stationary and mobile phases are not instantaneous and, consequently, complete equilibrium is not established under normal separation conditions.[2] The result is that the solute concentration profile in the stationary phase is always displaced slightly behind the equilibrium position and the mobile-phase profile is slightly in advance of the equilibrium position.[2] A high degree of displacement will lead to wider peaks and reduced resolution. In fact, the largest problem associated with mass transport in the packed column revolves around moving the solute from the stationary phase to the mobile phase.

The degree of band broadening of any chromatographic peak may be described in terms of the height equivalent to a theoretical plate, H, given by

$$H = \frac{L}{N} \tag{1}$$

where L is the length of the column (usually in cm) and N is the number of theoretical plates, which can be calculated from

$$N = 16\left(\frac{t_R}{W}\right)^2 \tag{2}$$

where t_R and W are the retention time and width of the peak of interest, respectively.

Because higher values of N correspond to lower degrees of band broadening and narrower peaks, the opposite is true for H. Therefore, the goal of any chromatographic separation is to obtain the lowest possible values for H.

The contribution of mass transfer and other factors to band broadening in LC can be quantitatively described by the following equation, which relates the column plate height H to the linear velocity of the solute, μ:

$$H = A\mu^{0.33} + \frac{B}{\mu} + C\mu = D\mu \tag{3}$$

In this equation, A, B, C, and D are constants for a given column[3]. The linear velocity μ is related to the mobile-phase-flow rate and is determined by

$$\mu = \frac{L}{t_0} \tag{4}$$

where t_0 (the so-called "dead time") is determined from the retention time of a solute, which is known not to interact with the stationary phase of the column.

The first term in Eq. 3, $A\mu^{0.33}$, includes the contribution of eddy diffusion to band broadening as well as that of mass transfer of the solute through the mobile phase. This contribution of this mobile-phase mass transfer to this term, H_i, increases with the square of the stationary-phase particle diameter d_p. It is also inversely proportional to the diffusion coefficient of the solute in the mobile phase, D_m, according to

$$H_i = \frac{C_m d_p{}^2 \mu}{D_m} \tag{5}$$

where C_m is a constant.

The third and fourth terms of Eq. 3 also relate to mass transfer. The third term, $C\mu$, describes the contribution of mass transfer of solutes to and from areas in the column where the mobile phase is stagnant (e.g., within the pores of the packing). The size of this term is related to stationary-phase particle diameter and solute diffusion coefficient according to

$$C\mu = \frac{C_{sm} d_p{}^2 \mu}{D_m} \tag{6}$$

where C_{sm} is a constant.

Finally, the fourth term in Eq. 3, $D\mu$, describes the contribution of mass transfer of solutes to and from the stationary phases. This term is related to the thickness d_f of the phase that coats the stationary phase and the diffusion coefficient D_s of the solute in the stationary phase according to

$$D\mu = \frac{C_s d_s{}^2 \mu}{D_s} \tag{7}$$

where C_s is a constant.

To minimize band broadening in LC, conditions must be established to minimize each of the terms described by Eqs. 5–7. Because each of these terms is directly proportional to mobile-phase linear velocity, employing the lowest possible mobile-phase flow rates would seem to serve this purpose. However, use of extremely low flow rates [$<$ 0.5 ml/min for a standard high-performance liquid chromatography (HPLC) column] can increase solute retention times to impractical levels and may actually increase band broadening due to increased longitudinal diffusion (described by the second term in Eq. 3). For this reason, other factors are usually adjusted to minimize these mass transfer terms. Such adjustments include (a) using monomerically bonded stationary phases with small particle diameters [this reduces the size of d_f and d_p terms in Eqs. 5–7, which, in turn, has an exponential effect on reducing the size of the mass transfer terms]; (b) employing mobile phases of low viscosity at high temperatures (this increases the sizes of the diffusion coefficients D_s and D_m in the equations, resulting in fast mass transfer and narrow chromatographic bands.[4])

Column manufacturers and researchers have optimized the above parameters to produce LC columns of remarkably high selectivities and efficiencies. However, there are practical limitations to adjustments of these parameters. For example, stationary phases with particle diameters below 3 μm generally cannot be routinely used, owing to excessively high back-pressures and short column lifetimes. Additionally, for obvious reasons, operating temperatures must be kept below the boiling points of the components of the mobile phase. Use of non-porous pellicular column packings has also been attempted in an effort to eliminate any areas of stagnant mobile phase in the chromatographic system, thus reducing the size of the third term in Eq. 3 to zero. However, such pellicular stationary phases have very low sample capacities, and diffusion coefficients of many solutes on their polymeric coatings are often low, which, of course, results in increased band broadening.[3]

At commonly used mobile-phase flow rates, mass transfer of solutes through and between the stationary phase and the mobile phase is generally the most important factor controlling the widths of chromatographic bands in LC. Although manufactures have designed packings and columns to minimize their effects, consideration of solute mass-transfer effects are extremely important in the development of any chromatographic method.

McReynolds Method for Stationary Phase Classification

Barbara Gawdzik
Faculty of Chemistry, MCS University, Lublin, Poland

Abstract
McReynolds constants were introduced for selectivity characterization of liquid stationary phases in partition gas chromatography (GC). They were soon applied to solid stationary phases, mainly of synthetic polymer nature, in adsorption GC.

INTRODUCTION

McReynolds constants were introduced for selectivity characterization of liquid stationary phases in partition gas chromatography (GC).[1,2] They were soon applied to solid stationary phases, mainly of synthetic polymer nature, in adsorption GC.

The system based on characteristic phase constants, known as the McReynolds constants, proved to be the most successful for describing phase selectivity. A similar system was introduced simultaneously by Rohrschneider,[3] but his characteristic phase constants have not become so popular.

Applying these systems, the phase selectivity, defined as its relative capacity to enter into specific intermolecular interactions, such as dispersion, induction, orientation, hydrogen-bond formation, and charge-transfer complexation, can be characterized by 5 or 10 constants. These constants represent differences in the Kováts retention indices[4] of test substances on the phase under study and on a reference column containing a non-polar phase, at the same temperature. McReynolds proposed 120°C as a standard reference temperature. As a standard non-polar phase, Rohrchneider introduced squalane.[3]

To choose proper test substances, McReynolds studied the behavior of a large number of substances of the following compound classes: alcohols, glycols, aldehydes, ketones, esters, acetals, ethers, oxides, hydrocarbons, chloro compounds, difunctional and polyfunctional compounds, and other miscellaneous substances.[1] For the stationary phase classification, he eventually proposed benzene, *n*-butanol, 2-pentanone, 1-nitropropane, and pyridine to represent compounds of different chemical interactions.[2] McReynolds' characteristic phase constants for these five compounds describe the selectivity of the phase.

The founding principle of both systems was that intermolecular forces were assumed to be additive, and that their individual contributions to retention can be evaluated from the differences in retention index values for a series of test solutes on the phase to be characterized and on a nonpolar reference phase.

This approach was immediately appreciated by scientists throughout the world. During the Symposium of the Biochemical Society in 1970, James stressed achievements of McReynolds and Rohrschneider, saying,

> This enables us to clarify our minds as to how to exploit interaction forces in solution and showed that since, in the nonpolar stationary phases such as long chain paraffin hydrocarbons, where London dispersion forces were operative, that the molecular weight (rather than BP) was the major factor controlling separation, with molecular configuration as the secondary, though still important, effect. In solvents such as alcohols and polyethers, hydrogen bonding with donor or acceptor solutes occurred in addition to London dispersion interactions.[5]

The studies of McReynolds and Rohrschneider had fundamental importance for chromatography. At present, the sum of five McReynolds constants is the most commonly accepted criterion for the overall polarity of the stationary phase.[6–10]

CHARACTERIZATION OF THE METHOD

McReynolds' characteristic phase constants are usually found in the contemporary scientific and commercial literature for characterization of liquid stationary phase selectivity. This method allows for direct comparison of the GC columns (both packed and capillary), provided the data for standard test compounds are obtained at the same temperature.

Such conditions were chosen by McReynolds after measuring and listing the retention data of more than 300 compounds on 74 liquid stationary phases at 100°C, 120°C, 140°C, and 160°C.[1] The solid support used in all columns was Celite® 545. The retention data were given as specific retention volumes (V_g) and retention index values (I). For determination of retention data of the studied

compounds, McReynolds used a specially constructed chromatograph.[2] The instrument permitted as many as 12 columns to be run simultaneously. This apparatus is presented in Fig. 1.

From the obtained data, 10 compounds representing different classes of organic compounds were selected in order to test correlation between the various sets of stationary phase constants and the retention data at 120°C.

To characterize liquid stationary phases in partition GC, McReynolds used benzene, 1-butanol, 2-pentanone, 1-nitropropane, and pyridine as test compounds. In their selection, he applied regression analyses to determine which compounds could be best for calculation of the retention indices of other compounds. These compounds had the same chemical nature as those proposed by Rohrschneider, but their BP were higher. In the approach of Rohrschneider, benzene, ethanol, methyl ethyl ketone, nitromethane, and pyridine were used. An inconvenience of this method is that since ethanol, methyl ethyl ketone, and nitromethane give index numbers near or below 500 with some liquid phases, it was necessary to use, for their determination, hydrocarbons, which were gases at ambient temperature and pressure, for their determinations.

McReynolds also studied the behavior of an additional five compounds: 2-methyl-2-pentanol, 1-iodobutane, 2-octyne, 1,4-dioxane, and *cis*-hydrindane. In the case of 2-methyl-2-pentanol and 1-iodobutane, he observed some improvements in prediction of retention indices of branched compounds, especially alcohols and halogen-containing compounds. For 2-octyne, 1,4-dioxane, and *cis*-hydrindane, only minor improvement was achieved. Finally, the latter five compounds were neglected.

The main assumption of their methods was that the retention index of a substance on a non-polar phase, such as

squalane, is associated only with dispersive interactions and that any differences in the retention index values for a polar phase (ΔI) are due to polar interactions. These interactions can be of different nature, e.g., induction, orientation, hydrogen-bond formation, and charge-transfer complexation.

In the approach of Rohrschneider, the difference in the retention index value for polar phase (ΔI) is represented as a series of terms composed of solute-specific contributions ($a,\ldots,e$) and the stationary phase characteristic term ($x',\ldots,s'$), which can be written as:[3,11]

$$\Delta I = ax' + by' + cz' + du' + es',$$

where a, b, c, d, and e are the coefficients determined by the multiple regression of the compound retention index on several characterized phases. In consequence, the characteristic phase constants represent mixed retention and intermolecular interactions.

The concept of McReynolds used five solutes (benzene = x, 1-butanol = y, 2-pentanone = z, 1-nitropropane = u, and pyridine = s) that are considered to represent typical chemical interactions.[2]

For each of them, the constants x', y', z', u', and s' are defined accordingly. They are shown in Table 1.

The sum of the retention index differences on a certain phase relative to squalane is a measure of the polarity of this phase (),

$$\sum = x' + y' + z' + u' + s',$$

where

$$x' = I_{\text{benzene}} - I^{\text{sq}}_{\text{benzene}},$$
$$y' = I_{1-\text{butanol}} - I^{\text{sq}}_{1-\text{butanol}},$$
$$z' = I_{2-\text{pentanone}} - I^{\text{sq}}_{2-\text{pentanone}},$$
$$u' = I_{1-\text{nitropropane}} - I^{\text{sq}}_{1-\text{nitropropane}},$$
$$s' = I_{\text{pyridine}} - I^{\text{sq}}_{\text{pyridine}}.$$

If, for example, the solute is an alcohol, it can be formally divided into the alkyl residue (which interacts only by weak dispersion forces with all phases) and the OH group, which is able to donate a hydrogen bond. Interaction with a stationary phase will lead to stronger retention on the polar phase and therefore a large increase in the retention index. This increase is represented by the constant y'.

Characteristic phase constants describe the liquid stationary phase accurately if differences in the retention data between stationary phases are accompanied by corresponding differences in the characteristic phase constants.

The McReynolds constants for liquid stationary phases, most commonly used in practice, are given by Kenndler.[12] These data are presented in Table 2. In his opinion, polarity of two phases can be considered as nearly equal if the sums of their indices differ by more than about 200. In general, it is not meaningful to use two such phases. This does not mean, however, that their selectivities concerning one special type of interaction are probably negligible.

The McReynolds method was also used for characterization of solid porous adsorbents in GC. Negative values of the McReynolds constants on solid porous polymeric phases of styrene-divinylbenzene led Smith, Tameesh, and Waddington[13] to introduce thermally graphitized carbon black (GTCB) as the standard non-polar phase for this kind of chromatographic solid stationary phase. He also increased the temperature for McReynolds constants determination to 140°C. After these modifications, the method, with the use of the sum of only three constants for benzene, *n*-butanol, and 2-pentanone, becomes the most convincing technique for solid porous polymeric stationary phase characterization. It was also used in the works reported by Gawdzik et al.[14] and Gawdzik[15].

The system of McReynolds constants inspired many researchers to carry out more extensive explorations. Based on this system, Tacács[16] constructed a unified system for the prediction of retention data in gas–liquid chromatography.

Table 1 McReynolds five solutes representing typical chemical interactions.

		Type of interaction				
Reference solute	**McReynolds constant**	**Dispersion**	**Dipole**	**H-donor**	**H-acceptor**	**Typical for**
Benzene	x'	+	−	−	+	Olefins, aromatic compounds
Butanol-1	y'	+	+	*Strong donor*	−	Alcohols, phenols, acids, amides
2-Pentanone	z'	+	+	−	*Acceptor*	Ketones, aldehydes, esters, ethers, epoxides
1-Nitro propane	u'	+	*Strong dipole*	−	+	Nitro-, nitrilo- compounds
Pyridine	s'	+	+	−	*Strong acceptor*	Aromatic amines

Table 2 McReynolds constants and their sum, $=x' + y' + z' + u' + s'$, used for characterization of liquid stationary phase polarity.

Stationary phase	Composition	x′	y′	z′	u′	s′	Σ
Squalane	Hydrocarbon	0	0	0	0	0	0
Dimethyl silicone	100% Methyl	17	57	45	67	43	229
Phenyl methyl	5% Phenyl	32	72	65	98	67	334
silicone	50% Phenyl	119	158	162	243	202	884
	75% Phenyl	178	204	208	305	208	1,103

Source: From *Gas Chromatography*, in Version 19/01/2004.[12]

To achieve a detailed classification of the possible interaction of solid porous non-polar polymeric phases with different functional groups of solute molecules, Castello and D'Amato[17] used the following polarity reference substances: ethanol, 2-butanone, nitromethane, benzene, pyridine, *n*-butanol, 2-pentanone, and 1-nitropropane. The first five represent the test substances proposed by Rohrschneider, while the last three were recommended by McReynolds. The retention indices of these substances enable evaluation of the polarity of any solid porous polymeric stationary phase. In their studies Porapak Q, as the least polar commercially available porous polymer, was used as the reference stationary phase.

Some authors[18] raise the question of experimental inaccuracy of McReynolds constants determination associated with inaccurate determination of retention times for *n*-alkanes on polar stationary phases. In such cases, retention depends on the amount of the analyte sample. To avoid such errors in the determination of McReynolds constants, Smith, Tameesh, and Waddington[19] proposed the use of trace amounts of the test solutes by dipping a 1 μl syringe needle (at the zero position of the piston) in the sample for 1 sec.

Kersten, Poole, and Furton[20] found that many ambiguities in the determination of the polarity with the McReynolds stationary phase constants are due to the use of *n*-alkanes as the reference series, and estimated on 15 columns spanning a wide polarity range the 2-alkanones as the universal retention index markers to replace the *n*-alkanes which do not partition with polar phases. Ketones were also suggested by many authors as a good alternative series to *n*-alkanes; however, Mathiasson et al.[21] found that, because of variation in retention volume with the amount injected, alkanols and 2-alkanones are unsuitable on both polar and non-polar columns. He suggested the use of alkylbenzenes as reference compounds, as these compounds seem to behave almost ideally on liquid phases of different polarities.

Some authors[22–24] proposed use of other homologous series as reference compounds for index calculation, or even other reference stationary phases.

In spite of some critical opinions, connected mainly with incorrect determination of retention indices of standard substances, the McReynolds constants system gave logical basis for stationary phase classification and allowed for selection of the proper gas chromatographic column. Until now, it has been the most common approach employed for stationary phase selectivity ranking in GC.

CONCLUSIONS

The system of McReynolds constants is a useful tool for characterization of the selectivity of stationary phases in GC. The founding principle of this approach is that intermolecular forces are additive and their individual contributions to retention can be evaluated from the difference in retention index values of selected test probes measured on a liquid phase to be characterized, and on the non-polar reference phase, i.e., squalane. To characterize the stationary phase polarity, the concept uses five special solutes (benzene, *n*-butanol, 2-pentanone, 1-nitropropane, and pyridine) that are considered to represent typical chemical interactions.

The simplicity of this method makes it the most commonly employed approach for liquid stationary phase selectivity ranking. The attempts to replace it by another system have been unsuccessful so far. It even inspired construction of an analogous system allowing for characterization of stationary phases in liquid chromatography.[25]

It is noteworthy that the method introduced by McReynolds has not only significant scientific but also practical importance.

Metal Ions: CPC Separation

Subra Muralidharan
Chemistry Department, Western Michigan University, Kalamazoo, Michigan, U.S.A.

INTRODUCTION

Centrifugal partition chromatography (CPC), a multistage countercurrent liquid–liquid distribution technique employing discrete stages and two immiscible bulk liquid phases, is ideally suited for the detailed examination through separation factors and efficiencies, the influence of bulk aqueous and liquid–liquid interfacial equilibria and kinetics, on the separations of metal ions. This has been demonstrated by separations of transition metals, platinum group metals, and trivalent lanthanides; the significant findings are as follows: (a) Separation efficiencies are mainly limited by back-extraction kinetics which occur in the bulk aqueous phase and at the organic–aqueous interface as indicated by a direct linear correlation between the half-lives ($t_{1/2}$) of the dissociation reactions and the reduced plate height. (b) The interfacial areas calculated through this correlation are much larger in many cases than those generated in highly stirred two-phase mixtures. (c) The addition of surfactants and interfacial catalysis of the formation and dissociation of the complexes dramatically improve efficiencies. Examples of the separation of platinum group metal and trivalent lanthanides and the kinetic information that can be derived from their chromatograms are discussed.

CENTRIFUGAL PARTITION CHROMATOGRAPHY

The CPC apparatus, manufactured by Sanki Engineering Company, Japan,[1] consists of a series of cartridges, with each cartridge containing 40–400 channels, depending on the desired internal volume. These channels serve as stages in the separation experiment and the total number of channels is sometimes 400–4800, depending on the number of cartridges employed. The cartridges are arranged in a rotor which is rotated at 700–1200 rpm and the centrifugal force generated keeps one of the two phases (usually the organic phase) stationary while the other phase (usually the aqueous phase) is moved through it at a constant flow rate. The injected analyte mixture is carried by the aqueous mobile phase into the cartridges where they are extracted into the organic stationary phase by simple distribution if they are organic or by complexation with a suitable ligand if they are metals. When the mobile phase is depleted of the analytes, further flow of the mobile phase of the same (isocraticelution) or different (gradient elution) composition causes the back-extraction of the analytes, which can be detected by a suitable method. If the analytes are completely separated, they appear as discrete peaks similar to conventional chromatographic methods such as high-performance liquid chromatography (HPLC), and, hence, it is called centrifugal partition chromatography. CPC has these unique features: a large number of discrete stages (400–4800 depending on the operational volume chosen); high loading capacity for extractants and analytes; negligible loss of stationary phase due to "bleeding"; flexible organic–aqueous phase volume ratios; high stationary phase to mobile phase ratio; and ready adaptability to the process scale.

The basic parameters employed in the analysis of the CPC chromatograms are the retention volume V_r, which is related to the stationary phase and mobile phase volumes V_s and V_m, respectively, and the distribution ratio of the analyte D (Eq. 1), the chromatographic efficiency, as measured by the number of theoretical plates N, which is calculated from the retention volume V_r and the width of the chromatogram w, (Eq. 2), the chromatographic inefficiency represented by the channel equivalent of a theoretical plate (CETP), which is analogous to reduced plate height and is the ratio of the number of channels (CH) (2400 in our experiments) to N (Eq. 3), and the selectivity I achieved in the separation of two analytes (1 and 2), which is the ratio of their distribution ratios D_1 and D_2 (Eq. 4)[2]:

$$V_r = V_m + DV_s \tag{1}$$

$$N = 16\left(\frac{V_r}{w}\right)^2 \tag{2}$$

$$\mathrm{CERP_{obs}} = \frac{\mathrm{CH}}{N} \tag{3}$$

$$\alpha = \frac{D_2}{D_1}\ (D_2 > D_1) \tag{4}$$

SEPARATION OF PLATINUM GROUP METALS

Separation, extraction, and purification of the platinum group metals (PGM) Pt, Pd, Ir, and Rh in their various oxidation states continues to be challenging and represent

interesting areas of research. The separation of PGM from chloride media by solvent extraction can be achieved either by complexation with a suitable ligand or through ion-pair formation with a large cation. Complexation with a ligand is more selective but generally suffers from slow complex formation and dissociation kinetics. By contrast, ion-pair formation is diffusion controlled and not very selective, but it is necessary to separate kinetically inert species such as $PtCl_6^{2-}$ and $IrCl_6^{2-}$.

Trioctylphosphine oxide (TOPO) is an organophosphorus compound and is a stable and inexpensive extractant. TOPO, as we have shown,[3–5] is unique in that it can function as a monodentate ligand and as a cation for ion-pair extraction when protonated and the extraction equilibrium for the neutral ligand is shown in Eq. 5, indicating the extraction of the neutral complex $MCl_2(TOPO)_2$ [M = Pd(II), Pt(II); $n = 2$–4]:

$$MCl_n^{(n-2)-} + 2TOPO_0 \underset{\longleftarrow}{\overset{k_{ex}}{\longrightarrow}} MCL_2(TOPO)_{2,0} + (n-2)Cl^- \quad (5)$$

The K_{ex} values for $PdCl_2$, $PdCl_3^-$ and $PdCl_4^{2}$ are 794.3 M^{-2}, 2.75 M^{-1} and 0.14 respectively. A single peak was observed in the CPC chromatogram of Pd(II) at any concentration of Cl^-, as its hydrolytic equilibria are rapid. The corresponding values for the three Pt(II) chloro species are 48 M^{-2}, 0.047 M^{-1} and 0.018, clearly indicating the better extractibility of Pd(II) over Pt(II). The difference in the K_{ex4} values for the MCl_4^{2} species can be exploited to obtain an efficient separation of Pt(II) and Pd(II) from Rh(III) and Ir(III).

Formation of $HTOPO^+$, at HCl concentrations of 0.1 M, resulted in the extraction of $(HTOPO)_2MCl_4$ (M = Pt or Pd):

$$MCl_4^2 + 2H^+ + 2TOPO_0 \underset{\longleftarrow}{\overset{k_{ex}}{\longrightarrow}} (HTOPO)_2MCl_{4,0} \quad (6)$$

The chromatogram of the separation of $RhCl_6^{3-}$, $PdCl_4^{2-}$, and $PtCl_4^{2-}$ by $HTOPO^+$ is shown in Fig. 1. The K_{ex} values of Pd(II) and Pt(II) are 93.3 M^{-4} and 1961 M^{-4} respectively, indicating that Pd(II) elutes ahead of Pt(II) in the ion-pair separation, whereas the opposite is true in the separation by complexation. While the chromatogram of Pt(II) involves only the formation of $(HTOPO)_2PtCl_4$, the chromatogram of Pd(II) also involves the formation of In fact, under the experimental conditions employed in these separations, this is the major Pd ion pair that is extracted. The extraction equilibrium constant for $(HTOPO)PdCl_3$ is 18.25 M^{-1}. Similarly, Pt(IV) and Ir(IV) could be separated $HTOPO^+$ by by ion-pair formation with their MCl_6^{2-} species. The K_{ex} values for the Pt(IV) and Ir(IV) species are 1576 M^{-4} and 8035 M^{-4} respectively.

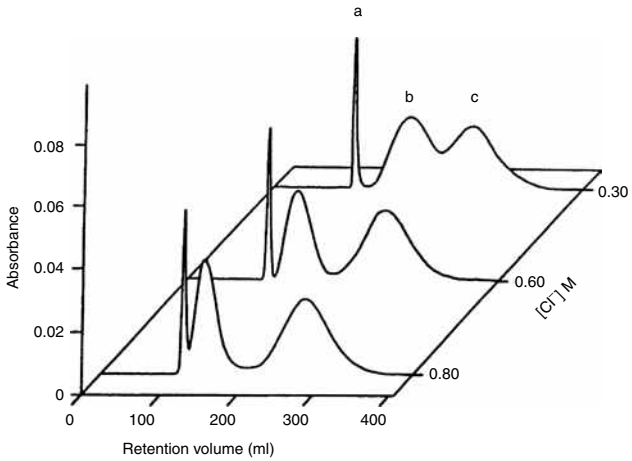

Fig. 1 Separation of 10^{-4} M $IrCl_6^{2-}$, $PtCl_4^{2-}$, and 10^{-3} M $PdCl_4^{2}$ as their ion pairs with $HTOPO^+$ as a function of $[Cl^-]$ with 0.5 MTOPO at 0.1 M HCl and 4.0 ml/min flow rate. Eluting species are (a) $IrCl_6^{2-}$, (b) $PdCl_4^{2-}$, and (c) $PtCl_4^{2-}$.

SEPARATION EFFICIENCIES OF PLATINUM GROUP METALS

We observed, early on, that CETP values are significantly larger for metal-ion separations than those for simple organic analytes under the same conditions. They are far larger than could be explained in terms of mass-transfer and diffusion factors. Moreover, they increase more rapidly with increasing flow rate than those of organic analytes, indicating a chemical kinetic component affecting the CETP. The CETP values observed with metal ions, after correction for mass transport and diffusion (achieved using an organic analyte with similar distribution characteristics), reflect the half-lives of chemical reactions causing the added inefficiencies. Metal-complex formation and dissociation reactions with half-lives of milliseconds (i.e., rapid enough that in batch experiments they reach equilibrium "instantaneously") will lower the efficiencies of CPC chromatograms. Conversely, CETP values can be used to study rapid reaction kinetics if this relationship is found to be generally valid. Thus, CPC is a useful tool not only for uncovering kinetics of metals separations but also for obtaining detailed mechanisms of those reactions responsible for inefficiencies in multistage metals separations. This demonstrates the utility of CPC for examining the kinetics of metal-complex formation and dissociation reactions in two-phase systems that are too rapid for the automated membrane extraction system (AMES).

It was evident, from the separations of PGM, that their experimental CETP values were much larger compared to that for an organic analyte at identical distribution ratios. These results indicated that factors other than mass transfer and diffusion were responsible for the additional bandwidths in the case of the metal ions. The most likely factor is the slow kinetics of back-extraction of the metal ions as

the forward extraction reactions are usually rapid. To test this hypothesis, 3-picoline was used as the model compound for the determination of the CPC bandwidth due to mass transfer and diffusion ($CETP_{dif}$), and the CETP value due to slow chemical kinetics ($CETP_{ck}$) was derived by expressing the experimental CETP ($CETP_{obs}$) as a sum of $CETP_{dif}$ and $CETP_{ck}$:

$$CETP_{obs} = CETP_{dif} + CETP_{ck} \quad (7)$$

The $CETP_{ck}$ values determined by varying the concentrations of the species in the aqueous and organic phases clearly showed that the slow back-extraction kinetics of the metal complexes were indeed responsible for the broad bands in the CPC chromatograms. On the basis of these results, a mechanism of the dissociation step could be deduced, which indicated that the dissociation of $MCl_2(TOPO)$ is rate limiting in the back-extraction of $MCl_2(TOPO)_2$ (M = Pd, Pt). A plot of the $CETP_{ck}$ values for $MCl_2(TOPO)_2$ against the $t_{1/2}$ values yielded a straight line. Further, these points and those for the Pd(II) system fall on a single line, indicating a general correlation for the separation of these two metals using TOPO in the heptane–H_2O phase pair.

Dissociation reactions with half-lives ranging from milliseconds to seconds can adversely affect the CPC efficiencies. It is important to realize the consequence of these findings: Extraction and back-extraction reactions that appear to be rapid in single-stage equilibrations may still be slow enough to reduce the efficiencies of multistage separations. A further significant finding of this work is that a direct linear correlation exists between $CETP_{ck}$ and $t_{1/2}$ for the Pd(II)–TOPO system and several other systems. Because the $CETP_{ck}$ values are a measure of the half-lives of the slow dissociation steps in metal-complex dissociation reactions, CPC is a useful tool for examining the kinetic and the equilibrium aspects of such reactions.

SEPARATION OF TRIVALENT LANTHANIDES

The trivalent lanthanides have been separated using acidic organophosphorous ligands and the acylpyrazolones.[6–8] The phosphinic acid bis(2,4,4-trimethylpentyl)phosphinic acid (Cyanex 272) in the heptane–water phase pair is dimeric and provides excellent separations of the adjacent light lanthanides at a fixed pH and a mixture of light and heavy lanthanides using a pH gradient (Fig. 2). Cyanex 272 is a chelating ligand that extracts the trivalent lanthanides by chelating them in its dimeric form (Eq. 8). The acylpyrazolones, 1-phenyl-3-methyl-4-benzoyl-5-pyrazolone (HPMBP) and 1-phenyl-3-methyl-4-capryloyl-5-pyrazolone (HPMCP, see structure below) have also been used in the toluene–H_2O phase pair for the extraction and separation of the

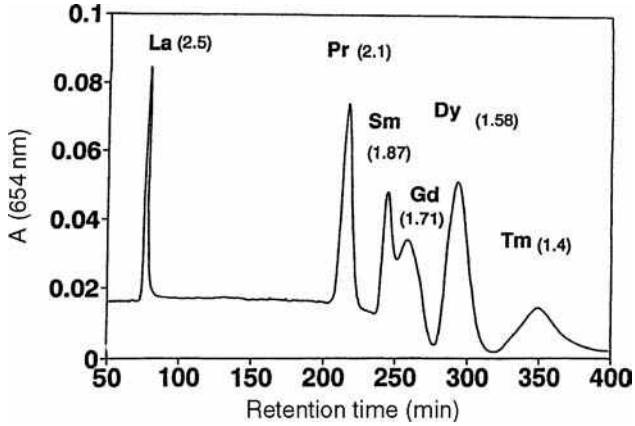

Fig. 2 Separation of lanthanides by use of a pH gradient with 0.1 *M* Cyanex 272 at $V_s/V_m = 0.18$ and flow rate of 1 ml/min. The concentrations and pH of elution are as follows: La (2 ppm; 2.5), Pr (6 ppm; 2.1), Sm (4 ppm; 1.87), Gd (4 ppm; 1.71), Dy (10 ppm; 1.58), and Tm (8 ppm; 1.4).

trivalent lanthanides. The extraction equilibrium constant for are given in Eq. 9.

$$M^{3+} + 3(HL)_{2(0)} \underset{\longleftarrow}{\overset{K_{ex}}{\longrightarrow}} M(HL_2)_{3(0)} + 3H^+ \quad (8)$$

$$M^{3+} + 3HL_0 \underset{\longleftarrow}{\overset{K_{ex}}{\longrightarrow}} ML_{3(0)} + 3H^+ \quad (9)$$

Significant differences are seen between Cyanex 272 and the acylpyrazolones. The extractibility of the trivalent lanthanides is higher with Cyanex 272 than with the acylpyrazolones, where HPMBP shows better extraction than HPMCP. The stability constants of the lanthanides increases from the light to heavy, and the values for the Cyanex 272 and HPMCP complexes are larger than those of HPMBP. The separation factor (or selectivity) for a pair of lanthanides is much better with Cyanex 272 than with HPMBP or HPMCP, which have similar separation factors.

The lanthanide complexes lack distinct ultraviolet–visible spectra and, hence, kinetic information on their complex formation and dissociation reactions was obtained indirectly by the metallochromic indicator method.[9] These studies indicate that in the case of the Cyanex 272 complexes, the CPC efficiencies are mainly limited by the slow dissociation of the $M(HL_2)HL^+$ complex at the heptane–H_2O interface. In the case of the complexes of the acylpyrazolones, the CPC efficiencies are again limited by the dissociation of the lanthanide–pyrazolone complexes at the organic–aqueous interface with the rate-limiting step being the dissociation of the ML^{2+} complex. It was also shown that because the dissociation reactions are interfacial separations, efficiencies can be dramatically improved by the addition of surfactants like Triton X-100 to the organic phase and by

interfacial catalysis by the addition of a aqueous soluble metallochromic indicator, which formed highly interfacially active lanthanide–indicator complex. The adsorption of this complex at the organic–aqueous interface catalyzed the metal-complex formation and dissociation reactions leading to high efficiencies in CPC separations.[10]

Two significant results have emerged from the CPC separations of metals ions, namely (a) separation efficiencies are significantly reduced by slow metal-complex formation and dissociation kinetics and (b) CPC separations can be entirely interfacially driven analogous to conventional liquid chromatography.

Metal Ions: Silica Gel Surface Modification for Selective Extraction

Mohamed E. Mahmoud
Medical Chemistry Department, King Abdullaziz University, Jeddah, Saudi Arabia

INTRODUCTION

Silica gel is the most commonly used inorganic solid support in the field of chromatographic applications. Silica gel is a polymeric type of silicic acid (H_4SiO_4), which is synthesized from the hydrolysis reactions of alkoxysilanes or sodium silicate, in the presence of an acid or a base; there are also other known routes of preparation and manufacturing.[1] The structure of silica gel is characterized by the presence of certain functional moieties owing to the presence of some groups such as siloxane, ≡Si–O–Si≡, with the oxygen located on the surface, as well as silanol groups, ≡Si–OH. Active silica gel is mostly characterized by the surface silanol groups that are known to exist in several forms,[2] as shown in Scheme 1.

Several other arrangements of the silanol groups are also known; they are dependent upon the possible interactions between them, as shown in Scheme 2.

The surface silanol groups are the major contributing factors that are responsible for binding, adsorption, and extraction processes with the target analytes of interest such as metal ions or their more complex species. The weak ion-exchange properties of silanol groups are to favor their low interaction behavior with the various species. Therefore, improvements of the adsorption efficiency and extraction power of the sorbent are always aimed via surface modification with certain functional groups. This objective can be accomplished by application of either physical adsorption or chemical immobilization methods.

MODIFICATION OF THE SILICA GEL SURFACE

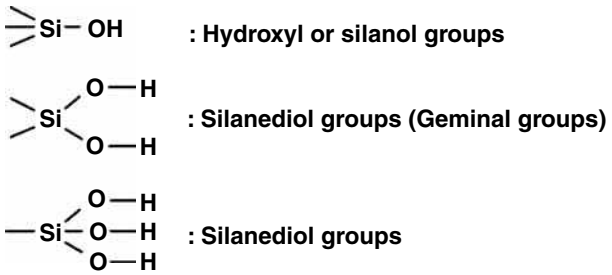
Two principle methods of surface modification are well known; they can be summarized as the physical adsorption method and the chemical immobilization technique of the organic modifier.[3] Each method is experienced with certain advantages and disadvantages over the other. For example, the physical adsorption approach is commonly accomplished in a single-step reaction; this requires less time for obtaining the final modified solid extractor, but the active donor centers or atoms in the physically modified phases may be consumed in the adsorption process. In addition, these modified phases were found to suffer from leaching or desorption processes under the influence of strong acidic or basic media.[4] The modified phases that are synthesized on the basis of a chemical immobilization method are characterized by good stability characteristics in acidic and basic media, but the disadvantage of this technique is the multistep reactions needed to obtain the modified solid extractors. The active donor atoms or groups in the modified sorbents, prepared by the chemical immobilization method, are well defined in such phases. The types of compounds that can be loaded onto the surfaces of solid phases are unlimited; these include:

1. Long chain and short chain hydrocarbons
2. Polar and non-polar organic compounds
3. Inorganic and organometallic compounds
4. Simple and macromolecular compounds
5. Chelating compounds.

Chelating compounds are the most important class of compounds that can be used and applied in the processes of solid-phase extraction (SPE) of transition and non-transition metal ions. The reason for this interest and conclusion is the presence of certain donor atoms, mainly nitrogen, oxygen, sulfur, and phosphorus in these compounds. The donor atoms are the active centers and are known to be responsible for the incorporation of certain selectivity characteristics into the newly modified solid phases. However, the reported rules controlling such incorporated selectivity toward certain metal ions are mainly based on several important factors:

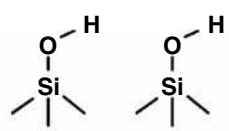
1. The size of the organic chelating modifiers as reported for crown ether derivatives
2. The reactivity and activity of the loaded surface group
3. The nature of the interacting donor atoms and metal ions
4. The length of hydrocarbon chain in separation of some rare earth elements
5. The reported formula of hard–soft acids-bases.

Metal ions and their species, either essential or toxic for living organisms, are finding their routes into the various samples, matrices, and environments from many sources. The accurate determinations, qualitative or quantitative, of the target metal ions or their species, especially in the environmental, biological, and industrial samples are considered of

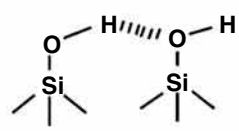


Scheme 1

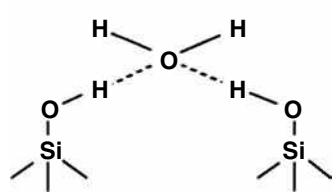
great challenge to the analytical chemist because of the huge number of interfering species and compounds. The determination procedure is principally started with an important step, i.e., extraction and/or preconcentration. Several available techniques are commonly used and applied in metal ion extraction; these include the direct precipitation of metal ions as hydroxides. Liquid or solvent extraction techniques are routinely used in this respect. Although this technique is a simple method for the extraction and preconcentration of the analyte of interest, it is always plagued with several major disadvantages such as the inability to directly apply it for poorly soluble species in the conventional non-polar organic solvents. In addition, the amount of organic solvent used in this technique, either in a single or multistep analysis, is commonly high and leads to a direct impact on environmental pollution, owing to the problem of waste generation and destruction. The problems of time, effort, and money consumption are also evident in practicing this technique.[5] The other alternative technique to liquid extraction is now known as SPE. This affords several advantages over the classical liquid extraction technique, including:



Free Silanol groups



Hydrogen-bonded silanol groups



Water hydrogen-bonded silanol groups

Scheme 2

1. No waste generation in the experimental process owing to non-dependence on extraction solvents.
2. Allows direct, simple, and fast sample applications in very small (microliter) or large (liter) volume sizes without sample loss.
3. Can be directly applied for different matrices without prior treatments.
4. The ability of SPE to be online or off-line, interfaced with major analytical instrumentation, is considered as another dimension and an advantage over the classical liquid extraction.

Solid-phase extraction is mainly based on the utilization of a solid support instead of an organic solvent onto which the target metal ion or analyte is loaded onto the surface. Solid-phase extractors are materials derived from organic or inorganic origins. The organic solid supports include polyurethane foams, filter paper, cellulose, naphthalene, ion exchange resins, and polymeric species. On the other hand, silica gel, alumina, magnesia, zirconia, and metal oxides are the major inorganic solid supports. The simple comparison between inorganic and organic solid-phase extractors such as silica and ion exchange resins, respectively, mainly points out the following:[6]

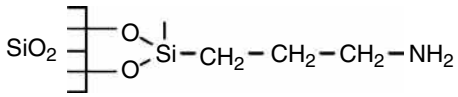
1. High ability and superiority of the inorganic ones for binding, extraction, removal, and preconcentration of transition metal ions already present with high concentrations of interfering alkali and alkaline earth metal ions.
2. Inorganic solid extractors can afford higher mechanical, chemical, and thermal stability.
3. Fast time of binding with the target metal ions as well as good kinetic properties.
4. Non-swelling properties as reported for organics.

EXAMPLES OF MODIFIED SILICA GEL PHASES, CLASSIFIED ACCORDING TO THE DONOR ATOMS AND THEIR APPLICATIONS

Silica Gel Phases with Nitrogen Donor Atom

Silica gel functionalized by reaction with γ-aminopropyltriethoxysilane was prepared and its selective adsorption characteristics for various metal ions such as Au(III), Pt(IV), and Pd(II) chlorocomplex ions from sample solutions containing Fe(III) and Cu(II) ions by ion exchange were studied.[7] The structure of the modified silica gel phase is shown in Scheme 3.

Silica gel phases modified via covalent bonding of γ-aminopropyltriethoxysilane, ethylenediamine, diethylenetriamine, and triethylenetetramine were synthesized and



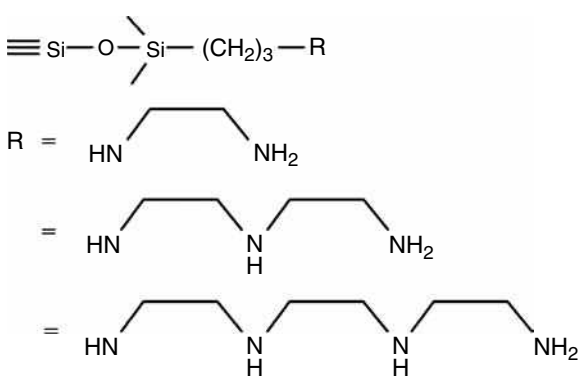
Scheme 3

the surfaces of these modified phases were characterized by secondary ion mass spectrometry and infrared spectrophotometry. The thermal stability from electron impact-mass spectrometry (EI-MS) as well as the potentiometric titration of these phases with Cu(II) was studied and evaluated. The selectivity properties incorporated into these phases via immobilization of the nitrogen donor atom were also reported for a series of metal ions.[8] The structures of these modified silica gel phases are given in Scheme 4.

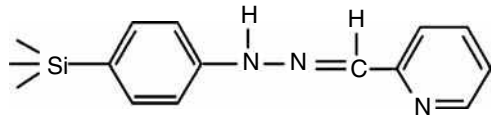
Preconcentration of metal ions from ethanolic solution by a packing material based on silica gel functionalized with 3-(1-imidazolyl) propyl groups for column chromatographic application was performed. The modified silica gel was applied to preconcentrate Cu, Ni, Fe, Zn, and Cd ions from commercial ethanol. The method is suitable for quantitative determination of these metals at low μg/L levels.[9]

Ir(IV), Rh(III), Pt(IV), Os(VIII), Pd(II), and Au(III) were sorbed from aqueous solution by silica gel, which was chemically modified with nitrogen-containing organic ligands. This was performed as a function of hydrochloric acid concentration, time of contact, concentration of the element, and the ionic strength. Extraction, followed by determination on the sorbent surface by x-ray fluorescence of Ir(IV), and Rh(III), from 10^{-8} to 10^{-7} *M* solutions, were achieved. An atomic emission method was used to determine Au(III) on the surface of the sorbent containing bonded diethylenetriamine groups.[10]

Preconcentration and removal of Co, Cu, Zn, Cd, and Hg by silica gel modified with pyridinium ions was developed and applied by using the column technique. Selective elution of these metals was accomplished by a



Scheme 4



Scheme 5

C_2H_5OH–H_2O binary mixture. For the elution mixture with a mole fraction of 0.5, the observed order was Co ~ Cd (~ 96%) > Cu ~ Zn (~ 30%) > Hg (not eluted).[11]

Metal ions sorption by 2-pyridine carboxaldehyde phenylhydrazone supported by chemical binding on a silica surface were confirmed to the Langmuir isotherm. The modified phase was used and applied as a metal-ion extractant for determination of trace amounts of iron, cobalt, nickel, and copper. The relative orders of the Langmuir constants *K* and the column retention capacity factors *K′* for the four transition metal ions are the same as the natural order of the stability constants for their metal chelates: Fe(II) < Co(II) < Ni(II) < Cu(II).[12] The structure is given in Scheme 5.

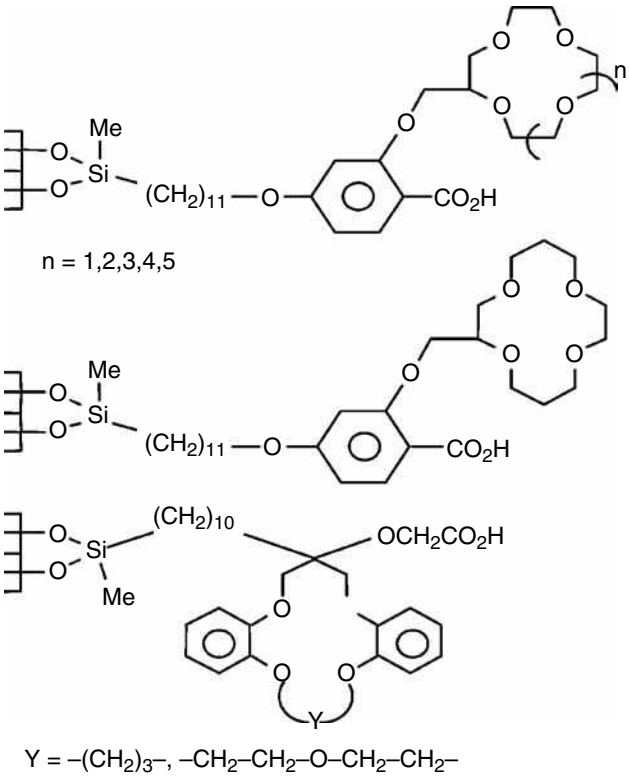
A silica-based sorbent-anion complexone polymer coating [24]ane-N_6 macrocycle was prepared. The chelation properties of this material were investigated for Cu(II), Cd(II), Co(II), and Zn(II). Oxalic acid was found to be the most effective eluent for the separation of these metal ions from seawater. The limits of these metal ions were identified to be 5×10^{-7} *M*, 1×10^{-5} *M*, 3×10^{-5} *M*, and 2×10^{-6} *M* for Cu(II), Cd(II), Co(II), and Zn(II), respectively.[13]

Silica Gel Phases with Oxygen Donor Atoms

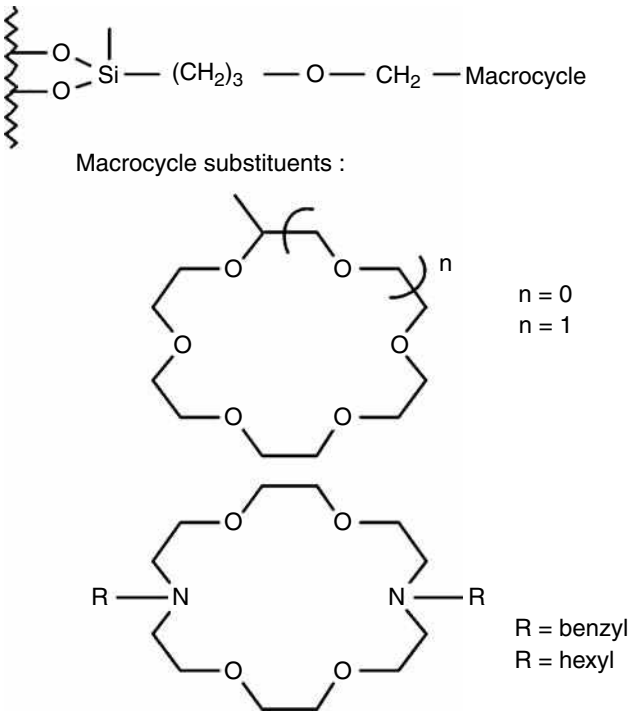
The effect of pH of the sample, eluent flow rate, and the amount of silica on sorption and elution experimental parameters were investigated by a new phase, which was synthesized from a high surface area silica gel with a 3-trimethoxysilyl-1-propanol group. In addition, both batch and column techniques were applied to identify the characteristics of this modified silica and its application to the preconcentration and separation of Co and Ni prior to determination by graphite furnace atomic absorption spectrometry (GFAAS).[14]

Column preconcentration of alkali metal cations by the newly synthesized silica gel phases-with chemically modified-pentadentate carboxylic acid groups were described.

1. The cavity size of the crown ether unit.
2. Conformational positioning of the proton-ionizable side arm with respect to the crown ether cavity.
3. Capping of residual silanol surface with trimethylsilyl was found to influence the selectivity and efficiency properties incorporated into these



Scheme 6



Scheme 7

newly modified silica phases.[15] The structures of the modified silica gel phases are shown in Scheme 6.

Macrocyclic substituents attachment to silica gel phases via hydrocarbon type linkage were reported. These modified phases were found to be capable of selective and quantitative removal of Ag(I), Hg(II), Tl(I), and Pb(II) from aqueous solutions.[16] The structures of these modified silica gel phases are shown in Scheme 7.

1,8-Dihydroxyanthraquinone anchored on silica gel was synthesized and used as a solid-phase extractant for Pb(II), Zn(II), and Cd(II) prior to their determination by flame atomic absorption spectrometry (FAAS).[17]

A highly selective solid phase for Fe(III) was synthesized and was based on chemically modified silica gel with purpurogallin as an oxygen donor atom-chelating compound. The modified phase was applied for selective extraction and preconcentration Fe(III) in the presence of other interfering metal ions from various matrices.[18]

Silica Gel Phases with Sulfur Donor Atom

Selective preconcentration of arsenite from natural waters was reported by the application of a surface-modified mercapto silica gel. Both column and batch preconcentration techniques were employed by this material for selective removal of arsenite from samples that also contain arsenite, monomethylarsonate, and dimethylarsinate.[19]

Silica modified by the addition of mercapto-chelating groups was developed for the preconcentration of trace amounts of Cd, Cu, Pb, and Zn from aqueous solution and natural waters. This material was found to remove and preconcentrate these metals by both column and batch techniques. Under column and batch conditions, recoveries larger than 95% were reported. For batch extraction of Cd, Zn, Cu, and Pb from seawater, recoveries of 96 ± 5% were obtained.[20]

Silica Gel Phases with Nitrogen and Oxygen Donor Atoms

The interaction of silica gel phases-modified-diethylenetriamine, with naphthaldehyde and salicylaldehyde, was found to produce four new solid-phase extractors. Characterization of these modified silica gel phases and their capability toward selective extraction and separation of six metal ions: Fe(III), Ni(II), Cu(II), Zn(II), Cd(II), and Pb(II), were studied and evaluated by both the batch and the column techniques as a function of pH and time of contact. The reactivity of metal ion sorption was discussed on the basis of effects of bulk as well as orientation of immobilized chelate on sorbent reactivity. Other aspects of synthesis,

characterization, and structural effects on metal ion(s) selectivity of these newly synthesized silica gel phases are also reported.[21]

A simple method was described for the extraction and determination of ultratrace amounts of Cu(II) ions using octadecyl-bonded silica membrane disks modified with a recently synthesized Schiff's base {2,2′-[1,2-ethanediyl-*bis*-(nitriloethylidyne)]-*bis*-(1-naphthalene)}. The pH effect, nature and amount of counter anions, flow rates, and type of stripping acid were evaluated as the important factors of extraction efficiency of metal ions. The capacity was found to be 396 μg of copper for the membrane disks modified by 5 mg of the ligand. The limit of detection of the proposed method is 4 ng/1000 ml.[22] The structure of the organic modifier is given in Scheme 8.

Separation, preconcentration, and purification of metal ions from dilute aqueous solutions were accomplished by silica gel impregnated with a mixture of Calcon and Aliquat 336 as chelating sorbents. The relative capacities of 33 metal ions were determined in different experimental conditions of pH range as well as the concentrations of hydrochloric acid and perchloric acid.[23]

Sorption of metal ions such as Ca, Mg, Al, Cu, Fe, Ni, Co, Cd, Zn, Pb, Hg, and Cr on silica gel impregnated with a mixture of Aliquat 336 and Titan Yellow was investigated in the pH range 1–9. The column extraction chromatography application of the sorbent to the separation of solutions of analytical reagent grade sodium, potassium, calcium, magnesium, and ammonium chloride from traces of Cu, Pb, Cd, and Zn, and the separation of some metal ion mixtures were also reported.[24]

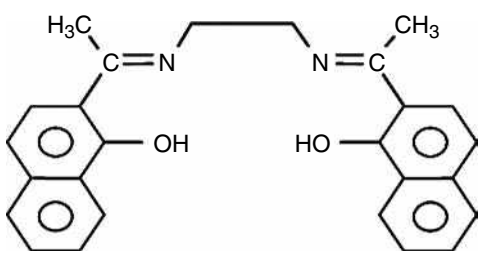
The chemical immobilization of formylsalicylic acid derivatives on the surface of amino group-containing silica gel phases was reported. The resulting phases were examined for the extraction of Fe(III) and showed an exchange capacity of 0.95–0.96 mmol/g. The other tested metal ions showed lower metal capacity than Fe(III). The selectivity incorporated into these silica gel phases for the extraction of Fe(III) from a mixture containing several other interfering metal ions was studied and evaluated by atomic absorption spectrophotometric analysis. In addition, a method for the recycling of the immobilized silica gel phases after metal extraction was also described on the basis of using ethylenediaminetetraacetic acid as a regeneration reagent.[25]

New silica gel phases were synthesized by a single-step reaction via immobilization of 5-formyl-3-arylazosalicylic acid derivatives on the surface of silica gel. These phases proved to show an excellent improvement in the Fe(III) extraction; the determined mmol/g is in the range 1.24–1.32. The process of selective extraction of Fe(III) in the presence of an interfering ion was studied by both column and batch equilibrium techniques. Cr(III) was found to cause interference based on the affinity for binding to the chelation centers of the salicylic acid moiety of the silica gel phase. Mg, Ca, and Mn ions exhibited minimum interference in Fe(III) extraction. A group of six divalent metal ions (Co, Ni, Cu, Zn, Cd, and Pb) were found to show a specific interference based on the availability and participation of arylazo-moiety.[26] The structures of these silica gel phases-immobilized-5-formyl-3-arylazosalicylic acids are shown in Scheme 9.

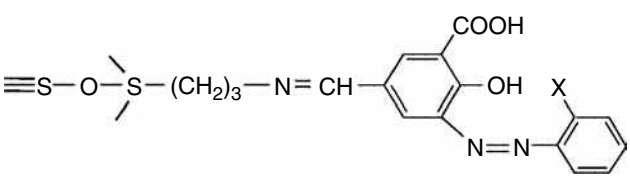
A batch equilibrium method, as a function of pH and shaking time, was performed to characterize the metal uptake properties of silica gel-immobilized-aminophenol and aminobenzoic acid. Studies were made and evaluated on the basis of column application of immobilized chelating sorbents for the removal of various metal ions from sugar cane molasses. These revealed that they have higher preference toward Mn(II), Fe(III), Co(II), Cu(II), and Zn(II) rather than alkali and alkaline earth metals.[27] The structures of the modified silica gel phases are shown in Scheme 10.

Modification of aliphatic mono- and poly-amine sorbents by incorporation of hard oxygen donor ligands, through Schiff's base reaction with carbonyl containing compounds, was found to significantly improve the uptake of Fe(III), known to act as hard acid.[28]

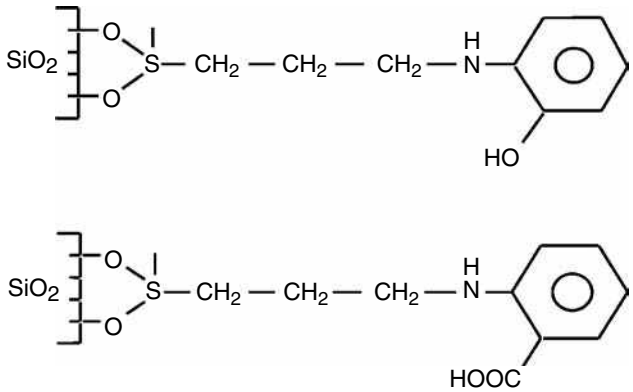
Physical adsorption and chemical immobilization techniques were used for the modification of silica gel surface by 1-aminoanthraquinone to produce three modified silica gel phases. These modified phases were studied for their metal sorption and extraction properties. The chemically modified silica phases were applied for selective extraction and preconcentration of Cu(II) and Cr(III) from seawater samples.[29]



Scheme 8



Scheme 9



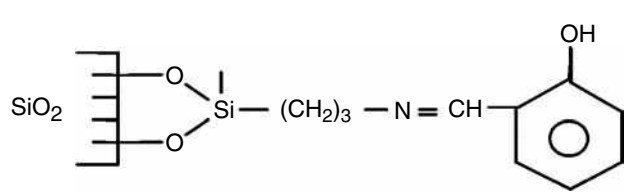
Scheme 10

Iminosalicyl groups attached to a silica gel surface were used for the adsorption of metal ions from ethanol (Scheme 11). Extraction of iron, nickel, cobalt, copper, zinc, and cadmium from ethanol by batch and column techniques was reported. The average distribution coefficient determined was: Fe(III), 4.5×10^2; Co(II), 1.4×10^2; Ni(II), 1.1×10^2; Cu(II), 3.6×10^2; Zn(II), 3.0×10^2; and Cd(II), 2.2×10^2.[30]

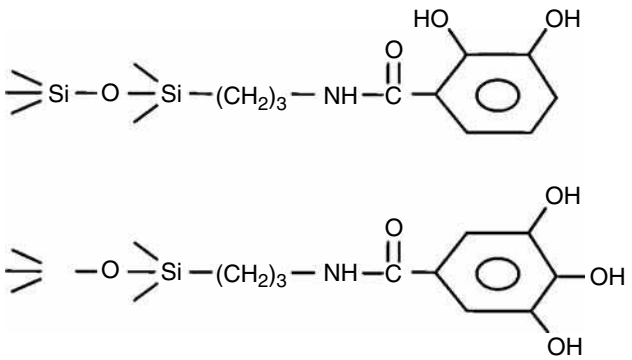
Immobilization of 2,3-dihydroxybenzoyl and 3,4,5-trihydroxybenzoyl amide functional groups on the surface of silica was reported. Significant affinity for preconcentration of transition metal ions and no affinity toward uptake of Ca, Mg, Na, and K ions from dilute aqueous solutions were identified by the synthesized phases.[31] The structures of these modified phases are shown in Scheme 12.

A successful method was applied for the determination of (parts per billion (ppb) levels of aluminum ion in tap water, river water, and tea samples by O, O′-dihydroxyazobenzene (dhab) via a selective and sensitive visual method. In this method, octadecylsilyl (ODS) - silica thin layer was used and a positively charged fluorescent 1 : 1 Al(III) chelate $[Al(dhab)]^+$ was retained at a spotting position. The immobilization of $[Al(dhab)^+]$ was attributed to the electrostatic interaction between it and the anionic charge of silanol groups on the ODS-silica plate.[32]

A combination of C_{18} reversed phase, Dowex anion-exchange resin, and the chelating resin, chelamine, in a three columns system, was described for the simultaneous preconcentration and differentiation between natural



Scheme 11



Scheme 12

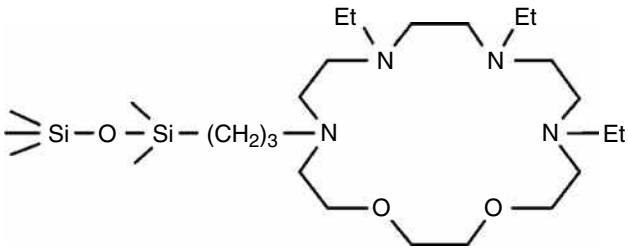
hydrophobic organic metal complexes, anionic complexes, and the free ion concentration of the transition metals in water samples with complex matrices. The method showed excellent reproducibility for the determination of Cu(II), Cd(II), Pb(II), and Mn(II) in several freshwater and seawater samples.[33]

Attachment of crown ethers and their derivatives to silica gel via a hydrocarbon-type linkage was applied for selective and quantitative removal of cations from aqueous solutions. The modified phases were found to be of potential value in preconcentration of nanogram per milliliter levels of some cations. In addition, these phases were operated without loss of the macrocycle and maintained the same selectivity toward metal ions in aqueous solution by the particular macrocycle in the free state.[34–36]

Immobilization of polyaza as well as mixed-donor (O, N) and (O, S) macrocycles to a silica gel matrix was described. These phases were used to investigate their selectivity toward preconcentration and separation of transition metal ions. A 17-membered O_2N_3-donor macrocycle exhibited a remarkable selectivity toward Cu(II) retention in presence of Ni(II), Zn(II), and Cd(II). The polyaza-macrocycles 1,4,7,10-tetraaza-18-crown-6, pentaaza-15-crown-5, and hexaaza-18-crown-6 were synthesized with macrocycles covalently bonded to silica gel via one of the nitrogen donor atoms. These bound macrocycles were found to have strong and selective interaction with soft heavy metal ions. Separation of ppb levels of these cations from concentrated mixtures of other cations such as alkali and alkaline earth cations were accomplished (Scheme 13).[37]

A number of methods for the immobilization of 8-hydroxyquinoline (8HQ) onto silica substrates have been proposed, characterized, and optimized. Examples of these modified silica gel phases with 8HQ as well as their applications are also reviewed in the following section.

A simple method for the preparation of silica immobilized 8HQ was described and investigated for its affinity for Cu, Ni, Co, Fe, Mn, Cr, Zn, Cd, Pb, and Hg. The metal uptake capacities for these metal ions were



Scheme 13

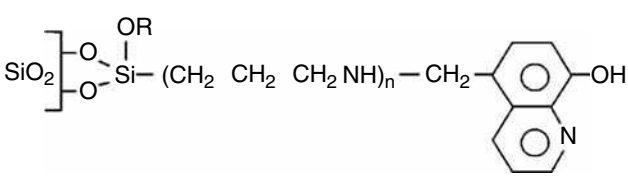
found to be in the range of 0.2–0.7 mmol/g. The distribution coefficients were found to be in the range from 1000 up to >90,000.[38] The structure of this modified sorbent is given in Scheme 14.

Silica-immobilized-8-hydroxyquinoline (SG-8HOQ) was reported for the purpose of solid–liquid extraction of metals. The separation of metals as their chelates by batch equilibrium or column chromatography was performed for trace amounts of Al(III), Cd(II), Co(II), Cu(II), Fe(III), Mn(II), Mg(II), Ni(II), and Zn(II) in solid-liquid back extraction.[39] The structure of SG-8HOQ is shown in Scheme 15.

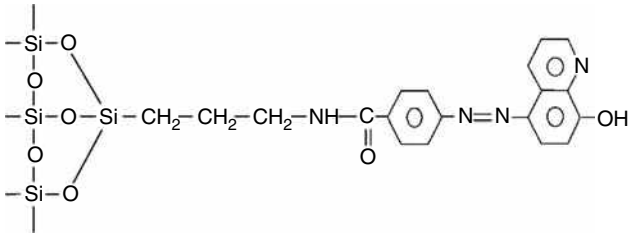
Procedures based on the application of immobilized quinoline-8-ol silica and stripping voltammetry were developed for the determination of copper, lead, cadmium, bismuth, indium, and zinc in seawater. Better sensitivity and lower detection limits were achieved with the application of smaller sample volumes. The feasibility and reliability of the developed procedures were confirmed by the analysis of a near shore seawater sample and CASS-2 reference seawater.[40]

A flow-system utilizing a miniature column packed with SG-8HOQ was used for the preconcentration of Cd, Pb, Zn, Cu, Fe, Mn, Ni, and Co from seawater prior to their determination by GFAAS. A preconcentration factor sufficient to permit the analysis of an open seawater reference material, using a 50 ml sample, was obtained. Recoveries of the above elements from seawater averaged 93% (range 87–97%) with absolute blanks ranging between 0.04 ng (Ni) and 4.0 ng (Fe).[41]

Several 8-quinolinol silica gel columns were used with metal-uptake capacities 10–156 μmol/g. Various transition and heavy metal ions were used in the form of nitrate, sulfate, phosphate, citrate, tartarate, oxalate, phthalate, and maleate mobile phases. Column capacity and pH were found to influence the metal ion retention.



Scheme 14



Scheme 15

Optimum capacity factors were obtained on columns of intermediate capacity (27 and 46 μmol/g). Retention times decreased with an increase in eluent buffer concentration, typically by half with a doubling of buffer concentration.[42]

8-hydroxyquinoline, 8-hydroxy-5-sulphonic acid quinoline, and 2-amino-1-cyclopentene-1-dithiocarboxylic acid silica gels, loaded with Cu(II), Ni(II), or Zn(II), were examined for the separation of some aromatic amines in the normal phase mode. All phases studied interact strongly with the sample compounds, but the presence of cations increases the selectivity of the column. Ni(II) or Zn(II) loading proved to be better than Cu(II) loading, because with these ions, strong peak broadening and disturbances of the base line are avoided. End capping of the chelating silica gels was indispensable to obtain good efficiencies.[43]

Silica Gel Phases with Nitrogen and Sulfur Donor Atoms

Selective solid-phase extractors and preconcentrators of Hg(II) were synthesized and studied. These modified silica gel phases are based on chemical immobilization and physical adsorption of dithizone as well as chemical immobilization of dithiocarbamate on some amine-modified silica gel phases. The mmol/g values as the metal capacities of these modified silica gel phases were determined for a series of metal ions under the effect of pH of metal ions and the equilibration shaking times by the batch equilibrium technique. The modified silica gel phases were found to exhibit excellent affinity toward selective extraction of Hg(II) in presence of other interfering metal ions. The potential applications of these modified silica gel phases as selective solid-phase extractors and preconcentrators for Hg(II) from natural water samples were also studied and the results indicated excellent extraction of Hg(II) with insignificant contributions by matrix effects.[6,44]

2-Mercaptobenzothiazole-modified silica gel was used for the flow injection (FI) online preconcentration, separation, and determination of silver by FAAS. The results showed that Ag(I) was selectively adsorbed from 0.05 to 6 M HNO_3 solution and was readily desorbed by thiourea solution. The ions coexisting with Ag(I) exhibit virtually

no interference in the determination, with only the exception of Cl^-. Silver in a geological sample, a copper metal sample, and a lead nitrate sample were determined satisfactorily (Scheme 16).[45]

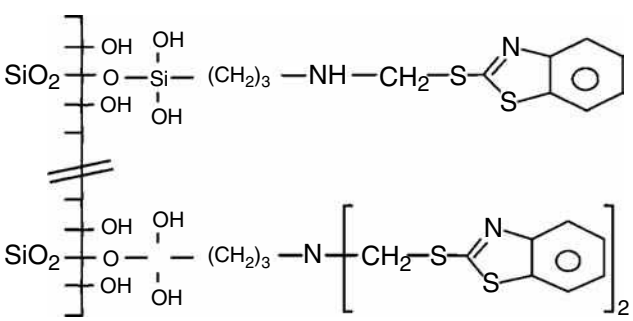
A method was presented for the immobilization of a thioglycolic acid moiety on the surface of active silica gel via a simple and direct synthetic route based on a single-step reaction for the formation of two solid-phase extractors. The selective removal and preconcentration of some heavy metal ions, viz. Cu(II), Zn(II), and Hg(II) from natural seawater was successfully accomplished.[46]

Diethyldithiocarbamate, pyrrolidin-1-yldithioformate, and diphenylthiocarbazone (dithizone), as three mercury chelate forming reagents, were used for the preconcentration of ultratrace amounts of inorganic mercury and methyl mercury in silica C_{18} minicolumn as the solid sorbent. Sample FI online sorbent extraction was coupled with continuous cold vapor atomic absorption spectrometry (CVAAS) for detection. The results showed the superiority of the carbamate type reagents over the dithizone for the online formation and preconcentration of the corresponding mercury chelate. The detection limit was found to be 16 ng/L of mercury.[47] The structures of these organic chelate modifiers are shown in Scheme 17.

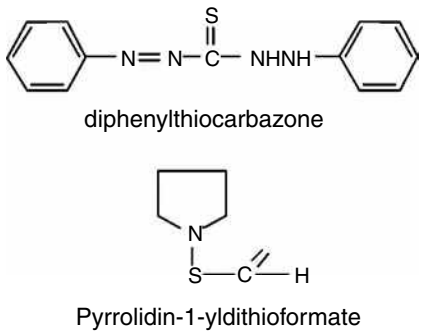
Chemical immobilization of 2-amino-1-cyclopentene-1-dithiocarboxylic acid as a chelating compound on the surface of silica gel was prepared. This showed great affinity for removal of Ag(I), Hg(II), and Pd(II) from dilute matrices, with exchange capacities in the range of 0.98–0.90 mmol/g. Fast equilibration times for these metal ions were determined (Scheme 18).[48]

Studies of the selective separation of Pd(II) from Rh(III) and Ir(III), in the presence of high concentrations of base metal ions, at pH 1, as well as preconcentration from dilute aqueous solutions, were performed using a column packed with silica gel-immobilized-2-[(2-triethoxysilyl) -ethyl thio] aniline. A quantitative elution of Pd (II) was effective with acidic 5% thiourea solution.[49]

Silica gel phases modified with aminopropyltriethoxysilane, ethylenediamine, diethylenetriamine, and triethylenetetramine were modified to the corresponding



Scheme 16



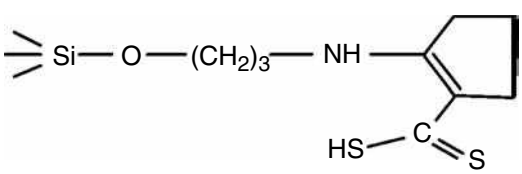
Scheme 17

dithiocarbamate derivatives. The surfaces of these modified phases were characterized by elemental analysis and infrared spectrophotometry. The thermal stability from EI-MS and the selectivity properties incorporated into these phases via immobilization of the nitrogen and sulfur donor atoms were also reported for a series of metal ions.[50]

A flow-injection online preconcentration and separation system with microwave-assisted desorption is proposed for the efficient determination of trace amounts of Pt by FAAS. A microcolumn packed with thiourea modified silica, placed in a microwave oven, was used to collect Pt from the sample solutions. The detection limit was 0.060 μg/ml. The results obtained by the proposed method for three metallurgical samples, a secondary nickel alloy, anode slim, and a $CoCl_2$ solution, were in good agreement with the recommended values.[51]

A new silica gel-based chelating sorbent, with thiourea as a functional group, was used for the FI online preconcentration and separation of trace levels of silver, gold, and palladium. The selected metal ions were adsorbed onto a column packed with thiourea-modified silica gel (TuSG). The sorbent exhibited excellent stability and the sorption properties of TuSG did not change after 1000 cycles of use. The selected metals in a secondary nickel alloy, an anode slim, an electrolytic solution, and three national certified ore samples were determined satisfactorily using the proposed method.[52]

A FI online sorbent extraction system was studied in conjunction with FAAS to determine cadmium, copper, and lead in a digest solution of solid environmental sample using octadecyl functional groups (C_{18})-bonded silica gel as sorbent with diethyl



Scheme 18

ammonium-*N*,*N*,diethyldithiocarbamate or ammonium diethyldithiophosphate as complexing agent and methanol as eluent. The results of the analysis of five environmental standard reference materials were in good agreement with the certified values, with the exception of cadmium. The detection limits were 0.8, 1.4, and 10.0 μg/L, respectively for cadmium, copper, and lead.[53]

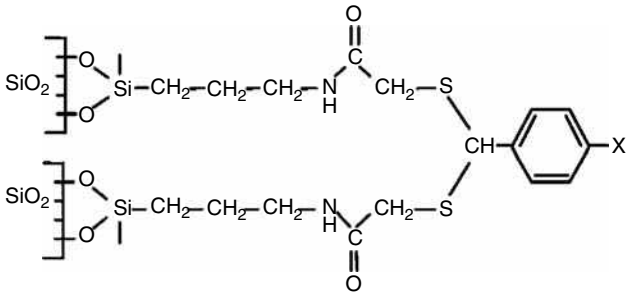
Silica Gel Phases with Nitrogen, Oxygen, and Sulfur Donor Atoms

Para-substituted, X = H, CH_3, OCH_3, Cl, and NO_2, dithioacetal derivatives were synthesized and chemically immobilized onto the surface of silica gel for the formation of five newly modified silica gel phases. The metal sorption properties of these silica gel phases were studied and the results revealed a general rule of excellent affinity for the selective extraction of Hg(II) in the presence of other interfering metal ions, giving rise to a range of 94–100% extraction of the spiked Hg(II) in the metal ion mixture. The potential applications of these modified silica gel phases for selective extraction of Hg(II) from two different natural water samples by a column technique, followed by cold vapor atomic absorption analysis, were also studied. The substituent effect on the process of selective extraction of Hg(II) by the modified silica gel phases was also presented.[5] The structures of silica gel-immobilized-dithioacetals are given in Scheme 19.

Silica gel-chemically immobilized-Eriochrome black T was synthesized and the surface coverage was found to be 0.38 mmol/g. The stability toward hydrolysis of this silica gel phase in various buffer solutions (pH 1.0–10.0) was studied and evaluated. The applicability of silica gel phase-immobilized-Eriochrome black T as a solid-phase extractor for Zn(II), Mg(II), and Ca(II) was performed by the batch equilibrium technique and was found to show an order similar to the formation constant values of the three metal ions with the indicator. The separation and selectivity of this modified silica gel for these metal ions, based on a column technique, were found to afford a reasonable performance of the three studied metal ions.[54] The structure of silica gel-chemically immobilized-Eriochrome black T is given in Scheme 20.

Azo dyes supported on silica gel were prepared and their adsorption behavior toward metal ions were investigated. The 1-(2-pyridylazo-2-naphthol)-immobilized silica gel and 2-(2-thiazolylazo)-*p*-cresol-immobilized silica gel showed greater affinity for UO(III) compared with Cu, Cd, Fe, and alkaline earths. Trace uranyl was quantitatively retained on the column at neutral pH. Matrix components in seawater did not interfere and the spiked recovery of uranyl in artificial seawater was found to average 98.6% with a relative standard deviation of 1.08%.[55]

Preconcentration and separation of trace Hg(II) with aminopropylbenzoylazo-2-mercaptobenzothiazole-bonded



X = H, CH_3,OCH_3,Cl,NO_2

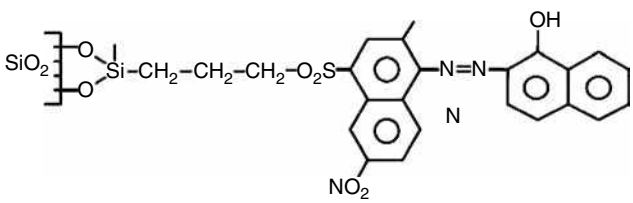
Scheme 19

to silica gel (ABMBT-SG) was reported. This phase was found to show an exchange capacity of 41.4 μmol/g. Determination of trace Hg(II) in environmental samples was accomplished by UV–Vis spectrophotometry. The described method is simple and efficient and can be applied for polluted soil (2 μg/L), incinerated biological material (18 ng/L), and spiked natural water (5 μg/L).[56] The structure of ABMBT-SG is given in Scheme 21.

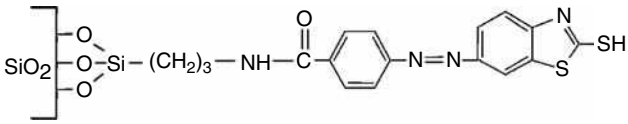
5-Methylene-2-(2′-thiazolylazo)-anisole was immobilized on silica gel via an Si–O–Si–C moiety. The capacity for palladium is about 0.070 mmol/g; this chelating silica was used to preconcentrate and separate palladium from a synthetic solution containing traces of palladium and large amounts of copper. Distribution coefficient studies of platinum metals, gold, and base metals showed that the chelating silica gel was found to be selective for Pd(II).[57] The structure of the modified silica gel phase is shown in Scheme 22 4-Amino-3-hydroxy-2-(chlorobenzene)-azo-1-naphthalene sulfonic acid was used as a chelating compound to improve the reactivity of silica gel surface toward selective extraction and binding with heavy metal ions. The modified silica gel phases showed high affinity and selectivity characteristics for binding with heavy metal ions, compared to alkali and alkaline earth metals.[58]

Silica Gel Phases with Oxygen and Sulfur Donor Atoms

Octadecyl-bonded-silica membrane disks modified with hexathia-18-crown-6-tetraone (Scheme 23) was synthesized



Scheme 20



Scheme 21

and applied as a rapid extraction and determination method of ultratrace amounts of Hg(II) ion by CVAAS. This method was used for the recovery of Hg(II) ions from synthetic samples and four different water samples.[59]

The macrocycles, 1,5-dithia-19-crown-6 ($T_2$19C6) and 1,4,7,10-tetrathia-18-crown-6 ($T_4$18C6), were chemically bonded to silica gel. The interaction of Pd(II), Au(III), Ag(I), and Hg(II) with the immobilized macrocycles was evaluated on the basis of determination of the binding constants (*K*). Other binding constants for Cu(II), Fe(III), and other base metals were at least 10 orders of magnitude less than constants for Pd(II), Au(III), Ag(I), and Hg(II). Values of *K* were higher for $T_4$18C6 than for $T_2$19C6. Immobilized thiamacrocycles effectively removed Au(III) and Pd(II) from 1L of 1*M*-HCl and 1*M*-$FeCl_3$. Palladium was also removed from an industrial silver electrolyte solution with 99.9% purity, in one pass through the column.[60] Structures of ($T_2$19C6) and ($T_4$18C6) are shown in Scheme 24.

Poly (crown ether) as well as the corresponding monocyclic crown ethers was immobilized on silica surface by covalent bonding. The chromatographic behavior of the modified silica gel phases for alkali metal salts was demonstrated. Poly (crown ether)-modified silica provided better separation of the metal salts compared to the corresponding monocyclic crown ether-modified one.[61] Other examples of modified silica and their applications (Table 1).

CONCLUSIONS

Silica gel is characterized by the presence of certain functionalities resulting from the presence of groups such as siloxane, ≡Si–O–Si≡, with the oxygen located on the surface, as well as silanol groups, ≡Si–OH. Surface silanol groups are the major contributing factors that are responsible for binding, adsorption, and extraction processes with the target analytes of interest such as metal ions or their more complex species. Improvements of the adsorption efficiency and extraction power of the sorbent are accomplished by surface modification with certain functional groups. The types of compounds that can be loaded onto the surfaces of solid phases are unlimited; these include long chain and short chain hydrocarbons, polar and non-polar organic compounds, inorganic and organometallic compounds, simple and macromolecular compounds, and chelating agents.

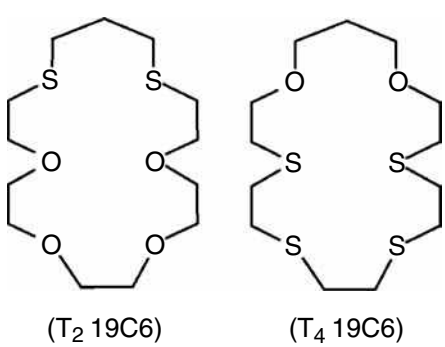

Scheme 24

Table 1 Examples of modified silica and their applications.

Modified silica gel	Possible applications	Refs.
Silica gel chemically modified with Zr(IV) phosphate	Preconcentration of lead and copper and their sequential determination by FAAS	[62]
Silica gel modified with 3-mercaptopropyltrimethoxy silane	Selective separation and preconcentration of selenite [Se(IV)] from aqueous solutions containing Se(IV) and Se(VI)	[63]
Octadecyl silica membrane disks modified by pentathia-15-crown-5	Selective concentration and determination of μg/L levels of Au(III) ions in aqueous solution by FAAS	[64]
Silica gel-modified-thioglycolic acid	Determination of copper ions in aqueous/ ethanolic solutions	[65]
Silica gel functionalized with methylthiosalicylate (TS-gel)	Online preconcentration of lead by flow injection system	[66]
Octadecyl silica membrane-modified-*bis* (2-hydroxyl phenyl amino) glyoxime	Selective adsorption and quantitative determination of the Cu^{2+} ions	[67]
Palladium-dimethylglyoxime complex on silica gel	Determination of palladium at trace levels by atomic absorption spectrometry	[68]
Reverse-phase C18 column	Determination of arsenite [As(III)], dimethyl arsenic acid, monomethyl arsenic and arsenate [As(V)] in Chinese brake fern by ion-pair reverse-phase HPLC–inductively coupled plasma (ICP) MS	[69]
Silica-immobilized brown alga *Pilayella littoralis*	Online metal preconcentration procedure in a flow-injection system for determination of Al, Co, Cu, and Fe in lake water samples by (ICP-OES)	[70]
Bis-naphthaldehyde and salicylaldehyde Schiff's base ligands immobilized on silica	Metal ions determination and preconcentration by atomic absorption analysis	[21]
Octadecyl (C_{18})-bonded silica gel	Separation and preconcentration of platinum group metals (Ru, Rh, Pd, Os, Ir, and Pt) as ion associates of their chlorocomplexes	[71]
C_{18}-bonded silica membrane disk modified with hexathia-18-crown-6	Selective separation and concentration of trace amounts of silver ion from aqueous samples for the subsequent measurement by atomic absorption spectrometry	[72]
Octadecyl-bonded silica membrane disks modified with pentathia-15-crown-5	Solid-phase extraction of gold	[64]
Octadecyl silica membrane disks with Schiff base ligand, thiophene-2-carbaldehyde (ethanamine 2,2′-[1,2-ethylene *bis*(oxy)]*N*,*N*′-*bis*(2-thienylmethylene))	Separation and preconcentration of trace amount of Pb^{2+} from aqueous solution and selective extraction and determination of ultra trace amounts of mercury	[73]
Octadecyl-bonded silica membrane disks modified with piroxicam	Extraction of uranium from aqueous solution using	[74]
2-Mercaptobenzothiazole impregnated on silica	Preconcentration of inorganic and organic mercury compounds from seawater and other metal ions from aqueous solution	[75]
Silica gel impregnated with 2-mercapto-*N*-2-naphthylacetamide	Extraction of Pd(II) from dilute solution	[76]
A chelating sorbent prepared by adsorption of 3,3′,4′,5, 7-pentahydroxyflavone on to a silica surface	Preconcentration and sorption-spectroscopic determination of Sn(IV) from aqueous solution at pH 1.8–2.2	[77]
Silica-based strongly basic anion exchanger with octadecyl silica Separon SGX C18 and Separon SGX RPS	Molybdenum was separated and preconcentrated as molybdate on microcolumns	[78]
Silica gel modified with 2-hydroxy-1-naphthaldehyde	Metal sorption and solid-phase extraction and their preconcentration properties	[79]
Physically immobilized-2-thiouracil	Selective extraction and pre concentration of heavy metals from seawater	[80]
Poly(benzo-15-crown-5) and *bis*(benzo-15-crown-5) modified silica gel	Extraction and chromatographic separation of alkali and alkaline earth metal ions	[81]
2-[(2-(Triethoxysilyl) ethyl) thio] aniline immobilized silica	Separation and preconcentration of Pd(II) from a matrix rich in Rh(III) and Ir(III)	[82]
Covalent grafting of 3-(2-aminoethyl-amino) propyl trimethoxysilane onto mesoporous sol–gel silica	Extraction of Cu(II) ions from aqueous solutions.	[83]
Silica gel phases-chemically immobilized-4-amino antipyrene	Selective extraction of heavy metal ions from natural waters	[84]
Silica gel-immobilized aliphatic amines 2-thiophenecarboxaldehyde Schiff's bases	Selective solid-phase extraction of Hg(II) from aqueous solutions at low pH values	[85]
